FUNDAMENTALS OF Anatomy Physiology

Tenth Edition

MARTINI | NATH | BARTHOLOMEW

Chapters

Clinical Cases

1	An Introduction to Anatomy and Physiology	1	Using A&P to Save a Life	2
2	The Chemical Level of Organization	26	What is Wrong with my Baby?	27
3	The Cellular Level of Organization	64	When Your Heart is in the Wrong Place	65
4	The Tissue Level of Organization	113	The Rubber Girl	114
5	The Integumentary System	150	Skin Cells in Overdrive	151
6	Osseous Tissue and Bone Structure	178	A Case of Child Abuse?	179
7	The Axial Skeleton	206	Knocked Out	207
8	The Appendicular Skeleton	241	The Orthopedic Surgeon's Nightmare	242
9	Joints	263	What's Ailing the Birthday Girl?	264
10	Muscle Tissue	289	A Real Eye Opener	290
11	The Muscular System	332	The Weekend Warrior	333
12	Neural Tissue	385	Did Franklin D. Roosevelt Really Have Polio?	386
13	The Spinal Cord, Spinal Nerves, and Spinal Reflexes	429	Prom Night	430
14	The Brain and Cranial Nerves	461	The Neuroanatomist's Stroke	462
15	Sensory Pathways and the Somatic Nervous System	508	Living with Cerebral Palsy	509
16	The Autonomic Nervous System and Higher-Order Functions	531	The First Day in Anatomy Lab	532
17	The Special Senses	563	A Chance to See	564
18	The Endocrine System	608	Stones, Bones, and Groans	609
19	Blood	652	A Mysterious Blood Disorder	653
20	The Heart	684	A Needle to the Chest	685
21	Blood Vessels and Circulation	723	Did Ancient Mummies Have Atherosclerosis?	724
22	The Lymphatic System and Immunity	781	Isn't There a Vaccine for That?	782
23	The Respiratory System	830	How Long Should a Cough Last?	831
24	The Digestive System	880	An Unusual Transplant	881
25	Metabolism and Energetics	935	The Miracle Supplement	936
26	The Urinary System	972	A Case of "Hidden" Bleeding	973
27	Fluid, Electrolyte, and Acid-Base Balance	1015	When Treatment Makes You Worse	1016
28	The Reproductive System	1050	A Post-Game Mystery	1051
29	Development and Inheritance	1095	The Twins That Looked Nothing Alike	1096

Spotlight Figures

 1-1	Levels of Organization 1–10 Diagnostic Imaging Techniques
2–3	Chemical Notation
 3–1 3–23	Anatomy of a Model Cell 3–7 Protein Synthesis, Processing, and Packaging 3–22 Overview of Membrane Transport DNA replication 3–24 Stages of a Cell's Life Cycle
4–20	Inflammation and Regeneration
5–3	The Epidermis
6–11	Endochondral Ossification 6–16 Types of Fractures and Steps in Repair
 7–4	Sectional Anatomy of the Skull
8–10	Sex Differences in the Human Skeleton
 9–2	Joint Movement
10–9 10–11	Events at the Neuromuscular Junction 10–10 Excitation-Contraction Coupling The Contraction Cycle and Cross-Bridge Formation
11–3	Muscle Action
12–9	Resting Membrane Potential 12–14 Generation of an Action Potential 12–15 Propagation of an Action Potential
 13–8	Peripheral Distribution of Spinal Nerves 13–14 Spinal Reflexes
14–4	Formation and Circulation of Cerebrospinal Fluid
 15–6	Somatic Sensory Pathways
16–2	Overview of the Autonomic Nervous System
17–2	Olfaction and Gustation 17–13 Refractive Problems 17–16 Photoreception
18–2 18–20	Structural Classification of Hormones 18–3 G Proteins and Second Messengers 18–18 Diabetes Mellitus The General Adaptation Syndrome
 19–1	The Composition of Whole Blood 19–8 Hemolytic Disease of the Newborn
20–10	Heart Disease and Heart Attacks 20–14 Cardiac Arrhythmias
 21–33	Congenital Heart Problems
 22–28	Cytokines of the Immune System
 23–15	Respiratory Muscles and Pulmonary Ventilation 23–25 Control of Respiration
24–15	Regulation of Gastric Activity 24–27 Chemical Events of Digestion
 25–11	Absorptive and Postabsorptive States
 26–16	Summary of Renal Function
 27–18	The Diagnosis of Acid-Base Disorders
28–12	Regulation of Male Reproduction 28–24 Regulation of Female Reproduction
 29–5	Extraembryonic Membranes and Placenta Formation

Frederic (Ric) H. Martini, Ph.D. *Author*

Dr. Martini received his Ph.D. from Cornell University in comparative and functional anatomy for work on the pathophysiology of stress. In addition to professional publications that include

journal articles and contributed chapters, technical reports, and magazine articles, he is the lead author of ten undergraduate texts on anatomy and physiology or anatomy. Dr. Martini is currently affiliated with the University of Hawaii at Manoa and has a long-standing bond with the Shoals Marine Laboratory, a joint venture between Cornell University and the University of New Hampshire. He has been active in the Human Anatomy and Physiology Society (HAPS) for over 20 years and was a member of the committee that established the course curriculum guidelines for A&P. He is now a President Emeritus of HAPS after serving as President-Elect, President, and Past-President over 2005-2007. Dr. Martini is also a member of the American Physiological Society, the American Association of Anatomists, the Society for Integrative and Comparative Biology, the Australia/New Zealand Association of Clinical Anatomists, the Hawaii Academy of Science, the American Association for the Advancement of Science, and the International Society of Vertebrate Morphologists.

Edwin F. Bartholomew, M.S.

Author

Edwin F. Bartholomew received his undergraduate degree from Bowling Green State University in Ohio and his M.S. from the University of Hawaii. Mr. Bartholomew has taught human

anatomy and physiology at both the secondary and undergraduate levels and a wide variety of other science courses (from botany to zoology) at Maui Community College and at historic Lahainaluna High School, the oldest high school west of the Rockies. He is a coauthor of *Visual Anatomy & Physiology, Essentials of Anatomy & Physiology, Visual Essentials of Anatomy & Physiology, Structure and Function of the Human Body,* and *The Human Body in Health and Disease* (all published by Pearson). Mr. Bartholomew is a member of the Human Anatomy and Physiology Society (HAPS), the National Association of Biology Teachers, the National Science Teachers Association, the Hawaii Science Teachers Association, and the American Association for the Advancement of Science.

Judi L. Nath, Ph.D. Author

Dr. Judi Nath is a biology professor at Lourdes University, where she teaches anatomy and physiology, pathophysiology, and medical terminology. She received her Bachelor's and Master's

degrees from Bowling Green State University and her Ph.D. from the University of Toledo. Dr. Nath is devoted to her students and strives to convey the intricacies of science in captivating ways that are meaningful, interactive, and exciting. She has won the Faculty Excellence Award—an accolade recognizing effective teaching, scholarship, and community service—multiple times. She is active in many professional organizations, notably the Human Anatomy and Physiology Society (HAPS), where she has served several terms on the board of directors. Dr. Nath is a coauthor of Visual Anatomy & Physiology, Visual Essentials of Anatomy & Physiology, and Anatomy & Physiology (all published by Pearson), and she is the sole author of Using Medical Terminology. Her favorite charities are those that have significantly affected her life, including the local Humane Society, the Cystic Fibrosis Foundation, and the ALS Association. On a personal note, Dr. Nath enjoys family life with her husband and their dogs.

William C. Ober, M.D.

Art Coordinator and Illustrator

Dr. Ober received his undergraduate degree from Washington and Lee University and his M.D. from the University of Virginia. He also studied in the Department of Art as Applied to Medicine at Johns Hopkins Univer-

sity. After graduation, Dr. Ober completed a residency in Family Practice and later was on the faculty at the University of Virginia in the Department of Family Medicine and in the Department of Sports Medicine. He also served as Chief of Medicine of Martha Jefferson Hospital in Charlottesville, VA. He is currently a Visiting Professor of Biology at Washington and Lee University, where he has taught several courses and led student trips to the Galapagos Islands. He was on the Core Faculty at Shoals Marine Laboratory for 24 years, where he taught Biological Illustration every summer. Dr. Ober has collaborated with Dr. Martini on all of his textbooks in every edition.

Claire E. Ober, R.N.

Illustrator

Claire E. Ober, R.N., B.A., practiced family, pediatric, and obstetric nursing before turning to medical illustration as a full-time career. She returned to school at Mary Baldwin College, where she re-

ceived her degree with distinction in studio art. Following a five-year apprenticeship, she has worked as Dr. Ober's partner in Medical & Scientific Illustration since 1986. She was on the Core Faculty at Shoals Marine Laboratory and co-taught the Biological Illustration course with Dr. Ober for 24 years. The textbooks illustrated by Medical & Scientific Illustration have won numerous design and illustration awards.

Kathleen Welch, M.D.

Clinical Consultant

Dr. Welch received her B.A. from the University of Wisconsin–Madison, her M.D. from the University of Washington in Seattle, and did her residency in Family Practice at the University of North

Carolina in Chapel Hill. Participating in the Seattle WWAMI rural medical education program, she studied in Fairbanks, Anchorage, and Juneau, Alaska, with time in Boise, Idaho, and Anacortes, Washington, as well. For two years, she served as Director of Maternal and Child Health at the LBJ Tropical Medical Center in American Samoa and subsequently was a member of the Department of Family Practice at the Kaiser Permanente Clinic in Lahaina, Hawaii, and on the staff at Maui Memorial Hospital. She has been in private practice since 1987 and is licensed to practice in Hawaii and Washington State. Dr. Welch is a Fellow of the American Academy of Family Practice and a member of the Maui County Medical Society and the Human Anatomy and Physiology Society (HAPS). With Dr. Martini, she has coauthored both a textbook on anatomy and physiology and the A&P Applications Manual. She and Dr. Martini were married in 1979, and they have one son.

Ralph T. Hutchings

Biomedical Photographer

Mr. Hutchings was associated with the Royal College of Surgeons for 20 years. An engineer by training, he has focused for years on photographing the structure of the human body. The result

has been a series of color atlases, including the *Color Atlas of Human Anatomy*, the *Color Atlas of Surface Anatomy*, and *The Human Skeleton* (all published by Mosby-Yearbook Publishing). For his anatomical portrayal of the human body, the International Photographers Association has chosen Mr. Hutchings as the best photographer of humans in the twentieth century. He lives in North London, where he tries to balance the demands of his photographic assignments with his hobbies of early motor cars and airplanes.

Ruth Anne O'Keefe, M.D.

Clinical Contributor

Dr. O'Keefe did her undergraduate studies at Marquette University, attended graduate school at the University of Wisconsin, and received her M.D. from George Washington University. She

was the first woman to study orthopedics at The Ohio State University during her residency. She did fellowship training in trauma surgery at Loma Linda University in California. In addition to her private orthopedic practice, she has done orthopedic surgery around the world, taking her own surgical teams to places such as the Dominican Republic, Honduras, Peru, New Zealand, and Burkina Faso. She serves on the board of Global Health Partnerships, a group that partners with a clinic serving 35,000 people in remote Kenya. Dr. O'Keefe has always enjoyed teaching and now supervises medical students from the University of New Mexico doing ongoing research in Kenya. She lives in Albuquerque with her Sweet Ed. She is mother of four, grandmother of nine, and foster mother to many.

Preface

The Tenth Edition of *Fundamentals of Anatomy & Physiology* is a comprehensive textbook that fulfills the needs of today's students while addressing the concerns of their professors. We focused our attention on the question "How can we make this information meaningful, manageable, and comprehensible?" During the revision process, we drew upon our content knowledge, research skills, artistic talents, and years of classroom experience to make this edition the best yet.

The broad changes to this edition are presented in the New to the Tenth Edition section below, and the specific changes are presented in the Chapter-by-Chapter Changes in the Tenth Edition section that follows.

New to the Tenth Edition

In addition to the many technical changes in this edition, such as updated statistics and anatomy and physiology descriptions, we have made the following key changes:

- NEW 50 Spotlight Figures provide highly visual one- and two-page presentations of tough topics in the book, with a particular focus on physiology. In the Tenth Edition, 18 new Spotlight Figures have been added for a total of 50 across the chapters. There is now at least one Spotlight Figure in every chapter, as well as one Spotlight Figure corresponding to every A&P Flix.
- **NEW 29 Clinical Cases** get students motivated for their future careers. Each chapter opens with a story-based Clinical Case related to the chapter content and ends with a Clinical Case Wrap-Up that incorporates the deeper content knowledge students will have gained from the chapter.
- NEW The repetition of the chapter-opening Learning Outcomes below the coordinated section headings within the chapters underscores the connection between the HAPS-based Learning Outcomes and the associated teaching points. Author Judi Nath sat on the Human Anatomy and Physiology Society (HAPS) committee that developed the HAPS Learning Outcomes, recommended to A&P instructors, and the Learning Outcomes in this book are based on them. Additionally, the assessments in MasteringA&P are organized by these Learning Outcomes. As in the previous edition, full-sentence section headings, correlated with the Learning Outcomes, state a core fact or concept to help students readily see and learn the chapter content; and Checkpoints, located at the close of each section, ask students to pause and check their understanding

of facts and concepts. If students cannot answer these questions within a matter of minutes, then they should reread the section before moving on. The Checkpoints reinforce the Learning Outcomes, resulting in a systematic integration of the Learning Outcomes over the course of the chapter. Answers to the Checkpoints are located in the blue Answers tab at the back of the book.

- **Easier narrative** uses simpler, shorter, more active sentences and a reading level that makes reading and studying easier for students.
- **Improved text-art integration** throughout the illustration program enhances the readability of figures. Several tables have been integrated directly into figures to help students make direct connections between tables and art.
- **Eponyms** are now included within the narrative, along with the anatomical terms used in *Terminologia Anatomica*.
- **NEW Assignable MasteringA&P activities** include the following:
 - NEW Spotlight Figure Coaching Activities are highly visual, assignable activities designed to bring interactivity to the Spotlight Figures in the book. Multi-part activities include the ranking and sorting types that ask students to manipulate the visuals.
 - NEW Book-specific Clinical Case Activities stem from the story-based Clinical Cases that appear at the beginning and end of each chapter in the book.
 - NEW Adaptive Follow-up Assignments allow instructors to easily assign personalized content for each individual student based on strengths and weaknesses identified by his or her performance on MasteringA&P parent assignments.
 - NEW Dynamic Study Modules help students acquire, retain, and recall information quickly and efficiently. The modules are available as a self-study tool or can be assigned by the instructor. They can be easily accessed with smartphones.

Chapter-by-Chapter Changes in the Tenth Edition

This annotated Table of Contents provides select examples of revision highlights in each chapter of the Tenth Edition. For a more complete list of changes, please contact the publisher.

Chapter 1: An Introduction to Anatomy and Physiology

- New Clinical Case: Using A&P to Save a Life
- New Spotlight Figure 1–10 Diagnostic Imaging Techniques
- New Clinical Note: Autopsies and Cadaver Dissection
- New Clinical Note: Auscultation
- Figure 1–7 Directional References revised
- Figure 1–8 Sectional Planes revised
- Figure 1–9 Relationships among the Subdivisions of the Body Cavities of the Trunk revised

Chapter 2: The Chemical Level of Organization

- New Clinical Case: What Is Wrong with My Baby?
- New Clinical Note: Radiation Sickness
- Clinical Note: Fatty Acids and Health revised
- Section 2-2 includes revised Molecular weight discussion
- Figure 2–4 The Formation of Ionic Bonds revised
- Figure 2–5 Covalent Bonds in Five Common Molecules revised
- Table 2–3 Important Functional Groups of Organic Compounds revised (to clarify structural group and R group)
- Protein Structure subsection includes new discussion of amino acids as zwitterions
- Figure 2–21 Protein Structure revised

Chapter 3: The Cellular Level of Organization

- New Clinical Case: When Your Heart Is in the Wrong Place
- New information added about cholesterol and other lipids
- New overview added about roles of microtubules
- Figure 3–5 The Endoplasmic Reticulum revised
- Clinical Note on DNA Fingerprinting revised
- Figure 3–13 The Process of Translation revised
- Figure 3–14 Diffusion revised
- Figure 3-17 Osmotic Flow across a Plasma Membrane revised
- New Spotlight Figure 3–22 Overview of Membrane Transport incorporates old Figures 3–18, 3–19, and 3–21 and old
- Table 3–2 • New Spotlight Figure 3–23 DNA Replication incorporates old Figure 3–23
- Spotlight Figure 3–24 Stages in a Cell's Life Cycle revised
- Chapter 4: The Tissue Level of Organization

• New Clinical Case: The Rubber Girl

- Intercellular Connections subsection updated
- Figure 4–2 Cell Junctions revised
- Figure 4–8 The Cells and Fibers of Connective Tissue Proper revised
- Adipose Tissue subsection includes updated discussion of brown fat
- Figure 4-10 Loose Connective Tissues revised
- Spotlight Figure 4–20 Inflammation and Regeneration revised

Chapter 5: The Integumentary System

- New Clinical Case: Skin Cells in Overdrive
- Figure 5–1 The Components of the Integumentary System revised
- New Figure 5–2 The Cutaneous Membrane and Accessory Structures
- New Spotlight Figure 5–3 The Epidermis incorporates old Figures 5–2 and 5–3
- New Figure 5–5 Vitiligo
- New Figure 5–6 Sources of Vitamin D₃

- Clinical Note: Decubitus Ulcers revised with new photo
- New Figure 5–8 Reticular Layer of Dermis
- Figure 5–10 Dermal Circulation revised
- Figure 5–12 Hair Follicles and Hairs revised
- New Figure 5–11 Hypodermis

Chapter 6: Osseous Tissue and Bone Structure

- New Clinical Case: A Case of Child Abuse?
- Figure 6-1 A Classification of Bones by Shape revised
- New Figure 6–2 An Introduction to Bone Markings incorporates old Table 6–1
- New Spotlight Figure 6–11 Endochondral Ossification incorporates old Figure 6–10
- New Figure 6–12 Intramembranous Ossification
- Spotlight Figure 6–16 Types of Fractures and Steps in Repair revised
- Clinical Note: Abnormal Bone Development revised

Chapter 7: The Axial Skeleton

- New Clinical Case: Knocked Out
- New Clinical Note: Sinusitis
- Figure 7–2 Cranial and Facial Subdivisions of the Skull revised
- Figure 7–3 The Adult Skull revised to incorporate old Table 7–1
- New Spotlight Figure 7–4 Sectional Anatomy of the Skull incorporates old Figure 7–4 and parts of old Table 7–1
- Figure 7–6 The Frontal Bone revised
- Figure 7–14 The Nasal Complex revised
- Figure 7–22 The Thoracic Cage revised

Chapter 8: The Appendicular Skeleton

- New Clinical Case: The Orthopedic Surgeon's Nightmare
- New Clinical Note: Hip Fracture
- New Clinical Note: Runner's Knee
- New Clinical Note: Stress Fractures
- Carpal Bones subsection now lists the 8 carpal bones in two groups of 4 (proximal and distal carpal bones)
- Figure 8–6 Bones of the Right Wrist and Hand revised
- New Spotlight Figure 8–10 Sex Differences in the Human Skeleton incorporates old Figure 8–10, old Table 8–1, and old bulleted list in text
- Clinical Note: Carpal Tunnel Syndrome includes new illustration
- Figure 8–14 Bones of the Ankle and Foot revised
- Clinical Note: Congenital Talipes Equinovarus includes new photo

Chapter 9: Joints

- Chapter title changed from Articulations to Joints
- New Clinical Case: What's Ailing the Birthday Girl?
- New Clinical Note: Dislocation and Subluxation
- New Clinical Note: Damage to Intervertebral Discs
- Table 9–1 Functional and Structural Classifications of Articulations redesigned
- Spotlight Figure 9–2 Joint Movement incorporates old Figures 9–2 and 9–6 and subsection on Types of Synovial Joints
- Revised discussion of synovial fluid function in shock absorption
- Figure 9-6 Intervertebral Articulations expanded
- Figure 9-7 The Shoulder Joint revised
- Figure 9-10 The Right Knee Joint rearranged and revised
- Clinical Note: Knee Injuries revised

Chapter 10: Muscle Tissue

- New Clinical Case: A Real Eye Opener
- New subsection Electrical Impulses and Excitable Membranes added in Section 10-4
- New Spotlight Figure 10–10 Excitation–Contraction Coupling incorporates old Figures 10–9 and 10–10
- New Figure 10–13 Steps Involved in Skeletal Muscle Contraction and Relaxation incorporates old Table 10–1
- Treppe subsection includes new discussion of treppe in cardiac muscle
- Motor Units and Tension Production subsection includes new discussion of fasciculation
- Figure 10-20 Muscle Metabolism revised
- Table 10–2 Properties of Skeletal Muscle Fiber Types revised to make column sequences better parallel text discussion

Chapter 11: The Muscular System

- New Clinical Case: The Weekend Warrior
- Figure 11–1 Muscle Types Based on Pattern of Fascicle Organization revised
- Figure 11-2 The Three Classes of Levers revised
- New Spotlight Figure 11-3 Muscle Action
- Figure 11–14 An Overview of the Appendicular Muscles of the Trunk revised
- Figure 11-18 Muscles That Move the Hand and Fingers revised
- Figure 11–22 Extrinsic Muscles That Move the Foot and Toes revised

Chapter 12: Neural Tissue

- New Clinical Case: Did President Franklin D. Roosevelt Really Have Polio?
- New Figure 12–1 A Functional Overview of the Nervous System
- Figure 12–7 Schwann Cells, Peripheral Axons, and Formation of the Myelin Sheath revised and new part c step art added
- New Spotlight Figure 12–9 Resting Membrane Potential incorporates old Figure 12–9
- Figure 12–10 Electrochemical Gradients for Potassium and Sodium Ions revised
- Added ligand-gated channels as an alternative term for chemically gated channels
- New Spotlight Figure 12–15 Propagation of an Action Potential incorporates old Figures 12–6 and 12–15
- New Figure 12–16 Events in the Functioning of a Cholinergic Synapse incorporates old Figure 12–17 and old Table 12–4

Chapter 13: The Spinal Cord, Spinal Nerves, and Spinal Reflexes

- New Clinical Case: Prom Night
- New "Tips & Tricks" added to Cervical Plexus subsection
- Figure 13-7 Dermatomes revised
- New information on the Jendrassik maneuver added to Section 13-8
- New Figure 13–10 The Cervical Plexus incorporates old Table 13–1 and old Figure 13–11
- New Figure 13–11 The Brachial Plexus incorporates old Table 13–2 and old Figure 13–12
- New in-art Clinical Note: Sensory Innervation in the Hand added to Figure 13–11
- New Figure 13–12 The Lumbar and Sacral Plexuses incorporates old Table 13–3 and old Figure 13–13
- New in-art Clinical Note: Sensory Innervation in the Ankle and Foot added to Figure 13–12

• New Spotlight Figure 13–14 Spinal Reflexes incorporates old Figures 13–15, 13–17, 13–19, and 13–20

Chapter 14: The Brain and Cranial Nerves

- New Clinical Case: The Neuroanatomist's Stroke
- New Spotlight Figure 14–4 Formation and Circulation of Cerebrospinal Fluid incorporates old Figure 14–4
- Figure 14-5 The Diencephalon and Brain Stem revised
- New Figures 14–6 The Medulla Oblongata and 14–7 The Pons incorporate old Figure 14–6 and old Table 14–2
- New Figure 14–8 The Cerebellum incorporates old Figure 14–7 and old Table 14–3
- New Figure 14–9 The Midbrain incorporates old Figure 14–8, old Table 14–4, and a new cadaver photograph
- New Figure 14–11 The Hypothalamus in Sagittal Section incorporates old Figure 14–10 and old Table 14–6
- New Figure 14–12 The Limbic System incorporates old Figure 14–11 and old Table 14–7
- Figure 14–14 Fibers of the White Matter of the Cerebrum revised
- Figure 14–15 The Basal Nuclei revised
- Figure 14–16 Motor and Sensory Regions of the Cerebral Cortex revised
- New information on circumventricular organs added to Section 14-2

Chapter 15: Sensory Pathways and the Somatic Nervous System

- New Clinical Case: Living with Cerebral Palsy
- New Figure 15–1 An Overview of Events Occurring along the Sensory and Motor Pathways
- New Figure 15–3 Tonic and Phasic Sensory Receptors
- Spotlight Figure 15-6 Somatic Sensory Pathways revised
- Figure 15–8 Descending (Motor) Tracts in the Spinal Cord reorganized

Chapter 16: The Autonomic Nervous System and Higher-Order Functions

- New Clinical Case: The First Day in Anatomy Lab
- New Spotlight Figure 16–2 Overview of the Autonomic Nervous System incorporates old Figures 16–3 and 16–7
- Figure 16–3 Sites of Ganglia in Sympathetic Pathways revised
- Figure 16–4 The Distribution of Sympathetic Innervation revised

Chapter 17: The Special Senses

- New Clinical Case: A Chance to See
- Figure 17–1 The Olfactory Organs revised
- Spotlight Figure 17–2 Olfaction and Gustation revised
- Figure 17-3 Gustatory Receptors revised
- Figure 17–22 The Middle Ear revised
- Figures 17–23, 17–24, and 17–25 revised to indicate different orientations of maculae in the utricle and saccule
- Figure 17-32 Pathways for Auditory Sensations revised

Chapter 18: The Endocrine System

- New Clinical Case: Stones, Bones, and Groans
- New Spotlight Figure 18–3 G Proteins and Second Messengers incorporates old Figure 18–3
- Figure 18–7 The Hypophyseal Portal System and the Blood Supply to the Pituitary Gland revised
- Figure 18–11 The Thyroid Follicles revised
- New Figure 18–14 The Adrenal Gland incorporates old Figure 18–14 and old Table 18–5

Chapter 19: Blood

- New Clinical Case: A Mysterious Blood Disorder
- Figure 19–3 The Structure of Hemoglobin revised
- Table 19–4 includes revised names for Factors IX and XI and source of Factor X

Chapter 20: The Heart

- New Clinical Case: A Needle to the Chest
- Figure 20–3 The Superficial Anatomy of the Heart revised
- Figure 20-6 The Sectional Anatomy of the Heart revised
- Figure 20–12 Impulse Conduction through the Heart revised
- Figure 20–16 Phases of the Cardiac Cycle revised
- Figure 20-21 Autonomic Innervation of the Heart revised
- Figure 20–24 A Summary of the Factors Affecting Cardiac Output revised

Chapter 21: Blood Vessels and Circulation

- New Clinical Case: Did Ancient Mummies Have Atherosclerosis?
- Figure 21-2 Histological Structures of Blood Vessels revised
- Figure 21–8 Relationships among Vessel Diameter, Cross-Sectional Area, Blood Pressure, and Blood Velocity within the Systemic Circuit revised
- Figure 21-9 Pressures within the Systemic Circuit revised
- Figure 21–11 Forces Acting across Capillary Walls revised
- Figure 21–20 Arteries of the Chest and Upper Limb revised
- Figure 21-25 Arteries of the Lower Limb revised
- Figure 21–29 Flowcharts of Circulation to the Superior and Inferior Venae Cavae revised
- Figure 21-30 Venous Drainage from the Lower Limb revised

Chapter 22: The Lymphatic System and Immunity

- New Clinical Case: Isn't There a Vaccine for That?
- Figure 22-6 The Origin and Distribution of Lymphocytes revised
- Figure 22–11 Innate Defenses revised
- Complement System subsection includes revised number of complement proteins in plasma (from 11 to more than 30)
- Figure 22-18 Antigens and MHC Proteins revised

Chapter 23: The Respiratory System

- New Clinical Case: How Long Should a Cough Last?
- Figure 23–1 The Structure of the Respiratory System reorganized
- Figure 23-3 The Structures of the Upper Respiratory System revised
- Figure 23-5 The Glottis and Surrounding Structures revised
- Figure 23-7 The Gross Anatomy of the Lungs revised
- Figure 23–9 The Bronchi, Lobules, and Alveoli of the Lung revised
- Figure 23–10 Alveolar Organization revised
- Figure 23–13 Mechanisms of Pulmonary Ventilation revised
- New Spotlight Figure 23–15 Respiratory Muscles and Pulmonary Ventilation incorporates old Figure 23–16
- Figure 23-16 Pulmonary Volumes and Capacities revised
- Spotlight Figure 23–25 Control of Respiration revised

Chapter 24: The Digestive System

- New Clinical Case: An Unusual Transplant
- Figure 24–10 The Esophagus revised
- Figure 24–12 The Stomach revised

- Figure 24–16 Segments of the Intestine revised
- Figure 24–21 The Anatomy and Physiology of the Gallbladder and Bile Ducts revised

Chapter 25: Metabolism and Energetics

- New Clinical Case: The Miracle Supplement
- Figure 25-9 Lipid Transport and Utilization revised
- Figure 25–12 MyPlate Plan revised
- Figure 25-14 Mechanisms of Heat Transfer revised

Chapter 26: The Urinary System

- New Clinical Case: A Case of "Hidden" Bleeding
- Revised all relevant figure labels by replacing "Renal lobe" with "Kidney lobe"
- Figure 26–6 The Functional Anatomy of a Representative Nephron and the Collecting System revised
- Spotlight Figure 26–16 Summary of Renal Function revised

Chapter 27: Fluid, Electrolyte, and Acid–Base Balance

- New Clinical Case: When Treatment Makes You Worse
- Figure 27–2 Cations and Anions in Body Fluids revised
- Figure 27-3 Fluid Gains and Losses revised
- Figure 27–11 The Role of Amino Acids in Protein Buffer Systems revised (to emphasize amino acids as zwitterions)
- Figure 27–13 Kidney Tubules and pH Regulation revised
- New Spotlight Figure 27–18 The Diagnosis of Acid–Base Disorders incorporates old Figure 27–18

Chapter 28: The Reproductive System

- New Clinical Case: A Post-Game Mystery
- Figure 28–1 The Male Reproductive System revised
- Figure 28–3 The Male Reproductive System in Anterior View revised and reorganized
- Figure 28–4 The Structure of the Testes revised
- Figure 28-7 Spermatogenesis revised
- Figure 28-13 The Female Reproductive System revised
- Figure 28–15 Oogenesis revised
- Figure 28–18 The Uterus revised

Chapter 29: Development and Inheritance

- New Clinical Case: The Twins That Looked Nothing Alike
- Revised all relevant chapter text by replacing "embryological" with "embryonic" for simplification
- New Spotlight Figure 29–5 Extraembryonic Membranes and Placenta Formation incorporates old Figure 29–5
- Table 29–2 An Overview of Prenatal Development includes revised sizes and weights at different gestational ages
- Figure 29-8 The Second and Third Trimesters revised
- Figure 29-9 Growth of the Uterus and Fetus revised
- Figure 29–13 Growth and Changes in Body Form and Proportion revised

Appendix

- New periodic table
- New codon chart

This textbook represents a group effort, and we would like to acknowledge the people who worked together with us to create this Tenth Edition.

Foremost on our thank-you list are the instructors who offered invaluable suggestions throughout the revision process. We thank them for their participation and list their names and affiliations below.

Lisa Conley, Milwaukee Area Technical College Theresa G. D'Aversa, Iona College Danielle Desroches, William Paterson University Debra Galba-Machuca, Portland Community College-Cascade Lauren Gollahon, Texas Tech University Gigi Goochey, Hawaii Community College Mark Haefele, Community College of Denver Anthony Jones, Tallahassee Community College William L' Amoreaux, College of Staten Island J. Mitchell Lockhart, Valdosta State University Scott Murdoch, Moraine Valley Community College Louise Petroka, Gateway Community College Cynthia Prentice-Craver, Chemeketa Community College S. Michele Robichaux, Nicholls State University Susan Rohde, Triton College Yung Su, Florida State University Bonnie Taylor, Schoolcraft College Carol Veil, Anne Arundel Community College Patricia Visser, Jackson College Theresia Whelan, State College of Florida – Manatee-Sarasota Samia Williams, Santa Fe College

The accuracy and currency of the clinical material in this edition and in the *A*&*P Applications Manual* in large part reflect the work of Kathleen Welch, M.D. Her professionalism and concern for practicality and common sense make the clinical information especially relevant for today's students. Additionally, our content expert on the Clinical Cases, Ruth Anne O'Keefe, M.D., provided constant, useful feedback on each chapter.

Virtually without exception, reviewers stressed the importance of accurate, integrated, and visually attractive illustrations in helping readers understand essential material. The revision of the art program was directed by Bill Ober, M.D. and Claire E. Ober, R.N. Their suggestions about presentation sequence, topics of clinical importance, and revisions to the proposed art were of incalculable value to us and to the project. The illustration program for this edition was further enhanced by the efforts of several other talented individuals. Jim Gibson designed most of the new Spotlight Figures in the art program and consulted on the design and layout of the individual figures. His talents have helped produce an illustration program that is dynamic, cohesive, and easy to understand. Anita Impagliazzo helped create the new photo/art combinations that have resulted in clearer presentations and a greater sense of realism in important anatomical figures. We are also grateful to the talented team at Imagineering (imagineeringart.com) for their dedicated and detailed illustrative work on key figures for this edition. The new color micrographs in this edition were provided by Dr. Robert Tallitsch, and his assistance is much appreciated. Many of the striking anatomy photos in the text and in *Martini's Atlas of the Human Body* are the work of biomedical photographer Ralph Hutchings; his images played a key role in the illustration program.

We also express our appreciation to the editors and support staff at Pearson Science.

We owe special thanks to Executive Editor, Leslie Berriman, for her creativity and dedication. Her vision helped shape this book in countless ways. Leslie's enthusiasm for publishing the highest quality material spills over onto the author/ illustrator team. She is our biggest advocate and is always willing to champion our cause—despite the challenges of working with authors. We are appreciative of all her efforts on our behalf.

Assistant Editor, Cady Owens, and Associate Project Editor, Lisa Damerel, are unquestionably the very finest at what they do. While it is expected that editors pay attention to details and keep projects moving forward, Cady and Lisa are true professionals and extremely skilled at not only preparing our material for publication, but making sure it is the best it could possibly be. This past year could not have happened without them.

Annie Reid, our Development Editor, played a vital role in revising the Tenth Edition. Her unfailing attention to readability, consistency, and quality was invaluable to the authors in meeting our goal of delivering complex A&P content in a more student-friendly way.

We are grateful to Mike Rossa for his careful attention to detail and consistency in his copyedit of the text and art.

This book would not exist without the extraordinary dedication of the Production team, including Caroline Ayres, who solved many problems under pressure with unfailing good cheer. Norine Strang skillfully led her excellent team at S4Carlisle to move the book smoothly through composition.

x Acknowledgments

The striking cover and clear, navigable interior design were created by tani hasegawa. Thanks also to Mark Ong, Design Manager, and Marilyn Perry, who devised innovative solutions for several complex design challenges.

Thanks to our photo researcher, Maureen Spuhler, and photo editor, Donna Kalal, for finding, obtaining, and coordinating all the photos in the photo program.

Thanks are also due to Sharon Kim, Editorial Assistant, who served as project editor for the print supplements for instructors and students and coordinated the administrative details of the entire textbook program. Dorothy Cox and Shannon Kong worked tirelessly to shepherd the print and media supplements through production. Thanks also to Stacey Weinberger for handling the physical manufacturing of the book.

We are also grateful to Joe Mochnick, Content Producer, and Liz Winer, Executive Content Producer, for their creative efforts on the media package, most especially MasteringA&P.

We would also like to express our gratitude to the following people at Pearson Science: Paul Corey, President, who continues to support all our texts; Barbara Yien, Director of Development, who kindly kept all phases moving forward under all circumstances; Allison Rona, Senior Marketing Manager; and the dedicated Pearson Science sales representatives for their continuing support of this project. Special thanks go to Frank Ruggirello, Vice President and Editorial Director, for working closely with Leslie in ensuring we have the resources necessary to publish what students need to succeed. And, a round of applause goes to Derek Perrigo, Senior A&P Specialist, our biggest cheerleader.

To help improve future editions, we encourage you to send any pertinent information, suggestions, or comments about the organization or content of this textbook to us directly, using the e-mail addresses below. We warmly welcome comments and suggestions and will carefully consider them in the preparation of the Eleventh Edition.

Contents

Preface v

UNIT 1 LEVELS OF ORGANIZATION

An Introduction to Anatomy and Physiology 1

An Introduction to Studying the Human Body 2

- 1-1 Anatomy and physiology directly affect your life 2
- **1-2** Anatomy is structure, and physiology is function 3
- 1-3 Anatomy and physiology are closely integrated 4 Anatomy 4 Physiology 5
- **1-4** Levels of organization progress from molecules to a complete organism 6
- 1-5 Homeostasis is the state of internal balance 7
- 1-6 Negative feedback opposes variations from normal, whereas positive feedback exaggerates them 10 The Role of Negative Feedback in Homeostasis 10 The Role of Positive Feedback in Homeostasis 12 Systems Integration, Equilibrium, and Homeostasis 13
- 1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections 14
 Superficial Anatomy 14
 Sectional Anatomy 16
- **1-8** Body cavities of the trunk protect internal organs and allow them to change shape 18 The Thoracic Cavity 22 The Abdominopelvic Cavity 22

Chapter Review 23

Autopsies and Cadaver Dissection 5 Auscultation 14

2

The Chemical Level of Organization 26

An Introduction to the Chemical Level of Organization 27

2-1 Atoms are the basic particles of matter 27 Atomic Structure 27 Elements and Isotopes 28 Atomic Weights 29

Electrons and Energy Levels 30

- 2-2 Chemical bonds are forces formed by atom interactions 31 Ionic Bonds 31 Covalent Bonds 34 Hydrogen Bonds 35 States of Matter 35
- 2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology 36
 Basic Energy Concepts 36
 Types of Chemical Reactions 37
- **2-4** Enzymes catalyze specific biochemical reactions by lowering the energy needed to start them 38
- **2-5** Inorganic compounds lack carbon, and organic compounds contain carbon 39
- 2-6 Physiological systems depend on water 39 The Properties of Aqueous Solutions 40 Colloids and Suspensions 41
- **2-7** Body fluid pH is vital for homeostasis 41
- 2-8 Acids, bases, and salts are inorganic compounds with important physiological roles 42
 Salts 43
 Buffers and pH Control 43
- 2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio 43 Monosaccharides 44 Disaccharides and Polysaccharides 45
- 2-10 Lipids often contain a carbon-to-hydrogen ratio of 1:2 46
 Fatty Acids 46
 Eicosanoids 47
 Glycerides 48
 Steroids 48
 - Phospholipids and Glycolipids 49

- 2-11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids 51
 Protein Structure 51
 Protein Shape 52
 Enzyme Function 54
 Glycoproteins and Proteoglycans 56
- 2-12 DNA and RNA are nucleic acids 56 Structure of Nucleic Acids 56 RNA and DNA 56
- **2-13 ATP is a high-energy compound used by cells** 58
- **2-14** Chemicals and their interactions form functional units called cells 59

Chapter Review 60

Radiation Sickness29Fatty Acids and Health48

The Cellular Level of Organization 64

An Introduction to Cells 65

3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions 65
 Membrane Lipids 68
 Membrane Proteins 69
 Membrane Carbohydrates 70

3-2 Organelles within the cytoplasm perform particular functions 70 The Cytosol 70 The Organelles 71

The Organeties 71

- 3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities 82
 Contents of the Nucleus 83
 Information Storage in the Nucleus 83
- 3-4 DNA controls protein synthesis, cell structure, and cell function 84
 The Role of Gene Activation in Protein Synthesis 84
 The Transcription of mRNA 84
 Translation and Protein Synthesis 86
 How the Nucleus Controls Cell Structure and Function 87
- 3-5 Diffusion is a passive transport mechanism that assists membrane passage 87
 Diffusion 89

Diffusion across Plasma Membranes 91

- **3-6 Carrier-mediated and vesicular transport assist membrane passage** 94 Carrier-Mediated Transport 94 Vesicular Transport 96
- 3-7 The membrane potential results from the unequal distribution of positive and negative charges across the plasma membrane 100
- 3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis 101
 DNA Replication 101
 Interphase, Mitosis, and Cytokinesis 101
 The Mitotic Rate and Energy Use 103
- **3-9** Several growth factors affect the cell life cycle 103
- **3-10** Tumors and cancers are characterized by abnormal cell growth and division 106
- **3-11** Differentiation is cellular specialization as a result of gene activation or repression 108

Chapter Review 109

Spotlights

Anatomy of a Model Cell 66 Protein Synthesis, Processing, and Packaging 78 Overview of Membrane Transport 98 DNA Replication 102 Stages of a Cell's Life Cycle 104

An Introduction to the Tissue Level of Organization 114

- 4-1 The four tissue types are epithelial, connective, muscle, and neural 114
- 4-2 Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions 114
 Functions of Epithelial Tissue 115
 Specializations of Epithelial Cells 115
 Maintaining the Integrity of Epithelia 116
- 4-3 Cell shape and number of layers determine the classification of epithelia 118
 Classification of Epithelia 119
 Glandular Epithelia 123

- 4-4 Connective tissue provides a protective structural framework for other tissue types 126
 Classification of Connective Tissues 126
 Connective Tissue Proper 126
- 4-5 Cartilage and bone provide a strong supporting framework 133 Cartilage 133 Bone 136
- 4-6 Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial 137 Mucous Membranes 137 Serous Membranes 137 The Cutaneous Membrane 139 Synovial Membranes 139
- 4-7 Connective tissue creates the internal framework of the body 139
- 4-8 The three types of muscle tissue are skeletal, cardiac, and smooth 140
 Skeletal Muscle Tissue 140
 Cardiac Muscle Tissue 142
 Smooth Muscle Tissue 142
- 4-9 Neural tissue responds to stimuli and propagates electrical impulses throughout the body 142
- 4-10 The response to tissue injury involves inflammation and regeneration 144 Inflammation 144 Regeneration 144
- With advancing age, tissue repair declines and cancer rates increase 144
 Aging and Tissue Structure 144
 Aging and Cancer Incidence 146
- Chapter Review 146

Spotlights

UNIT 2 SUPPORT AND MOVEMENT

The Integumentary System 150

An Introduction to the Integumentary System 151

5-1 The epidermis is composed of layers with various functions 153 Stratum Basale 153 Stratum Spinosum 153 Stratum Granulosum 155 Stratum Lucidum 155 Stratum Corneum 155

- 5-2 Factors influencing skin color are epidermal pigmentation and dermal circulation 155 The Role of Epidermal Pigmentation 156 The Role of Dermal Circulation 157
- 5-3 Sunlight causes epidermal cells to convert a steroid into vitamin D₃ 158
- **5-4** Epidermal growth factor has several effects on the epidermis and epithelia 159
- 5-5 The dermis is the tissue layer that supports the epidermis 160
 Dermal Strength and Elasticity 160
 Cleavage Lines 161
 The Dermal Blood Supply 161
 Innervation of the Skin 161
- **5-6** The hypodermis connects the dermis to underlying tissues 162
- 5-7 Hair is composed of keratinized dead cells that have been pushed to the surface 163

 Hair Production 165
 The Hair Growth Cycle 165
 Types of Hairs 165
 Hair Color 165
- 5-8 Sebaceous glands and sweat glands are exocrine glands found in the skin 166
 Sebaceous Glands 166
 Sweat Glands 167
 Other Integumentary Glands 168
 Control of Glandular Secretions and the Homeostatic Role of the Integument 168
- **5-9** Nails are keratinized epidermal cells that protect the tips of fingers and toes 169
- **5-10** Several phases are involved in repairing the integument following an injury 169
- 5-11 Effects of aging include skin thinning, wrinkling, and reduced melanocyte activity 172

```
The Axial Skeleton
                   206
```

An Introduction to the Axial Skeleton 207

- The 80 bones of the head and trunk make up the axial skeleton 207
- The skull is composed of 8 cranial bones and 14 facial bones 207
- Each orbital complex contains an eve, and the nasal complex encloses the nasal cavities 223 The Orbital Complexes 223 The Nasal Complex 223
- Fontanelles are non-ossified areas between cranial bones that allow for brain growth in infants and small children 224
- The vertebral column has four spinal curves 226 Spinal Curvature 226 Vertebral Anatomy 227
- The five vertebral regions are the cervical, thoracic, lumbar, sacral, and coccygeal regions 228 Cervical Vertebrae 229 Thoracic Vertebrae 232 Lumbar Vertebrae 232 The Sacrum 232 The Coccyx 235

The thoracic cage protects organs in the chest and provides sites for muscle attachment 235 The Ribs 235 The Sternum 236

- - Sectional Anatomy of the Skull 212

Knocked Out 207

Temporomandibular Joint Syndrome 222 Sinusitis 225 Craniostenosis 226 Kyphosis, Lordosis, and Scoliosis 229

The Appendicular Skeleton 241

An Introduction to the Appendicular Skeleton 242

The pectoral girdles—the clavicles and scapulae attach the upper limbs to the axial skeleton 242 The Clavicles 244 The Scapulae 244

- 8-2 The upper limbs are adapted for free movement 245 The Humerus 245 The Ulna 247 The Radius 247 The Carpal Bones 247 The Metacarpal Bones and Phalanges 248
 8-3 The pelvic girdle—two hip bones—attaches the lower limbs to the axial skeleton 250
- The Pelvis 250 The Pelvis 250

8-4 The lower limbs are adapted for movement and support 254
The Femur 254
The Patella 254
The Tibia 256
The Fibula 256
The Tarsal Bones 257

The Metatarsal Bones and Phalanges 258

- 8-5 Sex differences and age account for individual skeletal variation 258
- Chapter Review 260

Spotlights

Sex Differences in the Human Skeleton 253

Clinical Case

The Orthopedic Surgeon's Nightmare 242

Clinical Notes

Carpal Tunnel Syndrome 249 Hip Fracture 254 Runner's Knee 254 Stress Fractures 258 Congenital Talipes Equinovarus 258

Joints 263

An Introduction to Joints 264

9-1 Joints are categorized according to their range of motion or structure 264

9-2 Synovial joints are freely movable joints containing synovial fluid 266

 Articular Cartilage 266
 Synovial Fluid 267
 Accessory Structures 267
 Factors That Stabilize Synovial Joints 267

- 9-3 The structure and function of synovial joints enable various skeletal movements 268
 Types of Movements at Synovial Joints 269
- 9-4 Intervertebral discs and ligaments are structural components of intervertebral joints 274
 Intervertebral Discs 274
 Intervertebral Ligaments 275
 Vertebral Movements 275

- 9-5 The shoulder is a ball-and-socket joint, and the elbow is a hinge joint 276
 The Shoulder Joint 276
 The Elbow Joint 278
- 9-6 The hip is a ball-and-socket joint, and the knee is a hinge joint 279The Hip Joint 279

The Knee Joint 280

- 9-7 With advancing age, arthritis and other degenerative changes impair joint mobility 283
- **9-8** The skeletal system supports and stores energy and minerals for other body systems 284

Chapter Review 286

10

Muscle Tissue 289

An Introduction to Muscle Tissue 290

- **10-1** Skeletal muscle performs six major functions 290
- 10-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves 291
 Organization of Connective Tissues 292
 Blood Vessels and Nerves 292
- 10-3 Skeletal muscle fibers have distinctive features 292 The Sarcolemma and Transverse Tubules 292 Myofibrils 293 The Sarcoplasmic Reticulum 294 Sarcomeres 295 Sliding Filaments and Muscle Contraction 298

10-4 The nervous system communicates with skeletal muscles at the neuromuscular junction 299

Electrical Impulses and Excitable Membranes 302 The Control of Skeletal Muscle Activity 302 Excitation–Contraction Coupling 302 Relaxation 308

10-5 Sarcomere shortening and muscle fiber stimulation produce tension 308

Tension Production by Muscle Fibers308Tension Production by Skeletal Muscles312Motor Units and Tension Production312

- 10-6 ATP provides energy for muscle contraction 316 ATP and CP Reserves 316 ATP Generation 317 Energy Use and the Level of Muscular Activity 318 Muscle Fatigue 318 The Recovery Period 318 Hormones and Muscle Metabolism 320
- 10-7 Muscle performance capabilities depend on muscle fiber type and physical conditioning 320 Types of Skeletal Muscle Fibers 320 Muscle Performance and the Distribution of Muscle Fibers 321 Muscle Hypertrophy and Atrophy 321 Physical Conditioning 322
- 10-8 Cardiac muscle tissue differs structurally and functionally from skeletal muscle tissue 324
 Structural Characteristics of Cardiac Muscle Tissue 324
 Functional Characteristics of Cardiac Muscle Tissue 325
- **10-9** Smooth muscle tissue differs structurally and functionally from skeletal and cardiac muscle tissue 325

Structural Characteristics of Smooth Muscle Tissue326Functional Characteristics of Smooth Muscle Tissue327

The Muscular System 332

An Introduction to the Muscular System 333

- 11-1 Fascicle arrangement is correlated with muscle power and range of motion 333
 Parallel Muscles 333
 Convergent Muscles 333
 Pennate Muscles 334
 Circular Muscles 335
- **11-2** The three classes of levers increase muscle efficiency 335
- 11-3 Muscle origins are at the fixed end of muscles, and insertions are at the movable end of muscles 336
 Origins and Insertions 336
 Actions 337

11-4 Descriptive terms are used to name skeletal

muscles 339 Location in the Body 339 Origin and Insertion 339 Fascicle Organization 339 Position 339 Structural Characteristics 339 Action 340 Axial and Appendicular Muscles 341

- Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor 341 Muscles of the Head and Neck 341 Muscles of the Vertebral Column 351 Oblique and Rectus Muscles 354 Muscles of the Pelvic Floor 356
- Appendicular muscles are muscles of the shoulders, upper limbs, pelvis, and lower limbs 358
 Muscles of the Shoulders and Upper Limbs 358
 Muscles of the Pelvis and Lower Limbs 369
- **11-7** With advancing age, the size and power of muscle tissue decrease 379
- **11-8** Exercise produces responses in multiple body systems 379

Neural Tissue 385

286

An Introduction to Neural Tissue 386

12-1 The nervous system has anatomical and functional divisions 386

The Anatomical Divisions of the Nervous System386The Functional Divisions of the Nervous System387

- 12-2 Neurons are nerve cells specialized for intercellular communication 388
 The Structure of Neurons 388
 The Classification of Neurons 390
- 12-3 CNS and PNS neuroglia support and protect neurons 392 Neuroglia of the Central Nervous System 392 Neuroglia of the Peripheral Nervous System 397 Neural Responses to Injuries 398

- 12-4 The membrane potential is the electrical potential of the cell's interior relative to its surroundings 398 The Membrane Potential 398 Changes in the Membrane Potential 402 Graded Potentials 404
- 12-5 An action potential is an electrical event 406 The All-or-None Principle 406 Generation of Action Potentials 406 Propagation of Action Potentials 407
- 12-6 Axon diameter, in addition to myelin, affects propagation speed 412
- 12-7 At synapses, communication occurs among neurons or between neurons and other cells 413 Synaptic Activity 413 General Properties of Synapses 413 Cholinergic Synapses 414
- **12-8** Neurotransmitters and neuromodulators have various functions 416

The Activities of Other Neurotransmitters 416 Neuromodulators 417 How Neurotransmitters and Neuromodulators Work 420

 12-9 Individual neurons process information by integrating excitatory and inhibitory stimuli 421 Postsynaptic Potentials 421

> Presynaptic Inhibition and Presynaptic Facilitation 423 The Rate of Generation of Action Potentials 423

> The Spinal Cord, Spinal Nerves, and Spinal Reflexes 429

- An Introduction to the Spinal Cord, Spinal Nerves, and Spinal Reflexes 430
- **13-1** The brain and spinal cord make up the central nervous system (CNS), and the cranial nerves and spinal nerves make up the peripheral nervous system (PNS) 430
- 13-2 The spinal cord is surrounded by three meninges and carries sensory and motor information 431
 Gross Anatomy of the Spinal Cord 431
 Spinal Meninges 433

- 13-3 Gray matter integrates information and initiates commands, and white matter carries information from place to place 435
 Organization of Gray Matter 437
 Organization of White Matter 437
- 13-4 Spinal nerves form plexuses that are named according to their level of emergence from the vertebral canal 437

Anatomy of Spinal Nerves 437 Peripheral Distribution of Spinal Nerves 438 Nerve Plexuses 438

- **13-5** Interneurons are organized into functional groups called neuronal pools 447
- 13-6 Reflexes are rapid, automatic responses to stimuli 449 The Reflex Arc 449 Classification of Reflexes 452
- **13-7** Spinal reflexes vary in complexity 453 Monosynaptic Reflexes 453 Polysynaptic Reflexes 454
- 13-8 The brain can affect spinal cord-based reflexes 455
 Voluntary Movements and Reflex Motor Patterns 456
 Reinforcement and Inhibition 456

The Brain and Cranial Nerves 461

An Introduction to the Brain and Cranial Nerves 462

14-1 The brain has several principal structures, each with specific functions 462

Major Brain Regions and Landmarks 462 Embryology of the Brain 464 Ventricles of the Brain 464

- 14-2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood-brain barrier 465
 The Cranial Meninges 465
 Cerebrospinal Fluid 467
 - The Blood Supply to the Brain 469

- **14-3** The medulla oblongata is continuous with the spinal cord and contains vital centers 470
- **14-4** The pons contains nuclei and tracts that carry or relay sensory and motor information 472
- **14-5** The cerebellum coordinates learned and reflexive patterns of muscular activity at the subconscious level 473
- **14-6** The midbrain regulates auditory and visual reflexes and controls alertness 475
- 14-7 The diencephalon integrates sensory information with motor output at the subconscious level 477 The Thalamus 477 The Hypothalamus 478
- **14-8** The limbic system is a group of tracts and nuclei that function in emotion, motivation, and memory 480
- **14-9** The cerebrum, the largest region of the brain, contains motor, sensory, and association areas 482

The Cerebral Cortex 482 The White Matter of the Cerebrum 482 The Basal Nuclei 482 Motor and Sensory Areas of the Cortex 486

14-10 Cranial reflexes involve sensory and motor fibers of cranial nerves 503

Sensory Pathways and the Somatic Nervous System 508

- An Introduction to Sensory Pathways and the Somatic Nervous System 509
- **15-1** Sensory information from all parts of the body is routed to the somatosensory cortex 509
- **15-2** Sensory receptors connect our internal and external environments with the nervous system 510 The Detection of Stimuli 510

The Interpretation of Sensory Information 511 Adaptation 512

15-3 General sensory receptors are classified by the type of stimulus that excites them 513

Nociceptors 513 Thermoreceptors 514 Mechanoreceptors 514 Chemoreceptors 517

- 15-4 Separate pathways carry somatic sensory and visceral sensory information 518
 Somatic Sensory Pathways 518
 - Visceral Sensory Pathways 523
- **15-5** The somatic nervous system is an efferent division that controls skeletal muscles 523

The Corticospinal Pathway 524 The Medial and Lateral Pathways 525 The Basal Nuclei and Cerebellum 526

Levels of Processing and Motor Control 527

16 The Autonomic Nervous System and Higher-Order Functions 531

- An Introduction to the Autonomic Nervous System and Higher-Order Functions 532
- 16-1 The autonomic nervous system is involved in the unconscious regulation of visceral functions and has sympathetic and parasympathetic divisions 532
 Organization of the ANS 532
 Divisions of the ANS 533
- **16-2** The sympathetic division consists of preganglionic neurons and ganglionic neurons involved in using energy and increasing metabolic rate 536

Organization and Anatomy of the Sympathetic Division 537

Sympathetic Activation 540

16-3 Stimulation of sympathetic neurons leads to the release of various neurotransmitters 540 Sympathetic Stimulation and the Release of

NE and E 541 Sympathetic Stimulation and the Release of ACh and NO 541

Summary: The Sympathetic Division 542

16-4 The parasympathetic division consists of preganglionic neurons and ganglionic neurons involved in conserving energy and lowering metabolic rate 542
 Organization and Anatomy of the Parasympathetic Division 542
 Parasympathetic Activation 542

- Stimulation of parasympathetic neurons leads to the release of the neurotransmitter ACh 544
 Neurotransmitter Release 544
 Membrane Receptors and Responses 544
 Summary: The Parasympathetic Division 544
- 16-6 The sympathetic and parasympathetic divisions interact, creating dual innervation 545 Anatomy of Dual Innervation 545 Autonomic Tone 546
- 16-7 Visceral reflexes play a role in the integration and control of autonomic functions 549
 Visceral Reflexes 549
 Higher Levels of Autonomic Control 550
 The Integration of SNS and ANS Activities 551
- Higher-order functions include memory and states of consciousness 552
 Memory 552
 States of Consciousness 554
- 16-9 Neurotransmitters influence brain chemistry and behavior 556
- **16-10** Aging produces various structural and functional changes in the nervous system 557

The Endocrine System 608

An Introduction to the Endocrine System 609

- **18-1** Homeostasis is preserved through intercellular communication 609
- The endocrine system regulates physiological processes through the binding of hormones to receptors 611
 Classes of Hormones 611
 Secretion and Distribution of Hormones 612
 Mechanisms of Hormone Action 614

Control of Endocrine Activity by Endocrine Reflexes 616

18-3 The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones 619
 The Anterior Lobe of the Pituitary Gland 619

The Posterior Lobe of the Pituitary Gland623Summary: The Hormones of the Pituitary Gland625

- 18-4 The thyroid gland lies inferior to the larynx and requires iodine for hormone synthesis 626
 Thyroid Follicles and Thyroid Hormones 626
 Functions of Thyroid Hormones 628
 The C Cells of the Thyroid Gland and Calcitonin 629
- **18-5** The four parathyroid glands, embedded in the posterior surface of the thyroid gland, secrete parathyroid hormone to elevate blood Ca²⁺ 630
- 18-6 The adrenal glands, consisting of a cortex and medulla, cap the kidneys and secrete several hormones 631
 The Adrenal Cortex 631
 The Adrenal Medulla 634

- **18-7** The pineal gland, attached to the roof of the third ventricle, secretes melatonin 634
- 18-8 The pancreas is both an exocrine organ and endocrine gland 635
 The Pancreatic Islets 636
 Insulin 637

Glucagon 637

- 18-9 Many organs have secondary endocrine functions 639
 The Intestines 639
 The Kidnevs 639
 - The Heart 640 The Thymus 640 The Gonads 641 Adipose Tissue 643
- 18-10 Hormones interact to produce coordinated physiological responses 643

UNIT 4 FLUIDS AND TRANSPORT

19 Blood 652

An Introduction to Blood and the Cardiovascular System 653

- **19-1** Blood has several important functions and unique physical characteristics 653
- 19-2 Plasma, the fluid portion of blood, contains significant quantities of plasma proteins 656
 Plasma Proteins 656
- 19-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled 657 Abundance of RBCs 657 Structure of RBCs 658 Hemoglobin 659 RBC Formation and Turnover 660 RBC Production 661

19-4 The ABO blood types and Rh system are based on antigen-antibody responses 664 Cross-Reactions in Transfusions 666 Testing for Transfusion Compatibility 666

19-5 The various types of white blood cells contribute to the body's defenses 667

WBC Circulation and Movement 667Types of WBCs 670The Differential Count and Changes in WBC Profiles 671WBC Production 672

 19-6 Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process 674
 Platelet Functions 675
 Platelet Production 675

19-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation 675

The Vascular Phase 675 The Platelet Phase 676 The Coagulation Phase 677 Fibrinolysis 679

Blood Vessels and Circulation

An Introduction to Blood Vessels and Circulation 724

 21-1 Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and functional properties 724 The Structure of Vessel Walls 725 Differences between Arteries and Veins 726 Capillaries 729 Veins 732 The Distribution of Blood 733

723

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange 734

Pressure 734 Total Peripheral Resistance 734 An Overview of Cardiovascular Pressures 736 Capillary Pressures and Capillary Exchange 739

 21-3 Cardiovascular regulatory mechanisms involve autoregulation, neural mechanisms, and endocrine responses 742 Autoregulation of Blood Flow within Tissues 742 Neural Mechanisms 743

Hormones and Cardiovascular Regulation 746

21-4 The cardiovascular system adapts to physiological stress and maintains a special vascular supply to the brain, heart, and lungs 749

The Cardiovascular Response to Exercise 749

The Cardiovascular Response to Hemorrhaging 751 Vascular Supply to Special Regions 752

- 21-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns 753
- **21-6** In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins 754
- 21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the pulmonary exchange surfaces, and returns deoxygenated blood to the right atrium 755
 Systemic Arteries 755
 Systemic Veins 763
- 21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials, and independence occurs at birth 772
 Placental Blood Supply 772
 Fetal Circulation in the Heart and Great Vessels 772
 Cardiovascular Changes at Birth 773

21-9 Aging affects the blood, heart, and blood vessels 775

The Respiratory System 830

An Introduction to the Respiratory System 831

- 23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, has several basic functions 831
 Functions of the Respiratory System 831
 Organization of the Respiratory System 832
- 23-2 Located outside the thoracic cavity, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx 835
 The Nose, Nasal Cavity, and Paranasal Sinuses 835
 The Pharynx 837
- 23-3 Composed of cartilages, ligaments, and muscles, the larynx produces sound 837 Cartilages and Ligaments of the Larynx 837 Sound Production 838 The Laryngeal Musculature 839
- 23-4 The trachea and primary bronchi convey air to and from the lungs 839
 The Trachea 839
 The Primary Bronchi 840
- 23-5 Enclosed by pleural cavities, the lungs are paired organs containing alveoli, which permit gaseous exchange 841
 Lobes and Surfaces of the Lungs 841
 The Bronchi 841
 The Bronchioles 841
 - Alveolar Ducts and Alveoli 843
 - The Blood Supply to the Lungs 846

The Pleural Cavities and Pleural Membranes 846

- 23-6 External respiration and internal respiration allow gaseous exchange within the body 847
- 23-7 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs—involves pressure changes, muscle movement, and respiratory rates and volumes 848
 The Movement of Air 848
 Pressure Changes during Inhalation and Exhalation 849
 The Mechanics of Breathing 852
 - Respiratory Rates and Volumes 854
- 23-8 Gas exchange depends on the partial pressures of gases and the diffusion of molecules 856 The Gas Laws 856 Diffusion and Respiratory Function 858

23-9 Most oxygen is transported bound to hemoglobin; and carbon dioxide is transported in three ways: as carbonic acid, bound to hemoglobin, or dissolved in plasma 860 Oxygen Transport 860 Carbon Dioxide Transport 863 Summary: Gas Transport 864 23-10 Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration 864 Local Regulation of Gas Transport and Alveolar Function 865 The Respiratory Centers of the Brain 866 Respiratory Reflexes 870 Voluntary Control of Respiration 872 Changes in the Respiratory System at Birth 872 23-11 Respiratory performance declines with age 873 23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems 873 Chapter Review 876 **Spotlights** Respiratory Muscles and Pulmonary Ventilation 853 Control of Respiration 868 **Clinical Case** How Long Should a Cough Last? 831

25 Metabolism and Energetics 935

An Introduction to Metabolism and Energetics 936

- 25-1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy 936
- 25-2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis 939
 Glycolysis 939
 Mitochondrial ATP Production 939
 Energy Yield of Glycolysis and Cellular Respiration 945
 Gluconeogenesis 946
- 25-3 Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as free fatty acids and lipoproteins 947
 Lipid Catabolism 947
 Lipid Synthesis 949
 Lipid Transport and Distribution 949
- **25-4** Protein catabolism involves transamination and deamination, whereas protein synthesis involves amination and transamination 952

Amino Acid Catabolism 952 Protein Synthesis 952

- **25-5** The body experiences two patterns of metabolic activity: the absorptive and postabsorptive states 956
- **25-6** Adequate nutrition is necessary to prevent deficiency disorders and ensure physiological functioning 957

Food Groups and a Balanced Diet 957 Nitrogen Balance 957 Minerals 959 Vitamins 960 Diet and Disease 961

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms 962

An Introduction to Anatomy and Physiology

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **1-1** Explain the importance of studying anatomy and physiology.
- **1-2** Define anatomy and physiology, describe the origins of anatomical and physiological terms, and explain the significance of *Terminologia Anatomica (International Anatomical Terminology)*.
- **1-3** Explain the relationship between anatomy and physiology, and describe various specialties of each discipline.
- 1-4 Identify the major levels of organization in organisms, from the simplest to the most complex, and identify major components of each organ system.
- 1-5 Explain the concept of homeostasis.
- **1-6** Describe how negative feedback and positive feedback are involved in homeostatic regulation, and explain the significance of homeostasis.
- **1-7** Use anatomical terms to describe body regions, body sections, and relative positions.
- **1-8** Identify the major body cavities and their subdivisions, and describe the functions of each.

Clinical Notes

- Autopsies and Cadaver Dissection p. 5
- Auscultation p. 14

SPOTLIGHTS

- Levels of Organization pp. 8–9
- Diagnostic Imaging Techniques pp. 20–21

CLINICAL CASE

• Using A&P to Save a Life p. 2

Using A&P to Save a Life

The emergency medical technician (EMT) is on the way to the emergency room with a young victim

of street violence. A knife with a 6-inch blade had been found next to the bleeding, unconscious man.

"We have a young male with multiple stab wounds. He has lost a lot of blood and we can barely get a blood pressure," the EMT radioes to the triage nurse in the emergency room as the ambulance squeals through traffic. "We started an IV and we are pouring in fluid as fast as we can."

"Where are the wounds?" asks the receiving nurse. "He has a deep wound in his right upper quadrant, just inferior to the diaphragm. I can see bruising from the hub of the knife around the wound, and there is another wound in his anterior right thigh. His pulse is 120 and thready [weak]. His blood pressure is 60 over 30." "How long has he been down?" questions the nurse. "Less than a half hour. We intubated him [inserted a breathing tube] and started a large bore IV as soon as we got there. We are 10 minutes out now.""Keep the fluids going wide open, keep pressure on the thigh, and take him directly to Trauma Room 1," come the instruc-

tions. Meanwhile the nurse orders the trauma team to Trauma Room 1, orders x-ray to be on stand-by in the room, and requests 4 units of type O negative whole blood—the universal donor blood—from the blood bank. Will the team be ready to save this young man? To find out, turn to the Clinical Case Wrap-Up on p. 25.

An Introduction to Studying the Human Body

In this textbook we will introduce you to the inner workings of your body, giving information about both its structure (anatomy) and its function (physiology). Many students who use this book are preparing for jobs in health-related fields but regardless of your career choice, you will find the information within these pages relevant to your future. You do, after all, live in a human body! As a human, you are most likely very curious, and few subjects arouse so much curiosity as our own bodies. The study of anatomy and physiology will provide answers to many questions about the way your body works in both health and disease.

We will focus on the human body, but the principles you will learn apply to other living things as well. Our world contains an enormous diversity of living organisms. They vary widely in appearance and lifestyle. One aim of biology—the science of life—is to discover the unity and the patterns that underlie this diversity, and in this way shed light on what we have in common with other living things.

We can classify animals according to the characteristics that they share. Birds, fish, and humans are placed in a group called the *vertebrates*, characterized by a segmented vertebral column. Their shared characteristics and organizational patterns are clues about how these animals have evolved over time. Many of the complex structures and functions of the human body that we discuss in this book have distant evolutionary origins. When we compare human beings with other creatures, we find two important principles:

- There are obvious structural and functional similarities among vertebrates.
- Form determines function.

In this chapter we explore the structural and functional characteristics of living things. We look at the levels of organization that anatomical structures and physiological processes display. We also introduce *homeostasis*, the state of balance within the body, which is the goal of physiological regulation and the key to survival in a changing environment.

1-1 Anatomy and physiology directly affect your life

Learning Outcome Explain the importance of studying anatomy and physiology.

Welcome to the field of anatomy and physiology! Anatomy is the study of body structures and physiology is the study of body functions. You will discover how your body works under normal and abnormal conditions. This knowledge will serve as the foundation for understanding all other basic life sciences, and for making common sense decisions about your own life. Basic knowledge of normal physiological function, for example, will prove useful whenever you or a friend or relative becomes ill. We will explain how the body responds to normal and abnormal conditions and maintains homeostasis. As we proceed, you will see how your body copes with injury, disease, or anything that threatens homeostasis.

Anatomy is the oldest medical science. Egyptian drawings from 1600 BCE illustrated basic knowledge of blood vessels.

These drawings show that people have always been fascinated with the human body. Since that time, imaging techniques for studying the human body have evolved, enabling us to describe the locations and functions of body parts. Over the last two decades, the most rapid progress has taken place in the field of molecular biology, which studies processes at the level of individual genes. It uses principles of biology, chemistry, genetics, and biochemistry. Molecular biology helps us understand how the body works at the most fundamental level and reveals the underlying basis for many disorders and diseases.

Medical science is always expanding and affects our everyday lives. We are flooded with health information from the popular press, news media, and advertisements. Medical terms have become part of our common language, and we owe it to ourselves to understand them. This course will significantly expand your vocabulary and enhance your understanding of the origins and meanings of many medical terms.

CHECKPOINT

- 1. Identify the oldest medical science.
- 2. Why is studying human anatomy and physiology important?

See the blue Answers tab at the back of the book.

1-2 Anatomy is structure, and physiology is function

Learning Outcome Define anatomy and physiology, describe the origins of anatomical and physiological terms, and explain the significance of *Terminologia Anatomica (International Anatomical Terminology)*.

People have always been interested in the inner workings of the human body. Many medical terms have Greek roots, as do many other anatomical terms and phrases that originated more than 1500 years ago. For example, the term *anatomy* is derived from Greek roots that mean "a cutting open." **Anatomy** is the study of internal and external body structures and their physical relationships among other body parts. In contrast, **physiology**, another Greek term, is the study of how living organisms perform their functions. Someone studying anatomy might, for example, examine how a particular muscle attaches to the skeleton. Someone studying physiology might consider how a muscle contracts or what forces a contracting muscle exerts on the skeleton. You will be studying both anatomy and physiology in this book, so let's look at the relationships between these sciences.

Early anatomists faced serious problems in communication. Saying that a bump is "on the back," for example, does not give very precise information about its location. So anatomists created maps of the human body. Prominent anatomical structures serve as landmarks, distances are measured in centimeters or inches, and specialized directional terms are used. In effect, anatomy uses a special language that you must learn almost at the start of your study.

That special language, called **medical terminology**, involves using word roots, prefixes, suffixes, and combining forms to build terms related to the body in health and disease. Many of the anatomical and physiological terms you will encounter in this textbook are derived from Greek or Latin. Learning the word parts used in medical terminology will greatly assist in your study of anatomy and physiology, and in your preparation for any health-related career.

There are four basic building blocks—or word parts—of medical terms. *Word roots* are the basic, meaningful parts of a term that cannot be broken down into another term with another definition. *Prefixes* are word elements that are attached to the beginning of words to modify their meaning but cannot stand alone. *Suffixes* are word elements or letters added to the end of a word or word part to form another term. *Combining forms* are independent words or word roots that are used in combination with words, prefixes, suffixes, or other combining forms to build a new term. The table inside the back cover of your textbook lists many commonly used word roots, prefixes, suffixes, and combining forms.

To illustrate the building of medical terms, consider the word *pathology* (puh-THOL-ō-jē). Breaking this word into its basic elements reveals its meaning. The prefix *path*- refers to disease (the Greek term for disease is *pathos*). The suffix *-ology* means "study of." So pathology is the study of disease.

A familiarity with Latin and Greek word roots and patterns makes anatomical terms easier to understand. As we introduce new terms, we will provide notes on pronunciation and relevant word parts.

Latin and Greek terms are not the only ones that have been imported into the anatomical vocabulary over the centuries, and this vocabulary continues to expand. Many anatomical structures and clinical conditions were first named after either the discoverer or, in the case of diseases, the most famous victim. Over the last 100 years, most of these commemorative names, or **eponyms**, have been replaced by more precise terms. Where appropriate, we will give both the eponym and the more precise term, because in clinical medicine, both terms may be used. The Glossary at the end of this book includes a table listing important eponyms and related historical details.

It is important for scientists throughout the world to use the same name for each body structure. In 1998, two scientific organizations—the Federative Committee on Anatomical Terminology and the 56 member associations of the International Associations of Anatomists—published International Anatomical Terminology (Terminologia Anatomica, or TA). Terminologia Anatomica serves as a worldwide official standard of anatomical vocabulary. Latin continues to be the language of anatomy, but this reference provides an English equivalent term for each anatomical structure. For example, the tendo calcaneus (Latin) is also called the calcaneal tendon (English). You may know the structure better by its eponym, the Achilles tendon. Eponyms are not found in *TA*. We have used *TA* as our standard in preparing this text.

CHECKPOINT

- **3**. Define anatomy.
- 4. Define physiology.
- 5. Describe medical terminology.
- **6**. Define eponym.
- 7. Name the book that serves as the international standard for anatomical vocabulary.

See the blue Answers tab at the back of the book.

1-3 Anatomy and physiology are closely integrated

Learning Outcome Explain the relationship between anatomy and physiology, and describe various specialties of each discipline.

Anatomy and physiology are closely integrated, both theoretically and practically. Anatomical information provides clues about functions, and physiological processes can be explained only in terms of the underlying anatomy. This is a very important concept in living systems:

• All specific functions are performed by specific structures, and the form of a structure relates to its function. This is known as the *principle of complementarity of structure and function*.

The link between structure and function is always present, but not always understood. For example, the anatomy of the heart was clearly described in the 15th century, but almost 200 years passed before the heart's pumping action was demonstrated.

Anatomists and physiologists approach the relationship between structure and function from different perspectives. To understand the difference, suppose you asked an anatomist and a physiologist to examine a pickup truck and report their findings. The anatomist might begin by measuring and photographing the various parts of the truck and, if possible, taking it apart and putting it back together. The anatomist could then explain its key structural relationships-for example, how the pistons are seated in the engine cylinders, how the crankshaft is connected to the pistons, how the transmission links the drive shaft to the axles, and thus to the wheels. The physiologist also would note the relationships among the truck's parts, but he or she would focus mainly on its functional characteristics, such as how the combustion of gasoline in the cylinders moves the pistons up and down and makes the drive shaft rotate, and

how the transmission conveys this motion to the axles and wheels so that the car moves. Additionally, he or she might also study the amount of power that the engine could generate, the amount of force transmitted to the wheels in different gears, and so on.

Our basic approach in this text will be to start with the descriptive anatomy of body structures (appearance, size, shape, location, weight, and color) before considering the related functions. Sometimes the group of organs that make up an organ system perform very diverse functions, and in those cases we will consider the functions of each individual organ separately. A good example is our discussion of the digestive system. You will learn about the functions of the salivary glands in one section, and the functions of the tongue in another. In other systems, the organs work together so extensively that we present an overall discussion of their physiology, after we describe the system's anatomy. The lymphatic system and the cardiovascular system are examples of this approach.

Anatomy

How you look at things often determines what you see. You get a very different view of your neighborhood from a satellite photo than from your front yard. Similarly, your method of observation has a dramatic effect on your understanding of the structure of the human body. Based on the degree of structural detail being considered, we divide anatomy into gross (macroscopic) anatomy and microscopic anatomy.

Gross Anatomy

Gross anatomy, or *macroscopic anatomy*, involves examining relatively large structures. Gross anatomy can be seen without using a microscope and can involve the study of anatomy by dissecting a cadaver. There are many different forms of gross anatomy:

- *Surface anatomy* is the study of general form and superficial (toward the body surface) markings.
- *Regional anatomy* focuses on the anatomical organization of specific areas of the body, such as the head, neck, or trunk. Many advanced courses in anatomy stress a regional approach, because it emphasizes the spatial relationships among structures already familiar to students.
- Systemic anatomy is the study of the structure of organ systems, which are groups of organs that function together in a coordinated manner. Examples include the *skeletal system*, composed primarily of bones; the *muscular system*, made up of skeletal muscles; and the *cardiovascular system*, consisting of the heart, blood, and vessels. We take a systemic anatomy approach in this book because this format will better clarify the functional relationships among the

Clinical Note

Autopsies and Cadaver Dissection There is much to be learned from death. An *autopsy* is a thorough internal and external examination of the body after death to determine the cause of death. Autopsies and cadaver dissections reveal much about life. Historically, humans have been fascinated with the human body. Scientists, physicians, and artists shared this fascination. For example, as early as 304 BCE, Greek anatomist and royal physician Erasistratus and his physician colleague, Herophilus, dissected human cadavers to learn about internal anatomy. In the second century, physician Claudius Galen, often recognized as the "father of anatomy," was the first to show a connection between patient symptoms in life and the autopsy observations in death. In the late 1200s, the University of Bologna was the first institution to perform autopsies. In 1632, the Dutch painter, Rembrandt created The Anatomy Lesson of Dr. Nicolaes Tulp. An Italian anatomist, Giovanni Morgagni, advanced the field of anatomical pathology with his 1761 work, On the Seats

and Causes of Diseases. In 1910, Dr. Richard Cabot, an American physician, studied autopsies and learned that doctors had misdiagnosed their patients 40 percent of the time. Today, using cadavers to learn anatomy is commonplace. Many students consider it to be a profound experience.

component organs. We will introduce the 11 organ systems in the human body later in the chapter.

- Clinical anatomy includes a number of subspecialties important in clinical practice. Examples include *pathological* anatomy (anatomical features that change during illness), radiographic anatomy (anatomical structures seen using specialized imaging techniques), and surgical anatomy (anatomical landmarks important in surgery).
- Developmental anatomy describes the changes in form that take place between conception and adulthood. The techniques of developmental anatomists are similar to those used in gross anatomy and in microscopic anatomy (discussed next) because developmental anatomy considers anatomical structures over a broad range of sizes—from a single cell to an adult human. The most extensive structural changes take place during the first two months of development. The study of these early developmental processes is called **embryology** (em-brē-OL-ō-jē).

Microscopic Anatomy

Microscopic anatomy deals with structures that we cannot see without magnification. The boundaries of microscopic anatomy are set by the limits of the equipment we use. With a dissecting microscope you can see tissue structure. With a light microscope, you can see basic details of cell structure. And with an electron microscope, you can see individual molecules that are only a few nanometers (billionths of a meter) across.

Microscopic anatomy includes two major subdivisions: cytology and histology. Cytology (sī-TOL-ō-jē) is the study of the internal structure of individual cells, the simplest units of life. Cells are made up of chemical substances in various combinations, and our lives depend on the chemical processes taking place in the trillions of cells in the body. For this reason, we consider basic chemistry (Chapter 2) before we examine cell structure (Chapter 3). Histology (his-TOL-ō-jē) is the examination of tissues-groups of specialized cells and cell products that work together to perform specific functions (Chapter 4). Tissues combine to form **organs**, such as the heart, kidney, liver, or brain, each with specific functions. Many organs are easy to examine without a microscope, so at the organ level we cross the boundary from microscopic anatomy to gross anatomy. As we proceed through the text, we will consider details at all levels, from microscopic to macroscopic (Spotlight Figure 1-1).

Physiology

As noted earlier, physiology is the study of the function of anatomical structures. **Human physiology** is the study of the functions, or workings, of the human body. These functions are complex processes and much more difficult to examine than most anatomical structures. As a result, there are even more specialties in physiology than in anatomy. Examples include:

- *Cell physiology*, the study of the functions of cells, is the cornerstone of human physiology. Cell physiology looks at events involving the atoms and molecules important to life. It includes both chemical processes within cells and chemical interactions among cells.
- *Organ physiology* is the study of the function of specific organs. An example is *cardiac physiology*, the study of heart function—how the heart works.
- Systemic physiology includes all aspects of the functioning of specific organ systems. Cardiovascular physiology, respiratory physiology, and reproductive physiology are examples.
- Pathological physiology is the study of the effects of diseases on organ functions or system functions. Modern medicine depends on an understanding of both normal physiology and pathological physiology.

Physicians normally use a combination of anatomical, physiological, chemical, and psychological information when

they evaluate patients. When a patient presents **signs** (an objective disease indication like a fever) and **symptoms** (a subjective disease indication, such as tiredness) to a physician, the physician will look at the structures affected (gross anatomy), perhaps collect a fluid or tissue sample (microscopic anatomy) for analysis, and ask questions to find out what changes from normal functioning the patient is experiencing. Think back to your last trip to a doctor's office. Not only did the attending physician examine your body, noting any anatomical abnormalities, but he or she also evaluated your physiological processes by asking questions, observing your movements, listening to your body sounds, taking your temperature, and perhaps requesting chemical analyses of fluids such as blood or urine.

In evaluating all these observations to reach a diagnosis, physicians rely on a logical framework based on the scientific method. The **scientific method** is a system of advancing knowledge that begins by proposing a hypothesis to answer a question, and then testing that hypothesis with data collected through observation and experimentation. This method is at the core of all scientific thought, including medical diagnosis.

- CHECKPOINT

- 8. Describe how anatomy and physiology are closely related.
- **9**. What is the difference between gross anatomy and microscopic anatomy?
- 10. Identify several specialties of physiology.
- 11. Why is it difficult to separate anatomy from physiology?

See the blue Answers tab at the back of the book.

1-4 Levels of organization progress from molecules to a complete organism

Learning Outcome Identify the major levels of organization in organisms, from the simplest to the most complex, and identify major components of each organ system.

Over the next three chapters, we will consider the three most basic (chemical, cellular, and tissue) levels of organization of the human body. They interact with more complex structures and vital processes, as we describe in Chapters 5–29. The levels of organization of the human body include:

• *The Chemical Level.* **Atoms** are the smallest stable units of matter. They can combine to form molecules with complex shapes. The atomic components and unique three-dimensional shape of a particular molecule determine its function. For example, complex protein molecules form fil-aments that produce the contractions of muscle cells in the heart. We explore this level of organization in Chapter 2.

- *The Cellular Level.* **Cells** are the smallest living units in the body. Complex molecules can form various types of larger structures called organelles. Each organelle has a specific function in a cell. Energy-producing organelles provide the energy needed for heart muscle cell contractions. We examine the cellular level of organization in Chapter 3.
- *The Tissue Level.* A **tissue** is a group of cells working together to perform one or more specific functions. Heart muscle cells, also called cardiac muscle cells (*cardium*, heart), interact with other types of cells and with materials outside the cell to form cardiac muscle tissue. We consider the tissue level of organization in Chapter 4.
- The Organ Level. Organs are made of two or more tissues working together to perform specific functions. Layers of cardiac muscle tissue, in combination with another type of tissue called connective tissue, form the bulk of the wall of the heart, which is a hollow, three-dimensional organ.
- The Organ System Level. A group of organs interacting to perform a particular function forms an organ system. Each time it contracts, the heart pushes blood into a network of blood vessels. Together, the heart, blood, and blood vessels make up the cardiovascular system, one of 11 organ systems in the body. This system functions to distribute oxygen and nutrients throughout the body.
- The Organism Level. An organism—in this case, an individual human—is the highest level of organization that we consider. All of the body's organ systems must work together to maintain the life and health of the organism.

The organization at each level determines not only the structural characteristics, but also the functions, of higher levels. For example, the arrangement of atoms and molecules at the chemical level creates the protein filaments and organelles at the cellular level that give individual cardiac muscle cells the ability to contract. At the tissue level, these cells are linked, forming cardiac muscle tissue. The structure of the tissue ensures that the contractions are coordinated, producing a powerful heartbeat. When that beat occurs, the internal anatomy of the heart, an organ, enables it to function as a pump. The heart is filled with blood and connected to the blood vessels, and its pumping action circulates blood through the vessels of the cardiovascular system. Through interactions with the respiratory, digestive, urinary, and other systems, the cardiovascular system performs a variety of functions essential to the survival of the organism.

Something that affects a system will ultimately affect each of the system's parts. For example, after massive blood loss, the heart cannot pump blood effectively. When the heart cannot pump and blood cannot flow, oxygen and nutrients cannot be distributed to the heart or around the body. Very soon, the cardiac muscle tissue begins to break down as individual muscle cells die from oxygen and nutrient starvation. These changes will not be restricted to the cardiovascular system. All cells, tissues, and organs in the body will be damaged. **Spotlight Figure 1–1** illustrates the levels of organization and introduces the 11 interdependent, interconnected organ systems in the human body.

The cells, tissues, organs, and organ systems of the body coexist in a relatively small, shared environment, much like the residents of a large city. Just as city dwellers breathe the same air and drink the water supplied by the local water company, cells in the human body absorb oxygen and nutrients from the fluids that surround them. If a city is blanketed in smog or its water supply is contaminated, the people will become ill. Similarly, if the body fluid composition becomes abnormal, cells will be injured or destroyed. For example, suppose the temperature or salt content of the blood changes. The effect on the heart could range from the need for a minor adjustment (heart muscle tissue contracts more often, raising the heart rate) to a total disaster (the heart stops beating, so the individual dies).

CHECKPOINT

- 12. Identify the major levels of organization of the human body from the simplest to the most complex.
- 13. Identify the organ systems of the body and cite some major structures of each.
- 14. At which level of biological organization does a histologist investigate structures?
- See the blue Answers tab at the back of the book.

1-5 I Homeostasis is the state of internal balance

Learning Outcome Explain the concept of homeostasis.

Various physiological processes act to prevent harmful changes in the composition of body fluids and the environment inside our cells. **Homeostasis** (hō-mē-o-STĀ-sis; *homeo*, unchanging + *stasis*, standing) refers to the existence of a stable internal environment. Maintaining homeostasis is absolutely vital to an organism's survival. Failure to maintain homeostasis soon leads to illness or even death.

The principle of homeostasis is the central theme of this text and the foundation of all modern physiology. **Homeostatic regulation** is the adjustment of physiological systems to preserve homeostasis. Physiological systems have evolved to maintain homeostasis in an environment that is often inconsistent, unpredictable, and potentially dangerous. An understanding of homeostatic regulation is crucial to making accurate predictions about the body's responses to both normal and abnormal conditions.

Homeostatic regulation involves two general mechanisms: autoregulation and extrinsic regulation.

1. **Autoregulation** is a process that occurs when a cell, a tissue, an organ, or an organ system adjusts in response to some environmental change. For example, when oxygen levels decline in a tissue, the cells release chemicals that widen, or dilate, blood vessels. This dilation increases the rate of blood flow and provides more oxygen to the region.

2. Extrinsic regulation is a process that results from the activities of the nervous system or endocrine system. These organ systems detect an environmental change and send an electrical signal (nervous system) or chemical messenger (endocrine system) to control or adjust the activities of another or many other systems simultaneously. For example, when you exercise, your nervous system issues commands that increase your heart rate so that blood will circulate faster. Your nervous system also reduces blood flow to less active organs, such as the digestive tract. The oxygen in circulating blood is then available to the active muscles, which need it most.

In general, the nervous system directs rapid, short-term, and very specific responses. For example, when you accidentally set your hand on a hot stove, the heat produces a painful, localized disturbance of homeostasis. Your nervous system responds by ordering specific muscles to contract and pull your hand away from the stove. These contractions last only as long as the neural activity continues, usually a matter of seconds.

In contrast, the endocrine system releases chemical messengers called hormones into the bloodstream. These molecular messengers can affect tissues and organs throughout the body. The responses may not be immediately apparent, but they may persist for days or weeks. Examples of homeostatic regulation dependent on endocrine function include the long-term regulation of blood volume and composition, and the adjustment of organ system function during starvation. Regardless of the system involved, homeostatic regulation always works to keep the internal environment within certain limits. A homeostatic regulatory mechanism consists of three parts: (1) a receptor, a sensor that is sensitive to a particular stimulus or environmental change; (2) a control center, which receives and processes the information supplied by the receptor and sends out commands; and (3) an effector, a cell or organ that responds to the commands of the control center and whose activity either opposes or enhances the stimulus. You are probably already familiar with similar regulatory mechanisms, such as the one involving the thermostat in your house or apartment (Figure 1-2a).

The thermostat is the control center. It receives information about room temperature from an internal or remote thermometer (a receptor). The setting on the thermostat establishes the **set point**, or desired value, which in this case is the temperature you select. (In our example, the set point is 22°C, or about 72°F.) The function of the thermostat is to keep room temperature within acceptable limits, usually within a degree or so of the set point. In summer, the thermostat performs this function by controlling an air conditioner (an effector). When
SPOTLIGHT Figure 1–1 Levels of Organization

Interacting atoms form molecules that combine to form the protein filaments of a heart muscle cell. Such cells interlock, creating heart muscle tissue, which makes up most of the walls of the heart, a three-dimensional organ. The heart is only one component of the cardiovascular system, which also includes the blood and blood vessels. The various organ systems must work together to maintain life at the organism level.

Cellular Level

Heart muscle cell

THE ORGAN SYSTEMS

- Hair
- Sweat glands .
- Nails •

Functions

- Protects against environmental hazards
- Helps regulate body temperature
- Provides sensory information

- Bones
- Cartilages
- Associated ligaments
- Bone marrow

Functions

- Provides support and protection for other tissues
- Stores calcium and other minerals
- Forms blood cells

associated tendons

Functions

- Provides movement
- Provides protection . and support for other tissues
- Generates heat that maintains body temperature
- Brain
 - Spinal cord
- Peripheral nerves
- Sense organs

Functions

- Directs immediate responses to stimuli
- Coordinates or moderates activities of other organ systems
- Provides and interprets sensory information about external conditions

Protein filaments

- Thyroid gland
- Pancreas
- Adrenal glands Gonads
- Endocrine tissues in other systems

Functions

- Directs long-term changes in the activities of other organ systems
- Adjusts metabolic activity and energy use by the body
- Controls many structural and functional changes during development

- Blood
- Blood vessels

Functions

- Distributes blood cells, water and dissolved materials including nutrients, waste products, oxygen, and carbon dioxide
- Distributes heat and assists in control of body temperature

dioxide from

Sexual intercourse

In response to input from a receptor (a thermometer), a thermostat (the control center triggers an effector response (either an air conditioner or a heater) that restores normal temperature. In this case, when room temperature rises above the set point, the thermostat turns on the air conditioner, and the temperature returns to normal.

the temperature at the thermometer rises above the set point, the thermostat turns on the air conditioner, which then cools the room. Then, when the temperature at the thermometer returns to the set point, the thermostat turns off the air conditioner. The control is not precise because the room is large, and the thermostat is located on just one wall. Over time, the temperature in the center of the room fluctuates in a range above and below the set point (Figure 1–2b).

We can summarize the essential feature of temperature control by a thermostat very simply: A variation outside the set point triggers an automatic response that corrects the situation. This method of homeostatic regulation is called *negative feedback*, because an effector activated by the control center opposes, or *negates*, the original stimulus. In this way, negative feedback tends to minimize change, keeping variation in key body systems within acceptable ranges that are compatible with our long-term survival.

CHECKPOINT

- **15**. Define homeostasis.
- 16. Which general mechanism of homeostatic regulation always involves the nervous or endocrine system?
- 17. Why is homeostatic regulation important to an organism?

See the blue Answers tab at the back of the book.

1-6 Negative feedback opposes variations from normal, whereas positive feedback exaggerates them

Learning Outcome Describe how negative feedback and positive feedback are involved in homeostatic regulation, and explain the significance of homeostasis.

Besides negative feedback, the body also has another method of homeostatic regulation called *positive feedback*, which tends to increase the change that triggered it. Let's examine the roles of positive and negative feedback in homeostasis before considering the roles of organ systems in regulating homeostasis.

The Role of Negative Feedback in Homeostasis

Most homeostatic regulatory mechanisms involve **negative feedback**, a way of counteracting a change. An important example is the control of body temperature, a process called *thermoregulation*. In thermoregulation, the relationship between heat loss, which takes place mainly at the body surface, and heat production, which takes place in all active tissues, is altered.

In the homeostatic control of body temperature (Figure 1–3a), the control center is in the *hypothalamus*, a region of the brain. This control center receives information from

RECEPTORS Information Temperature affects sensors in skin and Normal hypothalamus temperature CONTROL disturbed CENTER STIMULUS: Body temperature rises HOMEOSTASIS Thermoregulatory Vessels Vessels center in brain Normal body dilate. constrict. temperature **RESPONSE:** sweating sweating Increased heat loss, increases decreases body temperature drops Body temperature (°C) 37.2 **EFFECTORS** Normal Normal Sends Set point 37 temperature Sweat glands range commands 36.7 restored in skin increase to secretion Blood vessels in skin dilate Time a Events in the regulation of body temperature, which are comparable to those b The thermoregulatory center keeps shown in Figure 1–2. A control center in the brain (the hypothalamus) functions as body temperature fluctuating within a thermostat with a set point of 37°C. If body temperature exceeds 37.2°C, heat an acceptable range, usually between 36.7°C and 37.2°C.

loss is increased through enhanced blood flow to the skin and increased sweating.

In our example, body temperature fluctuated around the setpoint temperature (Figure 1–3b). The regulatory process itself

two sets of temperature receptors, one in the skin and the other within the hypothalamus. At the normal set point, body temperature (as measured with an oral thermometer) is approximately 37°C (98.6°F).

If body temperature rises above 37.2°C, activity in the control center targets two effectors: (1) muscle tissue lining the walls of blood vessels supplying blood to the skin and (2) sweat glands. The muscle tissue relaxes so the blood vessels dilate (widen), increasing blood flow through vessels near the body surface, and the sweat glands speed up their secretion of sweat. The skin then acts like a radiator by losing heat to the environment, and the evaporation of sweat speeds the process.

As body temperature returns to normal, temperature at the hypothalamus declines, and the thermoregulatory control center becomes less active. Blood flow to the skin and sweat gland activity then decrease to previous levels. Body temperature drops below the set point as the secreted sweat evaporates.

Negative feedback is the primary mechanism of homeostatic regulation, and it provides long-term control over the body's internal conditions and systems. Homeostatic mechanisms using negative feedback normally ignore minor variations. They maintain a normal range rather than a fixed value.

is dynamic. That is, it is constantly changing because the set point may vary with changing environments or differing activity levels. For example, when you are asleep, your thermoregulatory set point is lower. When you work outside on a hot day (or when you have a fever), it is set higher. Body temperature can vary from moment to moment or from day to day for any individual, due to either (1) small fluctuations around the set point or (2) changes in the set point. Comparable variations take place in all other aspects of physiology.

The variability among individuals is even greater than that within an individual. Each of us has homeostatic set points determined by genetic factors, age, gender, general health, and environmental conditions. For this reason, it is impractical to define "normal" homeostatic conditions very precisely. By convention, physiological values are reported either as average values obtained by sampling a large number of individuals, or as a range that includes 95 percent or more of the sample population.

For example, for 95 percent of healthy adults, body temperature ranges between 36.7°C and 37.2°C (98.1°F and 98.9°F). The other 5 percent of healthy adults have resting body temperatures that are below 36.7°C or above 37.2°C. These temperatures are perfectly normal for them, and the variations have no clinical significance. Physicians must keep this variability in mind when they review lab reports, because unusual values—even those outside the "normal" range—may represent individual variation rather than disease.

The Role of Positive Feedback in Homeostasis

In **positive feedback**, an initial stimulus produces a response that exaggerates or enhances the original change in conditions, rather than opposing it. You seldom encounter positive feedback in your daily life, simply because it tends to produce extreme responses. For example, suppose that the thermostat in Figure 1–2a was accidentally connected to a heater rather than to an air conditioner. Now, when room temperature rises above the set point, the thermostat turns on

the heater, causing a further rise in room temperature. Room temperature will continue to increase until someone switches off the thermostat, turns off the heater, or intervenes in some other way. This kind of escalating cycle is often called a **positive feedback loop**.

In the body, positive feedback loops are typically found when a potentially dangerous or stressful process must be completed quickly to restore homeostasis. For example, the immediate danger from a severe cut is the loss of blood, which can lower blood pressure and reduce the efficiency of the heart. The body's response to this blood loss is blood clotting, diagrammed in Figure 1–4. We will examine blood clotting more closely in Chapter 19. Labor and delivery are another example of positive feedback in action, as we will discuss in Chapter 29.

The human body is amazingly effective in maintaining homeostasis. Nevertheless, an infection, an injury, or a genetic abnormality can sometimes have effects so severe that homeostatic mechanisms cannot fully compensate for them. One or more variables within the internal environment may then be

Figure 1–4 Positive Feedback: Blood Clotting. In positive feedback, a stimulus produces a response that exaggerates or enhances the original change in conditions, rather than opposing it.

pushed outside their normal range of values. When this happens, organ systems begin to malfunction, producing a state known as illness, or **disease**. In Chapters 5–29, we devote considerable attention to the mechanisms that bring about a variety of human diseases.

Systems Integration, Equilibrium, and Homeostasis

Homeostatic regulation controls aspects of the internal environment that affect every cell in the body. No single organ system has total control over any of these aspects. Instead, such control requires the coordinated efforts of multiple organ systems. In later chapters we will explore the functions of each organ system and see how the systems interact to preserve homeostasis. Table 1–1 lists the roles of various organ systems in regulating several important functions that are subject to homeostatic control. Note that in each case such regulation involves several organ systems.

A **state of equilibrium** exists when opposing processes or forces are in balance. In the case of body temperature, a state of equilibrium exists when the rate of heat loss equals the rate of heat production. Each physiological system functions to maintain a state of equilibrium that keeps vital conditions within a normal range of values. This is often called a state of **dynamic equilibrium** because physiological systems are continually adapting and adjusting to changing conditions. For example, when muscles become more active, more heat is produced. More heat must then be lost at the skin surface to reestablish a state of equilibrium before body temperature rises outside normal ranges. Yet the adjustments made to control body temperature have other consequences. The sweating that increases heat loss at the skin surface increases losses of both water and salts. Other systems must then compensate for these losses and reestablish an equilibrium state for water and salts.

Note this general pattern: Any adjustments made by one physiological system have direct and indirect effects on a variety of other systems. Maintaining homeostasis is like a juggling act that keeps lots of different objects in the air.

Each organ system interacts with and depends on other organ systems, but introductory students find it easier to learn the basics of anatomy and physiology one system at a time. Chapters 5–29 are organized around individual systems, but remember that these systems all work together. The 11 *System Integrators* in later chapters will help reinforce this message. Each provides an overview of one system's functions

Table 1–1 The Roles of Organ	The Roles of Organ Systems in Homeostatic Regulation			
Internal Stimulus	Primary Organ Systems Involved	Functions of the Organ Systems		
Body temperature	Integumentary system Muscular system Cardiovascular system Nervous system	Heat loss Heat production Heat distribution Coordination of blood flow, heat production, and heat loss		
Body fluid composition

and summarizes its functional relationships with systems covered in previous chapters.

CHECKPOINT

- 18. Explain the function of negative feedback systems.
- **19**. What happens to the body when homeostasis breaks down?
- 20. Explain how a positive feedback system works.
- 21. Why is positive feedback helpful in blood clotting but unsuitable for the regulation of body temperature?
- 22. Define equilibrium.
- 23. When the body continuously adapts by utilizing homeostatic systems, it is said to be in a state of ______ equilibrium.

• See the blue Answers tab at the back of the book.

1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections

Learning Outcome Use anatomical terms to describe body regions, body sections, and relative positions.

Anatomists use anatomical terms to describe body regions, relative positions and directions, and body sections, as well as major body cavities and their subdivisions. In the following sections we will introduce the terms used in superficial anatomy and sectional anatomy.

Superficial Anatomy

Superficial anatomy involves locating structures on or near the body surface. A familiarity with anatomical landmarks (structures that can be felt or palpated), anatomical regions (specific areas used for reference purposes), and terms for anatomical directions will make the material in subsequent chapters easier to understand. As you encounter new terms, create your own mental maps from the information provided in the accompanying anatomical illustrations.

Anatomical Landmarks

Figure 1–5 presents important anatomical landmarks. Understanding the terms and their origins will help you remember both the location of a particular structure and its name. For example, *brachium* refers to the arm, and later we will consider the *brachialis muscle* and the *brachial artery*, which are in the arm, as their names suggest.

The standard anatomical reference for the human form is the **anatomical position**. When the body is in this position, the hands are at the sides with the palms facing forward, and

Clinical Note

Auscultation *Auscultation* (aws-kul-tā-shun) is the action of listening to sounds from the heart, lungs, or other organs with a stethoscope. It is a valuable tool and serves as an important part of the medical diagnosis. These images show the general locations for listening to heart and lung sounds on both the anterior and posterior aspects of the body. *Aspect* refers to the side of the body that faces a particular direction.

the feet are together. Figure 1–5a shows an individual in the anatomical position as seen from the front, called an *anterior view*. Figure 1–5b shows the body as seen from the back, called a *posterior view*. Unless otherwise noted, all descriptions in this text refer to the body in the anatomical position. A person

Figure 1–5 Anatomical Landmarks. Anatomical terms are shown in boldface type and common names are in plain type.

lying down in the anatomical position is said to be **supine** (soo-PĪN) when face up, and **prone** when face down.

TIPS&TRICKS

Supine means up. In order to carry a bowl of *soup*, your hand must be in the *supine* position.

Anatomical Regions

To describe a general area of interest or injury, clinicians and anatomists often need broader terms in addition to specific landmarks. They use two methods to map the surface of the abdomen and pelvis.

Clinicians refer to four **abdominopelvic quadrants** (Figure 1–6a) formed by a pair of imaginary perpendicular

Figure 1–6 Abdominopelvic Quadrants and Regions.

a Abdominopelvic quadrants. The four abdominopelvic quadrants are formed by two perpendicular lines that intersect at the navel. The terms for these quadrants, or their abbreviations, are most often used in clinical discussions.

b Abdominopelvic regions. The nine abdominopelvic regions provide more precise regional descriptions.

c Anatomical relationships. The relationship between the abdominopelvic quadrants and regions and the locations of the internal organs are shown here.

lines that intersect at the umbilicus (navel). This simple method provides useful references for the description of aches, pains, and injuries. The location can help the clinician determine the possible cause. For example, tenderness in the right lower quadrant (RLQ) is a symptom of appendicitis. Tenderness in the right upper quadrant (RUQ), however, may indicate gallbladder or liver problems.

Anatomists prefer more precise terms to describe the location and orientation of internal organs. They recognize nine **abdominopelvic regions** (Figure 1–6b). Figure 1–6c shows the relationships among quadrants, regions, and internal organs.

TIPS&TRICKS

The imaginary lines dividing the abdominopelvic regions resemble a tic-tac-toe game.

Anatomical Directions

Figure 1–7 introduces the main directional terms and some examples of their use. There are many different terms, and some can be used interchangeably. For example, *anterior* refers to the front of the body when viewed in the anatomical position. In humans, this term is equivalent to *ventral*, which refers to the belly. *Posterior* refers to the back of the body; this term is equivalent to *dorsal*. When reading anatomical descriptions, remember that the terms *left* and *right* always refer to the *left* and *right* sides of the *subject*, not of the observer.

Before you read further, analyze the image in detail, and practice using the terms. We start using these terms in the rest of this chapter. If you are familiar with the basic vocabulary, the descriptions throughout this book will be easier to follow.

Sectional Anatomy

Sometimes the only way to understand the relationships among the parts of a three-dimensional object is to slice through it and look at the internal organization. A slice through a threedimensional object is called a *section*.

An understanding of sectional views is particularly important now that imaging techniques enable us to see inside the living body. These views are sometimes difficult to interpret, but it is worth spending the time required to understand what they show. Once you are able to interpret sectional views, you will have a good mental model for studying the anatomy and physiology of a particular region or system. Radiologists and other medical professionals responsible for interpreting medical scans spend much of their time analyzing sectional views of the body.

Figure 1–7 Directional References.

1

Figure 1–8 Sectional Planes.

Planes and Sections

Any section through a three-dimensional object can be described in reference to three **sectional planes**, as indicated in **Figure 1–8**. A *plane* is an axis, and three planes are needed to describe any three-dimensional object. A section is a single view or slice along one of these planes:

- A plane that lies at right angles to the long axis of the body is the transverse (or *horizontal*) plane. It divides the body into *superior* and *inferior* portions. A cut in this plane is called a transverse section, or *cross section*. Unless otherwise noted, in this book all anatomical diagrams that present cross-sectional views of the body are oriented as though the subject were supine with you, the observer, standing at the subject's feet and looking toward the head.
- Two planes are parallel to the long axis of the body. These are the **frontal** (*coronal*) **plane** and the **sagittal plane**.

The atlas that accompanies this text contains images of sections taken through the body in various planes.

- CHECKPOINT

- 24. What is the purpose of anatomical terms?
- **25**. In the anatomical position, describe an anterior view and a posterior view.
- See the blue Answers tab at the back of the book.

1–8 Body cavities of the trunk protect internal organs and allow them to change shape

Learning Outcome Identify the major body cavities of the trunk and their subdivisions, and describe the functions of each.

The body's trunk is subdivided into three major regions established by the body wall: the thoracic, abdominal, and pelvic regions (p. 15). Most of our vital organs are located within these regions of the trunk. The true **body cavities** are closed, fluid-filled, and lined by a thin tissue layer called a *serous membrane*, or *serosa*. The vital organs of the trunk are suspended within these body cavities; they do not simply lie there. Early

Figure 1–9 Relationships among the Subdivisions of the Body Cavities of the Trunk.

anatomists used the term "cavity" when referring to internal regions. For example, everything deep to the chest wall of the thoracic region is considered to be within the *thoracic cavity*, and all of the structures deep to the abdominal and pelvic walls are said to lie within the abdominopelvic cavity. Internally, the diaphragm (DI-uh-fram), a flat muscular sheet, separates these anatomical regions. The boundaries of the true body cavities and the regional "cavities" are not identical. For example, the thoracic cavity contains two pleural cavities, each surrounding a lung, the pericardial cavity of the heart, and a large tissue mass, the *mediastinum*, and the peritoneal cavity extends only partway into the pelvic cavity. Figure 1-9 shows the boundaries between the subdivisions of the thoracic cavity and the abdominopelvic cavity.

only one of the two pleural cavities can

be shown in a sagittal section.

The body cavities of the trunk have two essential functions: (1) They protect delicate organs from shocks and impacts; and (2) they permit significant changes in the size and shape of internal organs. For example, the lungs, heart, stomach, intestines, urinary bladder, and many other organs can expand and contract without distorting surrounding tissues or disrupting the activities of nearby organs because they project into body cavities.

otherwise noted, transverse or cross-sectional views in this text use this

same orientation (see Spotlight Figure 1-10).

The internal organs that are enclosed by these cavities are known as viscera (VIS-e-ruh). A delicate serous membrane lines the walls of these internal cavities and covers the surfaces of the enclosed viscera. A watery fluid, called serous fluid, moistens serous membranes, coats opposing surfaces, and reduces friction. The portion of a serous membrane that covers a visceral organ is called the visceral serosa. The opposing layer that lines the inner

SPOTLIGHT

Figure 1–10 Diagnostic Imaging Techniques

Over the past several decades, rapid progress has been made in discovering more accurate and more detailed ways to image the human body, both in health and disease.

X-rays

X-rays are the oldest and still the most common method of imaging. X-rays are a form of high-energy radiation that can penetrate living tissues. An x-ray beam travels through the body before striking a photographic plate. Not all of the projected x-rays arrive at the film. The body absorbs or deflects some of those

An x-ray of the skull, taken from the left side

x-rays. The ability to stop the passage of x-rays is referred to as **radiopacity**. When taking an x-ray, these areas that are impenetrable by x-rays appear light or white on the exposed film and are said to be **radiopaque**. In the body, air has the lowest radiopacity. Fat, liver, blood, muscle, and bone are increasingly radiopaque. As a result, radiopaque tissues look white, and less radiopaque tissues are in shades of gray to black.

To use x-rays to visualize soft tissues, a very radiopaque substance must be introduced. To study the upper digestive tract, a radiopaque barium solution is ingested by the patient. The resulting x-ray shows the contours of the stomach and intestines.

A **barium-contrast x-ray** of the upper digestive tract

Standard Scanning Techniques

More recently, a variety of **scanning techniques** dependent on computers have been developed to show the less radiopaque, soft tissues of the body in much greater detail.

Diagrammatic views showing the relative position and orientation of the CT scan below and the MRI to the right.

CT scan of the abdomen

CT (computed tomography) **scans** use computers to reconstruct sectional views. A single x-ray source rotates around the body, and the x-ray beam strikes a sensor monitored by the computer. The x-ray source completes one revolution around the body every few seconds. It then moves a short distance and repeats the process. The result is usually displayed as a sectional view in black and white, but it can be colorized for visual effect. CT scans show three-dimensional relationships and soft tissue structures more clearly than do standard x-rays.

• Note that when anatomical diagrams or scans present cross-sectional views, the sections are presented from an inferior perspective, as though the observer were standing at the feet of a person in the supine position and looking toward the head of the subject.

MRI scan of the abdomen

An **MRI** of the same region (in this case, the abdomen) can show soft tissue structure in even greater detail than a CT scan. Magnetic resonance imaging surrounds part or all of the body with a magnetic field 3000 times as strong as that of Earth. This field causes particles within atoms throughout the body to line up in a uniform direction. Energy from pulses of radio waves are absorbed and released by the different atoms. The released energy is used to create a detailed image of the soft tissue structure.

PET scan of the brain

Positron emission tomography (**PET**) is an imaging technique that assesses metabolic and physiological activity of a structure. A PET scan is an important tool in evaluating healthy and diseased brain function.

Ultrasound of the uterus

In ultrasound procedures, a small transmitter contacting the skin broadcasts a brief, narrow burst of high-frequency sound and then detects the echoes. The sound waves are reflected by internal structures, and a picture, or echogram, is assembled from the pattern of echoes. These images lack the clarity of other procedures, but no adverse effects have been reported, and fetal development can be monitored without a significant risk of birth defects. Special methods of transmission and processing permit analysis of the beating heart without the complications that can accompany dye injections.

Special Scanning Methods

Spiral scan of the heart [Courtesy of TeraRecon, Inc.]

A **spiral CT scan** is a form of three-dimensional imaging technology that is becoming increasingly important in clinical settings. During a spiral CT scan, the patient is on a platform that advances at a steady pace through the scanner while the imaging source, usually x-rays, rotates continuously around the patient. Because the x-ray detector gathers data quickly and continuously, a higher quality image is generated, and the patient is exposed to less radiation as compared to a standard CT scanner, which collects data more slowly and only one slice of the body at a time.

Digital subtraction angiography of coronary arteries

Digital subtraction angiography (DSA) is used to monitor blood flow through specific organs, such as the brain, heart, lungs, and kidneys. X-rays are taken before and after radiopaque dye is administered, and a computer "subtracts" details common to both images. The result is a high-contrast image showing the distribution of the dye. surface of the body wall or chamber is called the *parietal serosa*. Because the moist parietal and visceral serosae are usually in close contact, the body cavities are called *potential spaces*. In some clinical conditions, however, excess fluid can accumulate within these potential spaces, increasing their volume and exerting pressure on the enclosed viscera.

The Thoracic Cavity

The thoracic cavity (Figure 1–9a,c) contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus. The thoracic cavity is subdivided into the left and right **pleural cavities** (holding the lungs), separated by a mass of tissue called the **mediastinum** (mē-dē-a-STĪ-num). Each pleural cavity surrounds a lung and is lined by a shiny, slippery serous membrane that reduces friction as the lung expands and recoils during breathing. The serous membrane lining a pleural cavity is called a *pleura* (PLOOR-ah). The *visceral pleura* covers the outer surfaces of a lung, and the *parietal pleura* covers the mediastinal surface and the inner body wall.

The mediastinum consists of a mass of connective tissue that surrounds, stabilizes, and supports the esophagus, trachea, and thymus, as well as the major blood vessels that originate or end at the heart. The mediastinum also contains the pericardial cavity, a small chamber that surrounds the heart. The relationship between the heart and the pericardial cavity resembles that of a fist pushing into a balloon (Figure 1-9b). The wrist corresponds to the base (attached portion) of the heart, and the balloon corresponds to the serous membrane that lines the pericardial cavity. The serous membrane associated with the heart is called the pericardium (peri-, around + cardium, heart). The layer covering the heart is the visceral pericardium, and the opposing surface is the parietal pericardium. During each beat, the heart changes in size and shape. The pericardial cavity permits these changes, and the slippery pericardial serous membrane lining prevents friction between the heart and nearby structures in the thoracic cavity.

The Abdominopelvic Cavity

The abdominopelvic cavity extends from the diaphragm to the pelvis. It is subdivided into a superior **abdominal cavity** and an inferior **pelvic cavity** (Figure 1–9). The abdominopelvic cavity contains the *peritoneal* (per-i-tō-NĒ-al) *cavity*, a potential space lined by a serous membrane known as the *peritoneum* (per-i-tō-NĒ-um). The *parietal peritoneum* lines the inner surface of the body wall. A narrow space containing a small amount of fluid separates the parietal peritoneum from the *visceral peritoneum*, which covers the enclosed organs. You are probably already aware of the movements of the organs in this cavity. Most of us have had at least one embarrassing moment when a digestive organ contracted, producing a movement of liquid or

gas and a gurgling or rumbling sound. The peritoneum allows the organs of the digestive system to slide across one another without damage to themselves or the walls of the cavity.

The abdominal cavity extends from the inferior (toward the feet) surface of the diaphragm to the level of the superior (toward the head) margins of the pelvis. This cavity contains the liver, stomach, spleen, small intestine, and most of the large intestine. (Figure 1–6c shows the positions of most of these organs.) The organs are partially or completely enclosed by the peritoneal cavity, much as the heart and lungs are enclosed by the pericardial and pleural cavities, respectively. A few organs, such as the kidneys and pancreas, lie between the peritoneal lining and the muscular wall of the abdominal cavity. Those organs are said to be *retroperitoneal (retro*, behind).

The pelvic cavity is inferior to the abdominal cavity. The bones of the pelvis form the walls of the pelvic cavity, and a layer of muscle forms its floor. The pelvic cavity contains the urinary bladder, various reproductive organs, and the distal (farthest) portion of the large intestine. In females, the pelvic cavity contains the ovaries, uterine tubes, and uterus. In males, it contains the prostate gland and seminal glands (seminal vesicles). The pelvic cavity also contains the inferior portion of the peritoneal cavity. The peritoneum covers the ovaries and the uterus in females, as well as the superior portion of the urinary bladder in both sexes. Organs such as the urinary bladder and the distal portions of the ureters and large intestine, which extend inferior to the peritoneal cavity, are said to be *infraperitoneal*.

The true body cavities of the trunk in the adult share a common embryological origin. The term "dorsal body cavity" is sometimes used to refer to the internal chamber of the skull (cranial cavity) and the space enclosed by the vertebral bodies and vertebral arches (vertebral cavity). These chambers, which are defined by bony structures, are anatomically and embryologically distinct from true body cavities, and the term "dorsal body cavity" is not encountered in either clinical anatomy or comparative anatomy. For these reasons, we have avoided using that term in our discussion of body cavities.

A partial list of chambers, or spaces, within the body that are not true body cavities would include the cranial cavity, vertebral cavity, oral cavity, digestive cavity, orbits (eye sockets), tympanic cavity of each middle ear, nasal cavities, and paranasal sinuses (air-filled chambers within some cranial bones that are connected to the nasal cavities). These structures will be discussed in later chapters.

Spotlight Figure 1–10 Diagnostic Imaging Techniques highlights some clinical tests commonly used for viewing the interior of the body.

CHECKPOINT

- **26**. Name two essential functions of the body cavities of the trunk.
- 27. Describe the various body cavities of the trunk.
- See the blue Answers tab at the back of the book.

Related Clinical Terms

acute: A disease of short duration but typically severe.

- **chemotherapy:** The treatment of disease or mental disorder by the use of chemical substances, especially the treatment of cancer by cytotoxic and other drugs.
- **chronic:** Illness persisting for a long time or constantly recurring. Often contrasted with acute.
- **epidemiology:** The branch of science that deals with the incidence, distribution, and possible control of diseases and other factors relating to health.

etiology: The science and study of the cause of diseases.idiopathic: Denoting any disease or condition of unknown cause.morbidity: The state of being diseased or unhealthy, or the incidence of disease in a population.

- **pathophysiology:** The functional changes that accompany a particular syndrome or disease.
- **syndrome:** a condition characterized by a group of associated symptoms.

An Introduction to Studying the Human Body p. 2

1. Biology is the study of life. One of its goals is to discover the unity and the patterns that underlie the diversity of organisms.

1-1 Anatomy and physiology directly affect your life p. 2

This course will help you discover how your body works under normal and abnormal conditions, by serving as a base for understanding other life sciences and expanding your vocabulary.

1-2 Anatomy is structure, and physiology is function p. 3

- **3. Anatomy** is the study of internal and external structures of the body and the physical relationships among body parts. **Physiology** is the study of how living organisms perform their vital functions. All physiological functions are performed by specific structures.
- 4. Medical terminology is the use of prefixes, suffixes, word roots, and combining forms to construct anatomical, physiological, or medical terms.
- 5. *Terminologia Anatomica (International Anatomical Terminology)* was used as the standard in preparing your textbook.

1-3 Anatomy and physiology are closely integrated p. 4

- 6. All specific functions are performed by specific structures.
- 7. In gross (macroscopic) anatomy, we consider features that are visible without a microscope. This field includes surface anatomy (general form and superficial markings); regional anatomy (anatomical organization of specific areas of the body); and systemic anatomy (structure of organ systems). In developmental

anatomy, we examine the changes in form that occur between conception and physical maturity. In *embryology*, we study developmental processes that occur during the first two months of development. *Clinical anatomy* includes anatomical subspecialties important to the practice of medicine.

- 8. The equipment used determines the limits of *microscopic anatomy*. In cytology, we analyze the internal structure of individual cells. In histology, we examine tissues, groups of cells that perform specific functions. Tissues combine to form organs, anatomical structures with multiple functions. (*Spotlight Figure 1–1*)
- 9. Human physiology is the study of the functions of the human body. It is based on *cell physiology*, the study of the functions of cells. In *organ physiology*, we study the physiology of specific organs. In *systemic physiology*, we consider all aspects of the functioning of specific organ systems. In *pathological physiology*, we study the effects of diseases on organ or system functions.

1-4 Levels of organization progress from molecules to a complete organism p. 6

- Anatomical structures and physiological mechanisms occur in a series of interacting levels of organization. (Spotlight Figure 1–1)
- **11.** The 11 **organ systems** of the body are the integumentary, skeletal, muscular, nervous, endocrine, cardiovascular, lymphatic, respiratory, digestive, urinary, and reproductive systems. (*Spotlight Figure 1–1*)

1-5 Homeostasis is the state of internal balance p. 7

- **12.** Homeostasis is the existence of a stable environment within the body.
- **13.** Physiological systems preserve homeostasis through *homeostatic regulation*.
- 14. Autoregulation occurs when a cell, tissue, organ, or organ system adjusts its activities automatically in response to some environmental change. Extrinsic regulation results from the activities of the nervous system or endocrine system.
- **15.** Homeostatic regulation mechanisms usually involve a **receptor** that is sensitive to a particular stimulus; a **control center**, which receives and processes the information supplied by the receptor and then sends out commands; and an **effector** that responds to the commands of the control center and whose activity either opposes or enhances the stimulus. (*Figure 1–2*)

1-6 Negative feedback opposes variations from normal, whereas positive feedback exaggerates them p. 10

16. Negative feedback is a corrective mechanism involving an action that directly opposes a variation from normal limits. (Figure 1-3)

17. In **positive feedback**, an initial stimulus produces a response that exaggerates or enhances the change in the original conditions, creating a positive feedback loop. (Figure 1-4)

- 18. No single organ system has total control over the body's internal environment; all organ systems work together. (Table 1-1)
- 1-7 Anatomical terms describe body regions, anatomical positions and directions, and body sections p. 14
- 19. The standard arrangement for anatomical reference is called the anatomical position. If the person is shown lying down, it can be either **supine** (face up) or **prone** (face down). (Figure 1–5 and Spotlight Figure 1-10)
- 20. Abdominopelvic quadrants and abdominopelvic regions represent two approaches to describing anatomical regions of that portion of the body. (Figure 1-6)
- 21. The use of special directional terms provides clarity for the description of anatomical structures. (Figure 1-7)
- 22. The three sectional planes (transverse, or horizontal, plane; frontal, or coronal, plane; and sagittal plane) describe

relationships among the parts of the three-dimensional human body. (Figure 1–8)

1-8 Body cavities in the trunk protect internal organs and allow them to change shape p. 18

- 23. Body cavities protect delicate organs and permit significant changes in the size and shape of internal organs. The body cavities of the trunk surround organs of the respiratory, cardiovascular, digestive, urinary, and reproductive systems. (Figure 1-9)
- 24. The diaphragm divides the (superior) thoracic and (inferior) abdominopelvic cavities. The thoracic cavity consists of two pleural cavities (each surrounding a lung) with a central tissue mass known as the mediastinum. Within the mediastinum is the pericardial cavity, which surrounds the heart. The abdominopelvic cavity consists of the abdominal cavity and the pelvic cavity and contains the peritoneal cavity, a chamber lined by the peritoneum, a serous membrane. (Figure 1–9 and Spotlight Figure 1-10)
- 25. Diagnostic imaging techniques are used in clinical medicine to view the body's interior. (Spotlight Figure 1-10)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Label the directional terms in the figures below.

(a) (d) (c) (f) _ (e) (h) (g) (i) (i)

Match each numbered item with the most closely related lettered item. Use letters for answers in the spaces provided.

(f)

(g)

(i)

(j)

- 2. cytology 3. physiology
- 4. histology
- 5. anatomy
- 6. homeostasis
- 7. muscle 8. heart
- 9. endocrine
- 10. temperature regulation
- 11. labor and delivery
- 12. supine
- 13. prone
- (k) diaphragm 14. divides thoracic and ab-(1)

15. abdominopelvic cavity

16. pericardium

(5) organism

tissue dominopelvic body cavities (m) peritoneal cavity

See the blue Answers tab at the back of the book.

(a) study of tissues

(c) face up position

(d) study of functions (e) positive feedback

organ system

study of cells

(h) negative feedback

serous membrane

body structures

study of internal and external

(b) constant internal environment

- (n) organ
- (o) face down position

17. The following is a list of six levels of organization that make up the human body:

- (1) tissue
- (2) cell (4) chemical (3) organ
 - (6) organ system

The correct order, from the simplest to the most complex level, is (a) 2, 4, 1, 3, 6, 5, (b) 4, 2, 1, 3, 6, 5, (c) 4, 2, 1, 6, 3, 5,

(d) 4, 2, 3, 1, 6, 5, (e) 2, 1, 4, 3, 5, 6.

- 18. The study of the structure of tissue is called (a) gross anatomy,(b) cytology, (c) histology, (d) organology.
- **19.** The increasingly forceful labor contractions during childbirth are an example of **(a)** receptor activation, **(b)** effector shutdown, **(c)** negative feedback, **(d)** positive feedback.
- **20.** Failure of homeostatic regulation in the body results in (a) autoregulation, (b) extrinsic regulation, (c) disease, (d) positive feedback.
- 21. A plane through the body that passes perpendicular to the long axis of the body and divides the body into a superior and an inferior section is a (a) sagittal section, (b) transverse section, (c) coronal section, (d) frontal section.
- 22. Which body cavity would enclose each of the following organs?(a) heart, (b) small intestine, large intestine, (c) lung,(d) kidneys.
- 23. The mediastinum is the region between the (a) lungs and heart,(b) two pleural cavities, (c) chest and abdomen,(d) heart and pericardium.

LEVEL 2 Reviewing Concepts

- 24. (a) Define *anatomy*.(b) Define *physiology*.
- 25. The two major body cavities of the trunk are the(a) pleural cavity and pericardial cavity, (b) pericardial cavity and peritoneal cavity, (c) pleural cavity and peritoneal cavity, (d) thoracic cavity and abdominopelvic cavity.

- 26. What distinguishes autoregulation from extrinsic regulation?
- **27.** Describe the anatomical position.
- Which sectional plane could divide the body so that the face remains intact? (a) sagittal plane, (b) frontal (coronal) plane, (c) equatorial plane, (d) midsagittal plane, (e) parasagittal plane.
- 29. Which the following is *not* an example of negative feedback? (a) Increased pressure in the aorta triggers mechanisms to lower blood pressure, (b) A rise in blood calcium levels triggers the release of a hormone that lowers blood calcium levels, (c) A rise in estrogen during the menstrual cycle increases the number of progesterone receptors in the uterus, (d) Increased blood sugar stimulates the release of a hormone from the pancreas that stimulates the liver to store blood sugar.

LEVEL 3 Critical Thinking and Clinical Applications

- **30.** The hormone *calcitonin* is released from the thyroid gland in response to increased levels of calcium ions in the blood. If this hormone is controlled by negative feedback, what effect would calcitonin have on blood calcium levels?
- **31.** A stroke occurs when there is a disruption in blood flow to the brain, causing brain cells to die. Why might a stroke result in a rise or fall of normal body temperature?

CLINICAL CASE

Using A&P to Save a Life

The patient is wheeled through the door and into Trauma Room 1. He is barely alive. Because of the location of the abdominal wound, in the right upper quadrant, and the likely depth of the wound, more than 6 inches, the chances are good that the liver has been lacerated. Depending on the angle of the knife, sections of large intestine, containing bacteria that are deadly when released into the abdominal cavity, have probably also been lacerated. Any blood spilled onto the street or into the patient's abdominal cavity is lost from the cardiovascular system and cannot carry oxygen to body tissues. For this reason, the trauma nurse is ready with blood for transfusion.

An x-ray shows free air in the abdominal cavity, a sure sign the large intestine is cut. It also shows a fluid level indicating free blood in the abdominal cavity. Both conditions need immediate surgical attention. The patient is taken directly to the operating room where a surgeon performs open abdominal surgery. The lacerations of the liver and large intestine

Wrap-Up

are repaired and the bleeding is stopped. A diverting colostomy is performed, creating an opening from the large intestine through the abdominal wall in the right lower

quadrant, proximal to the level of injury. It will allow the injured large intestine to rest while healing. A life is saved because an EMT, trauma nurse, and surgeon know their anatomy and physiology.

- 1. Besides the liver and most of the large intestine, what other major organs are in the abdominal cavity?
- 2. If the deep knife wound had been superior to the diaphragm, what body cavity would the knife have entered, and what organs does it contain?

See the blue Answers tab at the back of the book.

The Chemical Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **2-1** Describe an atom and how atomic structure affects interactions between atoms.
- **2-2** Compare the ways in which atoms combine to form molecules and compounds.
- 2-3 Distinguish among the major types of chemical reactions that are important for studying physiology.
- **2-4** Describe the crucial role of enzymes in metabolism.
- **2-5** Distinguish between organic compounds and inorganic compounds.
- **2-6** Explain how the chemical properties of water make life possible.
- **2-7** Discuss the importance of pH and the role of buffers in body fluids.
- **2-8** Describe the physiological roles of inorganic compounds.
- **2-9** Discuss the structures and functions of carbohydrates.
- **2-10** Discuss the structures and functions of lipids.
- **2-11** Discuss the structures and functions of proteins.
- 2-12 Discuss the structures and functions of nucleic acids.
- 2-13 Discuss the structures and functions of high-energy compounds.
- **2-14** Explain the relationship between chemicals and cells.

Clinical Notes

- Radiation Sickness p. 29
- Fatty Acids and Health p. 48

CLINICAL CASE

What Is Wrong with My Baby?

Sean is Maureen's first baby. Maureen and her husband, Conner, had enjoyed an uncom-

plicated pregnancy and delivery. Maureen had felt healthy throughout the pregnancy, but something was wrong with her baby.

Sean is 1 month old, and not thriving. He seems to have a good appetite and breastfeeds as if he is starving; yet he has dropped 20 percent of his normal birth weight of 7 pounds, 8 ounces. He is down to only 6 pounds at his 1-month checkup, and his skin looks "wrinkly." He is having several greasy, almost foamy-looking stools each day. They remind Maureen of cake

icing. Maureen also notices the funniest thing. Sean's skin tastes salty.

Most alarmingly, he seems to be having some difficulty breathing recently. He sounds wheezy. Maureen and Conner are both from big families, and none of the babies have ever been sickly like this.

What is wrong with Baby Sean? To find out, turn to the Clinical Case Wrap-Up on p. 63.

An Introduction to the Chemical Level of Organization

In this chapter we consider the structure of atoms, the basic chemical building blocks. You will also learn how atoms can combine to form increasingly complex structures.

2-1 Atoms are the basic particles of matter

Learning Outcome Describe an atom and how atomic structure affects interactions between atoms.

Our study of the human body begins at the chemical level of organization. *Chemistry* is the science that deals with the structure of **matter**, defined as anything that takes up space and has mass. **Mass**, the amount of material in matter, is a physical property that determines the weight of an object in Earth's gravitational field. For our purposes, the mass of an object is the same as its weight. However, the two are not always equivalent: In orbit you would be weightless, but your mass would remain unchanged.

The smallest stable units of matter are called **atoms**. Air, elephants, oranges, oceans, rocks, and people are all composed of atoms in varying combinations. The unique characteristics of each object, living or nonliving, result from the types of atoms involved and the ways those atoms combine and interact.

Atoms are composed of **subatomic particles**. Many different subatomic particles exist, but only three, *protons, neutrons, and electrons,* are important for understanding the chemical properties of matter. Protons and neutrons are similar in size and mass, but **protons** (p^+) have a positive electrical charge.

Neutrons (n or n^0) are electrically *neutral*, or uncharged. **Electrons** (e^-) are much lighter than protons—only 1/1836 as massive—and have a negative electrical charge. For this reason, the mass of an atom is determined primarily by the number of protons and neutrons in the **nucleus**, the central region of an atom. The mass of a large object, such as your body, is the sum of the masses of all the component atoms.

Atomic Structure

Atoms normally contain equal numbers of protons and electrons. The number of protons in an atom is known as its **atomic number**. Hydrogen (H) is the simplest atom, with an atomic number of 1. An atom of hydrogen contains one proton, and one electron as well. Hydrogen's proton is located in the center of the atom and forms the nucleus. Hydrogen atoms seldom contain neutrons, but when neutrons are present, they are also located in the nucleus. All atoms other than hydrogen have both neutrons and protons in their nuclei.

Electrons travel around the nucleus at high speed, within a spherical area called the **electron cloud**. We often illustrate atomic structure in the simplified form shown in **Figure 2–1a**. In this two-dimensional representation, the electrons occupy a circular **electron shell**. One reason an electron tends to remain in its electron shell is that the negatively charged electron is attracted to the positively charged proton. The attraction between opposite electrical charges is an example of an *electrical force*. As you will see in later chapters, electrical forces are involved in many physiological processes.

The dimensions of the electron cloud determine the overall size of the atom. To get an idea of the scale involved, consider that if the nucleus were the size of a tennis ball, the

electron cloud of a hydrogen atom would have a radius of 10 km (about 6 miles!). In reality, atoms are so small that atomic measurements are most conveniently reported in nanometers (NAN- \bar{o} -m \bar{e} -ter) (nm). One nanometer is 10^{-9} meter (0.000000001 m), or one billionth of a meter. The very largest atoms approach 0.5 nm in diameter (0.000000005 m, or 0.00000002 in.).

Elements and Isotopes

An **element** is a pure substance composed of atoms of only one kind. Atoms are the smallest particles of an element that still retain the characteristics of that element. As a result, each element has uniform composition and properties. Each element includes all the atoms with the same number of protons, and thus the same atomic number. Only 92 elements exist in nature. Researchers have created about two dozen additional elements through nuclear reactions in laboratories.

Every element has a chemical symbol, an abbreviation recognized by scientists everywhere. Most of the symbols are easy to connect with the English names of the elements (O for oxygen, N for nitrogen, C for carbon, and so on), but a few are abbreviations of their Latin names. For example, the symbol for sodium, Na, comes from the Latin word *natrium*.

Atomic nuclei are unaltered by ordinary chemical processes. So, elements cannot be changed or broken down into simpler substances in chemical reactions. For example, an atom of carbon always remains an atom of carbon, regardless of the chemical events in which it may take part.

Our bodies consist of many elements, and the 13 most abundant elements are listed in Table 2–1. Our bodies also contain atoms of another 14 elements—called *trace elements* that are present in very small amounts.

Table 2–1	Principal Elements in the Human Body	
Element (% of total body weight)		Significance
Oxygen, O (65)		A component of water and other compounds; gaseous form is essential for respiration
Carbon, C (18.6)		Found in all organic molecules
Hydrogen, H (9.7)		A component of water and most other compounds in the body
Nitrogen, N (3.2)		Found in proteins, nucleic acids, and other organic compounds
Calcium, Ca (1.8)		Found in bones and teeth; important for membrane function, nerve impulses, muscle contraction, and blood clotting
Phosphorus, P (1	1.0)	Found in bones and teeth, nucleic acids, and high-energy compounds
Potassium, K (0.4)		Important for proper membrane function, nerve impulses, and muscle contraction
Sodium, Na (0.2)		Important for blood volume, membrane function, nerve impulses, and muscle contraction
Chlorine, Cl (0.2)		Important for blood volume, membrane function, and water absorption
Magnesium, Mg	(0.06)	A cofactor for many enzymes
Sulfur, S (0.04)		Found in many proteins
Iron, Fe (0.007)		Essential for oxygen transport and energy capture
lodine, l (0.0002)		A component of hormones of the thyroid gland
Trace elements: silicon (Si), fluorine (F), copper (Cu), manganese (Mn), zinc (Zn), selenium (Se), cobalt (Co), molybdenum (Mo), cadmium (Cd), chromium (Cr), tin (Sn), aluminum		Some function as cofactors; the functions of many trace elements are poorly understood

(AI), boron (B), and vanadium (V)

The atoms of a single element all have the same number of protons, but they can differ in the number of neutrons in the nucleus. For example, most hydrogen nuclei consist solely of a single proton, but 0.015 percent also contains one neutron, and a very small percentage contains two neutrons (Figure 2–1). Atoms of the same element whose nuclei contain different numbers of neutrons are called **isotopes**.

Different isotopes of an element have essentially identical chemical properties, and are alike except in mass. The **mass number**—the total number of protons plus neutrons in the nucleus—is used to designate isotopes. For example, hydrogen has three isotopes. Hydrogen-1, or ¹H, has one proton and one electron (**Figure 2–1a**). Hydrogen-2, or ²H, also known as *deuterium*, has one proton, one electron, and one neutron (**Figure 2–1b**). Hydrogen-3, or ³H, also known as *tritium*, has one proton, one electron, one electron, and two neutrons (**Figure 2–1c**).

The nuclei of some isotopes are unstable. That is, they spontaneously break down and give off subatomic particles or radiation in measurable amounts. Such isotopes are called **radioisotopes**. The breakdown process is called *radioactive decay*. Strongly radioactive isotopes are dangerous, because the particles or radiation they give off can ionize atoms, break apart molecules, and destroy cells and tissues.

Radiation Sickness *Radiation sickness*, or *acute radiation syndrome*, results from excessive exposure to radiation. It is commonly marked by fatigue, nausea, vomiting, loss of teeth and hair, and in more severe cases by damage to blood-forming tissue. Radiation sickness is also sometimes called radiation poisoning. In a clinical setting, it can occur when large doses of radiation are given to an individual over a short period of time to treat disease, such as cancer. (X-rays and CT scans use low-dose radiation and do not cause radiation sickness.) The amount of radiation received will determine how ill a person can become. Effects range from anorexia (loss of appetite), nausea, and vomiting, to anemia (low red blood cell count), central nervous system damage, and death. Widespread radiation sickness

occurred after the 2011 earthquake and tsunamigenerated nuclear reactor accident in Fukushima, Japan; the 1986 nuclear reactor accident in Chernobyl, Ukraine; and the atomic bombing of Japan during World War II.

Weakly radioactive isotopes are sometimes used in diagnostic procedures to monitor the structural or functional characteristics of internal organs.

Radioisotopes differ in how rapidly they decay (lose their radioactivity). The decay rate of a radioisotope is commonly expressed as its **half-life:** the time required for half of a given amount of the isotope to decay. The half-lives of radioisotopes range from fractions of a second to billions of years.

Atomic Weights

A typical *oxygen* atom has an atomic number of 8 and contains eight protons and eight neutrons. The mass number of this isotope is therefore 16. The mass numbers of other isotopes of oxygen depend on the number of neutrons present. Mass numbers are useful because they tell us the number of subatomic particles in the nuclei of different atoms. However, they do not tell us the *actual* mass of the atoms. For example, they do not take into account the masses of the electrons or the slight difference between the mass of a proton and that of a neutron. The actual mass of an atom of a specific isotope is known as its *atomic mass*.

The unit used to express atomic mass is the *atomic mass unit* (amu), or *dalton*. By international agreement, one amu is equal to one-twelfth the mass of a carbon-12 atom. One atomic mass unit is very close to the mass of a single proton or neutron. Thus, the atomic mass of an atom of the most common isotope of hydrogen is very close to 1, and that of the most common isotope of oxygen is very close to 16.

The **atomic weight** of an element is an average of the different atomic masses and proportions of its different isotopes. This results in the atomic weight of an element being very close to the mass number of the most common isotope of that element. For example, the mass number of the most common isotope of hydrogen is 1, but the atomic weight of hydrogen is 1.0079, primarily because some hydrogen atoms (0.015 percent) have a mass number of 2, and even fewer have a mass number of 3. (The periodic table of the elements in the Appendix at the back of this book shows the atomic weight of each element rounded to its nearest one-hundredth decimal place. For example, the atomic weight of hydrogen is shown as 1.01, rather than 1.0079.)

Atoms take part in chemical reactions in fixed numerical ratios. To form water, for example, exactly two atoms of hydrogen combine with one atom of oxygen. But individual atoms are far too small and too numerous to be counted, so chemists use a unit called the *mole*. For any element, a **mole** (abbreviated *mol*) is a specific quantity with a weight in grams equal to that element's atomic weight.

The mole is useful because one mole of a given element always contains the same number of atoms as one mole of any other element (just as we use *dozen* to stand for 12 items). That number (called *Avogadro's number*) is 6.023×10^{23} , or about 600 billion trillion. Expressing relationships in moles rather than in grams makes it much easier to keep track of the relative numbers of atoms in chemical samples and processes. For example, if a report stated that a sample contains 0.5 mol of hydrogen atoms and 0.5 mol of oxygen atoms, you would know immediately that the two atoms were present in equal numbers. That would not be so evident if the report stated that there were 0.505 g of hydrogen atoms and 8.00 g of oxygen atoms. Most chemical analyses and clinical laboratory tests report data in moles (mol), millimoles (mmol—1/1000 mol, or 10^{-3} mol), or micromoles (μ mol—1/1,000,000 mol, or 10^{-6} mol).

Electrons and Energy Levels

Atoms are electrically neutral. In other words, every positively charged proton is balanced by a negatively charged electron. Thus, each increase in the atomic number has a comparable increase in the number of electrons traveling around the nucleus.

Within the electron cloud, electrons occupy an orderly series of energy levels. The electrons in an energy level may travel in complex patterns around the nucleus, but for our purposes the patterns can be diagrammed as a series of concentric electron shells. The first electron shell is the one closest to the nucleus, and it corresponds to the lowest energy level.

Each energy level is limited in the number of electrons it can hold. The first energy level can hold at most 2 electrons. The next two levels can each hold up to 8 electrons. Note that the maximum number of electrons that may occupy shells 1 through 3 corresponds to the number of elements in rows 1 through 3 of the periodic table of the elements (see Appendix). The electrons in an atom occupy successive shells in an orderly manner: The first energy level fills before any electrons enter the second, and the second energy level fills before any electrons enter the third.

The outermost energy level forms the "surface" of the atom and is called the **valence shell**. The number of electrons in this level determines the chemical properties of the element. Atoms with unfilled energy levels are unstable—that is, they will react with other atoms, usually in ways that result in full outer electron shells. In contrast, atoms with a filled outermost energy level are stable and therefore do not readily react with other atoms.

As indicated in Figure 2–2a, a hydrogen atom has one electron in the first energy level, so that level is unfilled. A hydrogen atom readily reacts with other atoms. A helium atom has 2 electrons in its first energy level (Figure 2–2b). A helium atom is very stable because its outer energy level is filled. It will not ordinarily react with other atoms. A lithium atom has 3 electrons (Figure 2–2c). Its first energy level can hold only

Figure 2–2 The Arrangement of Electrons into Energy Levels. The electron-shell model is also used to indicate the relative energy of electrons in an atom.

2 of them, so lithium has a single electron in a second, unfilled energy level. Like hydrogen, lithium is also unstable and reactive. The second energy level is filled in a neon atom, which has an atomic number of 10 (Figure 2–2d). Neon atoms, like helium atoms and other elements in the last column of the periodic table, are very stable. The atoms of elements that are most important to biological systems are unstable. (Table 2–1, p. 28). Their instability promotes atom interactions to form larger structures.

CHECKPOINT

- 1. Define atom.
- 2. Atoms of the same element that have different numbers of neutrons are called _____.
- 3. How is it possible for two samples of molecular hydrogen to contain the same number of atoms, yet have different molecular weights?

• See the blue Answers tab at the back of the book.

2–2 Chemical bonds are forces formed by atom interactions

Learning Outcome Compare the ways in which atoms combine to form molecules and compounds.

Elements that do not readily participate in chemical processes are said to be *inert*. Helium, neon, and argon, which are known as noble gases, have filled outermost energy levels. These elements are also called *inert gases*, because their atoms do not react with one another and do not combine with atoms of other elements.

Elements with unfilled outermost energy levels, such as hydrogen and lithium, are called *reactive*, because they readily interact or combine with other atoms. Reactive atoms become stable by gaining, losing, or sharing electrons to fill their outermost energy level. The interactions often involve the formation of **chemical bonds**, which hold the participating atoms together once the reaction has ended. In the sections that follow, we will consider three basic types of chemical bonds: *ionic bonds*, *covalent bonds*, and *hydrogen bonds*.

When chemical bonding takes place, new chemical entities called *molecules* and *compounds* are created. The term **molecule** refers to any chemical structure consisting of atoms held together by shared electrons. A **compound** is a pure chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of the type of chemical bond joining them. The two categories overlap, but they are not the same. Not all molecules are compounds, because some molecules consist of atoms of only one element. (Two oxygen atoms, for example, can be joined by sharing electrons to form a molecule of oxygen.) And not all compounds consist of molecules, because some compounds, such as ordinary table salt (sodium chloride) are held together by bonds that do not involve shared electrons.

Many substances, however, fit both categories. Take water, for example. Water is a compound because it contains two different elements—hydrogen and oxygen—in a fixed proportion of two hydrogen atoms to one oxygen atom. It also consists of molecules, because the two hydrogen atoms and one oxygen atom are held together by shared electrons. As we will see in later sections, most biologically important compounds, from carbohydrates to DNA, are molecules.

Regardless of the type of bonding involved, a chemical compound has properties that can be quite different from those of its components. For example, a mixture of hydrogen gas and oxygen gas can explode, but the explosion is a chemical reaction that produces liquid water, a compound used to put out fires.

The **molecular weight** of a molecule or compound is the sum of the atomic weights of its component atoms. It follows from the definition of the mole given previously (p. 29) that the molecular weight of a molecule in grams is equal to the weight of one mole of molecules. Molecular weights are important because we cannot handle individual molecules nor can we easily count the billions of molecules involved in chemical reactions in the body.

As an example of how to calculate a molecular weight, let's use water, or H₂O. The atomic weight of hydrogen is 1.0079. To simplify our calculations, we will round that value up to 1.01. Then, one hydrogen molecule (H₂) with its two atoms has a molecular weight of 2.02 ($1.01 \times 2 = 2.02$). One oxygen atom has an atomic weight of 16.00. Summing up, the molecular weight of 1 molecule of H₂O is 18.02. One mole of water molecules would then have a mass of 18.02 grams.

The human body consists of countless molecules and compounds, so it is a challenge to describe these substances and their varied interactions. Chemists simplify such descriptions through a standardized system of *chemical notation*. The basic rules of this system are described in **Spotlight Figure 2–3**.

Ionic Bonds

An **ion** is an atom or group of atoms that has an electric charge, either positive or negative. Ions with a positive charge (+) are called **cations** (KAT-ī-onz). Ions with a negative charge (-) are called **anions** (AN-ī-onz). **Ionic bonds** are chemical bonds created by the electrical attraction between anions and cations.

TIPS&TRICKS

Think of the *t* in cation as a plus sign (+) to remember that a cation has a positive charge, and think of the *n* in anion as standing for *n*egative (–) to remember that anions have a *n*egative charge.

Ions have an unequal number of protons and electrons. Atoms become ions by losing or gaining electrons. We assign a value of +1 to the charge on a proton. The charge on an electron is -1. When the number of protons is equal to the number of electrons, an atom is electrically neutral. An atom that loses an electron becomes a cation with a charge of +1, because it then has one proton that lacks a corresponding

SPOTLIGHT Figure 2–3 Chemical Notation

Before we can consider the specific compounds that occur in the human body, we must be able to describe chemical compounds and reactions effectively. The use of sentences to describe chemical structures and events often leads to confusion. A simple form of "chemical shorthand" makes communication much more efficient. The chemical shorthand we will use is known as **chemical notation**. Chemical notation enables us to describe complex events briefly and precisely; its rules are summarized below.

VISUAL REPRESENTATION **CHEMICAL NOTATION** 0 (H)н 0 The symbol of an element one atom one atom one atom one atom of hydrogen of oxygen of hydrogen of oxygen (\mathbf{H}) (H)0 0 2H20 two atoms two atoms two atoms two atoms of hydrogen of hydrogen of oxygen of oxygen (H)(H)0 0 02 H_2 hydrogen molecule oxygen molecule hydrogen oxygen composed of two composed of two molecule molecule oxygen atoms hydrogen atoms H_2O water molecule (\mathbf{H}) composed of two hydrogen water atoms and one oxygen atom molecule $2H + O \longrightarrow H_2O$ **Balanced** equation Chemical reactions neither create nor destroy atoms; they merely rearrange atoms into new $2H + 2O \rightarrow H_2O$ combinations. Therefore, the numbers of atoms of each element must always be the same on both **Unbalanced** equation sides of the equation for a chemical reaction. When this is the case, the equation is balanced. Na⁺ Ca^{2+} CIsodium ion chloride ion calcium ion sodium chloride calcium the chlorine the sodium the calcium ion ion ion atom has lost atom has gained atom has lost one electron one electron two electrons A sodium atom becomes a sodium ion

Atoms

indicates one atom of that element. A number preceding the symbol of an element indicates more than one atom of that element.

Molecules

A numerical subscript following the symbol of an element indicates the number of atoms of that element in a molecule

Reactions

In a description of a chemical reaction, the participants at the start of the reaction are called reactants, and the reaction generates one or more products. Chemical reactions are represented by chemical equations. An arrow indicates the direction of the reaction, from reactants (usually on the left) to products (usually on the right). In the following reaction, two atoms of hydrogen combine with one atom of oxygen to produce a single molecule of water.

lons

32

A superscript plus or minus sign following the symbol of an element indicates an ion. A single plus sign indicates a cation with a charge of +1. (The original atom has lost one electron.) A single minus sign indicates an anion with a charge of -1. (The original atom has gained one electron.) If more than one electron has been lost or gained, the charge on ~ the ion is indicated by a number preceding the Na plus or minus sign.

> Sodium atom (Na)

Electron lost

(Na⁻

Sodium

ion (Na⁺)

electron. Losing a second electron would give the cation a charge of +2. Adding an extra electron to a neutral atom produces an anion with a charge of -1. Adding a second electron gives the anion a charge of -2.

In the formation of an ionic bond,

Figure 2–4 The Formation of Ionic Bonds.

- one atom-the electron donor-loses one or more electrons and becomes a cation, with a positive (+) charge.
- another atom-the *electron acceptor*-gains those same electrons and becomes an anion, with a negative (-) charge.
- attraction between the opposite charges then draws the two ions together.

Figure 2-4a illustrates the formation of an ionic bond. The sodium atom diagrammed in **1** has an atomic number of 11, so this atom normally contains 11 protons and 11 electrons. (Because neutrons are electrically neutral, they do not affect the formation of ions or ionic bonds.) Electrons fill the first and second energy levels, and a single electron occupies the outermost level. Losing that 1 electron would give the sodium atom a full outermost energy level-the second leveland would produce a **sodium ion**, with a charge of +1. (The chemical shorthand for a sodium ion is Na⁺.) But a sodium

atom cannot simply throw away the electron: The electron must be donated to an electron acceptor. A chlorine atom has seven electrons in its outermost energy level, so it needs only one electron to achieve stability. A sodium atom can provide the extra electron. In the process (1), the chlorine atom becomes a **chloride ion** (Cl^{-}) with a charge of -1.

Both atoms have now become stable ions with filled outermost energy levels. But the two ions do not move apart after the electron transfer, because the positively charged sodium ion is attracted to the negatively charged chloride ion (2). The combination of oppositely charged ions forms an *ionic compound*—in this case, **sodium chloride**, otherwise known as table salt (3). Large numbers of sodium and chloride ions interact to form highly structured crystals, held together by the strong electrical attraction of oppositely charged ions (Figure 2-4b).

Note that ionic compounds are not called molecules. That is because they consist of an aggregation of ions rather than atoms bonded by shared electrons. Sodium chloride and other ionic compounds are common in body fluids, but they are not present as intact crystals. When placed in water, many ionic compounds dissolve, and some, or all, of the component anions and cations separate.

a Formation of an ionic bond. **1** A sodium (Na) atom loses an electron, which is accepted by a chlorine (Cl) atom. (2) Because the sodium ion (Na⁺) and chloride ion (Cl⁻) have opposite charges, they are attracted to one another. 3 The association of sodium and chloride ions forms the ionic compound sodium chloride.

Photo of sodium chloride crystals (magnified 0.5X)

Covalent Bonds

Some atoms can complete their outer electron shells not by gaining or losing electrons, but by sharing electrons with other atoms. Such sharing creates **covalent** (kō-VĀ-lent) **bonds** between the atoms involved.

Individual hydrogen atoms, as diagrammed in Figure 2–2a, do not exist in nature. Instead, we find hydrogen molecules. Molecular hydrogen consists of a pair of hydrogen atoms (Figure 2–5). In chemical shorthand, molecular hydrogen is H_2 , where H is the chemical symbol for hydrogen, and the subscript 2 indicates the number of atoms. Molecular hydrogen is a gas that is present in the atmosphere in very small quantities. When the two hydrogen atoms share their electrons, each electron whirls around both nuclei. The sharing of one pair of electrons creates a **single covalent bond**, which can be represented by a single line (—) in the *structural formula* of a molecule.

Oxygen, with an atomic number of 8, has two electrons in its first energy level and six in its second. The oxygen atoms diagrammed in Figure 2–5 become stable by sharing two pairs of electrons, forming a **double covalent bond**, represented by two lines (=) in its structural formula. Molecular oxygen (O₂) is an atmospheric gas that most organisms need to survive. Our cells would die without a relatively constant supply of oxygen.

Figure 2–5 Covalent Bonds in Five Common Molecules.

In our bodies, chemical processes that consume oxygen generally also produce **carbon dioxide** (CO_2) as a waste product. Each of the oxygen atoms in a carbon dioxide molecule forms double covalent bonds with the carbon atom, as Figure 2–5 shows.

A triple covalent bond is the sharing of three pairs of electrons, and is indicated by three lines (\equiv) in a structural formula. A triple covalent bond joins two nitrogen atoms to form molecular nitrogen (N₂) (Figure 2–5). Molecular nitrogen accounts for about 79 percent of our planet's atmosphere, but our cells ignore it completely. In fact, deep-sea divers live for long periods while breathing artificial air that does not contain nitrogen. (We discuss the reasons for eliminating nitrogen under these conditions in the Decompression Sickness Clinical Note in Chapter 23.)

Covalent bonds usually form molecules in which the outer energy levels of the atoms involved are filled. An atom, ion, or molecule that contains unpaired electrons in its outermost energy level is called a *free radical*. Free radicals are highly reactive. Almost as fast as it forms, a free radical enters additional reactions that are typically destructive. For example, free radicals can damage or destroy vital compounds, such as proteins. Evidence suggests that the cumulative damage from free radicals inside and outside our cells is a major factor in the aging process. Free radicals sometimes form in the course of normal metabolism, but cells have several methods of removing or inactivating them.

Nitric oxide (NO), however, is a free radical with several important functions in the body (Figure 2–5). It reacts readily with other atoms or molecules, but it is involved in chemical communication in the nervous system, in the control of blood vessel diameter, in blood clotting, and in the defense against bacteria and other pathogens (disease-causing organisms).

TIPS&TRICKS

Remember this mnemonic for the covalent bonding of hydrogen, oxygen, nitrogen, and carbon atoms: HONC 1234. *H*ydrogen shares 1 pair of electrons (H–), *o*xygen shares 2 pairs

(-O-), **n** itrogen shares 3 pairs (-N-), and **c** arbon shares 4 pairs (-C-).

Nonpolar Covalent Bonds

Covalent bonds are very strong, because the shared electrons hold the atoms together. In typical covalent bonds the atoms remain electrically neutral, because each shared electron spends just as much time "at home" as away. (If you and a friend were tossing a pair of baseballs back and forth as fast as you could, on average, each of you would have just one baseball.)

Many covalent bonds involve an equal sharing of electrons. Such bonds are called **nonpolar covalent bonds**. They occur, for instance, between two atoms of the same type. Nonpolar covalent bonds are very common. In fact, those involving carbon atoms form most of the structural components of the human body.

Polar Covalent Bonds

Covalent bonds involving different types of atoms may involve an unequal sharing of electrons, because the elements differ in how strongly they attract electrons. An unequal sharing of electrons creates a **polar covalent bond**. For example, in a molecule of water, an oxygen atom forms covalent bonds with two hydrogen atoms (Figure 2–6). The oxygen nucleus (with its eight protons) has a much stronger attraction for the shared electrons than the hydrogen atoms (each with a single proton). As a result, the electrons spend more time orbiting the oxygen nucleus than orbiting the hydrogen nuclei.

Because the oxygen atom has two extra electrons most of the time, it develops a slight (partial) negative charge, indicated by δ^- , as shown in **Figure 2–6b**. At the same time, each hydrogen atom develops a slight (partial) positive charge, δ^+ , because its electron is away much of the time. (Suppose you and a friend were tossing a pair of baseballs back and forth, but one of you returned them as fast as possible while the

Figure 2–6 Water Molecules Contain Polar Covalent Bonds.

oxygen atom has two extra electrons much of the time, it develops a slight negative charge, and the hydrogen atoms become weakly positive. The bonds in a water molecule are polar covalent bonds. other held onto them for a while before throwing them back. One of you would now, on average, have more than one baseball, and the other would have less than one.)

The unequal sharing of electrons makes polar covalent bonds somewhat weaker than nonpolar covalent bonds. Polar covalent bonds often create *polar molecules*—molecules that have positive and negative ends. Water is the most important polar molecule in the body. We will consider its very interesting characteristics in a later section.

Hydrogen Bonds

Covalent and ionic bonds tie atoms together to form molecules and/or compounds. Other, comparatively weak forces also act between adjacent molecules, and even between atoms within a large molecule. The most important of these weak attractive forces is the hydrogen bond. A **hydrogen bond** is the attraction between a slight positive charge (δ^+) on the hydrogen atom of a polar covalent bond and a slight negative charge (δ^-) on an oxygen, nitrogen, or fluorine atom of another polar covalent bond. The polar covalent bond containing the oxygen, nitrogen, or fluorine atom can be in a different molecule from, or in the same molecule as, the hydrogen atom.

Hydrogen bonds are too weak to create molecules, but they can change the shapes of molecules or pull molecules closer together. For example, hydrogen bonding occurs between water molecules (Figure 2–7). At a water surface, this attraction between water molecules slows the rate of evaporation and creates what is known as *surface tension*. Surface tension acts as a barrier that keeps small objects from entering the water. For example, it allows insects to walk across the surface of a pond or puddle. Similarly, the surface tension in a layer of tears on the eye prevents dust particles from touching the surface of the eye. At the cellular level, hydrogen bonds affect the shapes and properties of complex molecules, such as proteins and nucleic acids (including DNA). Hydrogen bonds may also determine the three-dimensional relationships between molecules.

States of Matter

Most matter in our environment exists in one of three states: solid, liquid, or gas. *Solids* keep their volume and their shape at ordinary temperatures and pressures. A lump of granite, a brick, and a textbook are solid objects. *Liquids* have a constant volume, but no fixed shape. The shape of a liquid is determined by the shape of its container. Water, coffee, and soda are liquids. A *gas* has no constant volume and no fixed shape. Gases can be compressed or expanded, and unlike liquids they will fill a container of any size. The most familiar example is the air of our atmosphere.

Figure 2–7 Hydrogen Bonds Form between Water Molecules. The hydrogen atoms of a water molecule have a slight positive charge, and the oxygen atom has a slight negative charge (*see Figure 2–6b*). The distances between these molecules have been exaggerated for clarity.

What determines whether a substance is a solid, a liquid, or a gas? A matter's state depends on the degree of interaction among its atoms or molecules. The particles of a solid are held tightly together, while those of a gas are very far apart. Water is the only substance that occurs as a solid (ice), a liquid (water), and a gas (water vapor) at temperatures compatible with life. Water exists as a liquid over a broad range of temperatures primarily because of hydrogen bonding among the water molecules. We will talk more about water's unusual properties in a later section.

CHECKPOINT

- 4. Define chemical bond and identify several types of chemical bonds.
- 5. Which kind of bond holds atoms in a water molecule together? What attracts water molecules to one another?
- Both oxygen and neon are gases at room temperature. Oxygen combines readily with other elements, but neon does not. Why?

See the blue Answers tab at the back of the book.

2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology

Learning Outcome Distinguish among the major types of chemical reactions that are important for studying physiology.

Cells stay alive and functional by controlling chemical reactions. In a **chemical reaction**, new chemical bonds form between atoms, or existing bonds between atoms are broken. These changes take place as atoms in the reacting substances, called **reactants**, are rearranged to form different substances, or **products** (Spotlight Figure 2–3).

In effect, each cell is a chemical factory. Growth, maintenance and repair, secretion, and contraction all involve complex chemical reactions. Cells use chemical reactions to provide the energy they need to maintain homeostasis and to perform essential functions. All of the reactions under way in the cells and tissues of the body at any given moment make up its **metabolism** (me-TAB-ō-lizm).

Basic Energy Concepts

An understanding of some basic relationships between matter and energy is helpful for any discussion of chemical reactions. **Work** is the movement of an object or a change in the physical structure of matter. In your body, work includes movements like walking or running, and also the synthesis of organic (carbon-containing) molecules and the conversion of liquid water to water vapor (evaporation). **Energy** is the capacity to do work, and movement or physical change cannot take place without energy. The two major types of energy are kinetic energy and potential energy.

- 1. **Kinetic energy** is the energy of motion—energy that can be transferred to another object and do work. When you fall off a ladder, it is kinetic energy that does the damage.
- Potential energy is stored energy—energy that has the potential to do work. It may derive from an object's position (you standing on a ladder) or from its physical or chemical structure (a stretched spring or a charged battery).

Kinetic energy must be used in climbing the ladder, in stretching the spring, or in charging the battery. The resulting potential energy is converted back into kinetic energy when you descend, the spring recoils, or the battery discharges. The kinetic energy can then be used to perform work. For example, in an MP3 player, the chemical potential energy stored in small batteries is converted to kinetic energy that vibrates the sound-producing membranes in headphones or external speakers. Energy cannot be destroyed. It can only be converted from one form to another. A conversion between potential energy and kinetic energy is never 100 percent efficient. Each time an energy exchange occurs, some of the energy is released in the form of heat. *Heat* is an increase in random molecular motion, and the temperature of an object is proportional to the average kinetic energy of its molecules. Heat can never be completely converted to work or any other form of energy, and cells cannot capture it or use it to do work.

Cells do work as they synthesize complex molecules and move materials into, out of, and within the cell. The cells of a skeletal muscle at rest, for example, contain potential energy in the form of the positions of protein filaments and the covalent bonds between molecules inside the cells. When a muscle contracts, it performs work. Potential energy is converted into kinetic energy, and heat is released. The amount of heat is proportional to the amount of work done. As a result, when you exercise, your body temperature rises.

Types of Chemical Reactions

Three types of chemical reactions are important to the study of physiology: decomposition reactions, synthesis reactions, and exchange reactions.

Decomposition Reactions

A **decomposition** reaction breaks a molecule into smaller fragments. Here is a diagram of a simple *decomposition reaction*:

$$AB \longrightarrow A + B$$

Decomposition reactions take place outside cells as well as inside them. For example, a typical meal contains molecules of fats, sugars, and proteins that are too large and too complex to be absorbed and used by your body. Decomposition reactions in the digestive tract break these molecules down into smaller fragments that can be absorbed.

Decomposition reactions involving water are important in the breakdown of complex molecules in the body. In **hydrolysis** (hī-DROL-i-sis; *hydro-*, water + *lysis*, a loosening), one of the bonds in a complex molecule is broken, and the components of a water molecule (H and OH) are added to the resulting fragments:

 $A - B + H_2O \longrightarrow A - H + HO - B$

Collectively, the decomposition reactions of complex molecules within the body's cells and tissues are referred to as **catabolism** (ka-TAB-ō-lizm; *katabole*, a throwing down). When a covalent bond—a form of potential energy—is broken, it releases kinetic energy that can do work. By harnessing the energy released in this way, cells carry out vital functions such as growth, movement, and reproduction.

Synthesis Reactions

Synthesis (SIN-the-sis) is the opposite of decomposition. A *synthesis reaction* assembles smaller molecules into larger molecules. A simple synthetic reaction is diagrammed here:

$$A + B \longrightarrow AB$$

Synthesis reactions may involve individual atoms or the combination of molecules to form even larger products. The formation of water from hydrogen and oxygen molecules is a synthesis reaction. Synthesis always involves the formation of new chemical bonds, whether the reactants are atoms or molecules.

A **dehydration synthesis**, or *condensation reaction*, is the formation of a complex molecule by the removal of a water molecule:

$$A - H + HO - B \longrightarrow A - B + H_2O$$

Dehydration synthesis is the opposite of hydrolysis. We will see examples of both reactions in later sections.

Collectively, the synthesis of new molecules within the body's cells and tissues is known as **anabolism** (a-NAB-ō-lizm; *anabole*, a throwing upward). Anabolism is usually considered an "uphill" process because it takes energy to create a chemical bond (just as it takes energy to push something uphill). Cells must balance their energy budgets, with catabolism providing the energy to support anabolism and other vital functions.

TIPS&TRICKS

To remember the difference between anabolism (synthesis) and catabolism (breakdown), relate the terms to words you already know: *Anabolic* steroids are used to build up muscle tissue, while both *catastrophe* and *catabolism* involve destruction (breakdown).

Exchange Reactions

In an **exchange reaction**, parts of the reacting molecules are shuffled around to produce new products:

$$AB + CD \longrightarrow AD + CB$$

The reactants and products contain the same components (A, B, C, and D), but those components are present in different combinations. In an exchange reaction, the reactant molecules AB and CD must break apart (a decomposition) before they can interact with each other to form AD and CB (a synthesis).

Reversible Reactions

At least in theory, chemical reactions are reversible, so if $A + B \longrightarrow AB$, then $AB \longrightarrow A + B$. Many important biological reactions are freely reversible. Such reactions can be represented as an equation:

$$A + B \rightleftharpoons AB$$

2

This equation indicates that, in a sense, two reactions are taking place at the same time. One is a synthesis $(A + B \longrightarrow AB)$ and the other is a decomposition $(AB \longrightarrow A + B)$.

Recall from Chapter 1 that a state of *equilibrium* exists when opposing processes or forces are in balance. At equilibrium, the rates of the two reactions are in balance. As fast as one molecule of AB forms, another degrades into A + B.

What happens when equilibrium is disturbed—say, if you add more AB? In our example, the rate of the synthesis reaction is directly proportional to the frequency of encounters between A and B. In turn, the frequency of encounters depends on the degree of crowding. (You are much more likely to bump into another person in a crowded room than in a room that is almost empty.) So, adding more AB molecules will increase the rate of conversion of AB to A and B. The amounts of A and B will then increase, leading to an increase in the rate of the reverse reaction—the formation of AB from A and B. Eventually, a balance, or equilibrium, is again established.

TIPS&TRICKS

Jell-O provides an example of a physical reversible reaction. Once Jell-O has been refrigerated, the gelatin sets up and forms a solid, but if it sits without refrigeration for too long, it goes back to a liquid again.

CHECKPOINT

- 7. When using the rules for chemical notation, how is an ion's electrical charge represented?
- 8. Using the rules for chemical notation, write the molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms.
- 9. Identify and describe three types of chemical reactions important to human physiology.
- 10. In cells, glucose, a six-carbon molecule, is converted into two three-carbon molecules by a reaction that releases energy. How would you classify this reaction?

See the blue Answers tab at the back of the book.

2-4 Enzymes catalyze specific biochemical reactions by lowering the energy needed to start them

Learning Outcome Describe the crucial role of enzymes in metabolism.

Most chemical reactions do not take place spontaneously, or if they do, they occur so slowly that they would be of little value to living cells. Before a reaction can proceed, enough energy must be provided to activate the reactants. The amount of energy required to start a reaction is called the **activation energy**. Many reactions can be activated by changes in temperature or acidity, but such changes are deadly to cells. For example, every day your cells break down complex sugars as part of your normal metabolism. Yet to break down a complex sugar in a laboratory, you must boil it in an acidic solution. Your cells don't have that option! Temperatures that high and solutions that corrosive would immediately destroy living tissues. Instead, your cells use special proteins called *enzymes* to perform most of the complex synthesis and decomposition reactions in your body.

Enzymes promote chemical reactions by lowering the activation energy required (Figure 2–8). In doing so, they make it possible for chemical reactions, such as the breakdown of sugars, to proceed under conditions compatible with life. Cells make enzyme molecules, each of which promotes a specific reaction.

Enzymes belong to a class of substances called **catalysts** (KAT-uh-lists; *katalysis*, dissolution), compounds that speed up chemical reactions without themselves being permanently changed or consumed. Enzymatic reactions, which are reversible, can be written as

$$A + B = AB$$

An appropriate enzyme can accelerate, or speed up, a reaction, but an enzyme affects only the *rate* of the reaction, not its direction or the products that are formed. An enzyme cannot bring about a reaction that would otherwise be impossible. Enzymatic reactions are generally reversible, and they proceed until equilibrium is reached.

The complex reactions that support life take place in a series of interlocking steps, each controlled by a specific enzyme. Such a reaction sequence is called a *metabolic pathway*. A synthetic pathway can be diagrammed as

A
$$\xrightarrow[Step 1]{enzyme 1}$$
 B $\xrightarrow[Step 2]{enzyme 2}$ C $\xrightarrow[Step 3]{enzyme 3}$ and so on.

Figure 2–8 Enzymes Lower Activation Energy. Enzymes lower the activation energy required for a chemical reaction to proceed readily (in order, from 1–4) under conditions in the body.

In many cases, the steps in the synthetic pathway differ from those in the decomposition pathway, and separate enzymes are often involved.

It takes activation energy to start a chemical reaction, but once it has begun, the reaction as a whole may absorb or release energy as it proceeds to completion. If the amount of energy released is greater than the activation energy needed to start the reaction, there will be a net release of energy. Reactions that release energy are said to be **exergonic** (*exo-*, outside + *ergon*, work). Exergonic reactions are relatively common in the body. They generate the heat that maintains your body temperature.

If more energy is required to begin the reaction than is released as it proceeds, the reaction as a whole will absorb energy. Such reactions are called **endergonic** (*endo-*, inside). The synthesis of molecules such as fats and proteins result from endergonic reactions.

CHECKPOINT

11. What is an enzyme?

12. Why are enzymes needed in our cells?

See the blue Answers tab at the back of the book.

2-5 Inorganic compounds lack carbon, and organic compounds contain carbon

Learning Outcome Distinguish between organic compounds and inorganic compounds.

The human body is very complex, but it contains relatively few elements (Table 2–1, p. 28). Just knowing the identity and quantity of each element in the body will not help you understand the body any more than only memorizing the alphabet will help you understand this textbook. Just as 26 letters can be combined to form thousands of different words in this book, only about 26 elements combine to form thousands of different chemical compounds in our bodies. As we saw in Chapter 1, these compounds make up the living cells that form the framework of the body and carry on all its life processes. Learning about the major classes of chemical compounds will help you to understand the structure and function of the human body.

We now turn our attention to nutrients and metabolites. **Nutrients** are the substances from food that are necessary for normal physiological functions. Nutrients include carbohydrates, proteins, fats, vitamins, minerals, and water. **Metabolites** (me-TAB-ō-līts; *metabole*, change) are substances that are involved in, or a byproduct of, metabolism. We can broadly categorize nutrients and metabolites as either inorganic or organic. **Inorganic compounds** generally do not contain carbon and hydrogen atoms as their primary structural ingredients. In contrast, carbon and hydrogen always form the basis for **organic compounds**.

The most important inorganic compounds in the body are (1) carbon dioxide, a byproduct of cell metabolism; (2) oxygen, an atmospheric gas required in important metabolic reactions; (3) water, which accounts for most of our body weight; and (4) inorganic acids, bases, and salts—compounds held together partially or completely by ionic bonds. In the next section, we focus on water, its properties, and how those properties establish the conditions necessary for life. Most of the other inorganic molecules and compounds in the body exist in association with water, the primary component of our body fluids. Both carbon dioxide and oxygen, for example, are gas molecules that are transported in body fluids. Also, all the inorganic acids, bases, and salts we will discuss are dissolved in body fluids.

CHECKPOINT

- 13. Compare organic compounds to inorganic compounds.
- See the blue Answers tab at the back of the book.

2-6 Physiological systems depend on water

Learning Outcome Explain how the chemical properties of water make life possible.

Water (H_2O) is the most important substance in the body. It makes up to two-thirds of total body weight. A change in the body's water content can be fatal because virtually all physiological systems will be affected.

Although water is familiar to everyone, it has some highly unusual properties. These properties are due to the hydrogen bonding between nearby water molecules.

- Solubility. A remarkable number of inorganic and organic molecules are *soluble*, meaning they will dissolve or break up in water. The individual particles become distributed within the water, and the result is a **solution**—a uniform mixture of two or more substances. The liquid in which other atoms, ions, or molecules are distributed is called the **solvent**. The dissolved substances are the **solutes**. In *aqueous solutions*, water is the solvent. The solvent properties of water are so important that we will consider them further in the next section.
- Reactivity. In our bodies, chemical reactions take place in water, but water molecules also take part in some reactions. Hydrolysis and dehydration synthesis are two examples noted earlier in the chapter.

- 3. *High Heat Capacity*. **Heat capacity** is the quantity of heat required to raise the temperature of a unit mass of a substance 1°C. Water has an unusually high heat capacity. Why? The reason is that water molecules in the liquid state are attracted to one another through hydrogen bonding. Important consequences of this attraction include the following:
 - The temperature of water must be quite high before all the hydrogen bonds are broken between individual water molecules and they have enough energy to break free and become water vapor, a gas. Therefore, water remains a liquid over a broad range of environmental temperatures, and the freezing and boiling points of water are far apart.
 - Water carries a great deal of heat away with it when it changes from a liquid to a gas. This feature explains the cooling effect of perspiration on the skin.
 - An unusually large amount of heat energy is required to change the temperature of 1 g of water by 1°C. As a result, a large mass of water changes temperature slowly. This property is called *thermal inertia*. Thermal inertia helps stabilize body temperature because water accounts for up to two-thirds of the weight of the human body.
- 4. *Lubrication.* Water is an effective lubricant because there is little friction between water molecules. So, even a thin

distribution of charges, creating

positive and negative poles.

layer of water between two opposing surfaces will greatly reduce friction between them. (That is why driving on wet roads can be tricky. Your tires may start sliding on a layer of water rather than maintaining contact with the road.) Within joints such as the knee, an aqueous solution prevents friction between the opposing surfaces. Similarly, a small amount of fluid in the body cavities prevents friction between internal organs, such as the heart or lungs, and the body wall. \supset p. 19

The Properties of Aqueous Solutions

Water's chemical structure makes it an unusually effective solvent. The covalent bonds in a water molecule are oriented so that the hydrogen atoms are fairly close together. As a result, the water molecule has positive and negative ends, or poles (Figure 2–9a). For this reason, a water molecule is called a **polar molecule**.

Many inorganic compounds are held together partly or completely by ionic bonds. In water, these compounds undergo **dissociation** (di-sō-sē-Ā-shun), or **ionization** (i-on-i-ZĀ-shun). In this process, ionic bonds are broken as the individual ions interact with the positive or negative ends of polar water molecules (Figure 2–9b). The result is a mixture of cations and anions surrounded by water molecules. The water molecules around each ion form a *hydration sphere*.

b Sodium chloride in solution. Ionic compounds, such as sodium chloride, dissociate in water as the polar water molecules break the ionic bonds in the large crystal structure. Each ion in solution is surrounded by water molecules, creating hydration spheres.

C Glucose in solution. Hydration spheres also form around an organic molecule containing polar covalent bonds. If the molecule binds water strongly, as does glucose, it will be carried into solution—in other words, it will dissolve. Note that the molecule does not dissociate, as occurs for ionic compounds.

Table 2–2	Important Electrolytes That Dissociate in Body Fluids	
Electrolyte		lons Released
NaCl (sodium chloride)		\rightarrow Na ⁺ + Cl ⁻
KCI (potassium chloride)		\rightarrow K ⁺ + Cl ⁻
CaPO₄ (calcium phosphate)		\rightarrow Ca ²⁺ + PO ₄ ²⁻
NaHCO ₃ (sodium bicarbonate)		$\rightarrow Na^{+} + HCO_{3}^{-}$
MgCl₂ (magnesium chloride)		\rightarrow Mg ²⁺ + 2Cl ⁻
Na2HPO4 (sodium hydrogen phosphate)		$\rightarrow 2Na^{+} + HPO_{4}^{2-}$
Na ₂ SO ₄ (sodium	sulfate)	$\rightarrow 2Na^{+} + SO_{4}^{2-}$

An aqueous solution containing anions and cations will conduct an electrical current. When this happens, cations (+) move toward the negative side, and anions (-) move toward the positive side. Electrical forces across plasma membranes affect the functioning of all cells, and small electrical currents carried by ions are essential to muscle contraction and nerve function. In Chapters 10 and 12 we will discuss these processes in more detail.

Electrolytes and Body Fluids

Soluble inorganic substances whose ions will conduct an electrical current in solution are called **electrolytes** (e-LEK-trō-līts). Sodium chloride in solution is an electrolyte. The dissociation of electrolytes in blood and other body fluids releases a variety of ions. Table 2–2 lists important electrolytes and the ions released when they dissociate.

Changes in the concentrations of electrolytes in body fluids will disturb almost every vital function. For example, declining potassium levels will lead to a general muscular paralysis, and rising concentrations will cause weak and irregular heartbeats. The concentrations of ions in body fluids are carefully regulated, mostly by the coordination of activities at the kidneys (ion excretion), the digestive tract (ion absorption), and the skeletal system (ion storage or release).

Hydrophilic and Hydrophobic Compounds

Some organic molecules contain polar covalent bonds, which also attract water molecules. The hydration spheres that form may then carry these molecules into solution (Figure 2–9c). Molecules that interact readily with water molecules in this way are called **hydrophilic** (hī-drō-FIL-ik; *hydro-*, water + *philos*, loving). Glucose, an important soluble sugar, is one example.

Many other organic molecules have very few or no polar covalent bonds. Such molecules do not have positive and negative ends, and are said to be *nonpolar*. When nonpolar molecules are exposed to water, hydration spheres do not form and the molecules do not dissolve. Molecules that do not readily interact with water are called **hydrophobic** (hī-drō-FŌBik; *hydro-*, water + *phobos*, fear). Fats and oils of all kinds are some of the most familiar hydrophobic molecules. For example, body fat deposits consist of large, hydrophobic droplets trapped in the watery interior of cells. Gasoline and heating oil are hydrophobic molecules not found in the body. When accidentally spilled into lakes or oceans, they form long-lasting oil slicks instead of dissolving.

TIPS&TRICKS

To distinguish between hydrophobic and hydrophilic, remember that a phobia is a fear of something, and that -philic ends with "lic," which resembles "like."

Colloids and Suspensions

Body fluids may contain large and complex organic molecules, such as proteins and protein complexes, that are held in solution by their association with water molecules (Figure 2–9c). A solution containing dispersed proteins or other large molecules is called a **colloid**. Liquid Jell-O is a familiar viscous (thick) colloid. The particles or molecules in a colloid will remain in solution indefinitely.

In contrast, a **suspension** contains large particles in solution, but if undisturbed, its particles will settle out of solution due to the force of gravity. For example, stirring beach sand into a bucket of water creates a temporary suspension that will last only until the sand settles to the bottom. Whole blood is another temporary suspension, because the blood cells are suspended in the blood plasma. If clotting is prevented, the cells in a blood sample will gradually settle to the bottom of the container. Measuring that settling rate, or "sedimentation rate," is a common laboratory test.

CHECKPOINT

- 14. Explain how the chemical properties of water make life possible.
- See the blue Answers tab at the back of the book.

2-7 Body fluid pH is vital for homeostasis

Learning Outcome Discuss the importance of pH and the role of buffers in body fluids.

A hydrogen atom involved in a chemical bond or participating in a chemical reaction can easily lose its electron, to become a hydrogen ion, H⁺. Hydrogen ions are extremely reactive in solution. In excessive numbers, they will break chemical bonds, change the shapes of complex molecules, and generally disrupt cell and tissue functions. As a result, the concentration of hydrogen ions in body fluids must be regulated precisely.

A few hydrogen ions are normally present even in a sample of pure water, because some of the water molecules dissociate spontaneously, releasing cations and anions. The dissociation of water is a reversible reaction. We can represent it as:

$$H_2O \Longrightarrow H^+ + OH^-$$

Notice that the dissociation of one water molecule yields a hydrogen ion (H^+) and a *hydroxide* (hī-DROK-sīd) *ion*, OH⁻.

Very few water molecules ionize in pure water, so the number of hydrogen and hydroxide ions is small. The quantities are usually reported in moles, making it easy to keep track of the numbers of hydrogen and hydroxide ions. One liter of pure water contains about 0.0000001 mol of hydrogen ions and an equal number of hydroxide ions. In other words, the concentration of hydrogen ions in a solution of pure water is 0.0000001 mol per liter. This can be written as

$$[\mathrm{H^+}] = 1 \times 10^{-7} \mathrm{mol/L}$$

The brackets around the H⁺ signify "the concentration of," another example of chemical notation.

The hydrogen ion concentration in body fluids is so important to physiological processes that we use a special shorthand to express it. The **pH** of a solution is defined as the negative logarithm of the hydrogen ion concentration in moles per liter. So instead of using the equation $[H^+] = 1 \times 10^{-7} \text{ mol/L}$, we say that the pH of pure water is –(–7), or 7.

Using pH values saves space, but always remember that the pH number is an *exponent* and that the pH scale is logarithmic. For instance, a pH of 6 ($[H^+] = 1 \times 10^{-6}$, or 0.000001 mol/L) means that the concentration of hydrogen ions is 10 *times* greater than it is at a pH of 7 ($[H^+] = 1 \times 10^{-7}$, or 0.0000001 mol/L). The pH scale ranges from 0 to 14 (Figure 2–10).

Pure water has a pH of 7, but solutions display a wide range of pH values, depending on the nature of the solutes involved.

- A solution with a pH of 7 is said to be **neutral**, because it contains equal numbers of hydrogen and hydroxide ions.
- A solution with a pH below 7 is **acidic** (a-SI-dik), meaning that it contains more hydrogen ions than hydroxide ions.
- A pH above 7 is **basic**, or *alkaline* (AL-kuh-lin), meaning that it has more hydroxide ions than hydrogen ions.

The normal pH of blood ranges from 7.35 to 7.45. Abnormal fluctuations in pH can damage cells and tissues by breaking chemical bonds, changing the shapes of proteins, and altering cellular functions. *Acidosis* is an abnormal physiological state caused by low blood pH (below 7.35). A pH below 7 can produce coma. Likewise, *alkalosis* results from an abnormally high pH (above 7.45). A blood pH above 7.8 generally causes uncontrollable and sustained skeletal muscle contractions.

- CHECKPOINT

- **15**. Define pH, and explain how the pH scale relates to acidity and alkalinity.
- 16. What is the significance of pH in physiological systems?

• See the blue Answers tab at the back of the book.

2-8 Acids, bases, and salts are inorganic compounds with important physiological roles

Learning Outcome Describe the physiological roles of inorganic compounds.

The body contains both inorganic and organic *acids* and *bases* that may cause acidosis or alkalosis, respectively. An **acid** is any solute that dissociates in solution and releases hydrogen

ions, lowering the pH. A hydrogen atom that loses its electron consists solely of a proton, so we often refer to hydrogen ions simply as protons, and to acids as *proton donors*.

A *strong acid* dissociates completely in solution, and the reaction occurs essentially in one direction only. *Hydrochloric acid* (HCl) is a representative strong acid. In water, it ionizes as follows:

$$HCl \longrightarrow H^+ + Cl^-$$

The stomach produces this powerful acid to help break down food. Hardware stores sell HCl under the name muriatic acid, for cleaning concrete and swimming pools.

A **base** is a solute that removes hydrogen ions from a solution, raising the pH. It acts as a *proton acceptor*. In solution, many bases release a hydroxide ion (OH⁻). Hydroxide ions have an attraction for hydrogen ions and react quickly with them to form water molecules. A *strong base* dissociates completely in solution. *Sodium hydroxide*, NaOH, is a strong base. In solution, it releases sodium ions and hydroxide ions:

$$NaOH \longrightarrow Na^+ + OH^-$$

Strong bases have a variety of industrial and household uses. Drain openers (Drano) and lye are two familiar examples.

Weak acids and weak bases do not dissociate completely. At equilibrium, a significant number of molecules remains intact in the solution. For the same number of molecules in solution, weak acids and weak bases have less impact on pH than do strong acids and strong bases. *Carbonic acid* (H_2CO_3) is a weak acid found in body fluids. In solution, carbonic acid reversibly dissociates into a hydrogen ion and a *bicarbonate ion*, HCO_3^- :

$$H_2CO_3 \Longrightarrow H^+ + HCO_3$$

Salts

A **salt** is an ionic compound containing any cation except a hydrogen ion, and any anion except a hydroxide ion. Because they are held together by ionic bonds, many salts dissociate completely in water, releasing cations and anions. For example, sodium chloride (table salt) dissociates immediately in water, releasing Na⁺ and Cl⁻. Sodium and chloride are the most abundant ions in body fluids. However, many other ions are present in lesser amounts as a result of the dissociation of other inorganic compounds. Ionic concentrations in the body are regulated in ways we will describe in Chapters 26 and 27.

The ionization of sodium chloride does not affect the local concentrations of hydrogen ions or hydroxide ions. For this reason, NaCl, like many salts, is a "neutral" solute. It does not make a solution more acidic or more basic. Through their interactions with water molecules, however, other salts may indirectly affect the concentrations of H^+ and OH^- ions. Thus, the dissociation of some salts makes a solution slightly acidic or slightly basic.

Buffers and pH Control

Buffers are compounds that stabilize the pH of a solution by removing or replacing hydrogen ions. *Buffer systems* usually involve a weak acid and its related salt, which functions as a weak base. For example, the carbonic acid–bicarbonate buffer system (detailed in Chapter 27) consists of carbonic acid and sodium bicarbonate, NaHCO₃, otherwise known as baking soda. Buffers and buffer systems in body fluids help maintain the pH within normal limits. The pH of several body fluids is included in Figure 2–10.

The use of antacids such as Alka-Seltzer is one example of the type of reaction that takes place in buffer systems. Alka-Seltzer uses sodium bicarbonate to neutralize excess hydrochloric acid in the stomach.

Note that the effects of neutralization are most evident when you add a strong acid to a strong base. For example, by adding hydrochloric acid to sodium hydroxide, you neutralize both the strong acid and the strong base.

$$HCl + NaOH \longrightarrow H_2O + NaCl$$

This neutralization reaction produces water and a salt—in this case, the neutral salt sodium chloride.

- CHECKPOINT

- 17. Define the following terms: acid, base, and salt.
- 18. How does an antacid help decrease stomach discomfort?
- See the blue Answers tab at the back of the book.

2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio

Learning Outcome Discuss the structures and functions of carbohydrates.

Carbohydrates are one type of organic compound. Organic compounds always contain the elements carbon and hydrogen, and generally oxygen as well. Many organic molecules are made up of long chains of carbon atoms linked by covalent bonds. The carbon atoms typically form additional covalent bonds with hydrogen or oxygen atoms and, less commonly, with nitrogen, phosphorus, sulfur, iron, or other elements.

Many organic molecules are soluble in water. Our previous discussion focused on inorganic acids and bases, but there are also important organic acids and bases. For example, active muscle tissues generate *lactic acid*, an organic acid. It must be neutralized by the carbonic acid–bicarbonate buffer system to prevent a potentially dangerous pH decline in body fluids.

Organic compounds are diverse, but certain groupings of atoms occur again and again, even in very different types of molecules. These *functional groups* greatly influence the
Table 2–3	Important Functional Groups of Organic Compounds			
Functional Grou	р	Structural Formula*	Importance	Examples
Amino group —	- NH ₂	R — N H	Acts as a base, accepting H^+ , depending on pH; can form bonds with other molecules	Amino acids
Carboxyl group	—соон	OH R—C=0	Acts as an acid, releasing $\mathrm{H^+}$ to become $\mathrm{R}\mathrm{-\!\!-\!COO^-}$	Fatty acids, amino acids
Hydroxyl group	—он	R — O — H	May link molecules through dehydration synthesis (condensation); hydrogen bonding between hydroxyl groups and water molecules affects solubility	Carbohydrates, fatty acids, amino acids
Phosphate grou	р — РО ₄	0 R	May link other molecules to form larger structures; may store energy in high-energy bonds	Phospholipids, nucleic acids, high-energy compounds

*A structural formula shows the covalent bonds within a molecule or functional group. The letter R represents the term *R group* and is used to denote the rest of the molecule to which a functional group is attached.

properties of any molecule they are in. Table 2–3 details the functional groups you will study in this chapter.

A **carbohydrate** is an organic molecule that contains carbon, hydrogen, and oxygen in a ratio near 1:2:1. Familiar carbohydrates include the *sugars* and *starches* that make up about half of the typical U.S. diet. Carbohydrates typically account for less than 1 percent of total body weight. Carbohydrates are most important as energy sources that are catabolized. We will focus on *monosaccharides, disaccharides*, and *polysaccharides*.

Monosaccharides

A **monosaccharide** (mon- \bar{o} -SAK-uh-rīd; *mono-*, single + *sakcharon*, sugar), or *simple sugar*, is a carbohydrate with three to seven carbon atoms. A monosaccharide can be called a *triose* (three-carbon), *tetrose* (four-carbon), *pentose* (five-carbon), *hexose* (six-carbon), or *heptose* (seven-carbon). The hexose **glucose** (GLOO-k \bar{o} s), C₆H₁₂O₆, is the most important metabolic "fuel" in the body. As shown by diagrams known as *structural formulas*, the atoms in a glucose molecule may form either a straight chain (Figure 2–11a) or a ring (Figure 2–11b). In the body, the ring form is more common. A three-dimensional model shows the arrangement of atoms in the ring form most clearly (Figure 2–11c).

The three-dimensional structure of an organic molecule is an important characteristic, because it usually determines the molecule's fate or function. Some molecules have the same molecular formula—in other words, the same types and numbers of atoms—but different structures. Such molecules are called **isomers**. The body usually treats different

Figure 2–11 The Structures of Glucose.

isomers as distinct molecules. For example, the monosaccharides glucose and fructose are isomers. *Fructose* is a hexose found in many fruits and in secretions of the male reproductive tract. It has the same chemical formula as glucose, $C_6H_{12}O_6$, but the arrangement of its atoms differs from that of glucose. As a result, separate enzymes and reaction sequences control its breakdown and synthesis. Monosaccharides such as glucose and fructose dissolve readily in water and are rapidly distributed throughout the body by blood and other body fluids.

Disaccharides and Polysaccharides

Carbohydrates other than simple sugars are complex molecules composed of monosaccharide building blocks. Two monosaccharides joined together form a **disaccharide** (dī-SAK-uh-rīd; *di-*, two). Disaccharides such as *sucrose* (table sugar) have a sweet taste and, like monosaccharides, are quite soluble in water.

The formation of sucrose involves a dehydration synthesis, or condensation reaction (Figure 2–12a). Dehydration synthesis reactions link molecules together by the removal of a water molecule. The breakdown of sucrose into simple sugars is an example of hydrolysis, or breakdown by the addition of a water molecule (Figure 2–12b). Hydrolysis is the functional opposite of dehydration synthesis.

Many foods contain disaccharides, but all carbohydrates except monosaccharides must be broken apart through hydrolysis before they can provide useful energy. Most popular junk foods (high in calories but otherwise lacking in nutritional content), such as candies and sodas, abound in monosaccharides (commonly fructose) and disaccharides (generallysucrose). Some people cannot tolerate sugar for medical reasons. Others avoid it in an effort to control their weight (because excess sugars are converted to fat for long-term storage). Many of these people use *artificial sweeteners* in their foods and beverages. These compounds have a very sweet taste, but they either cannot be broken down in the body or are used in insignificant amounts.

More complex carbohydrates result when repeated dehydration synthesis reactions add additional monosaccharides or disaccharides. These large molecules are called **polysaccharides** (pol-ē-SAK-uh-rīdz; *poly-*, many). Polysaccharide chains can be straight or highly branched. *Cellulose*, a structural component of many plants, is a polysaccharide that our bodies cannot digest because the particular linkages between the glucose molecules cannot be cleaved by enzymes in the body. Foods such as celery, which contains cellulose, water, and little else, contribute bulk to digestive wastes but are useless as a source of energy.

Starches are large polysaccharides formed from glucose molecules. Most starches are manufactured by plants. Your digestive tract can break these molecules into monosaccharides. Starches such as those in potatoes and grains are a major dietary energy source.

The polysaccharide **glycogen** (GLI-kō-jen), or *animal starch*, has many side branches consisting of chains of glucose molecules (Figure 2–13). Like most other starches, glycogen does not dissolve in water or other body fluids. Muscle cells make and store glycogen. When muscle cells have a high demand for glucose, glycogen molecules are broken down. When the need is low, these cells absorb glucose from the blood-stream and rebuild glycogen reserves. Table 2–4 (on the next page) summarizes information about carbohydrates.

Figure 2–12 The Formation and Breakdown of Complex Sugars. Enzymes perform both these reactions.

b Breakdown of sucrose into simple sugars by hydrolysis. Hydrolysis reverses the steps of dehydration synthesis; a complex molecule is broken down by the addition of a water molecule.

Table 2–4	Carbohydrates in the B	ody	
Structural Class	Examples	Primary Function	Remarks
Monosaccharide (simple sugars)	s Glucose, fructose	Energy source	Manufactured in the body and obtained from food; distributed in body fluids
Disaccharides	Sucrose, lactose, maltose	Energy source	Sucrose is table sugar, lactose is in milk, and maltose is malt sugar found in germinating grain; all must be broken down to monosaccharides before absorption
Polysaccharides	Glycogen	Storage of glucose	Glycogen is in animal cells; other starches and cellulose are within or around plant cells

Figure 2–13 The Structure of the Polysaccharide Glycogen. Liver and muscle cells store glucose as the polysaccharide glycogen, a long, branching chain of glucose molecules. Note that this figure uses a kind of shorthand for representing a carbon ring structure: At five corners of each hexagon is a carbon atom. An oxygen atom occupies the remaining corner in each glucose ring.

CHECKPOINT

19. A food contains organic molecules with the elements C, H, and O in a ratio of 1:2:1. What class of compounds do these molecules belong to, and what are their major functions in the body?

See the blue Answers tab at the back of the book.

2-10 Lipids often contain a carbon-to-hydrogen ratio of 1:2

Learning Outcome Discuss the structures and functions of lipids.

Like carbohydrates, **lipids** (*lipos*, fat) contain carbon, hydrogen, and oxygen, and the carbon-to-hydrogen ratio is near 1:2. However, lipids contain much less oxygen than do carbohydrates with the same number of carbon atoms. The hydrogen-tooxygen ratio is therefore very large. For example, a representative lipid, such as lauric acid (found in coconut, laurel, and palm kernel oils), has a formula of $C_{12}H_{24}O_2$. Lipids may also contain small quantities of phosphorus, nitrogen, or sulfur. Familiar lipids include *fats*, *oils*, and *waxes*. Most lipids are insoluble in water, but special transport mechanisms carry them into the bloodstream.

Lipids form essential structural components of all cells. In addition, lipid deposits are important as energy reserves. On average, lipids provide twice as much energy as carbohydrates do, gram for gram, when broken down in the body. When the supply of lipids exceeds the demand for energy, the excess is stored in fat deposits. For this reason, there has been great interest in developing *fat substitutes* that provide less energy, but have the same desirable taste and texture as the fats found in many foods.

Lipids normally make up 12–18 percent of the total body weight of adult men, and 18–24 percent for adult women. Many kinds of lipids exist in the body. We will consider five classes of lipids: *fatty acids, eicosanoids, glycerides, steroids,* and *phospholipids and glycolipids*.

Fatty Acids

Fatty acids are long carbon chains with hydrogen atoms attached. One end of the carbon chain is always attached to a *carboxyl* (kar-BOK-sil) *group*, —COOH (Table 2–3). The name *carboxyl* should help you remember that a carbon and a hydroxyl (—OH) group are the important structural features of fatty acids. The carbon chain attached to the carboxyl group is known as the hydrocarbon *tail* of the fatty acid. Figure 2–14a shows a representative fatty acid, *lauric acid*. Fatty acids have a very limited solubility in water. When a fatty acid is in solution, only the carboxyl end associates with water molecules, because that is the only hydrophilic portion of the molecule. The hydrocarbon tail is hydrophobic. In general, the longer the hydrocarbon tail, the lower the solubility of the molecule.

Fatty acids may be either saturated or unsaturated (Figure 2–14b). These terms refer to the number of hydrogen atoms bound to the carbon atoms in the hydrocarbon tail. In a *saturated* fatty acid, each carbon atom in the tail has four single covalent bonds (Figure 2–14a). Within the tail, two

Figure 2–14 Fatty Acids.

a Lauric acid demonstrates two structural characteristics common to all fatty acids: a long chain of carbon atoms and a carboxyl group (—COOH) at one end.

b A fatty acid is either saturated (has single covalent bonds only) or unsaturated (has one or more double covalent bonds). The presence of a double bond causes a sharp bend in the molecule.

of those bonds bind adjacent carbon atoms, and the other two bind hydrogen atoms. The carbon atom at the end of the tail binds three hydrogen atoms. In an *unsaturated* fatty acid, one or more of the single covalent bonds between the carbon atoms have been replaced by a double covalent bond. As a result, the carbon atoms involved will each bind only one hydrogen atom rather than two. This changes the shape of the hydrocarbon tail, giving it a sharp bend, as you can see in **Figure 2–14b**. The change also affects the way the fatty acid is metabolized. A *monounsaturated* fatty acid has a single double bond in the hydrocarbon tail. A *polyunsaturated* fatty acid contains two or more double bonds.

Eicosanoids

Eicosanoids (ī-KŌ-sa-noydz) are lipids derived from *ara-chidonic* (ah-rak-i-DON-ik) *acid*, a fatty acid that must be absorbed in the diet because the body cannot synthesize it. The two major classes of eicosanoids are *leukotrienes* and *prostaglan-dins*. Leukotrienes (lū-kō-TRĪ-ēnz) are produced mostly by cells involved with coordinating the responses to injury or disease. We will consider leukotrienes in Chapters 18 and 22.

Prostaglandins (pros-tuh-GLAN-dinz) are short-chain fatty acids in which five of the carbon atoms are joined in a ring (Figure 2–15). These compounds are released by cells to coordinate or direct local cellular activities, and they are extremely powerful even in small quantities. Virtually all tissues synthesize and respond to them. The effects of prostaglandins vary with their structure and their release site. Prostaglandins released by damaged tissues, for example, stimulate nerve endings and produce the sensation of pain (Chapter 15). Those released in the uterus help trigger the start of labor contractions (Chapter 29).

The body uses several types of chemical messengers. Those that are produced in one part of the body and have effects on distant parts are called *hormones*. Hormones are distributed throughout the body in the bloodstream, but most prostaglandins affect only the area in which they are produced. As a result, prostaglandins are often called *local hormones*. The distinction is not a rigid one, however, as some prostaglandins also enter the bloodstream and affect other areas. We will discuss hormones and prostaglandins in Chapter 18.

Figure 2–15 Prostaglandins. Prostaglandins are unusual short-chain fatty acids.

Clinical Note

Fatty Acids and Health Humans love fatty foods. Unfortunately, a diet containing large amounts of saturated fats has been shown to increase the risk of heart disease and other cardiovascular problems. Saturated fats contain only saturated fatty acids. These fats are found in such popular foods as fatty meat and dairy products (including such favorites as butter, cheese, and ice cream).

Vegetable oils contain a mixture of monounsaturated and polyunsaturated fatty acids. Recent studies indicate that monounsaturated fats may be more effective than polyunsaturated fats in lowering the risk of heart disease. According to current research, perhaps the healthiest choices are olive and canola oils. These oils contain particularly abundant quantities of oleic acid, an 18-carbon monounsaturated fatty acid. Surprisingly, compounds called *trans* fatty acids, produced from polyunsaturated oils during the manufacturing of some margarines and vegetable shortenings, appear to increase the risk of heart disease. U.S. Food and Drug Administration (FDA) guidelines now require that *trans* fatty acids be declared in the nutrition label of foods and dietary supplements.

The Inuit people of the Arctic regions have lower rates of heart disease than do other populations, even though the typical

Inuit diet is high in fats and cholesterol. Interestingly, the main fatty acids in the Inuit diet are omega-3s. These fatty acids have an unsaturated bond three carbons before the last (or omega) carbon, a position known as "omega minus 3." Fish flesh and fish oils, a substantial portion of the Inuit diet, contain an abundance of omega-3 fatty acids. Why does the presence of omega-3 fatty acids in the diet reduce the risks of heart disease, rheumatoid arthritis, and other inflammatory diseases? The search for an answer provides research topics of great interest.

Glycerides

Unlike monosaccharides, individual fatty acids cannot be strung together in a chain by dehydration synthesis. But they can be attached to a modified simple sugar, **glycerol** (GLIS-er-ol), through a similar reaction. The result is a lipid known as a **glyceride** (GLIS-er-īd). Dehydration synthesis can produce a **monoglyceride** (mon-ō-GLI-ser-īd), consisting of glycerol plus one fatty acid. Subsequent reactions can yield a **diglyceride** (glycerol + two fatty acids) and then a **triglyceride** (glycerol + three fatty acids), as in Figure 2–16. Hydrolysis breaks the glycerides into fatty acids and glycerol. Comparing Figure 2–16 with Figure 2–12 shows that dehydration synthesis and hydrolysis operate the same way, whether the molecules involved are carbohydrates or lipids.

Triglycerides, also known as *triacylglycerols* or *neutral fats*, have three important functions.

- 1. *Energy Source*. Fat deposits in specialized sites of the body represent a significant energy reserve. In times of need, the triglycerides are taken apart by hydrolysis, yielding fatty acids that can be broken down to provide energy.
- 2. *Insulation.* Fat deposits under the skin serve as insulation, slowing heat loss to the environment. Heat loss across a layer of lipids is only about one-third of the heat loss through other tissues.

3. *Protection.* A fat deposit around a delicate organ such as a kidney provides a cushion that protects against bumps or jolts.

Triglycerides are stored in the body as lipid droplets within cells. The droplets absorb and accumulate lipid-soluble vitamins, drugs, or toxins that appear in body fluids. This accumulation has both positive and negative effects. For example, the body's lipid reserves retain both valuable lipid-soluble vitamins (A, D, E, K) and potentially dangerous lipid-soluble pesticides, such as the now-banned DDT.

Steroids

Steroids are large lipid molecules that share a distinctive four-ring carbon framework (**Figure 2–17**). They differ in the functional groups that are attached to this basic structure. The steroid **cholesterol** (koh-LES-ter-ol; *chole-*, bile + *stereos*, solid) and related steroids are important for several reasons:

- The outer boundary of all animal cells, called a plasma membrane, contains cholesterol (Figure 2–17a). Cells need cholesterol to maintain their plasma membranes, as well as for cell growth and division.
- Steroid hormones are involved in the regulation of sexual function. Examples include the sex hormones, *estrogen* and *testosterone* (Figure 2–17b,c).

Figure 2–16 Triglyceride Formation. The formation of a triglyceride involves the attachment of fatty acids to a glycerol molecule through dehydration synthesis. In this example, a triglyceride is formed by the attachment of one unsaturated and two saturated fatty acids to a glycerol molecule.

- Steroid hormones are important in the regulation of tissue metabolism and mineral balance. Examples include *corticosteroids* from the adrenal cortex, which play a role in carbohydrate and protein metabolism, and *calcitriol* from the kidneys, a hormone important in the regulation of the body's calcium ion concentrations.
- Steroid derivatives called *bile salts* are required for the normal processing of dietary fats. The liver produces bile salts and secretes them in bile. They interact with lipids in the intestinal tract and assist the digestion and absorption of lipids.

The body obtains cholesterol in two ways: (1) by absorbing it from animal products in the diet and (2) by synthesizing it. Liver, meat, shellfish, and egg yolks are especially rich dietary sources of cholesterol. A diet high in cholesterol can be harmful, because a strong link exists between high blood cholesterol levels (called *hypercholesterolemia*) and heart disease.

Figure 2–17Steroids Have a Complex Four-Ring Structure.

Individual steroids differ in the side chains attached to the carbon rings.

Current nutritional advice suggests limiting cholesterol intake to less than 300 mg per day. This amount represents a 40 percent reduction for the average adult in the United States. Unfortunately, blood cholesterol levels can be difficult to control by dietary restriction alone because the body can synthesize cholesterol as well. In fact, the body makes more than enough, so strict vegetarians do not need to eat animal products to ensure adequate amounts of cholesterol.

Phospholipids and Glycolipids

Phospholipids (FOS-fō-lip-idz) and **glycolipids** (GLĪ-kō-lip-idz) are structurally related, and our cells can synthesize both types of lipids, primarily from fatty acids. In a *phospho*-lipid, a *phosphate group* (PO_4^{3-}) links a diglyceride to a non-lipid group (**Figure 2–18a**). In a *glycolipid*, a carbohydrate is attached to a diglyceride (**Figure 2–18b**). Note that placing *-lipid* last in these names indicates that the molecule consists primarily of lipid.

The long hydrocarbon tails of phospholipids and glycolipids are hydrophobic, but the opposite ends, the nonlipid *heads*, are hydrophilic. In water, large numbers of these molecules tend to form droplets, or *micelles* (mi-SELZ), with the hydrophilic portions on the outside (Figure 2–18c). Most meals contain a mixture of lipids and other organic molecules, and micelles form as the food breaks down in your digestive tract. In addition to phospholipids and glycolipids, micelles may

contain other insoluble lipids, such as steroids, glycerides, and long-chain fatty acids.

Cholesterol, phospholipids, and glycolipids are called *structural lipids*, because they help form and maintain intracellular structures called membranes. At the cellular level, *membranes* are sheets or layers composed mainly of hydrophobic lipids. For example, the plasma membrane surrounding each cell is

composed primarily of phospholipids. It separates the aqueous solution inside the cell from the aqueous solution outside the cell. Also, various internal membranes subdivide the interior of the cell into specialized compartments, each with a distinctive chemical nature and, as a result, a different function.

The five types of lipids and their characteristics are summarized in Table 2–5.

Table 2–5	Representative Lipids and Their Functions in the Body			
Lipid Type	Example(s)	Primary Functions	Remarks	
Fatty acids	Lauric acid	Energy source	Absorbed from food or synthesized in cells; transported in the blood	
Eicosanoids	Prostaglandins, leukotrienes	Chemical messengers coordinating local cellular activities	Prostaglandins are produced in most body tissues	
Glycerides	Monoglycerides, diglycerides, triglycerides	Energy source, energy storage, insulation, and physical protection	Stored in fat deposits; must be broken down to fatty acids and glycerol before they can be used as an energy source	
Steroids	Cholesterol	Structural component of plasma membranes, hormones, digestive secretions in bile	All have the same four-carbon ring framework	
Phospholipids, glycolipids	Lecithin (a phospholipid)	Structural components of plasma membranes	Derived from fatty acids and nonlipid components	

CHECKPOINT

- **20**. Describe lipids.
- 21. Which lipids would you find in human plasma membranes?

- See the blue Answers tab at the back of the book.

2–11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids

Learning Outcome Discuss the structures and functions of proteins.

Proteins are the most abundant organic molecules in the human body and in many ways the most important. The human body contains many different proteins, and they account for about 20 percent of total body weight. All proteins contain carbon, hydrogen, oxygen, and nitrogen. Smaller quantities of sulfur and phosphorus may also be present. Amino acids (discussed shortly) are simple organic compounds that combine to form proteins.

Proteins carry out a variety of essential functions, which we can classify in seven major categories.

- **1.** *Support. Structural proteins* create a three-dimensional framework for the body. They provide strength, organization, and support for cells, tissues, and organs.
- **2.** *Movement. Contractile proteins* bring about muscular contraction. Related proteins are responsible for the movement of individual cells.
- **3.** *Transport.* Special *transport proteins* bind many substances for transport in the blood, including insoluble lipids, respiratory gases, special minerals such as iron, and several hormones. These substances would not otherwise be transported in the blood. Other specialized proteins move materials from one part of a cell to another.

- **4.** *Buffering.* Proteins provide a *buffering* action and in this way help prevent dangerous changes in the pH of body fluids.
- 5. *Metabolic Regulation*. Many proteins are *enzymes*, which speed up chemical reactions in cells. The sensitivity of enzymes to environmental factors such as temperature and pH is extremely important in controlling the pace and direction of metabolic reactions.
- **6.** *Coordination and Control.* Protein *hormones* can influence the metabolic activities of every cell in the body or affect the function of specific organs or organ systems.
- 7. *Defense.* Proteins defend the body in many ways. The tough, waterproof proteins of the skin, hair, and nails protect the body from environmental hazards. Proteins called *antibodies* help protect us from disease by taking part in the *immune response.* Special *clotting proteins* restrict bleeding after an injury.

Protein Structure

Proteins consist of long chains of organic molecules called **amino acids**. Twenty different amino acids occur in significant quantities in the body. All 20 amino acids are small, water-soluble molecules. A typical protein contains 1000 amino acids. The largest protein complexes have 100,000 or more.

Each amino acid consists of five parts (Figure 2–19):

- a central carbon atom
- a hydrogen atom
- an *amino group* $(-NH_2)$
- a *carboxyl group* (−COOH)
- an *R* group (a variable *side chain* of one or more atoms)

The name *amino acid* refers to the presence of the *amino* group and the carboxyl group, which all amino acids have in common. At physiological pH levels, the carboxyl group can act as **Figure 2–19 Amino Acids.** Each amino acid consists of a central carbon atom to which four different groups are attached: a hydrogen atom, an amino group $(-NH_2)$, a carboxyl group (-COOH), and a variable side group designated as R.

an acid by releasing a hydrogen ion to become a *carboxyl ion* (COO⁻). The amino group can act as a base by accepting a hydrogen ion, to become an amino ion $(-NH_3^+)$. The result is a molecule, which has both positive and negative charges, but a net charge of zero. Such molecules are called *zwitterions*, derived from the German word that means "hybrid." The different atoms of the R groups distinguish one amino acid from another, giving each its own chemical properties. For example, different R groups are polar, nonpolar, or electrically charged.

A protein begins to form as amino acids are strung together into long chains. **Figure 2–20** shows how dehydration synthesis can link two representative amino acids: *glycine* and *alanine*. This reaction creates a covalent bond between the carboxyl group of one amino acid and the amino group of another. Such a bond is known as a **peptide bond**. Molecules consisting of amino acids held together by peptide bonds are called **peptides**. The molecule created in this example is called a *dipeptide*, because it contains two amino acids.

The chain can be lengthened by the addition of more amino acids. Attaching a third amino acid produces a *tripeptide*. Tripeptides and larger peptide chains are called **polypeptides**. Polypeptides with more than 100 amino acids are usually called proteins. Familiar proteins include *hemoglobin* in red blood cells and *keratin* in fingernails and hair.

There are numerous amino acids, but only 20 form proteins. Amino acids with nonpolar R groups are hydrophobic, while amino acids with polar R groups that form hydrogen bonds with water are hydrophilic. Amino acids with electrically charged R groups are strongly hydrophilic. The properties of the R groups contribute to the overall shape and function of proteins.

Protein Shape

The characteristics of a particular protein are determined in part by the R groups on its amino acids. But the properties of a protein are more than just the sum of the properties of its **Figure 2–20** The Formation of Peptide Bonds. Peptides form as dehydration synthesis creates a peptide bond between the carboxyl group of one amino acid and the amino group of another. In this example, a peptide bond links the amino acids glycine (for which R = H) and alanine ($R = CH_3$) to form a dipeptide.

Peptide Bond Formation

parts, for polypeptides can have highly complex shapes that are important to their function. Proteins can have four levels of structural complexity (Figure 2–21).

- Primary structure is the sequence of amino acids along the length of a single polypeptide (Figure 2–21a). Peptide bonds are responsible for the primary structure of proteins.
- 2. Secondary structure is the shape that results from the presence of hydrogen bonds between atoms at different parts of the polypeptide chain. Hydrogen bonding may create either an *alpha helix* (simple spiral) or *beta sheet* (a flat pleated sheet) (Figure 2–21b). Which one forms depends on where hydrogen bonding takes place between the sequence of amino acids in the polypeptide chain. The alpha helix is the more common form, but a given polypeptide chain may have both helical and pleated sections. Ribbon diagrams are used to represent the three-dimensional structure of proteins. An alpha helix is shown as a coiled ribbon, beta sheets as arrows, and less-structured polypeptide chains as round tubes.
- 3. Tertiary structure is the complex coiling and folding that gives a protein its final three-dimensional shape (Figure 2–21c). Tertiary structure results primarily from hydrophobic and hydrophilic interactions between the R groups of the polypeptide chain and the surrounding

Figure 2–21 Protein Structure.

subunits interact to form a larger molecule. A single hemoglobin molecule contains four globular subunits. Hemoglobin transports oxygen in the blood; the oxygen binds reversibly to the heme units. In collagen, three helical polypeptide subunits intertwine. Collagen is the principal extracellular protein in most organs.

water molecules, and to a lesser extent from interactions between the R groups of amino acids in different parts of the molecule. Most such interactions are relatively weak. One, however, is very strong: the *disulfide bond*, a covalent bond that may form between the sulfur atoms of two molecules of the amino acid *cysteine* located at different sites along the chain. Disulfide bonds create permanent loops or coils in a polypeptide chain.

Quaternary structure is the interaction between individual polypeptide chains to form a protein complex (Figure 2–21d). Each of the polypeptide subunits has its own secondary and tertiary structures. For example, the protein

hemoglobin contains four subunits. Their positions are indicated by differences in the contrast of the colors used for each subunit in the ribbon diagram of hemoglobin. Stronger contrast represents structures at the front, and lower contrast is used for structures at the back. Hemoglobin is found within red blood cells, where it binds and transports oxygen. In *keratin*, two alpha helical polypeptides are wound together like the strands of a rope. Keratin is the tough, waterresistant protein at the surface of the skin and in nails and hair. *Collagen*, composed of three windings of alpha helical polypeptides, is the most abundant structural protein and is found in skin, bones, cartilages, and tendons. Collagen fibers form the framework that supports cells in most tissues.

Fibrous and Globular Proteins

Proteins fall into two general structural classes on the basis of their overall shape and properties:

- **Fibrous proteins** form extended sheets or strands. Fibrous proteins are tough, durable, and generally insoluble in water. They usually play structural roles in the body. Their shapes are usually due to secondary structure (for proteins with the pleated-sheet form) or quaternary structure (as we described for keratin and collagen in the previous section).
- Globular proteins are compact, generally rounded, and soluble in water. Many enzymes, hormones, and other molecules that circulate in the bloodstream are globular proteins. These proteins can function only if they remain in solution. The unique shape of each globular protein comes from its tertiary structure. *Myoglobin*, a protein in muscle cells, is a globular protein. Hemoglobin, the oxygen-carrying molecule in red blood cells is also a globular protein. The enzymes that control chemical reactions inside cells are also globular proteins.

Protein Shape and Function

The shape of a protein determines its functional characteristics, and the sequence of amino acids ultimately determines its shape. The 20 common amino acids can be linked in an astonishing number of combinations, creating proteins of enormously varied shape and function. Changing only one of the 10,000 or more amino acids in a protein can significantly alter the way the protein functions. For example, several cancers and *sickle cell anemia*, a blood disorder, result from changing just a single amino acid in the amino acid sequences of complex proteins.

The tertiary and quaternary shapes of complex proteins depend not only on their amino acid sequence, but also on the local environmental conditions. Small changes in the ionic composition, temperature, or pH of their surroundings can affect the function of proteins. Protein shape can also be affected by hydrogen bonding to other molecules in solution. The significance of these factors is most striking when we consider enzymes, for these proteins are essential to the metabolic operations in every one of our cells.

Enzyme Function

Enzymes are among the most important of all the body's proteins. As noted earlier in this chapter, enzymes speed up (catalyze) the chemical reactions that sustain life. Almost everything that happens inside the human body does so because a specific enzyme makes it possible.

The reactants in enzymatic reactions are called **substrates**. As in other types of chemical reactions, the interactions among substrates yield specific products. Before an enzyme can function as a catalyst—to accelerate a chemical reaction without itself being permanently changed or consumed—the substrates must bind to a special region of the enzyme. This region is called the **active site**. It is typically a groove or pocket into which one or more substrates nestle, like a key fitting into a lock. Weak electrical attractive forces, such as hydrogen bonding, reinforce the physical fit. The tertiary or quaternary structure of the enzyme molecule determines the shape of the active site. Although enzymes are proteins, any organic or inorganic compound that will bind to the active site can be a substrate.

Figure 2–22 presents one example of enzyme structure and function. Substrates bind to the enzyme at its active site (1). Substrate binding produces an enzyme-substrate complex (2). Substrate binding typically produces a temporary, reversible change in the shape of the enzyme that may place physical stresses on the substrate molecules, leading to product formation (3). Product release frees the enzyme, which can then repeat the process (4).

Enzymes work quickly, cycling rapidly between substrates and products. For example, an enzyme providing energy during a muscular contraction performs its reaction sequence 100 times per second. Hydrolytic enzymes can work even faster, breaking down almost 20,000 molecules a second!

Figure 2–22 shows an enzyme that catalyzes a synthesis reaction. Other enzymes may catalyze decomposition reactions, reversible reactions, or exchange reactions. Regardless of the reaction they catalyze, all enzymes share three basic characteristics:

 Specificity. Each enzyme catalyzes only one type of reaction, a characteristic called **specificity**. An enzyme's specificity is due to the ability of its active sites to bind only to substrates with particular shapes and charges. For this reason, differences in enzyme structure that do not affect the active site and do not change the response of the enzyme to substrate binding do not affect enzyme function. In fact, different tissues typically contain enzymes that differ slightly in structure, but catalyze the same reaction. Such enzyme variants are called **isozymes**. Figure 2–22 A Simplified View of Enzyme Structure and Function. Each enzyme contains a specific active site somewhere on its exposed surface.

- 2. Saturation Limits. The rate of an enzymatic reaction is directly related to the concentrations of substrate molecules and enzymes. An enzyme molecule must encounter appropriate substrates before it can catalyze a reaction. The higher the substrate concentration, the more frequent these encounters. When substrate concentrations are high enough that every enzyme molecule is cycling through its reaction sequence at top speed, further increases in substrate concentration will not affect the rate of reaction unless additional enzyme molecules are provided. The substrate concentration required to have the maximum rate of reaction is called the saturation limit. An enzyme that has reached its saturation limit is said to be saturated. To increase the reaction rate further, the cell must increase the number of enzyme molecules available. This is one important way that cells promote specific reactions.
- **3.** *Regulation.* Each cell contains an assortment of enzymes, and any particular enzyme may be active under one set of conditions and inactive under another. Virtually anything that changes the tertiary or quaternary shape of an enzyme can turn it "on" or "off" and in this way control reaction rates inside the cell. Because the shape change is immediate, enzyme activation or inactivation is an important method of short-term control over reaction rates and metabolic pathways. Here we will consider only one example of enzyme regulation: the presence or absence of *cofactors*.

Cofactors and Enzyme Function

A **cofactor** is an ion or a molecule that must bind to an enzyme before substrates can also bind. Without a cofactor, the

enzyme is intact but nonfunctional. With the cofactor, the enzyme can catalyze a specific reaction. Examples of ionic cofactors include calcium (Ca^{2+}) and magnesium (Mg^{2+}), which bind at the enzyme's active site. Cofactors may also bind at other sites, as long as they produce a change in the shape of the active site that makes substrate binding possible.

Coenzymes are nonprotein organic molecules that function as cofactors. Our bodies convert many vitamins into essential coenzymes. *Vitamins*, detailed in Chapter 25, are structurally related to lipids or carbohydrates, but have unique functional roles. Because the human body cannot synthesize most of the vitamins it needs, you must obtain them from your diet.

Effects of Temperature and pH on Enzyme Function

Each enzyme works best at specific temperatures and pH values. As temperatures rise, protein shape changes and enzyme function deteriorates. Eventually the protein undergoes **denaturation**, a change in tertiary or quaternary structure that makes it nonfunctional. You see permanent denaturation when you fry an egg. As the temperature rises, the proteins in the egg white denature. Eventually, the proteins become completely and irreversibly denatured, forming an insoluble white mass. In the body, death occurs at very high body temperatures (above 43 °C, or 110 °F) because structural proteins and enzymes soon denature, causing irreparable damage to organs and organ systems.

Enzymes are equally sensitive to changes in pH. *Pepsin*, an enzyme that breaks down food proteins in the stomach, works best at a pH of 2.0 (strongly acidic). Your small intestine contains *trypsin*, another enzyme that attacks proteins. Trypsin

works only in an alkaline environment, with an optimum pH of 7.7 (weakly basic).

Glycoproteins and Proteoglycans

Glycoproteins (GLĪ-kō-prō-tēnz) and **proteoglycans** (prō-tē-ō-GLĪ-kanz) are combinations of protein and carbohydrate molecules. Glycoproteins are large proteins with small carbohydrate groups attached. These molecules may function as enzymes, antibodies, hormones, or protein components of plasma membranes. Glycoproteins in plasma membranes play a major role in identifying normal versus abnormal cells. They are also important in the immune response (Chapter 22). Glycoprotein secretions called *mucins* absorb water to form **mucus**. Mucus coats and lubricates the surfaces of the reproductive and digestive tracts.

Proteoglycans are large polysaccharide molecules linked by polypeptide chains. Proteoglycans bind adjacent cells together, and give tissue fluids a syrupy consistency.

CHECKPOINT

- 22. Describe a protein.
- **23**. How does boiling a protein affect its structural and functional properties?
- See the blue Answers tab at the back of the book.

2-12 DNA and RNA are nucleic acids

Learning Outcome Discuss the structures and functions of nucleic acids.

Nucleic (noo-KLĀ-ik) **acids** are large organic molecules composed of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids store and process information at the molecular level inside cells. The two classes of nucleic acid molecules are **deoxyribonucleic** (dē-oks-ē-rī-bō-noo-KLĀ-ik) **acid (DNA)** and **ribonucleic** (rī-bō-noo-KLĀ-ik) **acid (RNA)**. As we will see, these two classes of nucleic acids differ in composition, structure, and function.

The DNA in our cells determines our inherited characteristics, including eye color, hair color, and blood type. DNA affects all aspects of body structure and function, because DNA molecules encode the information needed to build proteins. By directing the synthesis of structural proteins, DNA controls the shape and physical characteristics of our bodies. By controlling the manufacture of enzymes, DNA regulates not only protein synthesis, but also all aspects of cellular metabolism, including the creation and destruction of lipids, carbohydrates, and other vital molecules.

Several forms of RNA cooperate to build specific proteins by using the information provided by DNA. In Chapter 3 we will detail the ways that DNA and RNA work together.

Structure of Nucleic Acids

A nucleic acid consists of one or two long chains that are formed by dehydration synthesis. The individual subunits of a chain are called **nucleotides**. Each nucleotide has three parts (Figure 2–23a): (1) a *pentose* (five-carbon sugar) attached to both (2) a phosphate group and (3) a **nitrogenous** (nitrogencontaining) **base**. The pentose is either *ribose* (in RNA) or *deoxyribose* (in DNA).

Five nitrogenous bases occur in nucleic acids: **adenine (A)**, **guanine (G)**, **cytosine (C)**, **thymine (T)**, and **uracil (U)**. Adenine and guanine are double-ringed molecules called *purines* (Figure 2–23b). The other three bases are single-ringed molecules called *pyrimidines* (Figure 2–23c). Both RNA and DNA contain adenine, guanine, and cytosine. Uracil occurs only in RNA and thymine occurs only in DNA.

A nucleotide forms when a phosphate group binds to a pentose already attached to a nitrogenous base. A nucleic acid forms when nucleotides are joined. Dehydration synthesis attaches the phosphate group of one nucleotide to the sugar of another. The "backbone" of a nucleic acid molecule is a linear sugar-to-phosphate-to-sugar sequence, with the nitrogenous bases projecting to one side.

The primary role of nucleic acids is to store and transfer information—specifically, information essential to the synthesis of proteins within our cells. Regardless of whether we are speaking of DNA or RNA, it is the sequence of nitrogenous bases that carries the information.

RNA and DNA

Important structural differences distinguish RNA from DNA. A molecule of RNA consists of a single chain of nucleotides (Figure 2–24a). Its shape depends on the order of the nucleotides and the interactions among them. Our cells have various forms of RNA with different shapes and functions. As we will see in Chapter 3, protein synthesis requires three types of RNA: (1) *messenger RNA (mRNA)*, (2) *transfer RNA (tRNA)*, and (3) *ribosomal RNA (rRNA)*. The roles of other types of RNA, such as microRNAs and small interfering RNAs, in suppressing protein synthesis are under active research.

A DNA molecule consists of a *pair* of nucleotide chains (Figure 2–24b). Hydrogen bonding between opposing nitrogenous bases holds the two strands together. The shapes of the nitrogenous bases allow adenine to bond only to thymine, and cytosine to bond only to guanine. As a result, the combinations adenine–thymine (A–T) and cytosine–guanine (C–G) are known as **complementary base pairs**, and the two nucleotide chains of the DNA molecule are known as **complementary strands**. The two strands of DNA twist around one another in a double helix that resembles a spiral staircase. Each step of the staircase corresponds to one complementary base pair (Figure 2–24b).

Figure 2–23 Nucleotides and Nitrogenous Bases.

Figure 2–24 The Structure of Nucleic Acids. Nucleic acids are long chains of nucleotides. Each nucleic acid molecule starts at the phosphate group of the first nucleotide and ends at the sugar of the last member of the chain. This is also the direction in which DNA is synthesized.

Through a sequence of events described in Chapter 3, the cell uses one of the two complementary DNA strands to provide the information needed to synthesize a specific protein. Table 2–6 (on the next page) compares RNA with DNA.

CHECKPOINT

- 24. Describe a nucleic acid.
- **25**. A large organic molecule made of the sugar ribose, nitrogenous bases, and phosphate groups is which kind of nucleic acid?

See the blue Answers tab at the back of the book.

Table 2–6 Co		omparison of RNA with DNA		
Characteristic		RNA	DNA	
Sugar		Ribose	Deoxyribose	
Nitrogenous bas	es	Adenine (A)	Adenine	
		Guanine (G)	Guanine	
		Cytosine (C)	Cytosine	
		Uracil (U)	Thymine (T)	
Number of nucleotides in typical molecule	•	Varies from fewer than 100 nucleotides to about 50,000	Always more than 45 million	
Shape of molecu	ıle	Varies with hydrogen bonding along the length of the strand; three main types (mRNA, rRNA, tRNA)	Paired strands coiled in a double helix	
Function		Performs protein synthesis as directed by DNA	Stores genetic information that controls	

2-13 ATP is a high-energy compound used by cells

Learning Outcome Discuss the structures and functions of high-energy compounds.

To perform their vital functions, cells must use energy, which they obtain by breaking down organic substrates (catabolism). To be useful, that energy must be transferred from molecule to molecule or from one part of the cell to another.

The usual method of energy transfer involves the creation and breakdown of high-energy bonds by enzymes within cells. A *high-energy bond* is a covalent bond whose breakdown releases energy the cell can use directly. In our cells, a highenergy bond generally binds a phosphate group (PO_4^{3-}) to an organic molecule. The product with such a bond is called a **high-energy compound**. Most high-energy compounds are derived from nucleotides, the building blocks of nucleic acids.

The process of attaching a phosphate group to another molecule is called **phosphorylation** (fos-for-i-LĀ-shun). This process does not necessarily produce high-energy bonds. The creation of a high-energy compound requires (1) a phosphate group, (2) enzymes capable of catalyzing the reactions involved, and (3) suitable organic substrates to which the phosphate can be added.

The most important such substrate is the nucleotide *adenosine monophosphate* (*AMP*), which already contains one phosphate group. Attaching a second phosphate group produces **adenosine diphosphate (ADP)**. A significant energy input is required to convert AMP to ADP, and the second phosphate is attached by a high-energy bond. Even more energy is required to add a third phosphate and create the high-energy compound **adenosine triphosphate (ATP)** (Figure 2–25).

Figure 2–25 The Structure of ATP. A molecule of ATP is formed by attaching two phosphate groups to the nucleotide adenosine monophosphate. These two phosphate groups are connected by highenergy bonds incorporating energy released by catabolism. Cells most often obtain quick energy to power cellular operations by removing one phosphate group from ATP, forming ADP (adenosine diphosphate). ADP can later be reconverted to ATP, and the cycle repeated.

Adenosine triphosphate (ATP)

The conversion of ADP to ATP is the most important method of storing energy in our cells. The breakdown of ATP to ADP is the most important method of releasing energy. The relationships involved in this energy transfer can be diagrammed as

 $ADP + phosphate group + energy \implies ATP + H_2O$

The hydrolytic breakdown of ATP to ADP requires an enzyme known as **adenosine triphosphatase (ATPase)**. Throughout

2

life, cells continuously generate ATP from ADP and then use the energy provided by the breakdown of ATP to perform vital functions, such as the synthesis of proteins or the contraction of muscles.

ATP is our most abundant high-energy compound, but there are others. They are typically other nucleotides that have undergone phosphorylation. For example, *guanosine triphosphate (GTP)* and *uridine triphosphate (UTP)* are nucleotide-based high-energy compounds that transfer energy in specific enzymatic reactions.

 Table 2–7 summarizes the inorganic and organic compounds covered in this chapter.

2–14 Chemicals and their interactions form functional units called cells

Learning Outcome Explain the relationship between chemicals and cells.

The human body is more than a collection of chemicals. The biochemical building blocks discussed in this chapter form functional units called *cells*. \bigcirc **p**. **6** Each cell behaves like a miniature organism, responding to internal and external stimuli. This is possible only because cells are dynamic structures that adapt to changes in their environment. Such adaptations may involve changes in the chemical organization of the cell. These changes are easily made because organic molecules other than DNA are temporary rather than permanent components of the cell. They are continuously removed and replaced as part of the ongoing process of **metabolic turnover**.

Functions

insulation; structural components; chemical messengers; protection

INORGANIC			
Water	Hydrogen and oxygen atoms	Absorbed from the diet or generated by metabolism	Solvent; transport medium for dissolved materials and heat; cooling through evaporation; medium for chemical reactions; reactant in hydrolysis
Acids, bases, salts	$H^+,OH^-,various$ anions and cations	Obtained from the diet or generated by metabolism	Structural components; buffers; sources of ions
Dissolved gases	O, C, N, and other atoms	Atmosphere, metabolism	O2: required for cellular metabolism
			CO ₂ : generated by cells as a waste product
			NO: chemical messenger in cardiovascular, nervous, and lymphatic systems
ORGANIC			
Carbohydrates	C, H, O, in some cases N; CHO in a 1:2:1 ratio	Obtained from the diet or manufactured in the body	Energy source; some structural role when attached to lipids or proteins; energy storage
Lipids	C, H, O, in some cases N or P; CHO not	Obtained from the diet or manufactured	Energy source; energy storage;

in the body

Most of the organic molecules in a cell are replaced at intervals ranging from hours to months. The average time between synthesis and breakdown is known as the *turnover time*. **Table 2–8** lists the turnover times of the organic components of representative cells. In the next chapter we will learn more about the functions of these organic components as we explore the cellular level of organization.

CHECKPOINT

- **28**. Identify the biochemical building blocks discussed in this chapter that are the components of cells.
- 29. Define metabolic turnover.

See the blue Answers tab at the back of the book.

Table 2–8	Turnover Times		
Cell Type	Component	Average Recycling Time*	
Liver	Total protein	5–6 days	
	Enzymes	1 hour to several days, depending on the enzyme	
	Glycogen	1–2 days	
	Cholesterol	5–7 days	
Muscle cell	Total protein	30 days	
	Glycogen	12–24 hours	
Neuron	Phospholipids	200 days	
	Cholesterol	100+ days	
Fat cell	Triglycerides	15–20 days

An Introduction to the Chemical Level of Organization p. 27 1. Chemicals combine to form complex structures.

2-1 Atoms are the basic particles of matter p. 27

- **2.** Atoms are the smallest units of matter. They consist of **protons**, **neutrons**, and **electrons**. Protons and neutrons reside in the **nucleus** of an atom. (*Figure 2–1*)
- **3.** The number of protons in an atom is its **atomic number**. Each **element** includes all the atoms that have the same number of protons and thus the same atomic number.
- 4. Within an atom, an electron cloud surrounds the nucleus.
- 5. The **mass number** of an atom is the total number of protons and neutrons in its nucleus. **Isotopes** are atoms of the same element whose nuclei contain different numbers of neutrons.

- Electrons occupy an orderly series of energy levels, commonly
- illustrated as **electron shells**. The electrons in the outermost energy level determine an element's chemical properties. (*Figure 2–2*)

2-2 Chemical bonds are forces formed by atom interactions p. 31

- 7. Atoms can combine through chemical reactions that create **chemical bonds.** A **molecule** is any chemical structure consisting of atoms held together by covalent bonds. A **compound** is a chemical substance made up of atoms of two or more elements in a fixed proportion.
- **8.** The rules of **chemical notation** are used to describe chemical compounds and reactions. (*Spotlight Figure 2–3*)
- 9. An **ionic bond** results from the attraction between **ions**, atoms that have gained or lost electrons. **Cations** are positively charged; **anions** are negatively charged. (*Figure 2–4*)
- Atoms that share electrons to form a molecule are held together by covalent bonds. A sharing of one pair of electrons is a single covalent bond; a sharing of two pairs is a double covalent bond; and a sharing of three pairs is a triple covalent bond. A bond with equal sharing of electrons is a nonpolar covalent bond; a bond with unequal sharing of electrons is a polar covalent bond. (*Figures 2–5, 2–6*)
- **11.** A **hydrogen bond** is a weak, but important, electrical attraction that can affect the shapes and properties of molecules. (*Figure 2–7*)
- **12.** Matter can exist as a *solid*, a *liquid*, or a *gas*, depending on the nature of the interactions among the component atoms or molecules.
- **13.** The **molecular weight** of a molecule is the sum of the atomic weights of its component atoms.

2

2-3 Decomposition, synthesis, and exchange reactions are important chemical reactions in physiology p. 36

- 14. A chemical reaction occurs when **reactants** are rearranged to form one or more **products**. Collectively, all the **chemical reactions** in the body constitute its **metabolism**. Through metabolism, cells capture, store, and use energy to maintain homeostasis and to perform essential functions.
- **15.** Work is the movement of an object or a change in the physical structure of matter. **Energy** is the capacity to perform work.
- **16. Kinetic energy** is the energy of motion. **Potential energy** is stored energy that results from the position or structure of an object. Conversions from potential to kinetic energy (or vice versa) are not 100 percent efficient. Every such energy conversion releases *heat*.
- **17.** A chemical reaction is classified as a **decomposition**, a **synthesis**, or an **exchange reaction**.
- **18.** Cells gain energy to power their functions by **catabolism**, the breakdown of complex molecules. Much of this energy supports **anabolism**, the synthesis of new molecules.
- **19.** All chemical reactions are theoretically reversible. At **equilibrium**, the rates of two opposite reactions are in balance.

2-4 Enzymes catalyze specific biochemical reactions by lowering the energy needed to start them p. 38

- **20.** Activation energy is the amount of energy required to start a reaction. Enzymes are catalysts—compounds that accelerate chemical reactions without themselves being permanently changed or consumed. Enzymes promote chemical reactions by lowering the activation energy needed. (*Figure 2–8*)
- 21. Exergonic reactions release energy. Endergonic reactions absorb energy.

2-5 Inorganic compounds lack carbon, and organic compounds contain carbon p. 39

22. Nutrients are the essential elements and molecules normally obtained from the diet. Metabolites, on the other hand, are molecules that can be synthesized or broken down by chemical reactions inside our bodies. Nutrients and metabolites can be broadly categorized as either inorganic or organic compounds.

2-6 Physiological systems depend on water p. 39

- 23. Water is the most important constituent of the body.
- 24. A solution is a uniform mixture of two or more substances. It consists of a medium, or solvent, in which atoms, ions, or molecules of another substance, or solute, are individually dispersed. In *aqueous solutions*, water is the solvent. (*Figure 2–9*)
- 25. Many inorganic substances, called **electrolytes**, undergo **dissociation**, or **ionization**, in water to form ions. (*Figure 2–9; Table 2–2*) Molecules that interact readily with water molecules are called **hydrophilic**. Those that do not are called **hydrophobic**.

2-7 Body fluid pH is vital for homeostasis p. 41

26. The **pH** of a solution indicates the concentration of hydrogen ions it contains. Solutions are classified as **neutral**, **acidic**, or **basic** (*alkaline*) on the basis of pH. (*Figure 2–10*)

2-8 Acids, bases, and salts are inorganic compounds with important physiological roles p. 42

- 27. An acid releases hydrogen ions. A base removes hydrogen ions from a solution. *Strong acids* and *strong bases* ionize completely. In the case of *weak acids* and *weak bases*, only some of the molecules ionize.
- **28.** A salt is an electrolyte whose cation is not a hydrogen ion (H^+) and whose anion is not a hydroxide ion (OH^-) .

29. Buffers remove or replace hydrogen ions in solution. Buffers and *buffer systems* in body fluids maintain the pH within normal limits.

2-9 Carbohydrates contain carbon, hydrogen, and oxygen in a 1:2:1 ratio p. 43

- **30.** Carbon and hydrogen are the main constituents of **organic compounds**, which generally contain oxygen as well. The properties of the different classes of organic compounds are due to the presence of *functional groups* of atoms. (*Table 2–3*)
- **31.** Carbohydrates are most important as an energy source for metabolic processes. The three major types of carbohydrates are monosaccharides (*simple sugars*), disaccharides, and polysaccharides. Disaccharides and polysaccharides form from monosaccharides by dehydration synthesis. (*Figures 2–11* to *2–13; Table 2–4*)

2-10 Lipids often contain a carbon-to-hydrogen ratio of 1:2 p. 46

- **32.** Lipids include *fats, oils,* and *waxes.* Most are insoluble in water. The five important classes of lipids are fatty acids, eicosanoids, glycerides, steroids, and phospholipids and glycolipids. (*Figures 2–14 to 2–18; Table 2–5*)
- 33. Triglycerides (*neutral fats*) consist of three fatty acid molecules attached by dehydration synthesis to a molecule of glycerol. Diglycerides consist of two fatty acids and glycerol. Monoglycerides consist of one fatty acid plus glycerol. (*Figure 2–16*)
- 34. Steroids (1) are components of plasma membranes, (2) include sex hormones and hormones regulating metabolic activities, and (3) are important in lipid digestion. (*Figure 2–17*)
- **35. Phospholipids** and **glycolipids** are structural lipids that are components of *micelles* and plasma membranes.

2-11 Proteins contain carbon, hydrogen, oxygen, and nitrogen and are formed from amino acids p. 51

- **36. Proteins** perform a variety of essential functions in the body. Seven important types of proteins are *structural proteins, contractile proteins, transport proteins, buffering proteins, enzymes, hormones,* and *antibodies.*
- 37. Proteins are chains of amino acids. Each amino acid consists of an *amino group*, a *carboxyl group*, a *hydrogen atom*, and an *R group (side chain)* attached to a central carbon atom. A polypeptide is a linear sequence of amino acids held together by peptide bonds; proteins are polypeptides containing over 100 amino acids. (*Figures 2–19, 2–20*)
- **38.** The four levels of protein structure are **primary structure** (amino acid sequence), **secondary structure** (amino acid interactions, such as hydrogen bonds), **tertiary structure** (complex folding, disulfide bonds, and interaction with water molecules), and **quaternary structure** (formation of protein complexes from individual subunits). **Fibrous proteins**, such as *keratin* and *collagen*, are elongated, tough, durable, and generally insoluble. **Globular proteins**, such as *myoglobin* and *hemoglobin*, are generally rounded and water-soluble. (*Figure 2–21*)
- **39.** The reactants in an enzymatic reaction, called **substrates**, interact to yield a product by binding to the enzyme's **active site**. **Cofactors** are ions or molecules that must bind to the enzyme before the substrates can bind. **Coenzymes** are organic cofactors commonly derived from *vitamins*. (*Figure 2–22*)
- **40.** The shape of a protein determines its functional characteristics. Each protein works best at an optimal combination of temperature and pH and will undergo temporary or permanent **denaturation**, or change in shape, at temperatures or pH values outside the normal range.

2-12 DNA and RNA are nucleic acids p. 56

- 41. Nucleic acids store and process information at the molecular level. The two kinds of nucleic acids are deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). (Figures 2-23, 2-24; Table 2-6)
- 42. Nucleic acids are chains of nucleotides. Each nucleotide contains a sugar, a phosphate group, and a nitrogenous base. The sugar is ribose in RNA and deoxyribose in DNA. DNA is a two-stranded double helix containing the nitrogenous bases adenine, guanine, cytosine, and thymine. RNA consists of a single strand and contains uracil instead of thymine.

2-13 ATP is a high-energy compound used by cells p. 58

43. Cells store energy in the *high-energy bonds* of **high-energy** compounds. The most important high-energy compound is

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. An oxygen atom has eight protons. (a) Sketch in the arrangement of electrons around the nucleus of the oxygen atom in the following diagram. (b) How many more electrons will it take to fill the outermost energy level?

2. What is the following type of decomposition reaction called?

$$A-B-C-D + H_2O \longrightarrow A-B-C-H + HO-D$$

- 3. The subatomic particle with the least mass (a) carries a negative charge, (b) carries a positive charge, (c) plays no part in the atom's chemical reactions, (d) is found only in the nucleus
- 4. Isotopes of an element differ from each other in the number of (a) protons in the nucleus, (b) neutrons in the nucleus, (c) electrons in the outer shells, (d) a, b, and c are all correct.
- 5. The number and arrangement of electrons in an atom's outer energy level determines the atom's (a) atomic weight, (b) atomic number, (c) molecular weight, (d) chemical properties.
- 6. All organic compounds in the human body contain all of the following elements *except* (a) hydrogen, (b) oxygen, (c) carbon, (d) calcium, (e) both a and d.
- 7. A substance containing atoms of different elements that are bonded together is called a(n) (a) molecule, (b) compound, (c) mixture, (d) isotope, (e) solution.
- 8. All the chemical reactions that occur in the human body are collectively referred to as (a) anabolism, (b) catabolism, (c) metabolism, (d) homeostasis.
- 9. Which of the following chemical equations illustrates a typical decomposition reaction?
 - (a) $A + B \longrightarrow AB$
 - (b) $AB + CD \longrightarrow AD + CB$ (c) $2A_2 + B_2 \longrightarrow 2A_2B$

 - (d) $AB \longrightarrow A + B$
- **10.** The speed, or rate, of a chemical reaction is influenced by (a) the presence of catalysts, (b) the temperature, (c) the concentration of the reactants, (d) a, b, and c are all correct.

ATP (adenosine triphosphate). Cells make ATP by adding a phosphate group to ADP (adenosine diphosphate) through phosphorylation. When ATP is broken down to ADP and phosphate, energy is released. Cells can use this energy to power essential activities. (Figure 2–25; Table 2–7)

2-14 Chemicals and their interactions form functional units called cells p. 59

- 44. Biochemical building blocks form functional units called *cells*.
- 45. The continuous removal and replacement of cellular organic molecules (other than DNA), a process called metabolic turnover, allows cells to change and to adapt to changes in their environment. (Table 2-8)

See the blue Answers tab at the back of the book.

- **11.** A pH of 7.8 in the human body typifies a condition referred to as (a) acidosis, (b) alkalosis, (c) dehydration, (d) homeostasis.
- is a solute that dissociates to release hydrogen ions, and a(n) **12.** A(n) is a solute that removes hydrogen ions from solution. (a) base, acid, (b) salt, base, (c) acid, salt, (d) acid, base.
- 13. Special catalytic molecules called _____ control chemical reactions in the human body. (a) enzymes, (b) cytozymes, (c) cofactors, (d) activators, (e) cytochromes.
- 14. Which of the following is *not* a function of a protein? (a) support, (b) transport, (c) metabolic regulation, (d) storage of genetic information, (e) movement.
- 15. Complementary base pairing in DNA includes the pairs (a) adenineuracil and cytosine-guanine, (b) adenine-thymine and cytosineguanine, (c) adenine-guanine and cytosine-thymine, (d) guanineuracil and cytosine-thymine.
- 16. What are the three subatomic particles in atoms?
- 17. What four major classes of organic compounds are found in the body?
- 18. List three important functions of triglycerides (neutral fats) in the body.
- 19. List seven major functions performed by proteins.
- 20. (a) What three basic components make up a nucleotide of DNA?
 - (b) What three basic components make up a nucleotide of RNA?
- 21. What three components are required to create the high-energy compound ATP?

LEVEL 2 Reviewing Concepts

- 22. If a polypeptide contains 10 peptide bonds, how many amino acids does it contain? (a) 9, (b) 10, (c) 11, (d) 12.
- 23. A dehydration synthesis reaction between glycerol and a single fatty acid would yield a(n) (a) micelle, (b) omega-3 fatty acid, (c) triglyceride, (d) monoglyceride, (e) diglyceride.
- 24. Explain how enzymes function in chemical reactions.
- 25. What is a salt? How does a salt differ from an acid or a base?
- 26. Explain the differences among nonpolar covalent bonds, polar covalent bonds, and ionic bonds.
- 27. In an exergonic reaction, (a) large molecules are broken down into smaller ones, (b) small molecules are assembled into larger ones, (c) molecules are rearranged to form new molecules, (d) molecules move from reactants to products and back, (e) energy is released during the reaction.

- 28. The hydrogen bonding that occurs in water is responsible for all of the following, *except* (a) the high boiling point of water, (b) the low freezing point of water, (c) the ability of water to dissolve nonpolar substances, (d) the ability of water to dissolve inorganic salts, (e) the surface tension of water.
- **29.** A sample that contains an organic molecule has the following constituents: carbon, hydrogen, oxygen, nitrogen, and phosphorus. Is the molecule more likely to be a carbohydrate, a lipid, a protein, or a nucleic acid?

LEVEL 3 Critical Thinking and Clinical Applications

30. An atom of the element calcium has 20 protons and 20 neutrons. Determine the following information about calcium: (a) number of electrons, (b) atomic number, (c) atomic weight, (d) number of electrons in each energy level.

- **31.** A certain reaction pathway consists of four steps. How would decreasing the amount of enzyme that catalyzes the second step affect the amount of product produced at the end of the pathway?
- **32.** An important buffer system in the human body involves carbon dioxide (CO₂) and bicarbonate ion (HCO₃⁻) in the reversible reaction

$$CO_2 + H_2O \Longrightarrow H_2CO_3 \Longrightarrow H^+ + HCO_3^-$$

If a person becomes excited and exhales large amounts of CO_2 , how will the pH of the person's body be affected?

CLINICAL CASE

What Is Wrong with My Baby?

Baby Sean has cystic fibrosis (CF), a life-threatening genetic disease. He inherited a defective

gene from each of his parents, both mother and father. This faulty gene affects the movement of salt—sodium chloride (NaCl)—in and out of cells. As a result, the body produces thick, sticky secretions, including digestive juices that cannot get out of the pancreas into the small intestine.

Digestive juices contain enzymes that are the catalysts of digestion. These digestive enzymes aid in the decomposition reactions that break down lipids and carbohydrates in food, making them available for absorption and use by the body's cells. Without these enzymes, Sean cannot absorb food, so it passes right through him without being digested.

The defective gene also results in thick, heavy secretions that clog the lungs, making Sean short of breath, wheezy, and susceptible to repeated lung infections. It also makes his skin taste very salty. The diagnosis of cystic fibrosis is made with a sweat test. A sweatproducing chemical is applied to an area of Sean's skin, and the sweat is collected and tested for salt.

Wrap-Up

Sean's treatment starts immedi-

ately. He is able to absorb his food nearly normally by taking digestive enzymes before each feeding. Maureen and Conner learn to perform special exercises and treatments with Sean several times a day to clear the thick secretions from his lungs. Sean is also carefully monitored for signs of lung infections such as pneumonia. Soon Sean gains weight and begins to thrive.

- 1. What undigested substances would have made Baby Sean's stools greasy, almost foamy looking?
- 2. Why are digestive enzymes necessary for life?

See the blue Answers tab at the back of the book.

3

The Cellular Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **3-1** List the functions of the plasma membrane and the structural features that enable it to perform those functions.
- **3-2** Describe the organelles of a typical cell, and indicate the specific functions of each.
- **3-3** Explain the functions of the cell nucleus and discuss the nature and importance of the genetic code.
- **3-4** Summarize the role of DNA in protein synthesis, cell structure, and cell function.
- **3-5** Describe the processes of cellular diffusion and osmosis, and explain their role in physiological systems.
- **3-6** Describe carrier-mediated transport and vesicular transport mechanisms used by cells to facilitate the absorption or removal of specific substances.
- **3-7** Explain the origin and significance of the membrane potential.
- **3-8** Describe the stages of the cell life cycle, including mitosis, interphase, and cytokinesis, and explain their significance.
- **3-9** Discuss the regulation of the cell life cycle.
- **3-10 I** Discuss the relationship between cell division and cancer.
- **3-11** Define differentiation, and explain its importance.

CLINICAL CASE

When Your Heart Is in the Wrong Place

Five-year-old Jackson comes home from kindergarten with yet another ear infection. He is a happy child with a great appetite, but he can't seem to stay healthy. His nose is constantly plugged, and he always has a nasty cough. Sometimes he coughs so hard he vomits.

Jackson has been checked for cystic fibrosis, a genetic disease that causes thick, sticky, mucus secretions, to be sure this is not the cause of his earaches and chronic cough. There are no pets or smokers in the home. Because this cough has gone on so long, Jackson is now getting a chest x-ray. The radiology technologist asks if she can take another film and carefully checks to be sure she has the "right" marker on Jackson's right side.

"Now that's funny," the tech says. "It looks like this x-ray is backward, but I know I took it correctly. Jackson's heart

must be on the wrong side." Could Jackson's heart really be on the wrong side? To find out, turn to the Clinical Case Wrap-Up on p. 112.

An Introduction to Cells

In this chapter we will see how combinations of chemicals form *cells*, the smallest living units in the human body. We will also look at the chemical events that sustain life, which occur mostly inside cells.

Cells are very small. A typical cell is only about 0.1 mm in diameter. As a result, no one could actually examine the structure of a cell until effective microscopes were invented in the 17th century. In 1665, Robert Hooke inspected thin slices of cork and found that they were made of millions of small, irregular units. In describing what he saw, Hooke used the term *cell* because the many small, bare spaces reminded him of the rooms, or cells, in a prison or monastery. The Latin term, *cella*, means a storeroom or chamber. Hooke saw only the outlines of the cells, and not the cells themselves, but he stimulated broad interest in the microscopic world and in the nature of cellular life. The research that he began about 350 years ago has, over time, produced the *cell theory* in its current form. We can summarize its basic concepts as follows:

- Cells are the building blocks of all plants and animals.
- All cells come from the division of preexisting cells.
- Cells are the smallest units that carry out life's essential physiological functions.
- Each cell maintains homeostasis at the cellular level.
 Homeostasis at the level of the tissue, organ, organ system, and organism reflects the combined and coordinated actions of many cells.

The human body contains trillions of cells. All our activities from running to thinking—result from these combined and coordinated actions of millions or even billions of cells. Many insights into human physiology arose from studies of the functioning of individual cells. What we have learned over the years has given us a new understanding of cellular physiology and the mechanisms of homeostatic control. Today, the study of cellular structure and function, or **cytology**, is part of the broader discipline of **cell biology**, which integrates aspects of biology, chemistry, and physics.

The human body contains two general classes of cells: sex cells and somatic cells. **Sex cells** (also called *germ cells* or *reproductive cells*) are either the *sperm* (spermatozoa) of males or the *oocytes* (\overline{OO} -sīts) or "eggs" of females. The fusion of a sperm and an oocyte at fertilization is the first step in the creation of a new individual. **Somatic cells** (*soma*, body), or body cells, include all the other cells in the human body. In this chapter, we focus on somatic cells. We will discuss sex cells in Chapters 28 and 29 on the reproductive system and development, respectively.

In the rest of this chapter, we describe the structure of a typical somatic cell, consider some of the ways in which cells interact with their environment, and discuss how somatic cells reproduce. Keep in mind that the "typical" somatic cell is like the "average" person: Any description masks enormous individual variations. **Spotlight Figure 3–1** summarizes the anatomy of a model (representative) cell.

3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions

Learning Outcome List the functions of the plasma membrane and the structural features that enable it to perform those functions.

When you view a cell through a microscope, the first structure you encounter is its outer boundary, called the **plasma membrane**, or

SPOTLIGHT Figure 3–1 Anatomy of a Model Cell

In our model cell, a *plasma membrane* separates the cell contents, called the cytoplasm, from its surroundings. The cytoplasm can be subdivided into the cytosol, a fluid, and intracellular structures collectively known as organelles (or-ga-NELZ). Organelles are structures suspended within the cytosol that perform specific functions within the cell. They can be subdivided into membranous and nonmembranous organelles. Cells are surrounded by a watery medium known as the extracellular fluid. The extracellular fluid in most tissues is called interstitial (in-ter-STISH-ul) fluid.

Microvilli

Microvilli are extensions of the plasma membrane containing microfilaments.

Function

Increase surface area to facilitate absorption of extracellular materials

Cilia (see Figure 3-4b)

Cilia are long extensions of the plasma membrane containing microtubules. There are two types: primary and motile.

Functions

A primary cilium acts as a sensor. Motile cilia move materials over cell surfaces

Proteasomes

Functions

Hollow cylinders of proteolytic enzymes with regulatory proteins at their ends

8

Breakdown and recycling of damaged or abnormal intracellular proteins

RNA + proteins; fixed ribosomes bound to rough endoplasmic reticulum; free ribosomes scattered in cytoplasm

Function Protein synthesis

Peroxisomes

Vesicles containing degradative enzymes

Functions

Catabolism of fats and other organic compounds; neutralization of toxic compounds generated in the process

Golgi apparatus

Stacks of flattened membranes (cisternae) containing chambers

Functions

Storage, alteration, and packaging of secretory products and lysosomal enzymes

Mitochondria

Double membrane, with inner membrane folds (cristae) enclosing important metabolic enzymes

Function Produce 95% of the ATP required by the cell

Endoplasmic reticulum (ER)

Network of membranous channels extending throughout the cytoplasm

Functions

Synthesis of secretory products; intracellular storage and transport; detoxification of drugs or toxins

 Smooth ER synthesizes lipids and carbohydrates

Chromatin Nuclear envelope Nucleolus (site of rRNA synthesis and assembly of ribosomal subunits) Nuclear pore

NUCLEUS

Nucleoplasm containing nucleotides, enzymes, nucleoproteins, and chromatin; surrounded by a double membrane, the nuclear envelope

Functions

Control of metabolism; storage and processing of genetic information; control of protein synthesis **cell membrane**. The plasma membrane is extremely thin, ranging from 6 to 10 nm in thickness. Its general functions include:

- *Physical Isolation*. The plasma membrane is a physical barrier that separates the inside of the cell, or *cytoplasm*, from the surrounding extracellular fluid. For example, the plasma membrane keeps enzymes and structural proteins inside the cell. Conditions inside and outside the cell are very different, and those differences must be maintained to preserve homeostasis.
- Regulation of Exchange with the Environment. The plasma membrane acts as a kind of gate-keeper. It controls the entry of ions and nutrients, the elimination of wastes, and the release of secretions.
- Sensitivity to the Environment. The plasma membrane is the first part of the cell affected by changes in the composition, concentration, or pH of the extracellular fluid. It also contains a variety of special structural molecules known as *receptors* that allow the cell to recognize and respond to specific molecules in its environment. For instance, the plasma membrane may receive chemical signals from other cells. The binding of just one molecule to a receptor may trigger the activation or deactivation of enzymes that affect many cellular activities.

• *Structural Support.* Specialized connections between plasma membranes, or between membranes and extracellular materials, give tissues stability. For example, the cells at the surface of the skin are tightly bound together, while those in the deepest layers are attached to extracellular protein fibers in underlying tissues.

The plasma membrane contains lipids, proteins, and carbohydrates.

Membrane Lipids

Lipids form most of the surface area of the plasma membrane, but they make up only about 42 percent of its weight. The plasma membrane is called a **phospholipid bilayer**, because the phospholipid molecules in it form two layers (Figure 3–2).

Recall from Chapter 2 that a phospholipid has both a hydrophilic end (the phosphate portion) and a hydrophobic end (the lipid portion). \bigcirc p. 49 In each half of the bilayer, the phospholipids lie with their hydrophilic heads at the membrane surface and their hydrophobic tails on the inside. In this arrangement, the hydrophilic heads of the two layers are in contact with the aqueous environments on both sides of the membrane—the extracellular fluid outside the cell and

Figure 3–2 The Plasma Membrane.

the intracellular fluid, or *cytosol*, inside the cell. (The cytosol is the fluid component of the cytoplasm.) The hydrophobic tails form the interior of the membrane.

Note the similarities in lipid organization between the plasma membrane and a micelle (Figure 2–18c, p. 50). Ions and water-soluble compounds cannot enter a micelle, because the lipid tails of the phospholipid molecules are hydrophobic ("water-fearing") and will not associate with water molecules. For the same reason, such substances cannot cross the lipid portion of the plasma membrane. In this way, the hydrophobic center of the membrane isolates the cytoplasm from the surrounding fluid environment. Such isolation is important because the composition of cytoplasm is very different from that of extracellular fluid, and the cell must keep it that way to survive.

The lipid bilayer also contains cholesterol and other steroids, small quantities of other lipids, proteins, and glycolipids. Cholesterol is an important component of plasma membranes, with almost one cholesterol molecule for each phospholipid molecule. \bigcirc p. 48 Cholesterol "stiffens" the plasma membrane, making it less fluid and less permeable.

Membrane Proteins

Proteins, which are much denser than lipids, account for about 55 percent of the weight of a plasma membrane. There are two general structural classes of membrane proteins (Figure 3–2). Integral proteins are part of the plasma membrane structure and cannot be easily separated from it without damaging or destroying the membrane. Most integral proteins span the width of the membrane one or more times, and are known as *transmembrane proteins*. These proteins contain hydrophobic portions embedded within the hydrophobic lipid bilayer, with their hydrophilic portions extended into the extracellular environment and cytosol. **Peripheral proteins** are bound to the inner or outer surface of the membrane and (like Post-it notes) are easily separated from it. Integral proteins greatly outnumber peripheral proteins.

Membrane proteins carry out a variety of specialized functions. Here are some examples of important types of membrane proteins:

- 1. Anchoring Proteins. Anchoring proteins attach the plasma membrane to other structures and stabilize its position. Inside the cell, membrane proteins are bound to the *cytoskeleton*, a network of supporting filaments in the cytoplasm. Outer membrane proteins may attach the cell to extracellular protein fibers or to another cell.
- 2. *Recognition Proteins (Identifiers).* The cells of the immune system recognize other cells as normal or abnormal based on the presence or absence of characteristic **recognition proteins.** Many important recognition proteins

are glycoproteins. \bigcirc **p**. 56 (We will discuss one group, the *MHC proteins* involved in the immune response, in Chapter 22.)

- **3.** *Enzymes*. Enzymes in plasma membranes may be integral or peripheral proteins. They catalyze reactions in the extracellular fluid or in the cytosol, depending on the location of the protein and its active site. For example, dipeptides are broken down into amino acids by enzymes on the exposed membranes of cells that line the intestinal tract.
- 4. Receptor Proteins. Receptor proteins in the plasma membrane are sensitive to the presence of specific extracellular molecules called ligands (LĪ-gandz). A ligand can be anything from a small ion, like calcium, to a relatively large and complex hormone. When an extracellular ligand binds to the appropriate receptor, that binding may trigger changes in the activity of the cell. For example, the binding of the hormone *insulin* to a specific membrane receptor protein is the key step that leads to an increase in the cell's rate of glucose absorption. Plasma membranes differ in the type and number of receptor proteins they contain, and these differences account for a cell's sensitivity to specific hormones and other ligands.
- 5. *Carrier Proteins*. **Carrier proteins** bind solutes and transport them across the plasma membrane. Carrier proteins may require ATP as an energy source. ⁵ p. 58 For example, virtually all cells have carrier proteins that bring glucose into the cytoplasm without expending ATP. Yet these cells must use ATP to transport ions such as sodium and calcium across the plasma membrane and out of the cytoplasm.
- 6. *Channels.* Some integral proteins contain a **channel**, or central pore, that forms a passageway completely through the plasma membrane. The channel permits water and small solutes to move across the plasma membrane. Ions do not dissolve in lipids, so they cannot cross the phospholipid bilayer. For this reason, ions and other small water-soluble materials can cross the membrane only by passing through channels. Many channels are highly specific and permit only one particular ion to pass. The movement of ions through channels is involved in a variety of physiological mechanisms. Channels account for about 0.2 percent of the total surface area of the plasma membrane, but they are extremely important in physiological processes like muscle contraction and nerve impulse transmission, as we will see in Chapters 10 and 12.

Membranes are neither rigid nor uniform. At each location, the inner and outer surfaces of the plasma membrane may differ in important ways. For example, some enzymes are found only on the inner surface of the membrane, and some receptors are found only on the outer surface.

Some integral proteins are always confined to specific areas of the plasma membrane. These areas, called *rafts*, mark the location of anchoring proteins and some kinds of receptor proteins. Yet because membrane phospholipids are fluid at body temperature, many other integral proteins drift across the surface of the membrane like ice cubes in a bowl of punch. In addition, the composition of the entire plasma membrane can change over time as large areas of the membrane surface are removed and recycled in the ongoing process of metabolic turnover. \bigcirc p. 59

Membrane Carbohydrates

Carbohydrates account for about 3 percent of the weight of a plasma membrane. The carbohydrates in the plasma membrane are parts of complex molecules such as *proteoglycans*, *glycoproteins*, and *glycolipids*. \bigcirc **pp**. 49, 56 The carbohydrate portions of these large molecules extend beyond the outer surface of the membrane, forming a layer known as the **glycocalyx** (gl-ī-kō-KĀ-liks; *calyx*, cup). The glycocalyx has a variety of important functions, including:

- *Lubrication and Protection.* The glycoproteins and glycolipids form a viscous (thick and sticky) layer that lubricates and protects the plasma membrane.
- Anchoring and Locomotion. Because its components are sticky, the glycocalyx can help anchor the cell in place. It also takes part in the movement of specialized cells.
- Specificity in Binding. Glycoproteins and glycolipids can function as receptors, binding specific extracellular compounds. Such binding can change the properties of the cell surface and indirectly affect the cell's behavior.
- Recognition. Cells involved with the immune response recognize glycoproteins and glycolipids as normal or abnormal. The characteristics of the glycocalyx are genetically determined. The body's immune system recognizes its own membrane glycoproteins and glycolipids as "self" rather than as "foreign." This recognition system keeps your immune system from attacking your cells, and allows it to recognize and destroy invading pathogens (diseasecausing agents).

The plasma membrane forms a barrier between the cytosol and the extracellular fluid. If the cell is to survive, dissolved substances and larger compounds must be permitted to cross this barrier. Nutrients must be able to enter the cell, and metabolic wastes must be able to leave. The structure of the plasma membrane is ideally suited to this need for selective transport. We will discuss selective transport and other membrane functions further, after we have completed our overview of cellular anatomy.

CHECKPOINT

- 1. List the general functions of the plasma membrane.
- 2. Identify the components of the plasma membrane that allow it to carry out its functions.
- 3. Which component of the plasma membrane is primarily responsible for the membrane's ability to form a physical barrier between the cell's internal and external environments?
- 4. Which type of integral protein allows water, ions, and small water-soluble solutes to pass through the plasma membrane?

• See the blue Answers tab at the back of the book.

3-2 Organelles within the cytoplasm perform particular functions

Learning Outcome Describe the organelles of a typical cell, and indicate the specific functions of each.

Cytoplasm is a general term for the material between the plasma membrane and the membrane that surrounds the nucleus. It is a colloid with a consistency that varies between that of thin maple syrup and almost-set gelatin, and it contains many more proteins than does extracellular fluid, the watery medium that surrounds cells. ⁽⁾ p. 41 Proteins are so important to the cell that they make up about 30 percent of a typical cell's weight.

The cytoplasm contains cytosol and organelles. **Cytosol**, or *intracellular fluid*, contains dissolved nutrients, ions, soluble and insoluble proteins, and waste products. **Organelles** are structures suspended within the cytosol that perform specific functions for the cell.

The Cytosol

The most important differences between cytosol and extracellular fluid are as follows:

- 1. *The concentration of potassium ions is much higher in the cytosol* than in the extracellular fluid. Conversely, the concentration of sodium ions is much lower in the cytosol than in the extracellular fluid.
- 2. The cytosol contains a much higher concentration of suspended proteins than does extracellular fluid. Many of the proteins are enzymes that regulate metabolic operations. Others are associated with the various organelles. The consistency of the cytosol is determined in large part by the enzymes and cytoskeletal proteins.
- 3. The cytosol usually contains small quantities of carbohydrates, and small reserves of amino acids and lipids. The extracellular fluid is a transport medium only, and no amino acid or lipids are stored there. The carbohydrates in the cytosol are broken down to provide energy, and the amino acids

are used to manufacture proteins. Lipids, in particular triglycerides, are used primarily as a source of energy when carbohydrates are unavailable.

Masses of insoluble materials may be found in both the cytosol and the extracellular fluid. In the cytosol, these masses are known as **inclusions**. Common cytosol inclusions are stored nutrients, such as glycogen granules in liver or in skeletal muscle cells, lipid droplets in fat cells, and pigment granules such as the brown skin pigment, *melanin*. Melanin is synthesized intracellularly, thus it is a common cytosol inclusion, and then it is secreted into the extracellular fluid as an insoluble material. Another example of an insoluble material in the extracellular fluid is the mineral deposits in bone.

The Organelles

Organelles are the internal structures of cells that perform most of the tasks that keep a cell alive and functioning normally. Each organelle has specific functions related to cell structure, growth, maintenance, and metabolism. We can divide cellular organelles into two broad categories, nonmembranous and membranous. **Nonmembranous organelles** are not completely enclosed by membranes, and all of their components are in direct contact with the cytosol. **Membranous organelles** are isolated from the cytosol by phospholipid membranes, just as the plasma membrane isolates the cytosol from the extracellular fluid.

The cell's nonmembranous organelles include the *cytoskeleton, microvilli, centrioles, cilia, ribosomes,* and *proteasomes.* Membranous organelles include the *endoplasmic reticulum,* the *Golgi apparatus, lysosomes, peroxisomes,* and *mitochondria.* The *nucleus* is also surrounded by a membranous envelope and is, strictly speaking, a membranous organelle. It has so many vital functions that we will consider it in a separate section.

The Cytoskeleton

The **cytoskeleton** serves as the cell's skeleton. It is an internal protein framework that gives the cytoplasm strength and flexibility. The cytoskeleton of all cells is made of *microfilaments*, *intermediate filaments*, and *microtubules* (Figure 3–3). Muscle cells contain these cytoskeletal parts plus *thick filaments*. The filaments and microtubules of the cytoskeleton form a dynamic network whose continual reorganization affects cell shape and function.

We will consider only a few of the many functions of the cytoskeleton in this section. In addition to the functions we describe here, the cytoskeleton plays a role in the metabolic organization of the cell. It determines where in the cytoplasm key enzymatic reactions take place and where specific proteins are synthesized. For example, many enzymes (especially those involved with metabolism and energy production), ribosomes, and RNA molecules responsible for the synthesis of proteins are attached to the microfilaments and microtubules of the cytoskeleton. The varied metabolic functions of the cytoskeleton are now a subject of intensive research.

Microfilaments

The smallest of the cytoskeletal elements are the **microfilaments**. These protein strands are generally about 5 nm in diameter. Typical microfilaments are made of the protein **actin**. In most cells, actin filaments are common in the periphery of the cell, but rare in the region immediately surrounding the nucleus. In cells that form a layer or lining, such as the lining of the intestinal tract, actin filaments also form a layer, called the *terminal web*, just inside the plasma membrane at the exposed surface of the cell (Figure 3–3a).

Microfilaments have three major functions:

- 1. *Microfilaments anchor the cytoskeleton* to integral proteins of the plasma membrane. They give the cell additional mechanical strength and attach the plasma membrane to the enclosed cytoplasm.
- 2. Microfilaments, interacting with other proteins, determine the consistency of the cytoplasm. Where microfilaments form a dense, flexible network, the cytoplasm has a gelatinous consistency. Where they are widely dispersed, the cytoplasm is more fluid.
- **3.** *Actin can produce movement* of a portion of a cell or change the shape of the entire cell by interacting with the protein *myosin.*

Intermediate Filaments

The protein composition of **intermediate filaments** varies among cell types. These filaments range from 9 to 11 nm in diameter. They are so named because they are intermediate in size between microfilaments and thick filaments. Intermediate filaments, which are insoluble, are the most durable of the cytoskeletal elements.

Intermediate filaments: (1) *strengthen the cell* and help maintain its shape, (2) *stabilize the positions of organelles*, and (3) *stabilize the position of the cell with respect to surrounding cells* through specialized attachment to the plasma membrane. Many cells contain specialized intermediate filaments with unique functions. For example, the keratin fibers in superficial layers of the skin are intermediate filaments that make these layers strong and able to resist stretching.

Microtubules

Most cells contain **microtubules**, hollow tubes built from the globular protein **tubulin**. Microtubules are the largest components of the cytoskeleton, with diameters of about Figure 3–3 The Cytoskeleton.

25 nm. Microtubules extend outward into the periphery of the cell from a region near the nucleus called the *centrosome* (Spotlight Figure 3–1).

Microtubules play important roles in maintaining the shape of the cell, and they increase in number during mitosis (somatic cell division) and meiosis (germ cell division). Each microtubule forms by the aggregation of tubulin molecules, growing out from its origin at the centrosome. The entire structure persists for a time and then disassembles into individual tubulin molecules again. Microtubules have the following functions:

- 1. *Microtubules form the main portions of the cytoskeleton,* giving the cell strength and rigidity and anchoring the position of major organelles.
- 2. Microtubules change the shape of the cell, and may assist in cell movement, through the assembly and disassembly of microtubules
- **3.** Microtubules can serve as a kind of monorail system to move vesicles or other organelles within the cell. Proteins called

molecular motors create the movement. These motor proteins bind to the structure being moved and bind to a microtubule and move along its length. The direction of movement depends on the particular motor protein involved. For example, the molecular motors *kinesin* and *dynein* carry materials in opposite directions on a microtubule: Kinesin moves toward one end, dynein toward the other. Regardless of the direction of transport or the nature of the motor, the process requires ATP and is essential to normal cellular function.

- 4. During cell division, microtubules distribute duplicated chromosomes to opposite ends of the dividing cell by forming a network of microtubules called the *spindle apparatus*. We will look at this process in more detail in a later section.
- 5. *Microtubules form structural components of organelles,* such as *centrioles* and *cilia.*

Thick Filaments

Thick filaments are relatively massive bundles of subunits made of the protein **myosin**. Thick filaments are about 15 nm in diameter and 1.5 μ m (micrometers) long. They appear only in all types of muscle cells, where they produce powerful contractions by interacting with actin filaments.

Microvilli

Many cells have small, finger-shaped projections of the plasma membrane on their exposed surfaces (Figure 3–3b). These projections, called **microvilli** (singular, *microvillus*), greatly increase the surface area of the cell exposed to the extracellular environment. Accordingly, they cover the surfaces of cells that are actively absorbing materials from the extracellular fluid, such as the cells lining the digestive tract. Microvilli have extensive connections with the cytoskeleton. A core of micro-filaments stiffens each microvillus and anchors it to the cytoskeleton at the terminal web.

Centrosome and Centrioles

The **centrosome** is a region of cytoplasm located next to the nucleus in a cell. It is the microtubule organizing center of animal cells, and the heart of the cytoskeletal system. Microtubules of the cytoskeleton generally begin at the centrosome and radiate through the cytoplasm. In all animal cells capable of undergoing cell division, the centrosome surrounds a pair of cylindrical structures called **centrioles**. The centrioles lie perpendicular to each other and are composed of short microtubules (Figure 3–4a). The microtubules form nine groups, three in each group. Each of these nine "triplets" is connected to its nearest neighbors on either side. Because there are no central microtubules, this organization is called a 9 + 0 array.

During cell division, the centrioles aid the formation of the spindle apparatus needed for the movement of DNA strands. Mature red blood cells, skeletal muscle cells, cardiac muscle cells, and typical neurons have no centrioles, and as a result, these cells cannot divide. The centrioles also form the *basal bodies* found at the base of cilia and flagella.

Cilia and Flagella

Cilia (singular, *cilium*) are fairly long, slender extensions of the plasma membrane. Multiple *motile cilia* are found on cells lining both the respiratory and reproductive tracts, and at various other locations in the body. Motile cilia have an internal arrangement similar to that of centrioles. However, in cilia, nine *pairs* of microtubules (rather than triplets) surround a central pair (**Figure 3-4b**)—an organization known as a 9 + 2 *array*. The microtubules are anchored to a compact **basal body** situated just beneath the cell surface. The organization of microtubules in the basal body resembles the array of a centriole: nine triplets with no central pair.

A single, nonmotile **primary cilium** is found on the cells of a wide variety of tissues in the body. Its structure is similar to the 9 + 0 microtubule organization of a centriole and basal body. A primary cilium acts as a signal sensor, detecting environmental stimuli and coordinating activities such as embryonic development and homeostasis at the tissue level.

Motile cilia are important because they "beat" rhythmically to move fluids or secretions across the cell surface (Figure 3–4c). A motile cilium is relatively stiff during the *power stroke* and flexible during the *return stroke*. The ciliated cells along your trachea beat their cilia in synchronized waves to move sticky mucus and trapped dust particles toward the throat and away from delicate respiratory surfaces. If the cilia are damaged or immobilized by heavy smoking or a metabolic problem, this cleansing action is lost. When irritants are no longer removed, a chronic cough and respiratory infections develop. Ciliated cells also move oocytes along the uterine tubes, and sperm from the testes into the male reproductive tract. Defective primary cilia are known to be responsible for a wide range of human disorders, collectively known as *ciliopathies*.

A **flagellum** (plural, *flagella*) is also an extension of the plasma membrane. Flagella have the same 9 + 2 microtubule organization as motile cilia, but are much longer and beat in a wavelike fashion. The only human cell with a flagellum is a sperm cell.

Ribosomes

Proteins are produced within cells, using information provided by the DNA of the nucleus. **Ribosomes** are the organelles responsible for protein synthesis. The number of ribosomes in a particular cell varies with the type of cell and its demand for new proteins. For example, liver cells, which manufacture blood proteins, contain far more ribosomes than do fat cells, which primarily synthesize lipids.

Individual ribosomes are not visible with the light microscope. In an electron micrograph, they appear as dense granules approximately 25 nm in diameter. Each ribosome is about 60 percent RNA and 40 percent protein.

A functional ribosome consists of two subunits that are normally separate and distinct. One is called a **small ribosomal subunit** and the other a **large ribosomal subunit**. These subunits contain special proteins and **ribosomal RNA** (**rRNA**), one of the RNA types introduced in Chapter 2. Before protein synthesis can begin, a small and a large ribosomal subunit in the cytoplasm must join together with a strand of *messenger RNA* (*mRNA*), another type of RNA. Protein synthesis then begins in the cytoplasm. The two major types of functional ribosomes in cells are free ribosomes and fixed ribosomes. **Free ribosomes** are scattered throughout the cytoplasm. The proteins they manufacture directly enter the cytosol. Ribosomes synthesizing proteins with destinations other than the cytosol become temporarily bound, or fixed, to the *endoplasmic reticulum (ER)*, a membranous organelle. Proteins manufactured by such **fixed ribosomes** enter the ER, where they are modified and packaged for use within the cell or they are secreted from the cell. We will look at ribosomal structure and functions when we discuss the endoplasmic reticulum and protein synthesis in later sections.

Proteasomes

Proteasomes are organelles that contain an assortment of protein-digesting (proteolytic) enzymes, or *proteases*. They are smaller than free ribosomes and their job is to remove proteins from the cytoplasm. Cytoplasmic enzymes attach chains of *ubiquitin*, a molecular "tag," to proteins destined for recycling. Tagged proteins are quickly transported into a proteasome. Once inside, they are rapidly disassembled into amino acids and small peptides, which are released into the cytoplasm.

Proteasomes remove and recycle damaged or denatured proteins. They also break down abnormal proteins, such as those produced within cells infected by viruses. Proteasomes also play a key role in the immune response, as we will see in Chapter 22.

Check **Spotlight Figure 3–1** for a review of the characteristics of nonmembranous organelles before reading about membranous organelles in the next sections.

The Endoplasmic Reticulum

The **endoplasmic reticulum** (en-dō-PLAZ-mik re-TIK-ūlum), or **ER**, is a network of intracellular membranes continuous with the *nuclear envelope*, which surrounds the nucleus. The name *endoplasmic reticulum* is very descriptive. *Endo*- means "within," *plasm* refers to the cytoplasm, and a *reticulum* is a network. The ER has four major functions:

- 1. *Synthesis*. Specialized regions of the ER synthesize proteins, carbohydrates, and lipids.
- **2.** *Storage.* The ER can store synthesized molecules or materials absorbed from the cytosol without affecting other cellular operations.

- **3.** *Transport.* Materials can travel from place to place within the ER.
- 4. *Detoxification*. The ER can absorb drugs or toxins and neutralize them with enzymes.

The ER forms hollow tubes, flattened sheets, and chambers called **cisternae** (sis-TUR-nē; singular, *cisterna*, a reservoir for water). Two types of ER exist: *smooth endoplasmic reticulum* and *rough endoplasmic reticulum* (Figure 3–5).

Smooth Endoplasmic Reticulum

The term "smooth" refers to the fact that no ribosomes are associated with the smooth endoplasmic reticulum (SER). The SER is involved with the synthesis of lipids, fatty acids, and carbohydrates; the sequestering of calcium ions; and the detoxification of drugs. Important functions of the SER include the following:

- *Synthesis of the phospholipids and cholesterol* needed for maintenance and growth of the plasma membrane, ER, nuclear membrane, and Golgi apparatus in all cells
- *Synthesis of steroid hormones,* such as *androgens* and *estrogens* (the dominant sex hormones in males and in females, respectively) in the reproductive organs
- *Synthesis and storage of glycerides, especially triacylglycerides,* in liver cells and fat cells
- *Synthesis and storage of glycogen* in skeletal muscle and liver cells

In muscle cells, neurons, and many other types of cells, the SER also adjusts the composition of the cytosol by absorbing and storing ions, such as Ca^{2+} , or large molecules. In addition, the SER in liver and kidney cells detoxifies or inactivates drugs.

Figure 3–5 The Endoplasmic Reticulum.

Rough Endoplasmic Reticulum

The rough endoplasmic reticulum (RER) functions as a combination workshop and shipping warehouse. It is where many newly synthesized proteins are chemically modified and packaged for export to their next destination, the *Golgi apparatus*.

The fixed ribosomes on the outer surface of the rough endoplasmic reticulum give the RER a beaded, grainy, or rough appearance (Figure 3–5). Both free and fixed ribosomes synthesize proteins using instructions provided by messenger RNA.

The new polypeptide chains produced at fixed ribosomes are released into the cisternae of the RER. Inside the RER, each protein assumes its secondary and tertiary structures. \bigcirc **p.** 52 Some of the proteins are enzymes that will function inside the endoplasmic reticulum. Other proteins are chemically modified by the attachment of carbohydrates, creating glycoproteins.

Most of the proteins and glycoproteins produced by the RER are packaged into small membranous sacs that pinch off from the tips of the cisternae. These **transport vesicles** then deliver their contents to the Golgi apparatus (Spotlight Figure 3–7).

The amount of endoplasmic reticulum and the proportion of RER to SER vary with the type of cell and its ongoing activities. For example, pancreatic cells that manufacture digestive enzymes contain an extensive RER, but the SER is relatively small. The situation is just the reverse in the cells of reproductive organs that synthesize steroid hormones.

The Golgi Apparatus

When a transport vesicle carries a newly synthesized protein or glycoprotein that is destined for export from the cell, it travels from the ER to the **Golgi** (GOL-jē) **apparatus**, or **Golgi complex**, an organelle that looks a bit like a stack of dinner plates (Figure 3–6). This organelle typically consists of five or six flattened membranous discs called *cisternae*. A single cell may contain several of these organelles, most often near the nucleus.

The Golgi apparatus has three major functions (Spotlight Figure 3–7). It

- 1. *modifies and packages secretions,* such as hormones or enzymes, for release from the cell;
- 2. renews or modifies the plasma membrane; and
- **3.** *packages special enzymes within vesicles (lysosomes)* for use in the cytoplasm.

Lysosomes

Cells often need to break down and recycle large organic molecules and even complex structures like organelles. The breakdown process requires powerful enzymes, and it often generates toxic chemicals that could damage or kill the cell. **Lysosomes** (LĪ-sō-sōmz; *lyso-*, a loosening + *soma*, body) are special vesicles that provide an isolated environment for potentially dangerous chemical reactions. These vesicles, produced by the Golgi apparatus, contain digestive enzymes. Lysosomes are small, often spherical bodies with contents that look dense and dark in electron micrographs.

Lysosomes have several functions (see Figure 3–8 on p. 80). One is to remove damaged organelles. *Primary lysosomes* contain inactive enzymes. When these lysosomes fuse with the membranes of damaged organelles (such as mitochondria or fragments of the ER), the enzymes are activated and *secondary lysosomes* are formed. The enzymes then break down the contents. The

Figure 3–6 The Golgi Apparatus.

cytosol reabsorbs released nutrients, and the remaining material is expelled from the cell.

Lysosomes also destroy bacteria (as well as liquids and organic debris) that enter the cell from the extracellular fluid. The cell encloses these substances in a small portion of the plasma membrane, which is then pinched off to form a transport vesicle, or *endosome*, in the cytoplasm. (We will discuss this method of transporting substances into the cell, called *endocytosis*, later in this chapter.) Then a primary lysosome fuses with the vesicle, forming a secondary lysosome. Activated enzymes inside break down the contents and release usable substances, such as sugars or amino acids. In this way, the cell both protects itself against harmful substances and obtains valuable nutrients.

Lysosomes also do essential cleanup and recycling inside the cell. For example, when muscle cells are inactive, lysosomes gradually break down their contractile proteins. (This mechanism accounts for the reduction in muscle mass that accompanies aging.) The process is usually precisely controlled, but in a damaged or dead cell, the regulatory mechanism fails. Lysosomes then disintegrate, releasing enzymes that become activated within the cytosol. These enzymes rapidly destroy the cell's proteins and organelles in a process called **autolysis** (aw-TOL-i-sis; *auto-*, self). We do not know how to control lysosomal activities or why the enclosed enzymes do not digest the lysosomal membranes unless the cell is damaged.

Problems in producing lysosomal enzymes cause more than 30 serious diseases affecting children. In these conditions, called *lysosomal storage diseases*, the lack of a specific lysosomal enzyme results in the buildup of waste products and debris that lysosomes normally remove and recycle. Affected individuals may die when vital cells, such as those of the heart, can no longer function.

Peroxisomes

Peroxisomes are smaller than lysosomes and carry a different group of enzymes. In contrast to lysosomes, which are produced at the Golgi apparatus, new peroxisomes are produced by the growth and subdivision of existing peroxisomes. Their enzymes are produced at free ribosomes and transported from the cytosol into the peroxisomes by carrier proteins.

Peroxisomes absorb and break down fatty acids and other organic compounds. As they do so, peroxisomes generate hydrogen peroxide (H_2O_2), a potentially dangerous free radical. \supset p. 34 Catalase, the most abundant enzyme within the peroxisome, then breaks down the hydrogen peroxide to oxygen and water. In this way, peroxisomes protect the cell from the potentially damaging effects of free radicals produced during catabolism. Peroxisomes are present in all cells, but their numbers are highest in metabolically active cells, such as liver cells.

Membrane Flow

When the temperature changes markedly, you change your clothes. Similarly, when a cell's environment changes, it changes the structure and properties of its plasma membrane. With the exception of mitochondria, all membranous organelles in the cell are either interconnected or in communication through the movement of vesicles. The membranes of the RER and SER are continuous and are connected to the nuclear envelope. Transport vesicles connect the ER with the Golgi apparatus, and secretory vesicles link the Golgi apparatus with the plasma membrane. Finally, vesicles forming at the exposed surface of the cell remove and recycle segments of the plasma membrane. This continuous movement and exchange of membrane segments is called **membrane flow**. In an actively secreting cell, an area equal to the entire membrane surface may be replaced each hour.

Membrane flow is an example of the dynamic nature of cells. It provides a way for cells to change the characteristics of their plasma membranes by altering their lipids and the proteins serving as receptors, channels, anchors, and enzymes— as they grow, mature, or respond to a specific environmental stimulus.

Mitochondria

The cells of all living things require energy to carry out the functions of life. The organelles that produce energy are the **mitochondria** (mī-tō-KON-drē-ūh; singular, *mitochondrion; mitos*, thread + *chondrion*, granule). These small structures vary widely in shape, from long and slender to short and fat. The number of mitochondria in a particular cell varies with the cell's energy demands. These organelles may account for 30 percent of the volume of a heart muscle cell, yet are absent in red blood cells.

Mitochondria have an unusual double membrane (Figure 3-9a). The outer membrane surrounds the organelle. The inner membrane contains numerous folds called **cristae**, which surround the fluid contents, or **matrix**, of the mitochondrion. Cristae increase the membrane surface area in contact with the matrix and the number of attached protein complexes and enzymes involved in making ATP from ADP and P. Metabolic enzymes in the matrix catalyze reactions that release carbon dioxide and provide some additional energy for cellular functions.

Mitochondria contain their own DNA (mtDNA) and ribosomes. The mtDNA codes for small numbers of RNA and polypeptide molecules. The polypeptides are used in enzymes required for energy production. Although mitochondria contain their own genetic system, their functions depend on imported proteins coded by nuclear DNA.

Most of the chemical reactions that release energy take place in the mitochondria, yet most of the cellular activities

SPOTLIGHT

The Golgi apparatus plays a major role in modifying and packaging newly synthesized proteins. Some proteins and glycoproteins synthesized in the rough endoplasmic reticulum (RER) are delivered to the Golgi apparatus by transport vesicles. Here's a summary of the process, beginning with DNA.

6 The transport vesicles carry the proteins and glycoproteins generated in the ER toward the Golgi apparatus. The transport vesicles then fuse to create the forming cis face ("receiving side") of the Golgi apparatus. Multiple transport vesicles combine to form cisternae on the cis face. Further protein and glycoprotein modification and packaging occur as the cisternae move toward the maturing (trans) face. Small transport vesicles return resident Golgi proteins to the forming cis face for reuse. **8** The maturing trans face ("shipping side") generates vesicles that carry modified proteins away from the Golgi apparatus. One type of vesicle becomes a lysosome, which contains digestive enzymes. 9 Two other types of vesicles proceed to the plasma membrane: secretory and membrane renewal. Secretory vesicles fuse with the plasma membrane and empty their products outside the cell by exocytosis. Membrane renewal vesicles add new lipids and proteins to the plasma membrane.

that require energy occur in the surrounding cytoplasm. For this reason, cells must store energy in a form that can be moved from place to place. Recall from Chapter 2 that cellular energy is stored and transferred in the form of *high-energy bonds*. The best example is the high-energy bond that attaches a phosphate group (PO_4^{3-}) to adenosine diphosphate (ADP), creating the high-energy compound *adenosine triphosphate* (ATP). Cells can then break this high-energy bond under controlled conditions, reconverting ATP to ADP and phosphate and releasing energy for the cell's use when and where it is needed.

Mitochondrial Energy Production. Most cells generate ATP and other high-energy compounds as they break down carbohydrates, especially glucose. We will examine the entire process in Chapter 25, but a few basic concepts now will help you follow discussions of muscle contraction, neuron function, and endocrine function in Chapters 10–18.

Most ATP is produced inside mitochondria, but the first steps take place in the cytoplasm (**Figure 3–9b**). A reaction sequence called **glycolysis** (*glycos*, sugar + *-lysis*, a loosening) breaks down a glucose molecule into two molecules of *pyruvate*. Mitochondria then absorb the pyruvate molecules.

In the mitochondrial matrix, a carbon dioxide (CO_2) molecule is removed from each absorbed pyruvate molecule. The

Clinical Note

Inheritable Mitochondrial Disorders Several inheritable disorders result from abnormal mitochondrial activity. Mitochondria are not totally self-sufficient, but they do contain DNA and ribosomes to manufacture many of their own specific proteins. The mitochondria involved in congenital diseases contain abnormal DNA. As a result, the enzymes they produce reduce the efficiency of ATP production. Cells throughout the body may be affected. Symptoms involving muscle cells, neurons, and the receptor cells in the eye are most common because these cells have especially high energy demands.

remainder then enters the **citric acid cycle** (also known as the *Krebs cycle* and the *tricarboxylic acid cycle* or *TCA cycle*). The citric acid cycle is an enzymatic pathway that breaks down the absorbed pyruvate.

The remnants of pyruvate molecules contain carbon, oxygen, and hydrogen atoms. The carbon and oxygen atoms are

Figure 3–9 Mitochondria.

a Shown here is the three-dimensional organization and a color-enhanced TEM of a typical mitochondrion in longitudinal section.

released as carbon dioxide, which diffuses out of the cell. The hydrogen atoms are delivered to carrier protein complexes in the cristae. There the electrons are removed from the hydrogen atoms and passed along a chain of coenzymes and ultimately transferred to oxygen atoms. The energy released during these steps indirectly supports the enzymatic conversion of ADP to ATP. \supset p. 58

Because mitochondrial activity requires oxygen, this method of ATP production is known as **aerobic metabolism** (*aer*, air + *bios*, life), or *cellular respiration*. Aerobic metabolism in mitochondria produces about 95 percent of the ATP needed to keep a cell alive. (Enzymatic reactions, including glycolysis, in the cytoplasm produce the rest.)

CHECKPOINT

- 5. Differentiate between the cytoplasm and the cytosol.
- 6. What are the major differences between cytosol and extracellular fluid?
- 7. Identify the nonmembranous organelles, and cite a function of each.
- 8. Identify the membranous organelles, and cite their functions.
- 9. Explain why certain cells in the ovaries and testes contain large amounts of smooth endoplasmic reticulum (SER).
- 10. What does the presence of many mitochondria imply about a cell's energy requirements?

See the blue Answers tab at the back of the book.

3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities

Learning Outcome Explain the functions of the cell nucleus and discuss the nature and importance of the genetic code.

The **nucleus** is usually the largest and most conspicuous structure in a cell. If you look at a human cell under a light microscope, it may be the only organelle you see. The nucleus is the control center for cellular operations. A single nucleus stores all the information needed to direct the synthesis of more than 100,000 different proteins in the human body. The nucleus determines the structure of the cell and what functions it can perform by controlling which proteins are synthesized, under what circumstances, and in what amounts. A cell without

a nucleus cannot repair itself, so it will disintegrate within three or four months.

Most cells contain a single nucleus, but exceptions exist. For example, skeletal muscle cells have many nuclei, but mature red blood cells have none. Figure 3–10 details the structure of a typical nucleus. Surrounding the nucleus and separating it from the cytosol is a **nuclear envelope**, a double membrane with its two layers separated by a narrow perinuclear space (peri-, around). At several locations, the nuclear envelope is connected to the rough endoplasmic reticulum (Spotlight Figure 3–1).

To direct processes that take place in the cytoplasm, the nucleus must receive information about conditions and activities in other parts of the cell. Chemical communication between the nucleus and the cytoplasm takes place through nuclear pores. These pores cover about 10 percent of the

nuclear envelope, and the cut edge of the nucleus can be seen.

3

surface of the nucleus. They are large enough to allow ions and small molecules to enter or leave, but are too small for proteins or DNA to pass freely. Each nuclear pore contains regulatory proteins that govern the transport of specific proteins and RNA into or out of the nucleus.

Contents of the Nucleus

The fluid contents of the nucleus are called the *nucleoplasm*. The nucleoplasm contains the **nuclear matrix**, a network of fine filaments that provides structural support and may be involved in the regulation of genetic activity. The nucleoplasm also contains ions, enzymes, RNA and DNA nucleotides, small amounts of RNA, and DNA.

Most nuclei contain several dark-staining areas called **nucleoli** (noo-KLĒ-ō-lī; singular, *nucleolus*). Nucleoli are transient nuclear organelles that synthesize ribosomal RNA. They also assemble the ribosomal subunits, which then enter the cytoplasm through nuclear pores. Nucleoli are composed of RNA, enzymes, and proteins called **histones**. The nucleoli form around portions of DNA that contain the instructions for producing ribosomal proteins and RNA when those instructions are being carried out. Nucleoli are most prominent in cells that manufacture large amounts of proteins, such as liver, nerve, and muscle cells, because those cells need large numbers of ribosomes.

The DNA in the nucleus stores the instructions for protein synthesis. Interactions between the DNA and the histones help determine which information is available to the cell at any moment. The organization of DNA within the nucleus is shown in **Figure 3–11**. At intervals, the DNA strands wind around the histones, forming a complex known as a **nucleosome**. Such winding allows a great deal of DNA to be packaged in a small space.

The entire chain of nucleosomes may coil around other proteins. The degree of coiling varies, depending on whether cell division is underway. In cells that are not dividing, the nucleosomes are loosely coiled within the nucleus, forming a tangle of fine filaments known as **chromatin**. Chromatin gives the nucleus a clumped, grainy appearance. Just before cell division begins, the coiling becomes tighter, forming distinct structures called **chromosomes** (*chroma*, color). In humans, the nuclei of somatic cells contain 23 pairs of chromosomes. One member of each pair is derived from the mother, and one from the father.

Information Storage in the Nucleus

As we saw in Chapter 2, each protein molecule consists of a unique sequence of amino acids. $\supset p$. 51 Any "recipe" for a protein must specify the order of amino acids in the polypeptide chain. This information is stored in the chemical structure of the DNA strands in the nucleus. The chemical

Figure 3–11 The Organization of DNA within the Nucleus. DNA strands are coiled around histones to form nucleosomes. Nucleosomes form coils that may be very tight or rather loose. In cells that are not dividing, the DNA is loosely coiled, forming a tangled network known as chromatin. When the coiling becomes tighter, as it does in preparation for cell division, the DNA becomes visible as distinct structures called chromosomes.

"language" the cell uses is known as the **genetic code**. An understanding of the genetic code has enabled researchers to figure out how cells build proteins and how various structural and functional characteristics are inherited from generation to generation.

How does the genetic code work? Recall the basic structure of nucleic acids described in Chapter 2. \bigcirc p. 56 A single DNA molecule consists of a pair of DNA strands held together by hydrogen bonding between complementary nitrogenous bases. Information is stored in the sequence of nitrogenous bases along the length of the DNA strands. Those nitrogenous bases are adenine (A), thymine (T), cytosine (C), and guanine (G).

The genetic code is called a *triplet code*, because a sequence of three nitrogenous bases represents a single amino acid. Thus, the information encoded in the sequence of nitrogenous bases must be read in groups of three. For example, the triplet thymine–guanine–thymine (TGT) on one DNA strand, called

C Clinical Note

DNA Fingerprinting Every nucleated somatic cell in the body carries a set of 46 chromosomes that are copies of the set formed at fertilization. Not all the DNA of these chromosomes codes for proteins. Within the non-protein coding DNA are regions called Short Tandem Repeats (STRs), which contain the same nucleotide sequence repeated over and over. The number of STRs and the number of repetitions vary among individuals. In the United States, 13 core STRs are used for identifying individuals. The individual differences are reflected in the different lengths of these STRs. The chance that any two individuals, other than identical twins, will have the same length and pattern of repeating DNA segments in 13 STRs is approximately one in 575 trillion. For this reason, individuals can be identified on the basis of their DNA pattern, just as they can on the basis of a fingerprint. Skin scrapings, blood, semen, hair, or other tissues can serve as the DNA source. Information from DNA fingerprinting has been used to convict or acquit people accused of violent crimes, such as rape or murder. The U.S. Crime Act of 1994 mandates that DNA fingerprints of individuals convicted of certain crimes be kept in a retrievable archive. The science of molecular biology has become a useful addition to the crime-fighting arsenal.

the *coding strand*, is the code for the amino acid cysteine. More than one triplet may stand for the same amino acid, how-ever. For example, the DNA triplet thymine–guanine–cytosine (TGC) also codes for cysteine.

A **gene** is the functional unit of heredity. It is the sequence of nucleotides of a DNA strand that specifies the amino acids needed to produce a specific protein. The needed number of triplet nucleotides, each coding for an amino acid, depends on the size of the polypeptide represented. A relatively short polypeptide chain might need fewer than 100 triplets, but the instructions for building a large protein might involve 1000 or more triplets.

Not all the nucleotide sequences of a DNA strand carry instructions for assembling proteins. Some sequences contain instructions for synthesizing ribosomal RNA or another type that we will discuss shortly, called *transfer RNA*. Others have a regulatory function, and still others have as yet no known function.

CHECKPOINT

11. Describe the contents and structure of the nucleus.

12. What is a gene?

See the blue Answers tab at the back of the book.

3-4 DNA controls protein synthesis, cell structure, and cell function

Learning Outcome Summarize the role of DNA in protein synthesis, cell structure, and cell function.

The DNA of the nucleus controls the cell by directing the synthesis of specific proteins. Through protein synthesis, the DNA of the nucleus controls cell structure and function. The major events of protein synthesis are gene activation, transcription, and translation.

The Role of Gene Activation in Protein Synthesis

Each DNA molecule contains thousands of genes—the information needed to synthesize thousands of proteins. Normally, the genes are tightly coiled, and histones bound to the DNA keep the genes inactive. Before a gene can affect a cell, the portion of the DNA molecule containing that gene must be uncoiled and the histones temporarily removed in a process called **gene activation**.

The factors controlling this process are only partially understood. We know, however, that every gene contains segments responsible for regulating its own activity. In effect, these are triplets of nucleotides that say "read this message" or "do not read this message," "message starts here," or "message ends here." These "read me," "don't read me," and "start" signals form a special region of DNA called the *promoter*, or control segment, at the start of each gene. Each gene ends with a "stop" signal. Gene activation begins with the temporary disruption of the weak hydrogen bonds between the nitrogenous bases of the two DNA strands and the removal of the histone that guards the promoter.

The Transcription of mRNA

After the complementary DNA strands have separated and the histones have been removed, the enzyme **RNA polymerase** binds to the promoter of the gene. This binding is the first step in the process of **transcription**, the synthesis of RNA from a DNA template. The use of the term *transcription* makes sense, as it means "to copy" or "rewrite."

All three types of RNA are formed through the transcription of DNA, but we will focus here on the transcription of mRNA, which carries the information needed to synthesize proteins. The synthesis of **messenger RNA (mRNA)** is essential, because the DNA is too large to leave the nucleus. Instead, its information is copied to messenger RNA, which is smaller and *can* leave the nucleus and carry the information to the cytoplasm, where protein synthesis takes place.

Recall that the two DNA strands in a gene are complementary. The strand containing the triplets that specify the sequence of amino acids in the polypeptide is the **coding strand**. The other strand, called the **template strand**, contains complementary triplets that will be used as a template for mRNA production. The resulting mRNA will have a nucleotide sequence identical to that of the coding strand, but with uracil substituted for thymine.

Figure 3–12 illustrates the steps in transcription:

1 *RNA polymerase binding.* Once the DNA strands have separated and the promoter has been exposed, transcription can begin. The key event is the binding of RNA polymerase to the template strand.

2 RNA polymerase forms and joins mRNA codons. RNA polymerase promotes hydrogen bonding between the nitrogenous bases of the template strand nucleotides and complementary nucleotides in the nucleoplasm. This enzyme begins at a "start" signal in the promoter region. It then strings nucleotides together by covalent bonding. The RNA polymerase travels along the DNA strand, interacting with

only a small portion of the template strand at any one time. The complementary DNA strands separate in front of the enzyme as it moves one nucleotide at a time, and they reassociate behind it.

The enzyme collects additional nucleotides and attaches them one by one to the growing chain. The nucleotides involved are those characteristic of RNA, not of DNA. In other words, RNA polymerase can attach adenine, guanine, cytosine, or uracil, but never thymine. For this reason, wherever an A occurs in the DNA strand, the enzyme attaches a U rather than a T to the growing mRNA strand. In this way, RNA polymerase assembles a complete strand of mRNA.

Notice that the nucleotide sequence of the DNA template strand determines the nucleotide sequence of the mRNA strand. Each DNA triplet corresponds to a sequence of three nucleotides in the mRNA strand. Such a three-base mRNA sequence is called a **codon** (KŌ-don). Codons contain nitrogenous bases that are complementary to those of the triplets in the DNA template strand. For example, if the DNA triplet

Figure 3–12 mRNA Transcription. In this figure, a small portion of a single DNA molecule, containing a single gene, is undergoing transcription. 1 The two DNA strands separate, and RNA polymerase binds to the promoter of the gene. 2 The RNA polymerase moves from one nucleotide to another along the length of the template strand. At each site, complementary RNA nucleotides form hydrogen bonds with the DNA nucleotides of the template strand. The RNA polymerase then strings the arriving nucleotides together into a strand of mRNA. 3 On reaching the stop signal at the end of the gene, the RNA polymerase and the mRNA strand detach, and the two DNA strands reassociate.

is TCG, the corresponding mRNA codon will be AGC. This method of copying ensures that the mRNA exactly matches the coding strand of the gene (except for the substitution of uracil for thymine).

3 Detachment of mRNA. At the "stop" signal, the enzyme and the mRNA strand detach from the DNA strand, and transcription ends. The complementary DNA strands now complete their reassociation as hydrogen bonding takes place again between complementary base pairs.

The nucleotide sequence of each gene includes a number of triplets that are not needed to build a functional protein. As a result, the mRNA strand assembled during transcription, sometimes called immature mRNA or *pre-mRNA*, must be "edited" before it leaves the nucleus to direct protein synthesis. In this **RNA processing**, non-coding intervening sequences, called **introns**, are snipped out, and the remaining coding segments, or **exons**, are spliced together. The process creates a much shorter, functional strand of mRNA that then enters the cytoplasm through a nuclear pore.

Intron removal is extremely important and tightly regulated. An error in the editing will produce an abnormal protein with potentially disastrous results. Moreover, we now know that by changing the editing instructions and removing different introns, a single gene can produce mRNAs that code for several different proteins. Some introns, however, act as enzymes to catalyze their own removal. How this variable editing is regulated is unknown.

Translation and Protein Synthesis

Protein synthesis is the assembling of functional polypeptides in the cytoplasm. Protein synthesis takes place through **translation**, the formation of a linear chain of amino acids, using the information from an mRNA strand. Again, the name makes sense: To *translate* is to present the same information in a different language. In this case, a message written in the "language" of nucleic acids (the sequence of nitrogenous bases) is translated into the "language" of proteins (the sequence of amino acids in a polypeptide chain). Each mRNA codon designates a particular amino acid to be inserted into the polypeptide chain.

The amino acids are provided by **transfer RNA (tRNA)**, a relatively small and mobile type of RNA. Each tRNA molecule binds and delivers a specific type of amino acid. More than 20 kinds of transfer RNA exist—at least one for each of the 20 amino acids used in protein synthesis.

A tRNA molecule has a tail that binds an amino acid. Roughly midway along its length, the nucleotide chain of the tRNA forms a tight loop that can interact with an mRNA strand. The loop contains three nitrogenous bases that form an **anticodon**. During translation, the anticodon bonds with a complementary mRNA codon. The anticodon base sequence indicates the type of amino acid carried by the tRNA. For

Clinical Note

Mutations Mutations are permanent changes in a cell's DNA that affect the nucleotide sequence of one or more genes.

The simplest is a *point mutation*, a change in a single nucleotide that affects one codon. The triplet code has some flexibility, because several different codons can specify the same amino acid. But a point mutation that produces a codon that specifies a different amino acid will usually change the structure of the completed protein. A single change in the amino acid sequence of a structural protein or enzyme can prove fatal. Certain cancers and two potentially lethal blood disorders discussed in Chapter 19, *thalassemia* and *sickle cell anemia*, result from changes in a single nucleotide.

Several hundred inherited disorders have been traced to abnormalities in enzyme or protein structure that reflect single changes in nucleotide sequence. More extensive mutations, such as additions or deletions of nucleotides, can affect multiple codons in one gene or in several adjacent genes. They can also affect the structure of one or more chromosomes.

Most mutations occur during DNA replication, when cells are duplicating their DNA in preparation for cell division. A single cell, a group of cells, or an entire individual may be affected. This last prospect occurs when the changes are made early in development. For example, a mutation affecting the DNA of an individual's sex cells will be inherited by that individual's children. Our understanding of DNA is opening the possibility of diagnosing and correcting some of these problems.

example, a tRNA with the anticodon GGC always carries the amino acid *proline*, whereas a tRNA with the anticodon CGG carries *alanine*. Table 3–1 lists examples of several codons and anticodons that specify individual amino acids and summarizes the relationships among DNA triplets, codons, anticodons, and amino acids.

As we have just described, the tRNA molecules provide the physical link between codons and amino acids. During translation, each codon along the mRNA strand binds a complementary anticodon on a tRNA molecule. For example, if the mRNA has the three-codon sequence AUG–CCG–AGC, it will bind to three tRNAs with anticodons UAC, GGC, and UCG, respectively. The amino acid sequence of the polypeptide chain depends on the resulting sequence of codons along the mRNA strand. In this case, the amino acid sequence in the resulting polypeptide would be methionine–proline–serine. (You can follow the correspondence among codons, anticodons, and amino acids in Table 3–1. For a complete table of mRNA

CGG	GCC	GCC	CGG	Alanine

codons, the amino acids, and the start or stop signals they represent, see the Appendix at the back of the book.)

Recall that ribosomes are organelles that play a key role in protein synthesis. A functional ribosome consists of two subunits, a *small ribosomal subunit* and a *large ribosomal subunit*. At the beginning of the translation process in protein synthesis, a small and a large ribosomal subunit must join together with an mRNA strand. **Figure 3–13** illustrates the three phases of the translation process: *initiation, elongation,* and *termination*.

How the Nucleus Controls Cell Structure and Function

As we noted previously, the DNA of the nucleus controls the cell by directing the synthesis of specific proteins. Through the control of protein synthesis, virtually every aspect of cell structure and function can be regulated. Two levels of control are involved:

- 1. *Direct control.* The DNA of the nucleus has *direct* control over the synthesis of structural proteins, such as cyto-skeletal components, membrane proteins (including receptors), and secretory proteins with various functional roles. By issuing appropriate instructions, in the form of mRNA strands, the nucleus can alter the internal structure of the cell, its sensitivity to substances in its environment, or its secretory functions to meet changing needs.
- 2. *Indirect control.* The DNA of the nucleus has *indirect* control over all other aspects of cellular metabolism, because it regulates the synthesis of enzymes. By ordering or stopping the production of appropriate enzymes, the nucleus can regulate all metabolic activities and functions of the cell. For example, the nucleus can accelerate the rate of glycolysis (p. 80) by increasing the number of needed enzymes in the cytoplasm.

How does the nucleus "know" what genes to activate? We don't have all the answers, but we know that in many cases gene activation or deactivation is triggered by changes in the surrounding cytoplasm. Such changes in the intracellular environment can affect the nucleoplasm enough to turn specific genes on or off. Alternatively, messengers or hormones may enter the nucleus through nuclear pores and bind to specific receptors or promoters along the DNA strands. In other words, continual chemical communication takes place between the cytoplasm and the nucleus. That communication is relatively selective, thanks to the barrier posed by the nuclear envelope and the restrictive characteristics of the nuclear pores.

Of course, continual communication also takes place between the cytoplasm and the extracellular fluid across the plasma membrane, and what crosses the plasma membrane today may alter gene activity tomorrow. In the next section, we will examine how the plasma membrane selectively regulates the passage of materials in and out of the cell.

CHECKPOINT

- **13**. Define gene activation.
- 14. Describe transcription and translation.
- **15**. What process would be affected by the lack of the enzyme RNA polymerase?
- See the blue Answers tab at the back of the book.

3-5 Diffusion is a passive transport mechanism that assists membrane passage

Learning Outcome Describe the processes of cellular diffusion and osmosis, and explain their role in physiological systems.

The plasma membrane is a barrier that isolates the cytoplasm from the extracellular fluid. Because the plasma membrane is effective as a barrier, conditions inside the cell can be much different from conditions outside the cell. However, the barrier cannot be perfect, because cells are not self-sufficient. Each day they require nutrients to provide the energy they need to stay alive and function normally. They also generate waste products that must be removed. Your body has passageways and openings for nutrients, gases, and wastes, but a continuous, relatively uniform membrane surrounds the cell. So how do materials—whether nutrients or waste products—get across the plasma membrane without damaging it or reducing its effectiveness as a barrier?

The key to answering this question is **permeability**, the property of the plasma membrane that determines precisely which substances can enter or leave the cytoplasm. A membrane through which nothing can pass is **impermeable**. A membrane through which any substance can pass without

Figure 3–13 The Process of Translation.

difficulty is **freely permeable**. Plasma membranes are called **selectively permeable**, however, because their permeability lies somewhere between those extremes.

A selectively permeable membrane permits the free passage of some materials and restricts the passage of others. The distinction may be based on size, electrical charge, molecular shape, lipid solubility, or other factors. Cells differ in their permeabilities, depending on the lipids and proteins in the plasma membrane and how these components are arranged.

Passage across the membrane is either passive or active. *Passive processes* move ions or molecules across the plasma membrane with no expenditure of energy by the cell. *Active processes* require that the cell expend energy, generally in the form of ATP.

Elongation ends when the ribosome

intact, and it can interact with other

reaches the stop codon at the end of the

mRNA strand. The mRNA strand remains

ribosomes to create additional copies of

Termination

Elongation

In elongation, amino acids are added one by one to the growing polypeptide chain, as the ribosome moves along the mRNA strand. Translation proceeds swiftly, producing a typical protein in about 20 seconds. Although only two mRNA codons are "read" by a ribosome at any one time, many ribosomes can bind to a single mRNA strand, and a multitude of identical proteins may be quickly and efficiently produced.

We categorize transport processes according to the mechanism involved: diffusion, carrier-mediated transport, and vesicular transport.

Diffusion

Diffusion is a passive process that results from the random motion and collisions of ions and molecules. Driven by thermal energy, ions and molecules are constantly in motion, colliding and bouncing off one another and off obstacles in their paths. The movement is both passive and random: A molecule can bounce in any direction. One result of this continuous random motion is that, over time, the molecules in any given space will tend to become evenly distributed. This distribution process, the net movement of a substance from an area of higher concentration to an area of lower concentration, is called **diffusion**. The difference between the high and low concentrations is a **concentration gradient** (and thus a potential energy gradient). Diffusion tends to eliminate that gradient.

After the gradient has been eliminated, the molecular motion continues, but net movement no longer occurs in any particular direction. (For simplicity, we restrict use of the term *diffusion* to the directional movement that eliminates concentration gradients—a process sometimes called *net diffusion*.) Because diffusion tends to spread materials from a region of higher concentration to one of lower concentration, it is often described as proceeding "down a concentration gradient" or "downhill."

Diffusion in air and water is a slow process, and it is most important over very short distances. A simple, everyday example can give you a mental image of how diffusion works. Consider what happens when you drop a colored sugar cube into water (Figure 3–14). Placing the cube in a large volume of clear water sets up a steep concentration gradient for both ingredients as they dissolve: The sugar and dye concentrations are higher near the cube and negligible elsewhere. As time passes, the dye and sugar molecules spread through the solution until they are distributed evenly. However, compared to a cell, a beaker of water is enormous, and additional factors (which we will ignore) account for dye and sugar distribution over distances of centimeters as opposed to micrometers.

Diffusion is important in body fluids, because it tends to eliminate local concentration gradients. For example, every cell in the body generates carbon dioxide, and the intracellular

Clinical Note

Drugs and the Plasma Membrane Many clinically important drugs affect the plasma membrane. For some anesthetics, such as chloroform, ether, halothane, and nitrous oxide, potency is directly correlated with their lipid solubility. Presumably, high lipid solubility speeds the drug's entry into cells and enhances its ability to block ion channels or change other properties of plasma membranes. These changes reduce the sensitivity of neurons and muscle cells. However, some common anesthetics have relatively low lipid solubility. For example, the local anesthetics, procaine and lidocaine, affect nerve cells by blocking sodium channels in their plasma membranes. This blockage reduces or eliminates the responsiveness of these cells to painful (or any other) stimuli. Both procaine and lidocaine are effective local anesthetics, even though procaine has very low lipid solubility.

concentration is fairly high. Carbon dioxide concentrations are lower in the surrounding interstitial fluid, and lower still in the circulating blood. Plasma membranes are freely permeable to carbon dioxide (CO_2), so CO_2 can diffuse down its concentration gradient. It travels from the cell's interior into the interstitial fluid and then into the bloodstream, for eventual delivery to the lungs.

To be effective, the diffusion of nutrients, waste products, and dissolved gases must keep pace with the demands of active cells. Several important factors influence diffusion rates:

- *Distance*. The shorter the distance, the more quickly concentration gradients are eliminated. In the human body, few cells are farther than 25 μm from a blood vessel.
- *Molecule Size*. The smaller the molecule size, the faster the rate of diffusion. Ions and small organic molecules, such as glucose, diffuse more rapidly than do large proteins.
- *Temperature*. The higher the temperature, the faster the diffusion rate. Diffusion proceeds somewhat more quickly at human body temperature (about 37°C, or 98.6°F) than at cooler environmental temperatures.
- *Concentration Gradient.* The steeper the concentration gradient, the faster diffusion proceeds. When cells become more active, they use more oxygen, so intracellular concentration of oxygen declines. This change increases the concentration gradient for oxygen between the inside of the cell (somewhat low) and the interstitial fluid outside (somewhat high). The rate of oxygen diffusion into the cell then increases.
- Electrical Forces. Opposite electrical charges (+ and -) attract each other, and like charges (+ and + or - and -) repel each other. The inner cellular cytoplasmic surface of the plasma membrane has a net negative charge relative to the exterior surface, due in part to the high concentration

of proteins in the cell. This negative charge tends to attract positive ions from the extracellular fluid into the cell, while repelling the entry of negative ions. For example, interstitial fluid contains higher concentrations of sodium ions (Na⁺) and chloride ions (Cl⁻) than does cytosol. Both the concentration gradient, or *chemical gradient*, and the electrical gradient favor diffusion of the positively charged sodium ions into the cell. In contrast, diffusion of the negatively charged chloride ions into the cell is favored by the chemical gradient, but opposed by the electrical gradient. For any ion, the net result of the chemical and electrical forces acting on it is called the *electrochemical gradient*.

Diffusion across Plasma Membranes

In extracellular fluids, water and dissolved solutes diffuse freely. A plasma membrane, however, acts as a barrier that selectively restricts diffusion: Some substances pass through easily, but others cannot penetrate the membrane. An ion or a molecule can diffuse across a plasma membrane only by (1) crossing the lipid portion of the membrane by simple diffusion or (2) passing through a membrane channel (Figure 3–15).

• *Simple Diffusion.* Alcohol, fatty acids, and steroids can enter cells easily, because they can diffuse through the lipid portions of the membrane. Lipid-soluble drugs, dissolved gases, such as oxygen and carbon dioxide, and

Figure 3–15 Diffusion across the Plasma Membrane. The path a substance takes in crossing a plasma membrane depends on the substance's size and lipid solubility.

water molecules also enter and leave our cells by diffusing through the phospholipid bilayer.

The situation is more complicated for ions and watersoluble compounds, which are not lipid-soluble. To enter or leave the cytoplasm, these substances must pass through a membrane channel.

Channel-Mediated Diffusion. Membrane channels are very small passageways created by transmembrane proteins. On average, the channel is about 0.8 nm in diameter. Water molecules can enter or exit freely, but even a small organic molecule, such as glucose, is too big to fit through the channels. Whether an ion can cross a particular membrane channel depends on many factors, including the size and charge of the ion, the size of the hydration sphere, and interactions between the ion and the channel walls. D p. 40 Leak channels, also called passive channels, remain open and allow ions to pass across the plasma membrane.

The mechanics of diffusion through membrane channels is more complex than simple diffusion. For example, the rate at which a particular ion diffuses across the membrane can be limited by the availability of suitable channels. However, many ions, including sodium, potassium, and chloride, move across the plasma membrane at rates comparable to those for simple diffusion.

Osmosis: A Special Case of Diffusion

The net diffusion of water across a membrane is so important that it has a special name: **osmosis** (oz-MŌ-sis; *osmos*, a push). We will always use the term *osmosis* for the movement of water, and the term *diffusion* for the movement of solutes.

Intracellular and extracellular fluids are solutions with a variety of dissolved materials. Each solute diffuses as though it were the only material in solution. The diffusion of sodium ions, for example, takes place only in response to a concentration gradient for sodium. A concentration gradient for another ion has no effect on the rate or direction of sodium ion diffusion.

Some solutes diffuse into the cytoplasm, others diffuse out, and a few (such as proteins) are unable to diffuse across the plasma membrane at all. Yet if we ignore the individual identities and simply count ions and molecules, we find that the *total* concentration of dissolved ions and molecules on either side of the plasma membrane stays the same. This state of equilibrium persists because a typical plasma membrane is freely permeable to water.

To understand the basis for such equilibrium, consider that whenever a solute concentration gradient exists, a concentration gradient for *water* also exists. Dissolved solute molecules occupy space that would otherwise be taken up by water molecules, so the higher the solute concentration, the lower the water concentration. As a result, water molecules tend to flow across a membrane toward the solution with the higher solute concentration, because this movement is *down* the concentration gradient for water. Water will move until water concentrations—and thus solute concentrations—are the same on either side of the membrane. Remember these basic characteristics of osmosis:

- Osmosis is the diffusion of water molecules across a selectively permeable membrane.
- Osmosis takes place across a selectively permeable membrane that is freely permeable to water, but not freely permeable to solutes.
- In osmosis, water flows across a selectively permeable membrane toward the solution that has the higher concentration of solutes, because that is where the concentration of water is lower.

Osmosis and Osmotic Pressure. Figure 3–16 diagrams the process of osmosis. 1 shows two solutions (A and B), with different solute concentrations, separated by a selectively permeable membrane. As osmosis takes place, water molecules cross the membrane until the solute concentrations in the two solutions are identical (2). For this reason, the volume of solution B increases while that of solution A decreases. The greater the initial difference in solute concentrations, the stronger is the osmotic flow.

The **osmotic pressure** of a solution is an indication of the force with which pure water moves into that solution as a result of its solute concentration. We can measure a solution's osmotic pressure in several ways. For example, an opposing pressure can prevent the osmotic flow of water into the solution. Pushing against a fluid generates **hydrostatic pressure**. In **3** hydrostatic pressure opposes the osmotic pressure of solution B, so no net osmotic flow occurs.

Osmosis eliminates solute concentration differences more rapidly than solute diffusion. Why? In large part this happens because water molecules can also cross a membrane through abundant water channels called *aquaporins*, which exceed the number of solute channels, through which water can also pass. This difference results in a higher membrane permeability for water than for solutes.

Osmolarity and Tonicity. The total solute concentration in an aqueous solution is the solution's **osmolarity**, or **osmotic concentration**. The nature of the solutes, however, is often as important as the total osmolarity. Therefore, when we describe the effects of various osmotic solutions on cells, we usually use the term **tonicity** instead of osmolarity. A solution that does not cause an osmotic flow of water into or out of a cell is called **isotonic** (*iso-*, same + *tonos*, tension).

The terms *osmolarity* and *tonicity* do not always mean the same thing, although they are often used interchangeably. Osmolarity refers to the solute concentration of the solution, but tonicity is a description of how the solution affects

Figure 3–16 Osmosis. The osmotic pressure of solution B is equal to the amount of hydrostatic pressure required to stop the osmotic flow.

the shape of a cell. For example, consider a solution with the same osmolarity as the intracellular fluid, but a higher concentration of one or more individual ions. What happens if you put a cell into this solution? If any of those ions can cross the plasma membrane and diffuse into the cell, the osmolarity of the intracellular fluid will increase, and that of the extracellular solution will decrease. Osmosis will then also occur, moving water into the cell. If the process continues, the cell will gradually inflate like a water balloon. In this case, the extracellular solution and the intracellular fluid were initially equal in osmolarity, but they were not isotonic.

Figure 3–17a shows a red blood cell (RBC) in an isotonic solution, where no osmotic flow takes place and the shape of the cell looks normal. But if you put a red blood cell into a **hypotonic** solution, water will flow into the cell, causing it to swell up like a balloon (**Figure 3–17b**). The cell may eventually burst, releasing its contents. This event is **hemolysis** (*hemo-*, blood + *lysis*, a loosening). In contrast, a cell in a **hypertonic** solution will lose water by osmosis. As it does, the cell shrivels and dehydrates. The shrinking of red blood cells is called **crenation** (**Figure 3–17c**).

It is often necessary to give patients large volumes of fluid to combat severe blood loss or dehydration. The procedure used in many cases is called an intravenous, or IV, drip and the fluids enter a patient's vein. One fluid frequently administered is a 0.9 percent (0.9 g/dL) solution of sodium chloride (NaCl). This solution, called *normal saline*, approximates the normal osmotic concentration of extracellular fluids. It is used because sodium and chloride are the most abundant ions in the extracellular fluid. Little net movement of either ion across plasma membranes takes place, so normal saline is essentially isotonic to body cells. An alternative IV treatment involves the use of an isotonic saline solution containing *dextran*, a carbohydrate that cannot cross plasma membranes. The dextran molecules elevate the osmolarity and osmotic pressure of the blood, and as water enters the blood vessels from the surrounding tissue fluid by osmosis, blood volume increases.

3-6 Carrier-mediated and vesicular transport assist membrane passage

Learning Outcome Describe carrier-mediated transport and vesicular transport mechanisms used by cells to facilitate the absorption or removal of specific substances.

Besides diffusion, substances are taken into or removed from cells in two additional ways: carrier-mediated transport and vesicular transport. *Carrier-mediated transport* requires specialized integral membrane proteins. It can be passive or active, depending on the substance transported and the nature of the transport mechanism. *Vesicular transport* involves moving materials within small membranous sacs, or *vesicles*. Vesicular transport is always an active process.

Carrier-Mediated Transport

In **carrier-mediated transport**, integral proteins bind specific ions or organic substrates and carry them across the plasma membrane. All forms of carrier-mediated transport have the following characteristics, which they share with enzymes:

• *Specificity*. Each carrier protein in the plasma membrane binds and transports only certain substances. For example,

the carrier protein that transports glucose will not transport other simple sugars.

- *Saturation Limits.* The availability of substrate molecules and carrier proteins limits the rate of transport into or out of the cell, just as the availability of substrates and enzymes limits enzymatic reaction rates. When all the available carrier proteins are operating at maximum speed, the carriers are said to be *saturated.* The rate of transport cannot increase further, regardless of the size of the concentration gradient.
- Regulation. Just as enzyme activity often depends on the presence of cofactors, the binding of other molecules, such as hormones, can affect the activity of carrier proteins. For this reason, hormones provide an important means of coordinating carrier protein activity throughout the body. We will examine the interplay between hormones and plasma membranes when we study the endocrine system (Chapter 18) and metabolism (Chapter 25).

Many examples of carrier-mediated transport involve the movement of a single substrate molecule across the plasma membrane. However, a few carrier proteins may move more than one substrate at a time. In **cotransport**, or *symport*, the carrier transports two substances in the same direction

simultaneously, either into or out of the cell. In **countertrans**-**port**, or *antiport*, one substance moves into the cell and the other moves out.

Let's look at two examples of carrier-mediated transport: *facilitated diffusion* and *active transport*.

Facilitated Diffusion

Many essential nutrients, such as glucose and amino acids, are insoluble in lipids and too large to fit through membrane channels. These substances can be passively transported across the membrane by carrier proteins in a process called **facili-tated diffusion** (Figure 3–18). The molecule to be transported must first bind to a **receptor site** on the carrier protein. The shape of the protein then changes, moving the molecule across the plasma membrane and releasing it into the cytoplasm. This takes place without ever creating a continuous open channel between the cell's exterior and interior.

TIPS&TRICKS

To understand the mechanism of cellular channels, think about entering a store that has a double set of automated sliding doors. When you near the first set of automated doors, it opens. As you step onto the mat between the sets of doors, the doors behind you close, trapping you in the vestibule. When you take another step forward, the second set of doors opens, enabling you to enter the store.

As in the case of simple or channel-mediated diffusion, no ATP is expended in facilitated diffusion: The molecules simply move from an area of higher concentration to one of lower concentration. However, once the carrier proteins are saturated, the rate of transport cannot increase, regardless of further increases in the concentration gradient. Facilitated diffusion may occur in either direction across a plasma membrane.

All cells move glucose across their membranes through facilitated diffusion. However, several different carrier proteins are involved. In muscle cells, fat cells, and many other types of cells, the glucose transporter functions only when stimulated by the hormone *insulin*. Inadequate production of this hormone is one cause of *diabetes mellitus*, a metabolic disorder characterized by high blood glucose levels, which we will discuss in Chapter 18.

Active Transport

In **active transport**, a high-energy bond (in ATP or another high-energy compound) provides the energy needed to move ions or molecules across the membrane. Despite the energy cost, active transport offers one great advantage: It does not depend on a concentration gradient. As a result, the cell can import or export specific substrates, *regardless of their intracellular or extracellular concentrations*.

All cells contain carrier proteins called **ion pumps**, which actively transport the cations sodium (Na⁺), potassium (K⁺), calcium (Ca²⁺), and magnesium (Mg²⁺) across their plasma membranes. Specialized cells can transport additional ions, such as iodide (I⁻), chloride (Cl⁻), and iron (Fe²⁺).

Many of these carrier proteins move a specific cation or anion in one direction only, either into or out of the cell. Sometimes, one carrier protein will move more than one kind of ion at the same time. If countertransport occurs, the carrier protein is called an **exchange pump**.

Figure 3–18 Facilitated Diffusion. In facilitated diffusion, a molecule, such as glucose, binds to a specific receptor site on a carrier protein. This binding permits the molecule to diffuse across the plasma membrane. If the direction of the glucose concentration gradient is reversed, then facilitated diffusion would occur in the opposite direction.

The Sodium–Potassium Exchange Pump. Sodium and potassium ions are the principal cations in body fluids. Sodium ion concentrations are high in the extracellular fluids, but low in the cytoplasm. The distribution of potassium in the body is just the opposite: low in the extracellular fluids and high in the cytoplasm. Because of leak channels in plasma membranes, sodium ions slowly diffuse into the cell, and potassium ions diffuse out. Homeostasis within the cell depends on removing sodium ions and recapturing lost potassium ions. This exchange takes place by a **sodium–potassium exchange pump**. The carrier protein involved in the process is called *sodium–potassium ATPase*.

The sodium-potassium exchange pump exchanges intracellular sodium for extracellular potassium (Figure 3–19). On average, for each ATP molecule consumed, three sodium ions are ejected and two potassium ions are reclaimed by the cell. If ATP is readily available, the rate of transport depends on the concentration of sodium ions in the cytoplasm. When the concentration rises, the pump becomes more active. The energy demands are impressive: Sodiumpotassium ATPase may use up to 40 percent of the ATP produced by a resting cell!

Secondary Active Transport. In **secondary active transport**, the transport mechanism itself does not require energy from ATP, but the cell often needs to expend ATP at a later time to

Figure 3–19 The Sodium–Potassium Exchange Pump. The operation of the sodium–potassium exchange pump is an example of active transport. For each ATP converted to ADP, this carrier protein pump, also called sodium–potassium ATPase, carries three Na⁺ out of the cell and two K⁺ into the cell.

preserve homeostasis. As with facilitated diffusion, a secondary active transport mechanism moves a specific substrate down its concentration gradient. Unlike the proteins in facilitated diffusion, however, these carrier proteins can also move another substrate at the same time, without regard to its concentration gradient. In effect, the concentration gradient for one substance provides the driving force needed by the carrier protein, and the second substance gets a "free ride."

The concentration gradient for sodium ions most often provides the driving force for cotransport mechanisms that move materials into the cell. For example, sodium-linked cotransport is important in the absorption of glucose and amino acids along the intestinal tract. The initial transport activity proceeds without direct energy expenditure, but the cell must then expend ATP to pump the arriving sodium ions out of the cell by using the sodium–potassium exchange pump (Figure 3–20).

Sodium ions are also involved with many countertransport mechanisms. For example, sodium–calcium countertransport keeps intracellular calcium ion concentrations very low.

Vesicular Transport

In **vesicular transport**, materials move into or out of the cell in **vesicles**, small membranous sacs that form at, or fuse with, the plasma membrane. Because these vesicles move tiny droplets of fluid and solutes rather than single molecules, this process is also known as *bulk transport*. The two major types of vesicular transport are *endocytosis* and *exocytosis*.

Endocytosis

We saw earlier in this chapter that extracellular materials can be packaged in vesicles at the cell surface and imported into the cell. This process, called **endocytosis**, involves relatively large volumes of extracellular material. The three major types of endocytosis are (1) receptor-mediated endocytosis, (2) *pinocytosis*, and (3) *phagocytosis*. All three are active processes that require energy in the form of ATP.

The vesicles of endocytosis are generally known as *endo*somes. Endosomes formed by pinocytosis are also called *pi*nosomes, and those formed by phagocytosis are called *phago*somes. Their contents remain isolated from the cytoplasm, trapped within the vesicle. The enclosed materials may move into the surrounding cytoplasm by active transport, simple or facilitated diffusion, or the destruction of the vesicle membrane.

Receptor-Mediated Endocytosis. A highly selective process, **receptor-mediated endocytosis** produces vesicles that contain a specific target molecule in high concentrations. Receptor-mediated endocytosis begins when materials in the extracellular fluid bind to receptors on the membrane surface (Figures 3–21 and Spotlight Figure 3–22). Most receptor

Figure 3–20 Secondary Active Transport. In secondary active transport, glucose transport by a carrier protein will take place only after the carrier has bound two sodium ions. In three cycles, three glucose molecules and six sodium ions are transported into the cytoplasm. The cell then pumps the sodium ions across the plasma membrane by the sodium-potassium exchange pump, at a cost of two ATP molecules.

Figure 3–21 Receptor-Mediated Endocytosis.

SPOTLIGHT Figure 3–22 Overview of Membrane Transport

0

Passive Processes No cellular energy expended

Diffusion

Diffusion is the movement of molecules from an area of higher concentration to an area of lower concentration. That is, the movement occurs down a concentration gradient (high to low).

Factors Affecting Rate: Size of gradient, molecular size, electric charge, lipid solubility, temperature, and the presence of membrane channel proteins

Substances Involved: Gases, small inorganic ions and molecules, lipidsoluble materials

Example:

When the concentration of CO₂ inside a cell is greater than outside the cell, the CO₂ diffuses out of the cell and into the extracellular fluid.

Osmosis

Osmosis is the diffusion of water molecules across a selectively permeable membrane. Movement occurs toward higher solute concentration because that is where the concentration of water is lower. Osmosis continues until the concentration gradient is eliminated.

Factors Affecting Rate: Concentration gradient; opposing pressure

Substances Involved: Water only

Example:

If the solute concentration outside a cell is greater than inside the cell, water molecules will move across the plasma membrane into the extracellular fluid.

Facilitated diffusion

Facilitated diffusion is the movement of materials across a membrane by a carrier protein. Movement follows the concentration gradient.

Factors Affecting Rate: Concentration gradient, availability of carrier proteins

Substances Involved: Glucose and amino acids

Example:

Nutrients that are insoluble in lipids and too large to fit through membrane channels may be transported across the plasma membrane by carrier proteins. Many carrier proteins move a specific substance in one direction only, either into or out of the cell.

Active Processes

Active transport

Receptor-Mediated

Active transport requires carrier proteins that move specific substances across a membrane against their concentration gradient. If the carrier moves one solute in one direction and another solute in the opposite direction, it is called an **exchange pump**.

Factors Affecting Rate: Availability of carrier protein, substrate, and ATP

Substances Involved: Na⁺, K⁺, Ca²⁺, Mg²⁺; other solutes in special cases

Extracellular fluid Sodium-potassium exchange pump 3 Na⁺ 2 K⁺ ATP ADP Cytoplasm

Example: The sodium-potassium exchange pump. One ATP molecule is hydrolyzed for each 3 sodium ions that are ejected from the cell, while 2 potassium ions are reclaimed.

Endocytosis Endocytosis is the packaging of extracellular materials into a vesicle for transport into the cell.

Factors Affecting Rate: Number of receptors on the plasma membrane and the concentration of target molecules

Substances Involved: Target molecules called ligands

Pinocytosis

In **pinocytosis**, vesicles form at the plasma membrane and bring fluids and small molecules into the cell. This process is often called "cell drinking."

Factors Affecting Rate: Stimulus and mechanism not understood

Substances Involved: Extracellular fluid, with dissolved molecules such as nutrients

Phagocytosis

In **phagocytosis**, vesicles form at the plasma membrane to bring solid particles into the cell. This process is often called "cell eating."

Factors Affecting Rate: Presence of pathogens and cellular debris

Substances Involved: Bacteria, viruses, cellular debris, and other foreign material

Example: Large particles are brought into the cell by cytoplasmic extensions (called **pseudopodia**) that engulf the particle and pull it into the cell.

Exocytosis

In **exocytosis**, intracellular vesicles fuse with the plasma membrane to release fluids and/or solids from the cells. Factors Affecting Rate: Stimulus and mechanism incompletely understood

Substances Involved: Fluid and cellular wastes; secretory products from some cells

Material ejected from cell

Cell

Example: Cellular wastes in vesicles are ejected from the cell.

99

molecules are glycoproteins, and each binds a specific ligand, or target molecule, such as a transport protein or a hormone. Some receptors are distributed widely over the surface of the plasma membrane, and others are restricted to specific regions or in depressions on the plasma membrane.

Many important substances, including cholesterol and iron ions (Fe^{2+}), are distributed through the body attached to special transport proteins. These proteins are too large to pass through membrane pores, but they are able to enter cells by receptor-mediated endocytosis.

Pinocytosis. "Cell drinking," or **pinocytosis** (pi-nō-sī-TŌ-sis), is the formation of endosomes filled with extracellular fluid. Most cells carry out pinocytosis. This process is not as selective as receptor-mediated endocytosis, because no receptor proteins are involved. The target appears to be the fluid contents in general, rather than specific bound ligands. In pinocytosis, a deep groove or pocket forms in the plasma membrane and then pinches off (**Spotlight Figure 3–22**). The steps involved are similar to the steps in receptor-mediated endocytosis, except that ligand binding is not involved.

Phagocytosis. "Cell eating," or **phagocytosis** (fag-ō-sī-TŌ-sis), produces phagosomes containing solid objects that may be as large as the cell itself. In this process, cytoplasmic extensions called **pseudopodia** (soo-dō-PŌ-dē-ah; *pseudo-*, false + *podon*, foot; singular *pseudopodium*) surround the object, and their membranes fuse to form a phagosome (**Spotlight Figure 3–22**). This vesicle then fuses with many lysosomes, and lysosomal enzymes digest its contents. Phagocytosis is performed only by specialized cells, such as the *macrophages*, that protect tissues by engulfing bacteria, cell debris, and other abnormal materials.

Exocytosis

Exocytosis (ek-sō-sī-TŌ-sis), introduced in our discussion of the Golgi apparatus, is the functional reverse of endocytosis. In exocytosis, a vesicle formed inside the cell fuses with, and becomes part of, the plasma membrane. When this takes place, the vesicle contents are released into the extracellular environment (**Spotlight Figure 3–22**). The ejected material may be secretory products, such as mucins or hormones, or waste products, such as those accumulating in endocytic vesicles.

In a few specialized cells, endocytosis produces vesicles on one side of the cell that are discharged through exocytosis on the opposite side. This method of bulk transport is common in cells lining capillaries, which use a combination of pinocytosis and exocytosis to transfer fluid and solutes from the bloodstream into the surrounding tissues. This overall transport process is called *vesicular transport*.

CHECKPOINT

- 22. Describe the process of carrier-mediated transport.
- 23. During digestion in the stomach, the concentration of hydrogen ions (H⁺) rises to higher levels than in the cells lining the stomach. Which transport process must be operating?
- 24. Describe endocytosis.
- **25**. Describe exocytosis.
- 26. What is the process called whereby certain types of white blood cells engulf bacteria?
- See the blue Answers tab at the back of the book.

3-7 The membrane potential results from the unequal distribution of positive and negative charges across the plasma membrane

Learning Outcome Explain the origin and significance of the membrane potential.

Recall that the cell's interior has a slight negative charge with respect to the outside. The cause is a slight excess of positive charges (due to cations) outside the plasma membrane, and a slight excess of negative charges (due primarily to negatively charged proteins) along the cytoplasmic side of the plasma membrane and inside the cell. This unequal charge distribution is created by differences in the permeability of the membrane to various ions, as well as by active transport mechanisms.

The positive and negative charges are attracted to each other and would normally rush together, but the plasma membrane keeps them apart. When positive and negative charges are held apart, a **potential difference** exists between them. We refer to the potential difference across a plasma membrane as the **membrane potential**, also called the **transmembrane potential**.

The unit of measurement of potential difference is the *volt* (V). Most cars, for example, have 12-V batteries. The membrane potentials of cells are much smaller, typically in the vicinity of 0.07 V. Such a value is usually expressed as 70 mV, or 70 *millivolts* (thousandths of a volt).

The membrane potential in an undisturbed cell is called the **resting membrane potential**. Each type of cell has a characteristic resting membrane potential between -10 mV (-0.01 V) and -100 mV (-0.1 V), with the minus sign signifying that the cytoplasm and inner surface of the plasma membrane (cell) contains an excess of negative charges compared with the outside. Examples include fat cells (-40 mV), thyroid cells (-50 mV), neurons (-70 mV), skeletal muscle cells (-85 mV), and cardiac muscle cells (-90 mV).

If the lipid barrier were removed, the positive and negative charges would rush together and the potential difference would be eliminated. Instead, the plasma membrane acts like a dam across a stream. Just as a dam resists the water pressure that builds up on the upstream side, a plasma membrane resists electrochemical forces that would otherwise drive ions into or out of the cell. The water retained behind a dam and the ions held on either side of the plasma membrane have *potential energy*—stored energy that can be released to do work. People have designed many ways to use the potential energy stored behind a dam-for example, turning a mill wheel or a turbine. Similarly, cells have ways of using the potential energy stored in the membrane potential. For example, changes in the membrane potential make possible the transmission of information in the nervous system, and thus our perceptions and thoughts. As we will see in later chapters, changes in the membrane potential also trigger the contractions of muscles and the secretions of glands.

CHECKPOINT

- 27. What is the membrane potential, and in what units is it expressed?
- 28. If the plasma membrane were freely permeable to sodium ions (Na⁺), how would the membrane potential be affected?

See the blue Answers tab at the back of the book.

3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis

Learning Outcome Describe the stages of the cell life cycle, including mitosis, interphase, and cytokinesis, and explain their significance.

The period between fertilization and physical maturity involves tremendous changes in organization and complexity. At fertilization, a single cell is all there is, but at maturity, your body has about 75 trillion cells. This amazing transformation involves a form of cellular reproduction called **cell division**. A single cell divides to produce a pair of **daughter cells**, each half the size of the original. Before dividing, each daughter cell will grow to the size of the original cell.

Even when development is complete, cell division continues to be essential to survival. Cells are highly adaptable, but physical wear and tear, toxic chemicals, temperature changes, and other environmental stresses can damage them. And, like individuals, cells age. The life span of a cell varies from hours to decades, depending on the type of cell and the stresses involved. Many cells apparently self-destruct after a certain period of time because specific "suicide genes" in the nucleus are activated. This genetically controlled death of cells is called **apoptosis** (ap-op- $T\bar{O}$ -sis; *apo-*, separated from + *ptosis*, a falling). Researchers have identified several genes involved in the regulation of this process. For example, a gene called *bcl-2* produces a regulator protein that appears to prevent apoptosis and to keep a cell alive and functional. If something interferes with the function of this gene, the cell self-destructs.

Because a typical cell does not live nearly as long as a typical person, cell populations must be maintained over time by cell division. For cell division to be successful, the genetic material in the nucleus must be duplicated accurately, and one copy must be distributed to each daughter cell. The duplication of the cell's genetic material is called **DNA replication**, and nuclear division is called **mitosis** (mī-TŌ-sis). Mitosis occurs during the division of somatic cells. The production of sex cells involves a different process, **meiosis** (mī-Ō-sis), described in Chapter 28.

DNA Replication

Recall that each DNA molecule consists of a pair of DNA strands joined by hydrogen bonds between complementary nitrogenous bases. ⊃ p. 56 DNA replication begins when enzymes called *helicases* unwind the strands and disrupt the weak hydrogen bonds between the bases. As the strands unwind, molecules of **DNA polymerase** bind to the exposed nitrogenous bases. This enzyme (1) promotes bonding between the nitrogenous bases of the DNA strand and complementary DNA nucleotides in the nucleoplasm and (2) links the nucleotides by covalent bonds. **Spotlight Figure 3–23** diagrams DNA replication.

Interphase, Mitosis, and Cytokinesis

Spotlight Figure 3–24 (pp. 104–105) depicts the life cycle of a typical cell. That life cycle includes a fairly brief period of mitosis alternating with an *interphase* of variable duration. In a cell preparing to divide, interphase can be divided into the G_1 , S, and G_2 phases. DNA replication takes place during the S phase.

Mitosis is the duplication of the chromosomes in the nucleus and their separation into two identical sets in the process of somatic cell division. Although we describe mitosis in stages, *prophase, metaphase, anaphase,* and *telophase,* it is really one continuous process.

TIPS&TRICKS

In order to remember the correct sequence of events during mitosis, imagine the U-shaped contour rug surrounding your toilet as the P-MAT, for **p**rophase, **m**etaphase, **a**naphase, and **t**elophase.

Cytokinesis is the division of the cytoplasm during mitosis. This process usually begins in late anaphase and continues

SPOTLIGHT Figure 3–23 DNA Replication

Segment 2

DNA replication begins when helicase enzymes unwind the strands and disrupt the hydrogen bonds between the bases. As the strands unwind, molecules of **DNA polymerase** bind to the exposed nitrogenous bases. This enzyme (1) promotes bonding between the nitrogenous bases of each separated strand with complementary DNA nucleotides in the nucleoplasm and (2) links the nucleotides by covalent bonds.

Thus, a second molecule of DNA polymerase must bind closer to the point of unzipping and assemble a complementary copy that grows in sequence until it bumps into the segment created by the first DNA polymerase. Enzymes called ligases (liga, to tie) then splice together the two DNA segments.

DNA polymerase on the other polymerase to bind to it must work from left to right, adding nucleotides in the sequence 12345. But as the original strands continue to unzip, additional nucleotides are continuously exposed. This molecule of DNA polymerase cannot go into reverse. It can only continue working from left to right.

Eventually, the unzipping completely separates the original strands. The copying and last splicing are completed, and two identical DNA molecules are formed. Once the DNA has been replicated, the centrioles duplicated, and the necessary enzymes and proteins have been synthesized, the cell leaves interphase and is ready to proceed to mitosis.

Duplicated DNA double helices

throughout telophase, producing two daughter cells.. The completion of cytokinesis marks the end of cell division, creating two separate and complete cells, each surrounded by its own plasma membrane.

The Mitotic Rate and Energy Use

The preparations for cell division that take place between G_1 and mitosis are difficult to recognize in a light micrograph. However, the start of mitosis is easy to recognize, because the chromosomes become condensed and highly visible. The frequency of cell division in a tissue can be estimated by the number of cells in mitosis at any time. As a result, we often use the term **mitotic rate** when we discuss rates of cell division. In general, the longer the life expectancy of a cell type, the slower the mitotic rate. Long-lived cells, such as muscle cells and neurons, either never divide or do so only under special circumstances. Other cells, such as those covering the surface of the skin or the lining of the digestive tract, are subject to attack by chemicals, pathogens, and abrasion. They survive for only days or even hours. Special cells called **stem cells** maintain these cell populations through repeated cycles of cell division.

Stem cells are relatively unspecialized. Their only function is to produce daughter cells. Each time a stem cell divides, one of its daughter cells develops functional specializations while the other prepares for further stem cell divisions. The rate of stem cell division can vary with the type of tissue and the demand for new cells. In heavily abraded skin, stem cells may divide more than once a day, but stem cells in adult connective tissues may remain inactive for years.

Dividing cells use an unusually large amount of energy. For example, they must synthesize new organic materials and move organelles and chromosomes within the cell. All these processes require ATP in substantial amounts. Cells that do not have adequate energy sources cannot divide. In a person who is starving, normal cell growth and maintenance grind to a halt. For this reason, prolonged starvation stunts childhood growth, slows wound healing, lowers resistance to disease, thins the skin, and changes the lining of the digestive tract.

CHECKPOINT

- Give the biological terms for (a) cellular reproduction and (b) cellular death.
- **30**. What enzymes must be present for DNA replication to proceed normally?
- 31. Describe interphase, and identify its stages.
- **32**. A cell is actively manufacturing enough organelles to serve two functional cells. This cell is probably in what phase of its life cycle?
- 33. Define mitosis, and list its four stages.
- 34. What would happen if spindle fibers failed to form in a cell during mitosis?

See the blue Answers tab at the back of the book.

TIPS&TRICKS

When considering the relative length of time that a cell spends in interphase compared to mitosis, think about taking a test. You prepare a long time (interphase) for something that happens quickly (mitosis).

3-9 Several growth factors affect the cell life cycle

Learning Outcome Discuss the regulation of the cell life cycle.

In normal adult tissues, the rate of cell division balances the rate of cell loss or destruction. Mitotic rates are genetically controlled, and many different stimuli may be responsible for activating genes that promote cell division. Some of the stimuli are internal, and many cells set their own pace of mitosis and cell division.

An important internal trigger is the level of **M-phase pro-moting factor (MPF)**, also known as *maturation-promoting factor*. MPF is assembled from two parts: a cell division cycle protein called *Cdc2* and a second protein called *cyclin*. Cyclin levels climb as the cell life cycle proceeds. When levels are high enough, MPF appears in the cytoplasm and mitosis gets underway.

Various natural body substances, such as hormones, peptides, or nutrients, derived from food can stimulate the division of specific types of cells. These substances are known as **growth factors**. Table 3–2 on p. 106 lists some of these chemical factors and their target tissues. We will discuss them in later chapters.

Researchers have identified genes that inhibit cell division. Such genes are known as *repressor genes*. One gene, called p53, synthesizes a protein that binds to DNA in the nucleus. The binding, in turn, activates another gene that directs the production of growth-inhibiting factors inside the cell. Roughly half of all cancers are associated with abnormal forms of the p53 gene.

There are indications that in humans, the *number* of cell divisions that a cell and its descendants undergoes is regulated at the chromosome level by structures called **telomeres**. Telomeres are terminal segments of DNA with associated proteins. These DNA-protein complexes bend and fold repeatedly to form caps at the ends of chromosomes, much like the plastic sheaths on the tips (aglets) of shoestrings. Telomeres have several functions, notably to attach chromosomes to the nuclear matrix and to protect the ends of the chromosomes from damage during mitosis. The telomeres themselves, however, are subject to wear and tear over the years. Each time a cell divides during adult life, some of the repeating segments break off, and the telomeres get shorter. When they get too short, repressor gene activity signals the cell to stop dividing.

SPOTLIGHT Figure 3–24 Stages of a Cell's Life Cycle

INTERPHASE

Most cells spend only a small part of their time actively engaged in cell division. Somatic cells spend the majority of their functional lives When the activities of G_1 have been completed, in a state known as interphase. During the cell enters the **S phase**. Over the next 6-8 interphase, a cell performs all its normal hours, the cell duplicates its chromosomes. functions and, if necessary, prepares This involves DNA replication and the for cell division. synthesis of histones and other proteins in the nucleus. A cell that is ready to divide first enters the G1 6 to 8 hours phase. In this phase, the cell Once DNA makes enough mitochondria, replication has S cytoskeletal elements, endoplasmic ended, there is a DNA reticula, ribosomes, Golgi membrief (2-5-hour) G2 phase replication, branes, and cytosol for two devoted to last-minute protein synthesis functional cells. An interphase cell in the **G**₀ **phase** is not preparing for division, but is performing all of the other functions appropriate for that particular cell type. Some mature cells, such as skeletal muscle cells and most neurons, remain in G_{n} indefinitely and never divide. In contrast, stem cells, which divide repeatedly with very brief interphase periods, never enter $G_{0.}$

During interphase, the DNA strands are loosely coiled and chromosomes cannot be seen.

Watch the Mastering $A\&P^{\circ} > A\&PFlix$ on Mitosis.

MITOSIS AND CYTOKINESIS

The M phase of the cell cycle includes mitosis and cytokinesis. Mitosis separates the duplicated chromosomes of a cell into two identical nuclei. The term mitosis specifically refers to the division and duplication of the cell's nucleus; division of the cytoplasm to form two distinct new cells involves a separate but related process known as cytokinesis.

Prophase (PRŌ-fāz; pro, before) begins when the chromosomes coil so tightly they become visible as single structures under a light microscope. An array of microtubules called spindle fibers extends between the centriole pairs. Smaller microtubules called astral rays radiate into the cytoplasm.

As a result of DNA replication during the S phase, two copies of each chromosome now exist. Each copy, called a chromatid (KRŌ-ma-tid), is connected to its duplicate copy at a single point, the centromere (SEN-tro-mer). Kinetochores (ki-NĒ-tō-korz) are the protein-bound areas of the centromere; they attach to spindle fibers forming chromosomal microtubules.

Metaphase (MET-a-fāz; meta, after) begins as the chromatids move to a narrow central zone called the metaphase plate. Metaphase ends when all the chromatids are aligned in the plane of the metaphase plate.

Anaphase (AN-a-fāz; ana-, apart) begins when the centromere of each chromatid pair splits and the chromatids separate. The two daughter chromosomes are now pulled toward opposite ends of the cell along the chromosomal microtubules.

The two daughter

chromosomes are pulled apart and drawn

to opposite ends of the

During telophase (TELō-fāz; telo-, end), each new cell prepares to return to the interphase state. The nuclear membranes re-form, the nuclei enlarge, and the chromosomes gradually uncoil. This stage marks the end of mitosis.

Cytokinesis is the division of the cytoplasm into two daughter cells. Cytokinesis usually begins with the formation of a cleavage furrow and continues throughout telophase. The completion of cytokinesis marks the end of cell division.

Table 3–2 Chemical	Chemical Factors Affecting Cell Division				
Factor	Sources	Effects	Targets		
M-phase promoting factor (maturation-promoting factor	Forms within cytoplasm from r) (MPF) Cdc2 and cyclin	n Initiates mitosis	Regulatory mechanism active in all dividing cells		
Growth hormone	Anterior lobe of the pituitary gland	Stimulation of growth, cell division, differentiation	All cells, especially in epithelial and connective tissues		
Prolactin	Anterior lobe of the pituitary gland	Stimulation of cell growth, division, development	Gland and duct cells of mammary glands		
Nerve growth factor (NGF)	Salivary glands; other sources suspected	s Stimulation of nerve cell repair and development	Neurons and neuroglia		
Epidermal growth factor (EG	F) Duodenal glands; other sources suspected	Stimulation of stem cell divisions and epithelial repairs	Epidermis		
Fibroblast growth factor (FG	•) Wide range of cells	Division and differentiation of fibroblasts and related cells	Connective tissues		
Erythropoietin (EPO)	Kidneys (primary source)	Stimulation of stem cell divisions and maturation of red blood cells	Red bone marrow		
Thymosins and related compounds	Thymus	Stimulation of division and differentiation of lymphocytes (especially T cells)	Thymus and other lymphoid tissues and organs		
Chalones	Many tissues	Inhibition of cell division	Cells in the immediate area		

CHECKPOINT

35. Define growth factor, and identify several growth factors that affect cell division.

See the blue Answers tab at the back of the book.

3–10 Tumors and cancers are characterized by abnormal cell growth and division

Learning Outcome Discuss the relationship between cell division and cancer.

When the rates of cell division and growth exceed the rate of cell death, a tissue begins to enlarge. A **tumor**, or *neoplasm*, is a mass or swelling produced by abnormal cell growth and division. In a *benign tumor*, the cells usually remain within the epithelium (one of the four primary tissue types) or a connective tissue capsule. Such a tumor seldom threatens an individual's life and can usually be surgically removed if its size or position disturbs tissue function.

Cells in a *malignant tumor* no longer respond to normal controls. These cells do not remain confined within the epithelium or a connective tissue capsule, but spread into surrounding tissues. The tumor of origin is called the *primary tumor* (or *primary neoplasm*), and the spreading process is called **invasion**. Malignant cells may also travel to distant tissues and organs and establish *secondary tumors*. This dispersion, called **metastasis** (me-TAS-ta-sis; *meta-*, after + *stasis*, standing still), is very difficult to control. **Cancer** is an illness that results from the abnormal proliferation of any of the cells in the body. It is characterized by mutations that disrupt normal cell regulatory controls and produce potentially malignant cells. Normal cells begin the path to becoming malignant when a mutation occurs in a gene involved with cell growth, differentiation, or division. The modified genes are called **oncogenes** (ON-kō-gēn*z; oncōs,* tumor).

Agents that cause a mutation (a change in DNA) are called **mutagens**. Cancer-causing agents, which include many mutagens, are known as **carcinogens**. Examples of carcinogens include radiation, chemicals, bacteria, and viruses. Some chemical carcinogens, such as alcohol and estrogen, are not directly mutagenic. Instead, they promote cancer by promoting rapid cell divisions, which increase the chances that a mutation will occur.

Normal cells become malignant in a multistep process. For example, a mutation may occur in one cell, which is passed on to its daughter cells. One of those cells may undergo another mutation that speeds its rate of cell division. Further growth promoting mutations in one of those cells and its proliferating descendants may produce a primary tumor. The tumor now contains descendants of the original abnormal cell that have been selected for rapid growth. While these tumor cells are ultimately all descended from one abnormal cell, they are not identical to it due to their accumulated mutations.

Cancer cells do not resemble normal cells. They have a different shape and typically become abnormally larger or smaller. Malignant tumor cells are also less subject to controls limiting adhesion and movement between adjacent cells

Figure 3–25 The Development of Cancer.

and extracellular tissues. At first, the growth of the primary tumor distorts the tissue, but the basic tissue organization remains intact. Metastasis begins with invasion as malignant cells "break out" of the primary tumor and invade the surrounding tissue. They may then enter the lymphatic system and accumulate in nearby lymph nodes. When metastasis involves the penetration of blood vessels, the cancer cells circulate throughout the body. Cancer progresses in the steps diagrammed in Figure 3–25.

Responding to cues that are as yet unknown, cancer cells in the bloodstream ultimately escape out of blood vessels to establish secondary tumors at other sites. The cancer cells in these tumors are extremely active metabolically, and their presence stimulates the growth of new blood vessels (*angiogenesis*) into the area. The increased blood supply provides additional nutrients to the cancer cells and further accelerates tumor growth and metastasis.

As malignant tumors grow, organ function begins to deteriorate. The malignant cells may no longer perform their original functions, or they may perform normal functions in an abnormal way. For example, endocrine cancer cells may produce normal hormones, but in excessively large amounts.

Cancer cells do not use energy very efficiently. They grow and multiply at the expense of healthy tissues, competing for space and nutrients with normal cells. This competition contributes to the starved appearance of many patients in the late stages of cancer. Death may result from the compression of vital organs when nonfunctional cancer cells have killed or replaced the healthy cells in those organs, or when the cancer cells have starved normal tissues of essential nutrients. We will discuss cancer further in later chapters that deal with specific systems.

CHECKPOINT

 An illness characterized by mutations that disrupt normal control mechanisms and produce potentially malignant cells is termed _____.

37. Define metastasis.

See the blue Answers tab at the back of the book.

Clinical Note

Telomerase, Aging, and Cancer Each telomere contains a sequence of about 8000 nitrogenous bases, but they are multiple copies of the same six-base sequence, TTAGGG, repeated over and over again. Telomeres are not formed by DNA polymerase. Instead, they are created by an enzyme called *telomerase*. Telomerase is functional early in life, but by adulthood it has become inactive. As a result, the telomere segments lost during each mitotic division are not replaced. Eventually, shortening of the telomere reaches a point at which the cell no longer divides.

This mechanism is a factor in the aging process, since many of the signs of age result from the gradual loss of functional stem cell populations. Experiments are in progress to determine whether activating telomerase (or a suspected alternative repair enzyme) can forestall or reverse the effects of aging. This would seem to be a very promising area of research. Activate telomerase, and halt aging—sounds good, doesn't it? Unfortunately, there's a catch: In adults, telomerase activation is a key step in the development of cancer.

If for some reason a cell with short telomeres does not respond normally to repressor genes, it will continue to divide. The result is mechanical damage to the DNA strands, chromosomal abnormalities, and mutations. Interestingly, one of the first consequences of such damage is the abnormal activation of telomerase. Once this occurs, the abnormal cells can continue dividing indefinitely. Telomerase is active in at least 90 percent of all cancer cells. Research is underway to find out how to turn off telomerase that has been improperly activated.

Clinical Note

Parkinson's Disease In most cases, differentiation is irreversible. Once genes are turned off, they won't be turned back on. However, some cells, such as stem cells, are relatively undifferentiated. These cells can differentiate into any of several different types of cell, depending on local conditions. For example, if nutrients are abundant, stem cells in many parts of the body can differentiate into fat cells. Researchers are gradually discovering what chemical cues and genes control the differentiation of specific cell types. Recently, this research has resulted in the ability to "turn back the clock" in some types of adult somatic cells and reprogram them into a form of stem cells called *induced pluripotent stem (iPS) cells*. The ability to take a person's stem cells or somatic cells and create new cells or neurons to treat disease may one day revolutionize the practice of medicine. **Parkinson's disease** is a neurodegenerative disease characterized by progressive degeneration and loss of dopamine-producing neurons. (Dopamine is one kind of neurotransmitter, a substance that one neuron releases to communicate with other neurons.) Parkinson's disease may be the first disorder suited to treatment by implanting stem cells. Several laboratories have induced either iPS cells or *embryonic stem cells* to differentiate into cells that function as dopamine-producing neurons. In studies on animal models, both iPS and embryonic stem cell-derived dopamine neurons reinnervated the brains of rats with Parkinson's disease. These cells also released dopamine and improved motor function.

3–11 Differentiation is cellular specialization as a result of gene activation or repression

Learning Outcome Define differentiation, and explain its importance.

An individual's liver cells, fat cells, and neurons all contain the same chromosomes and genes, but in each case a different set of genes has been turned *off*. In other words, your liver cells and fat cells differ because liver cells have one set of genes accessible for transcription, and fat cells another.

When a gene is functionally eliminated, the cell loses the ability to produce a particular protein—and to perform any functions involving that protein. Each time another gene switches off, the cell's functional abilities become more restricted. This development of specific cellular characteristics and functions that are different from the original cell is called **differentiation**.

Fertilization produces a single cell with all its genetic potential intact. Repeated cell divisions follow, and differentiation begins as the number of cells increases. Differentiation produces specialized cells with limited capabilities. These cells form organized collections known as *tissues*, each with discrete functional roles. In Chapter 4, we will examine the structure and function of tissues and consider the role of tissue interactions in maintaining homeostasis.

CHECKPOINT

38. Define differentiation.

• See the blue Answers tab at the back of the book.

Related Clinical Terms

- **anaplasia:** An irreversible change in the size and shape of tissue cells.
- **dysplasia:** A reversible change in the normal shape, size, and organization of tissue cells.
- **genetic engineering:** A general term that encompasses attempts to change the genetic makeup of cells or organisms, including humans.
- **hyperplasia:** An increase in the number of normal cells (not tumor formation) in a tissue or organ, thus enlarging that tissue or organ.
- **hypertrophy:** The enlargement of an organ or tissue due to an increase in the size of its cells.

- **liposome:** A minute spherical sac of lipid molecules enclosing a water droplet. Often formed artificially to carry drugs into the tissues.
- **necrosis:** Death of one or more cells in an organ or tissue due to disease, injury, or inadequate blood supply.
- **oncologist:** Physician who specializes in the identification and treatment of cancers.
- **prion:** A protein particle that is not visible microscopically, contains no nucleic acid, is resistant to destruction, and is thought to be the cause of some brain diseases such as bovine spongiform encephalopathy (BSE), scrapie, and Creutzfeldt-Jakob disease.

- **scanning electron micrograph (SEM):** An image produced by an electron microscope in which a beam of focused electrons moves across an object with that object producing secondary electrons that are scattered and formatted into a three-dimensional image on a cathode-ray tube—also called *scanning microscope*.
- **transmission electron micrograph (TEM):** A cross-sectional image produced by an electron microscope that passes a beam of electrons through an extremely small specimen. After passing through the sample the electrons are focused to form a magnified sectional view.

An Introduction to Cells p. 65

- Contemporary *cell theory* incorporates several basic concepts:

 Cells are the building blocks of all plants and animals;
 cells are produced by the division of preexisting cells;
 cells are the smallest units that perform all vital physiological functions; and (4) each cell maintains homeostasis
 - at the cellular level. (*Spotlight Figure 3–1*)
- 2. Cytology, the study of cellular structure and function, is part of cell biology.
- 3. The human body contains two types of cells: sex cells (*sperm* and *oocytes*) and somatic cells (all other cells). (*Spotlight Figure* 3–1)
- 3-1 The plasma membrane separates the cell from its surrounding environment and performs various functions p. 65
- 4. A typical cell is surrounded by **extracellular fluid**—specifically, the **interstitial fluid** of the tissue. The cell's outer boundary is the **plasma membrane (cell membrane)**.
- 5. The plasma membrane's functions include physical isolation, regulation of exchange with the environment, sensitivity to the environment, and structural support. (*Figure 3–2*)
- 6. The plasma membrane is a **phospholipid bilayer**, which contains other lipids, proteins, and carbohydrates.
- 7. Integral proteins are part of the membrane itself; peripheral proteins are attached to, but can separate from, the membrane.
- Membrane proteins can act as anchors (anchoring proteins), identifiers (recognition proteins), enzymes, receptors (receptor proteins), carriers (carrier proteins), or channels.
- 9. The **glycocalyx** on the outer cell surface is formed by the carbohydrate portions of *proteoglycans*, *glycoproteins*, and *glycolipids*. Functions include lubrication and protection, anchoring and locomotion, specificity in binding, and recognition.

- **3-2** Organelles within the cytoplasm perform particular functions p. 70
- **10.** The **cytoplasm** contains the fluid **cytosol** and the **organelles** suspended in the cytosol.
- **11.** Cytosol (intracellular fluid) differs from extracellular fluid in composition and in the presence of **inclusions**.
- **12.** Nonmembranous organelles are not completely enclosed by membranes, and all of their components are in direct contact with the cytosol. They include the *cytoskeleton, microvilli, centrioles, cilia, ribosomes,* and *proteasomes.* (*Spotlight Figure 3–1*)
- **13.** Membranous organelles are surrounded by phospholipid membranes that isolate them from the cytosol. They include the *endoplasmic reticulum*, the *Golgi apparatus*, *lysosomes*, *peroxisomes*, *mitochondria*, and *nucleus*. (*Spotlight Figure 3–1*)
- 14. The cytoskeleton gives the cytoplasm strength and flexibility. It has four components: microfilaments (typically made of actin), intermediate filaments, microtubules (made of tubulin), and thick filaments (made of myosin). (*Figure 3–3*)
- **15.** Microvilli are small projections of the plasma membrane that increase the surface area exposed to the extracellular environment. (*Figure 3–3*)
- **16.** The **centrosome** is a region of the cytoplasm near the nucleus. It is the microtubule organizing center surrounding the paired centrioles. **Centrioles** direct the movement of chromosomes during cell division. (*Figure 3–4*)
- 17. Multiple motile **cilia**, each anchored by a **basal body**, beat rhythmically to move fluids or secretions across the cell surface. A single **primary cilium** is sensitive to environmental stimuli. (*Figure 3–4*)
- **18. Ribosomes**, responsible for manufacturing proteins, are composed of a **small** and a **large ribosomal subunit**, both of which contain **ribosomal RNA (rRNA)**. **Free ribosomes** are in the cytoplasm, and **fixed ribosomes** are attached to the endoplasmic reticulum. (*Spotlight Figure 3–1*)
- **19. Proteasomes** remove and break down damaged or abnormal proteins that have been tagged with *ubiquitin*.
- 20. The endoplasmic reticulum (ER) is a network of intracellular membranes that function in synthesis, storage, transport, and detoxification. The ER forms hollow tubes, flattened sheets, and chambers called cisternae. Smooth endoplasmic reticulum (SER) is involved in lipid synthesis; rough endoplasmic reticulum (RER) contains ribosomes on its outer surface and forms transport vesicles. (*Figure 3–5; Spotlight Figure 3–7*)
- 21. The Golgi apparatus, or Golgi complex, forms secretory vesicles and new plasma membrane components, and packages *lysosomes*. Secretions are discharged from the cell by exocytosis. (*Figure 3–6*; *Spotlight Figure 3–7*)

- 22. Lysosomes, vesicles filled with digestive enzymes, are responsible for the **autolysis** of injured cells. (*Figures 3–6, 3–8; Spotlight Figure 3–7*)
- **23. Peroxisomes** carry enzymes that neutralize potentially dangerous free radicals.
- 24. Membrane flow refers to the continuous movement and recycling of the membrane among the ER, vesicles, the Golgi apparatus, and the plasma membrane.
- **25. Mitochondria** are responsible for ATP production through aerobic metabolism. The **matrix**, or fluid contents of a mitochondrion, lies inside the **cristae**, or folds of an inner membrane. (*Figure 3–9*)

3-3 The nucleus contains DNA and enzymes essential for controlling cellular activities p. 82

- **26.** The **nucleus** is the control center of cellular operations. It is surrounded by a **nuclear envelope** (a double membrane with a **perinuclear space**), through which it communicates with the cytosol by way of **nuclear pores.** (*Spotlight Figure 3–1; Figure 3–10*)
- 27. The nucleus contains a supportive **nuclear matrix**; one or more **nucleoli** typically are present.
- **28.** The nucleus controls the cell by directing the synthesis of specific proteins, using information stored in **chromosomes**, which consist of DNA bound to **histones**. In nondividing cells, DNA and associated proteins form a tangle of filaments called **chromatin**. (*Figure 3–11*)
- **29.** The cell's information storage system, the **genetic code**, is called a *triplet code* because a sequence of three nitrogenous bases specifies the identity of a single amino acid. Each **gene** contains all the DNA triplets needed to produce a specific polypeptide chain.

3-4 DNA controls protein synthesis, cell structure, and cell function p. 84

- **30.** As **gene activation** begins, **RNA polymerase** must bind to the gene.
- 31. Transcription is the production of RNA from a DNA template. After transcription, a strand of messenger RNA (mRNA) carries instructions from the nucleus to the cytoplasm. (*Figure 3–12*)
- **32.** During **translation**, a functional polypeptide is constructed using the information contained in the sequence of **codons** along an mRNA strand. The mRNA codons correspond to DNA triplets. The sequence of codons determines the sequence of amino acids in the polypeptide.
- **33.** During translation, complementary base pairing of **anticodons** to mRNA codons occurs, and **transfer RNA (tRNA)** molecules bring amino acids to the ribosomal complex. Translation includes three phases: **initiation**, **elongation**, and **termination**. (*Spotlight Figure 3–13; Table 3–1*)
- 34. By controlling protein synthesis, the DNA of the nucleus has both direct control (through the synthesis of structural proteins) and indirect control (through the synthesis of enzymes) over the structure and functions of the cell.

3-5 Diffusion is a passive transport mechanism that assists membrane passage p. 87

35. The **permeability** of a barrier such as the plasma membrane is an indication of the barrier's effectiveness. Nothing can pass through an **impermeable** barrier; anything can pass through a **freely permeable** barrier. Plasma membranes are **selectively permeable**.

- **36.** Diffusion is the net movement of a substance from an area of higher concentration to an area of lower concentration. Diffusion occurs until the concentration gradient is eliminated. (*Figures 3–14, 3–15*)
- **37.** Most lipid-soluble materials, water, and gases freely diffuse across the phospholipid bilayer of the plasma membrane. Small water-soluble molecules and ions rely on channel-mediated diffusion through a passageway within a transmembrane protein. **Leak channels** are passive channels that allow ions across the plasma membrane.
- 38. Osmosis is the net flow of water across a selectively permeable membrane in response to differences in solute concentration. Osmotic pressure of a solution is the force of water movement into that solution resulting from its solute concentration. Hydrostatic pressure can oppose osmotic pressure. (*Figure 3-16*)
- **39.** Tonicity describes the effects of osmotic solutions on cells. A solution that does not cause an osmotic flow is isotonic. A solution that causes water to flow into a cell is hypotonic and can lead to hemolysis of red blood cells. A solution that causes water to flow out of a cell is hypertonic and can lead to crenation. (*Figure 3–17*)

3-6 Carrier-mediated and vesicular transport assist membrane passage p. 94

- **40.** Carrier-mediated transport involves the binding and transporting of specific ions by integral proteins. **Cotransport** moves two substances in the same direction; **countertransport** moves them in opposite directions.
- **41.** In **facilitated diffusion**, compounds are transported across a membrane after binding to a **receptor site** within the channel of a carrier protein. (*Figure 3–18*)
- **42.** Active transport mechanisms consume ATP and are not dependent on concentration gradients. Some ion pumps are exchange pumps. Secondary active transport may involve cotransport or countertransport. (*Figures 3–19, 3–20*)
- **43.** In **vesicular transport**, materials move into or out of the cell in membranous **vesicles**. Movement into the cell is accomplished through **endocytosis**, an active process that can take three forms: **receptor-mediated endocytosis** (by means of **coated vesicles**), **pinocytosis**, or **phagocytosis** (using **pseudopodia**). The ejection of materials from the cytoplasm is accomplished by **exocytosis**. (*Figure 3–21; Spotlight Figure 3–22*)

3-7 The membrane potential results from the unequal distribution of ions across the plasma membrane p. 100

44. The **potential difference**, measured in volts, between the two sides of a plasma membrane is a **membrane (transmembrane) potential**. The membrane potential in an undisturbed cell is the cell's **resting potential**.

3-8 Stages of a cell's life cycle include interphase, mitosis, and cytokinesis p. 101

- **45.** Cell division is the reproduction of cells. Apoptosis is the genetically controlled death of cells. Mitosis is the nuclear division of somatic cells. Sex cells are produced by meiosis. (*Spotlight Figures 3–23, 3–24*)
- 46. Most somatic cells spend the majority of their time in interphase, which includes the G₁, S (DNA replication), and G₂ phases. (*Spotlight Figures 3–23, 3–24*)
- **47.** Mitosis proceeds in four stages: **prophase**, **metaphase**, **anaphase**, and **telophase**. (*Spotlight Figure 3–24*)

3

- **48.** During **cytokinesis**, the cytoplasm is divided to form two daughter cells and cell division ends. (*Spotlight Figure 3–24*)
- **49.** In general, the longer the life expectancy of a cell type, the slower is the **mitotic rate. Stem cells** undergo frequent mitosis to replace other, more specialized cells.

3-9 Several growth factors affect the cell life cycle p. 103

- **50.** A variety of hormones and **growth factors** can stimulate cell division and growth. (*Table 3–2*)
- **3-10** Tumors and cancers are characterized by abnormal cell growth and division p. 106
- **51.** Produced by abnormal cell growth and division, a **tumor**, or *neoplasm*, can be *benign* or *malignant*. Malignant cells may

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. In the following diagram, identify the type of solution (hypertonic, hypotonic, or isotonic) in which the red blood cells are immersed.

- 2. The process that transports solid objects such as bacteria into the cell is called (a) pinocytosis, (b) phagocytosis, (c) exocytosis, (d) receptor-mediated endocytosis, (e) channel-mediated transport.
- Plasma membranes are said to be (a) impermeable, (b) freely permeable, (c) selectively permeable, (d) actively permeable, (e) slightly permeable.
- 4. _____ ion concentrations are high in extracellular fluids, and _____ ion concentrations are high in the cytoplasm.
 (a) Calcium; magnesium, (b) Chloride; sodium,
 (c) Potassium; sodium, (d) Sodium; potassium.
- 5. At resting membrane potential, the inside of the cell is ______ and the cell exterior is ______ (a) slightly negative; slightly positive; slightly negative, (b) slightly positive; slightly negative, (c) slightly positive; neutral; (d) slightly negative; neutral.
- The organelle responsible for a variety of functions centering on the synthesis of lipids and carbohydrates is (a) the Golgi apparatus, (b) the rough endoplasmic reticulum, (c) the smooth endoplasmic reticulum, (d) mitochondria.

spread locally (by **invasion**) or to distant tissues and organs (through **metastasis**). The resultant illness is called **cancer**. Modified genes called **oncogenes** often cause malignancy. (*Figure 3–25*)

3-11 Differentiation is cellular specialization as a result of gene activation or repression p. 108

52. Differentiation, a process of cellular specialization, results from the inactivation of particular genes in different cells, producing populations of cells with limited capabilities. Specialized cells form organized collections called *tissues*, each of which has certain functional roles.

See the blue Answers tab at the back of the book.

- 7. The synthesis of a functional polypeptide by using the information in an mRNA strand is (a) translation, (b) transcription, (c) replication, (d) gene activation.
- Our somatic cell nuclei contain _____ pairs of chromosomes
 (a) 8, (b) 16, (c) 23, (d) 46.
- The movement of water across a membrane from an area of low solute concentration to an area of higher solute concentration is known as (a) osmosis, (b) active transport, (c) diffusion, (d) facilitated transport, (e) filtration.
- 10. The interphase of the cell life cycle is divided into
 (a) prophase, metaphase, anaphase, and telophase,
 (b) G₀, G₁, S, and G₂, (c) mitosis and cytokinesis,
 (d) all of these.
- 11. List the four basic concepts that make up modern-day cell theory.
- 12. What are four general functions of the plasma membrane?
- 13. What are the primary functions of membrane proteins?
- 14. By what three major transport mechanisms do substances get into and out of cells?
- 15. List five important factors that influence diffusion rates.
- **16.** What are the four major functions of the endoplasmic reticulum?

LEVEL 2 Reviewing Concepts

- 17. Diffusion is important in body fluids, because it tends to(a) increase local concentration gradients, (b) eliminate local concentration gradients, (c) move substances against concentration gradients, (d) create concentration gradients.
- Microvilli are found (a) mostly in muscle cells, (b) on the inside of plasma membranes, (c) in large numbers on cells that secrete hormones, (d) in cells that are actively engaged in absorption, (e) only on cells lining the reproductive tract.
- 19. When a cell is placed in a(n) _____ solution, the cell will lose water through osmosis. This process results in the _____ of red blood cells (a) hypotonic; crenation, (b) hypertonic; crenation, (c) isotonic; hemolysis, (d) hypotonic; hemolysis.

- **20.** Suppose that a DNA segment has the following nucleotide sequence: CTC-ATA-CGA-TTC-AAG-TTA. Which nucleotide sequences would a complementary mRNA strand have?
 - (a) GAG-UAU-GAU-AAC-UUG-AAU,
 - (b) GAG-TAT-GCT-AAG-TTC-AAT,
 - (c) GAG-UAU-GCU-AAG-UUC-AAU,(d) GUG-UAU-GGA-UUG-AAC-GGU.
- 21. How many amino acids are coded in the DNA segment in Review Question 20? (a) 18, (b) 9, (c) 6, (d) 3.
- 22. The sodium-potassium exchange pump (a) is an example of facilitated diffusion, (b) does not require the input of cellular energy in the form of ATP, (c) moves the sodium and potassium ions along their concentration gradients, (d) is composed of a carrier protein located in the plasma membrane, (e) is not necessary for the maintenance of homeostasis.
- 23. If a cell lacked ribosomes, it would not be able to (a) move,(b) synthesize proteins, (c) produce DNA, (d) metabolize sugar, (e) divide.
- 24. List, in sequence, the phases of the interphase stage of the cell life cycle, and briefly describe what happens in each.
- **25.** List the stages of mitosis, and briefly describe the events that occur in each.

26. (a) What is cytokinesis? (b) What is the role of cytokinesis in the cell cycle?

LEVEL 3 Critical Thinking and Clinical Applications

- 27. The transport of a certain molecule exhibits the following characteristics (1) The molecule moves down its concentration gradient;(2) at concentrations above a given level, the rate of transport does not increase; and (3) cellular energy is not required for transport to occur. Which transport process is at work?
- **28.** Solutions A and B are separated by a selectively permeable barrier. Over time, the level of fluid on side A increases. Which solution initially had the higher concentration of solute?
- 29. A molecule that blocks the ion channels lining integral proteins in the plasma membrane would interfere with (a) cell recognition, (b) the movement of lipid-soluble molecules, (c) producing changes in the electrical charges across a plasma membrane, (d) the ability of protein hormones to stimulate the cell, (e) the cell's ability to divide.
- **30.** What is the benefit of having some of the cellular organelles enclosed by a membrane similar to the plasma membrane?

CLINICAL CASE

When Your Heart Is in the Wrong Place

Jackson is diagnosed with primary ciliary dyskinesia (*dys*, something wrong with; *kinesia*, movement), an inherited disorder of cilia in every cell where cilia are found in the body. For this reason, his ears, sinuses, airways, and reproductive tract are all affected. Without the sweeping, wavelike motion of cilia to keep the lining of these areas clear of debris and infecting organisms, frequent infections of the ears, nose, throat, sinuses, and lungs occur.

It is thought that the motion of cilia also has something to do with the arrangement of the organs during fetal development. The tech initially thought she had reversed the right/left markers on Jackson's chest x-ray, but it turns out that his heart really is on the wrong side. In fact, all of the organs in Jackson's chest are arranged in a mirror-image of normal, a condition known as *situs inversus*.

Wrap-Up

Because there are only about 25,000 people with primary ciliary dyskinesia in the United States, it is

classified as an "orphan" disease (any disease that affects fewer than 200,000 people). Many orphan diseases are genetic and therefore chronic (long-lasting).

- 1. What other cell, with a "tail" that has the same microtubule structure as motile cilia, might also be affected as a result of Jackson's primary ciliary dyskinesia?
- 2. What other consequences could result from Jackson's disorder once he reaches adulthood?

See the blue Answers tab at the back of the book.

The Tissue Level of Organization

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 4-1 Identify the four major types of tissues in the body and describe their roles.
- **4-2** Discuss the types and functions of epithelial tissue.
- **4–3** Describe the relationship between structure and function for each type of epithelium.
- **4-4** Compare the structures and functions of the various types of connective tissue.
- **4-5** Describe how cartilage and bone function as a supporting connective tissue.
- **4-6** Explain how epithelial and connective tissues combine to form four types of tissue membranes, and specify the functions of each.
- **4-7** Describe how connective tissue establishes the framework of the body.
- **4-8** Describe the three types of muscle tissue and the special structural features of each type.
- **4-9** Discuss the basic structure and role of neural tissue.
- **4-10** Describe how injuries affect the tissues of the body.
- 4-11 Describe how aging affects the tissues of the body.

SPOTLIGHT

• Inflammation and Regeneration p. 145

CLINICAL CASE

• The Rubber Girl p. 114

Clinical Notes

- Exfoliative Cytology p. 120
- Marfan's Syndrome p. 129

CLINICAL CASE

The Rubber Girl

All her life Anne Marie has felt "delicate." She is a horrible athlete. She once dislocated both shoul-

ders attempting to play high school volleyball. And she has an unstable feeling, as if her kneecaps will dislocate, when she tries dancing or any other twisting activity. She sprains one ankle or the other at least once a year. She has always been "double jointed," with fingers that she can bend back until they nearly touch her dorsal forearm. Her elbows and knees all hyperextend, moving beyond their normal anatomical position.

Anne Marie's skin has always been delicate, pale, and very stretchy. She seems to get abrasions and cuts easily. These heal slowly, leaving huge scars that are also fragile. Once, she had stitches in her face and they cut right through the skin. Now she has a wide scar over her eyebrow. She bruises easily, too.

Anne Marie thinks she is a lot like her dad. He has the same easy-bruising skin that seems to tear with minimal trauma and heal poorly. He was never very athletic and is also loose jointed. He has twisted both ankles many times. Luckily he has a desk job. What

is the cause of Anne Marie's unusual physical traits? To find out, turn to the Clinical Case Wrap-Up on p. 149.

An Introduction to the Tissue Level of Organization

In this chapter we discuss how a variety of cell types arranged in various combinations form *tissues*, which are structures with discrete structural and functional properties. Tissues in combination form *organs*, such as the heart or liver, and in turn organs can be grouped into 11 *organ systems*. \bigcirc **p**. 6

4–1 The four tissue types are epithelial, connective, muscle, and neural

Learning Outcome Identify the four major types of tissues in the body and describe their roles.

The human body contains trillions of cells, but only about 200 *types* of cells. To work efficiently, several different types of cells must coordinate their efforts. Cells working together form **tissues**—collections of specialized cells and cell products that carry out a limited number of functions. The study of tissues is called **histology**. Histologists recognize four basic types of tissue:

- **1.** *Epithelial tissue* covers exposed surfaces, lines internal passageways and chambers, and forms glands.
- **2.** *Connective tissue* fills internal spaces, provides structural support for other tissues, transports materials within the body, and stores energy.
- **3.** *Muscle tissue* is specialized for contraction and includes the skeletal muscles of the body, the muscle of the heart, and the muscular walls of hollow organs.
- 4. *Neural tissue* carries information from one part of the body to another in the form of electrical impulses.

In this chapter we introduce the basic characteristics of these tissues. This information will help you understand the descriptions of organs and organ systems in later chapters. It will also help you make the connections between anatomical structures and their physiological functions. ATLAS: Embryology Summary 1: The Formation of Tissues

CHECKPOINT

- 1. Define histology.
- 2. Identify the four major types of tissues in the body.
- See the blue Answers tab at the back of the book.

4–2 Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions

Learning Outcome Discuss the types and functions of epithelial tissue.

Let's begin our discussion with **epithelial tissue**, because it includes a very familiar feature—the surface of your skin. Epithelial tissue includes *epithelia* and *glands*. **Epithelia** (ep-i-THĒ-lē-a; singular, *epithelium*) are layers of cells that cover internal or external surfaces. **Glands** are structures that produce fluid secretions. They are either attached to or derived from epithelia.

Epithelia cover every exposed surface of your body. Epithelia form the surface of the skin and line the digestive, respiratory, reproductive, and urinary tracts. In fact, they line all passageways that communicate with the outside world. The more delicate epithelia line internal cavities and passageways, such as the chest cavity, fluid-filled spaces in the brain, the inner surfaces of blood vessels, and the chambers of the heart. Epithelia have several important characteristics:

- Cellularity. Epithelia are made almost entirely of cells bound closely together by interconnections known as cell junctions. In other tissue types, the cells are often widely separated by extracellular materials.
- Polarity. An epithelium has an exposed surface, which faces the exterior of the body or an internal space, and a base, which is attached to underlying tissues. The term **polarity** refers to the presence of structural and functional differences between the exposed and attached surfaces. An epithelium consisting of a single layer of cells has an exposed **apical surface** and an attached **basal surface**. The two surfaces differ in plasma membrane structure and function.
- Attachment. The base of an epithelium is bound to a thin, noncellular basement membrane, which is also called the basal lamina. The basement membrane is a complex structure produced by the basal surface of the epithelium and the underlying connective tissue.
- Avascularity. Epithelia are avascular (ā-VAS-kū-lar; a-, without + vas, vessel), which means that they lack blood vessels. Epithelial cells get nutrients by diffusion or absorption across either the exposed or the attached epithelial surface.
- *Regeneration.* Epithelial cells that are damaged or lost at the exposed surface are continuously replaced through stem cell divisions in the epithelium. Regeneration is a characteristic of other tissues as well, but the rates of cell division and replacement are typically much higher in epithelia than in other tissues.

Functions of Epithelial Tissue

Epithelia perform four essential functions:

- 1. *Provide Physical Protection*. Epithelia protect exposed and internal surfaces from abrasion, dehydration, and destruction by chemical or biological agents.
- 2. Control Permeability. Any substance that enters or leaves your body must cross an epithelium. Some epithelia are relatively impermeable. Others are easily crossed by compounds as large as proteins. Many epithelia contain the molecular "machinery" needed for selective absorption or secretion. The epithelial barrier can also be regulated and modified in response to stimuli. For example, hormones can affect the transport of ions and nutrients through epithelial cells. Even physical stress can alter the structure and properties of epithelia. For example, calluses form on your hands when you do manual labor for some time.
- **3.** *Provide Sensation.* Most epithelia are extremely sensitive to stimulation, because they have a large sensory nerve supply. These sensory nerves continually provide information about the external and internal environments. For

example, the lightest touch of a mosquito will stimulate sensory neurons that tell you where to swat. A *neuroepithelium* is an epithelium that is specialized to perform a particular sensory function. Our neuroepithelia contain sensory cells that provide the sensations of smell, taste, sight, equilibrium, and hearing.

4. *Produce Specialized Secretions.* Epithelial cells that produce secretions are called *gland cells.* Individual gland cells are usually scattered among other cell types in an epithelium. In a **glandular epithelium**, most or all of the epithelial cells produce secretions. These cells either discharge their secretions onto the surface of the epithelium (to provide physical protection or temperature regulation) or release them into the surrounding interstitial fluid and blood (to act as chemical messengers).

Specializations of Epithelial Cells

How are epithelial cells different from other body cells? They have several structural specializations. For the epithelium as a whole to perform the functions just listed, individual epithelial cells may be specialized for (1) the movement of fluids over the epithelial surface, providing protection and lubrication; (2) the movement of fluids through the epithelium, to control permeability; or (3) the production of secretions that provide physical protection or act as chemical messengers. Specialized epithelial cells generally possess a strong polarity. **Figure 4–1** shows one common type of epithelial polarity.

The epithelial cell is often divided into two functional regions. One is the *apical surface*, where the cell is exposed to an internal or external environment. The other consists of the *basolateral surfaces*, which include both the base, where the cell attaches to underlying epithelial cells or deeper tissues, and the sides, where the cell contacts its neighbors.

Many epithelial cells that line internal passageways have *microvilli* on their exposed surfaces. \bigcirc **p**. **73** Just a few may be present, or microvilli may carpet the entire surface. Microvilli are especially abundant on epithelial surfaces where absorption and secretion take place, such as along portions of the digestive system and kidneys. The epithelial cells in these locations are transport specialists. Each cell has at least 20 times more surface area to transport substances than it would have without microvilli.

Cilia are characteristic of surfaces covered by a **ciliated epithelium**. A typical ciliated cell contains about 250 cilia that beat in a coordinated manner. The synchronized beating of the cilia moves substances over the epithelial surface. For example, the ciliated epithelium that lines the respiratory tract moves mucus up from the lungs and toward the throat, as though on an escalator. The sticky mucus traps inhaled particles, including dust, pollen, and pathogens. The ciliated epithelium then carries the mucus and the trapped debris to the throat. There they are swallowed or expelled by coughing. If abrasion
Figure 4–1 The Polarity of Epithelial Cells. Many epithelial cells have functional specializations associated with an apical surface that is exposed to either the external environment or internal spaces, and basolateral surfaces (base and sides) that interact with deeper tissues and adjacent cells. Often, the apical surface has microvilli; sometimes it has cilia. This functional polarity is also evident in the uneven distribution of organelles between the free surface (here, the top) and the basement membrane. In some epithelia, such as the lining of the kidney tubules, mitochondria are concentrated near the base of the cell, where energy is in high demand for the cell's transport activities.

or toxic compounds such as nicotine and carbon monoxide in cigarette smoke injure the cilia or the epithelial cells, ciliary movement can stop. Without the protective upward flow of mucus, infection or disease become more likely.

Maintaining the Integrity of Epithelia

To be effective as a barrier, an epithelium must form a complete cover or lining. Three factors help maintain the physical integrity of an epithelium: (1) intercellular connections, (2) attachment to the basement membrane, and (3) epithelial maintenance and repair.

Intercellular Connections

Cells in an epithelium are firmly attached to one another, and the epithelium as a unit is attached to extracellular fibers of the superficial clear layer of the basement membrane. Many cells in your body form permanent or temporary bonds with other cells or extracellular material. Epithelial cells, however, are specialists in intercellular connection. Intercellular connections involve either extensive areas of opposing plasma membranes or specialized attachment sites, discussed shortly. Large areas of opposing plasma membranes are interconnected by transmembrane proteins called **cell adhesion molecules (CAMs)**, which bind to each other and to extracellular materials. For example, CAMs on the basolateral surface of an epithelium help bind the cell to the underlying basement membrane. The membranes of adjacent cells may also be bonded by a thin layer of proteoglycans that contain polysaccharide derivatives known as *glycosaminoglycans (GAGs)*, most notably **hyaluronan** (*hyaluronic acid*).

Cell junctions are specialized areas of the plasma membrane that attach a cell to another cell or to extracellular materials. The three most common types of cell junctions are (1) tight junctions, (2) gap junctions, and (3) desmosomes (Figure 4–2a).

Some epithelial functions require rapid intercellular communication. At a **gap junction** (Figure 4–2b), two cells are held together by two interlocking transmembrane proteins called *connexons*. Each connexon is composed of six *connexin* proteins that form a cylinder with a central pore. Two aligned connexons form a narrow passageway that lets small molecules and ions pass from cell to cell. Gap junctions are common among epithelial cells, where the movement of ions helps coordinate functions such as the beating of cilia. Gap junctions are also common in other tissues. For example, gap junctions in cardiac muscle tissue and smooth muscle tissue are essential in coordinating muscle cell contractions. A number of human diseases are caused by mutations in the genes that code for different connexin proteins.

At a **tight junction** (also known as an occluding junction), the lipid portions of the two plasma membranes are tightly bound together by interlocking membrane proteins (Figure 4–2c). Inferior to the tight junctions, a continuous *adhesion belt* forms a band that encircles cells and binds them to their neighbors. The bands are attached to the microfilaments of the terminal web. \bigcirc p. 71 This kind of attachment is so tight that tight junctions largely prevent water and solutes from passing between the cells.

When the epithelium lines a tube, such as the intestinal tract, the apical surfaces of the epithelial cells are exposed to the space inside the tube, a passageway called the **lumen** (LOO-men). Tight junctions effectively isolate the contents of the lumen from the basolateral surfaces of the cell. For example, tight junctions near the apical surfaces of cells that line the digestive tract help keep enzymes, acids, and wastes in the lumen from reaching the basolateral surfaces and digesting or otherwise damaging the underlying tissues and organs.

Most epithelial cells are subject to mechanical stresses stretching, bending, twisting, or compression—so they must have durable interconnections. At a **desmosome** (DEZ-mō-sōm; *desmos*, ligament + *soma*, body), CAMs and proteoglycans link the opposing plasma membranes. Desmosomes are very strong and can resist stretching and twisting.

Figure 4–2 Cell Junctions.

adjacent cells together.

A typical desmosome is formed by two cells. Within each cell, a complex known as a *dense area* is connected to the cytoskeleton (Figure 4–2d). This connection to the cytoskeleton gives the desmosome—and the epithelium—its strength. For example, desmosomes are abundant between cells in the superficial layers of the skin. As a result, damaged skin cells are usually lost in sheets rather than as individual cells. (That is why your skin peels rather than sheds off as a powder after a sunburn.)

There are two types of desmosomes:

- Spot desmosomes are small discs connected to bands of intermediate filaments (Figure 4–2d). The intermediate filaments stabilize the shape of the cell.
- Hemidesmosomes resemble half of a spot desmosome. Rather than attaching one cell to another, a hemidesmosome attaches a cell to extracellular filaments in the basement membrane (Figure 4–2e). This attachment helps stabilize the position of the epithelial cell and anchors it to underlying tissues.

Attachment to the Basement Membrane

Not only do epithelial cells hold onto one another, but they also remain firmly connected to the rest of the body. The inner surface of each epithelium is attached to a two-part basement membrane. The layer closer to the epithelium, the *clear layer*, (also called the lamina lucida) contains glycoproteins and a network of fine protein filaments (Figure 4–2e). It is secreted by the adjacent layer of epithelial cells. The clear layer acts as a barrier that restricts the movement of proteins and other large molecules from the underlying connective tissue into the epithelium.

The deeper portion of the basement membrane, the *dense layer*, contains bundles of coarse protein fibers produced by connective tissue cells. The dense layer gives the basement membrane its strength. Attachments between the fibers of the clear layer and those of the dense layer hold the two layers together, and hemidesmosomes attach the epithelial cells to the composite basement membrane. The dense layer also acts as a filter that determines what substances can diffuse between the adjacent tissues and the epithelium.

Epithelial Maintenance and Repair

Epithelial cells lead hard lives. They are exposed to disruptive enzymes, toxic chemicals, pathogenic bacteria, and mechanical abrasion. Consider the lining of your small intestine, where epithelial cells are exposed to a variety of enzymes and abraded by partially digested food. In this extreme environment, an epithelial cell may last just a day or two before it is shed or destroyed. The only way the epithelium can maintain its structure over time is by the continual division of *stem cells*. **D p.** 103 Most epithelial stem cells, also called **germinative cells**, are located near the basement membrane, in a relatively protected location. 4–3 Cell shape and number of layers determine the classification of epithelia

Learning Outcome Describe the relationship between structure and function for each type of epithelium.

There are many different specialized types of epithelia. You can easily sort these into categories based on (1) the cell shape, and (2) the number of cell layers between the basement membrane and the exposed surface of the epithelium. Using these two criteria, we can describe almost every epithelium in the body (Table 4–1).

Classification of Epithelia

Epithelial cells have three basic shapes: squamous, cuboidal, and columnar. For classification purposes, we look at the superficial cells in a section perpendicular to both the apical surface and the basement membrane. In sectional view, squamous cells appear thin and flat, cuboidal cells look like little boxes, and columnar cells are tall and relatively slender rectangles.

Once you have determined whether the superficial cells are squamous, cuboidal, or columnar, then look at the number of cell layers. There are only two options: simple or stratified.

If only one layer of cells covers the basement membrane, that layer is a **simple epithelium**. Simple epithelia are necessarily thin. All the cells have the same polarity, so the distance from the nucleus to the basement membrane does not change from one cell to the next.

Because they are so thin, simple epithelia are fragile. A single layer of cells cannot provide much mechanical protection, so simple epithelia are located only in protected areas inside the body. They line internal compartments and passageways, such as the pleural, pericardial, and peritoneal cavities, the heart chambers, and blood vessels.

Simple epithelia are also characteristic of regions in which secretion or absorption occurs. Examples are the lining of the intestines and the gas-exchange surfaces of the lungs. In these places, thinness is an advantage. It reduces the time required for materials to cross the epithelial barrier.

In a stratified epithelium, several layers of cells cover the basement membrane. Stratified epithelia are generally located in areas that are exposed to mechanical or chemical stresses. The surface of the skin and the lining of the mouth are examples.

TIPS & TRICKS

To help you remember the meanings of the terms squamous and stratified, associate the word "squamous" with "scaly," and the word "stratified" with "stratosphere," an upper layer of Earth's atmosphere.

Squamous Epithelia

The cells in a squamous epithelium (SKWA-mus; squama, plate or scale) are thin, flat, and somewhat irregular in shape, like pieces of a jigsaw puzzle (Figure 4–3). From the surface, the

Figure 4–3 Squamous Epithelia.

b Surface of tongue

cells resemble fried eggs laid side by side. In sectional view, the disc-shaped nucleus occupies the thickest portion of each cell.

A **simple squamous epithelium** is the body's most delicate type of epithelium. This type of epithelium is located in protected regions where absorption or diffusion takes place, or where a slick, slippery surface reduces friction. Examples are the respiratory exchange surfaces (*alveoli*) of the lungs, the lining of the thoracic and abdominopelvic body cavities of the trunk (**Figure 4–3a**), and the lining of the heart and blood vessels. Smooth linings are extremely important. For example, any irregularity in the lining of a blood vessel may result in the formation of a potentially dangerous blood clot.

Special names have been given to the simple squamous epithelia that line chambers and passageways that do not communicate with the outside world. The simple squamous epithelium that lines the body cavities enclosing the lungs, heart, and abdominal organs is called a **mesothe-lium** (mez-ō-THĒ-lē-um; *mesos*, middle). The pleura, pericardium, and peritoneum each contain a superficial layer of mesothelium. The simple squamous epithelium lining the inner surface of the heart and all blood vessels is called an **endothelium** (en-dō-THĒ-lē-um; *endo-*, inside).

A **stratified squamous epithelium** (Figure 4–3b) is generally located where mechanical stresses are severe. The cells form a series of layers, like the layers in a sheet of plywood. The surface of the skin and the lining of the mouth, esophagus, and anus are areas where this type of epithelium protects against physical and chemical attacks.

On exposed body surfaces, where mechanical stress and dehydration are potential problems, apical layers of epithelial cells are packed with filaments of the protein *keratin*. As a result, superficial layers are both tough and water resistant. Such an epithelium is said to be *keratinized*. A *nonkeratinized* stratified squamous epithelium resists abrasion, but will dry out and deteriorate unless kept moist. Nonkeratinized stratified squamous epithelia are found in the oral cavity, pharynx, esophagus, anus, and vagina.

Cuboidal Epithelia

The cells of a **cuboidal epithelium** resemble hexagonal boxes from their apical surfaces. (In typical sectional views they appear square.) The spherical nuclei are near the center of each cell, and the distance between adjacent nuclei is roughly equal to the height of the epithelium.

A **simple cuboidal epithelium** provides limited protection and occurs where secretion or absorption takes place. Such an epithelium lines portions of the kidney tubules (Figure 4–4a).

Stratified cuboidal epithelia are relatively rare. They are located along the ducts of sweat glands (Figure 4–4b) and in the larger ducts of the mammary glands.

Clinical Note

Exfoliative Cytology *Exfoliative cytology* (eks-FO-lēa-tiv; *ex*-, from + *folium*, leaf) is the study of cells shed or removed from epithelial surfaces. The cells are examined for a variety of reasons—for example, to check for cellular changes that indicate cancer, or for genetic screening of a fetus. Cells are collected by sampling the fluids that cover the epithelia lining the respiratory, digestive, urinary, or reproductive tract; by removing fluid from the pleural, pericardial, or peritoneal body cavities; or by removing cells from an epithelial surface.

One common sampling procedure is a *Pap test*, named after Dr. George Papanicolaou, who pioneered its use. The most familiar Pap test is that for cervical cancer. This test involves scraping cells from the tip of the *cervix*, the portion of the uterus that projects into the vagina.

Amniocentesis is also based on exfoliative cytology. In this procedure, shed epithelial cells are collected from a sample of *amniotic fluid*, which surrounds and protects a developing fetus. Examination of these cells can determine if the fetus has a chromosomal abnormality, such as occurs in *Down's syndrome*.

Transitional Epithelia

A **transitional epithelium** (Figure 4–4c) is an unusual stratified epithelium. Unlike most epithelia, it tolerates repeated cycles of stretching and recoiling (returning to its previous shape) without damage. It is called transitional because the appearance of the epithelium changes as stretching occurs. A transitional epithelium is found in regions of the urinary system, such as the urinary bladder, where large changes in volume occur. In an empty urinary bladder, the superficial cells of the epithelium are typically plump and cuboidal. In the full urinary bladder, when the volume of urine has stretched the lining to its limits, the epithelium appears flattened, and more like a stratified squamous epithelium.

Columnar Epithelia

In a typical sectional view, **columnar epithelial cells** appear rectangular. In reality, the densely packed cells are hexagonal, but they are taller and more slender than cells in a cuboidal epithelium (Figure 4–5). The elongated nuclei are crowded into a narrow band close to the basement membrane. The height of the epithelium is several times the distance between adjacent nuclei.

Figure 4–5 Columnar Epithelia.

Simple Columnar Epithelium

Pseudostratified Ciliated Columnar Epithelium

Stratified Columnar Epithelium

A **simple columnar epithelium** is typically found where absorption or secretion takes place, such as in the small intestine (Figure 4–5a). In the stomach and large intestine, the secretions of simple columnar epithelia protect against chemical stresses.

Portions of the respiratory tract contain a **pseudostratified columnar epithelium**, a columnar epithelium that includes several types of cells with varying shapes and functions. The distances between the cell nuclei and the exposed surface vary, so the epithelium appears to be layered, or stratified (Figure 4–5b). It is not truly stratified, though, because every epithelial cell contacts the basement membrane. Pseudostratified columnar epithelial cells typically have cilia. Epithelia of this type line most of the nasal cavity, the trachea (windpipe), the bronchi (branches of the trachea leading to the lungs), and portions of the male reproductive tract.

Stratified columnar epithelia are relatively rare, providing protection along portions of the pharynx, epiglottis, anus, and urethra, as well as along a few large excretory ducts. The epithelium has either two layers or multiple layers (**Figure 4–5c**). In the latter case, only the superficial cells are columnar.

Now that we have considered the classes of epithelia, we turn to a specialized type of epithelium: glandular epithelia.

Glandular Epithelia

Many epithelia contain gland cells that are specialized for secretion. Collections of epithelial cells (or structures derived from epithelial cells) that produce secretions are called *glands*. They range from scattered cells to complex glandular organs. Some of these glands, called **endocrine glands**, release their secretions into the interstitial fluid. Others, known as **exocrine glands**, release their secretions into passageways called **ducts** that open onto an epithelial surface.

Endocrine Glands

An endocrine gland produces *endocrine* (*endo-*, inside + *krino*, to separate) *secretions*, which are released directly into the surrounding interstitial fluid. These secretions, also called *hormones*, then enter the bloodstream for distribution throughout the body. Hormones regulate or coordinate the activities of various tissues, organs, and organ systems. Examples of endocrine glands include the thyroid gland and the pituitary gland. Because their secretions are not released into ducts, endocrine glands are often called *ductless glands*.

Endocrine cells may also be part of an epithelial surface, such as the lining of the digestive tract, or they may be found in separate organs, such as the pancreas, thyroid gland, thymus, and pituitary gland. We will consider endocrine cells, organs, and hormones further in Chapter 18.

Exocrine Glands

Exocrine glands produce *exocrine* (*exo-*, outside) *secretions*, which are discharged onto an epithelial surface. Most exocrine secretions reach the surface through tubular ducts, which empty onto the skin surface or onto an epithelium lining an internal passageway that communicates with the exterior. Examples of exocrine secretions are enzymes entering the digestive tract, perspiration on the skin, tears in the eyes, and milk produced by mammary glands.

Exocrine glands have several different methods of secretion. For this reason, they are classified by their mode and type of secretion, and by the structure of the gland cells and associated ducts.

Modes of Secretion. A glandular epithelial cell releases its secretions by (1) merocrine secretion, (2) apocrine secretion, or (3) holocrine secretion.

In **merocrine secretion** (MER-ō-krin; *meros*, part), the product is released from secretory vesicles by exocytosis (Figure 4–6a). **)** p. 100 This is the most common mode of exocrine secretions. *Mucin* is a merocrine secretion that mixes with water to form **mucus**. Mucus is a lubricant, a protective barrier, and a sticky trap for foreign particles and microorganisms. The mucous secretions of the salivary glands coat food and reduce friction during swallowing. In the skin, merocrine sweat glands produce the watery perspiration that helps cool you on a hot day.

Apocrine secretion (AP-ō-krin; *apo-*, off) involves the loss of cytoplasm as well as the secretory product (**Figure 4–6b**). The apical portion of the cytoplasm becomes packed with secretory vesicles and is then shed. Milk production in the mammary glands involves a combination of merocrine and apocrine secretions.

Merocrine and apocrine secretions leave a cell relatively intact and able to continue secreting. **Holocrine secretion** (HOL-ō-krin; *holos*, entire), by contrast, destroys the gland cell. During holocrine secretion, the entire cell becomes packed with secretory vesicles and then bursts, releasing the secretion, but killing the cell (**Figure 4–6c**). Further secretion depends on replacing destroyed gland cells by the division of stem cells. Sebaceous glands, associated with hair follicles, produce an oily hair coating by means of holocrine secretion.

Types of Secretions. We also categorize exocrine glands by the types of secretion produced:

- Serous glands secrete a watery solution that contains enzymes. The parotid salivary glands are serous glands.
- Mucous glands secrete mucins that hydrate to form mucus. The sublingual salivary glands and the submucosal glands of the small intestine are mucous glands.
- Mixed exocrine glands contain more than one type of gland cell. These glands may produce two different exocrine secretions, one serous and the other mucous. The submandibular salivary glands are mixed exocrine glands.

Figure 4–6 Modes of Glandular Secretion.

Salivary gland

Mammarv

gland

Hair

Sebaceous gland

Hair follicle

In merocrine secretion, the product is released from secretory vesicles at the apical surface of the gland cell by exocytosis.

(b) Apocrine secretion

Apocrine secretion involves the loss of apical cytoplasm. Inclusions, secretory vesicles, and other cytoplasmic components are shed in the process. The gland cell then grows and repairs itself before it releases additional secretions.

(c) Holocrine secretion

Holocrine secretion occurs as superficial gland cells burst. Continued secretion involves the replacement of these cells through the mitotic divisions of underlying stem cells.

Gland Structure. The final method of classifying exocrine glands is by structure. In epithelia that have independent, scattered gland cells, the individual secretory cells are called **unicellular glands**. **Multicellular glands** include glandular epithelia and aggregations of gland cells that produce exocrine or endocrine secretions.

The only **unicellular exocrine glands** in the body are **mucous (goblet) cells**, which secrete mucins. Mucous cells are scattered among other epithelial cells. Both the pseudostratified ciliated columnar epithelium that lines the trachea and the columnar epithelium of the small and large intestines have an abundance of mucous cells.

The simplest **multicellular exocrine gland** is a *secretory sheet*, in which gland cells form an epithelium that releases secretions into an inner compartment. Mucin-secreting cells that line the stomach, for instance, protect that organ from its own acids and enzymes by continuously secreting mucin.

Most other multicellular exocrine glands are in pockets set back from the epithelial surface. Their secretions travel through one or more ducts to the surface. Examples include the salivary glands, which produce mucins and digestive enzymes.

Three characteristics are useful in describing the structure of multicellular exocrine glands (Figure 4–7):

- The Structure of the Duct. A gland is simple if it has a single duct that does not divide on its way to the gland cells (top row of Figure 4–7). The gland is *compound* if the duct divides one or more times on its way to the gland cells (bottom row of Figure 4–7).
- 2. The Shape of the Secretory Portion of the Gland. Glands whose glandular cells form tubes are *tubular*; the tubes may be straight or coiled. Those that form blind pockets are *alveolar* (al-VĒ-ō-lar; *alveolus*, sac) or *acinar* (AS-i-nar; *acinus*, chamber). Glands whose secretory cells form both tubes and pockets are called *tubuloalveolar* and *tubuloacinar*.
- **3.** The Relationship between the Ducts and the Glandular Areas. A gland is *branched* if several secretory areas (tubular or acinar) share a duct. ("Branched" refers to the glandular areas and not to the duct.)

The vast majority of glands in the body produce either exocrine or endocrine secretions. However, a few complex organs, including the digestive tract and the pancreas, produce both kinds of secretions. We will look at the organization of these glands in Chapters 18 and 24.

Figure 4–7 A Structural Classification of Exocrine Glands.

CHECKPOINT

- 8. Identify the three cell shapes characteristic of epithelial cells.
- When classifying epithelial tissue, the number of cell layers determines whether it is simple or stratified. A single layer of cells is termed _____, whereas multiple layers of cells are known as _____.
- 10. Using a light microscope, a tissue appears as a simple squamous epithelium. Can this be a sample of the skin surface? Why or why not?
- 11. Why do the pharynx, esophagus, anus, and vagina have a similar epithelial organization?
- 12. Name the two primary types of glandular epithelia.
- 13. The secretory cells of sebaceous glands fill with vesicles and then rupture, releasing their contents. Which mode of secretion is this?
- 14. Which type of gland releases its secretions directly into the interstitial fluid?

• See the blue Answers tab at the back of the book.

4-4 Connective tissue provides a protective structural framework for other tissue types

Learning Outcome Compare the structures and functions of the various types of connective tissue.

It is impossible to discuss epithelial tissue without mentioning an associated type of tissue: **connective tissue**. Recall that the dense layer of the basement membrane of all epithelial tissues is created by connective tissue. In essence, connective tissue connects the epithelium to the rest of the body. Other types of connective tissue include bone, fat, and blood. They provide structure, store energy, and transport materials throughout the body, respectively.

Connective tissues vary widely in appearance and function, but they all share three basic components: (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid known as **ground substance**. Together, the extracellular fibers and ground substance make up the **matrix**, which surrounds the cells. Cells make up the bulk of epithelial tissue, but the matrix typically accounts for most of the volume of connective tissues. ATLAS: Embryology Summary 3: The Origins of Connective Tissues

Connective tissues occur throughout the body, but they are never exposed to the outside environment. Many connective tissues are highly vascular (that is, they have many blood vessels) and contain sensory receptors that detect pain, pressure, temperature, and other stimuli.

Among the specific functions of connective tissues are the following:

- Establishing a structural framework for the body.
- Transporting fluids and dissolved materials.

- Protecting delicate organs.
- Supporting, surrounding, and interconnecting other types of tissue.
- Storing energy, especially in the form of triglycerides.
- Defending the body from invading microorganisms.

Classification of Connective Tissues

We classify connective tissues by their physical properties. The three general categories of connective tissue are connective tissue proper, fluid connective tissues, and supporting connective tissues.

- 1. **Connective tissue proper** includes those connective tissues with many types of cells and extracellular fibers in a syrupy ground substance. This broad category contains a variety of connective tissues that are grouped into (a) *loose connective tissues* and (b) *dense connective tissues*. These groupings are based on the number of cell types present, and on the relative properties and proportions of fibers and ground substance. Both *adipose tissue* or fat (a loose connective tissue) and *tendons* (a dense connective tissue) are connective tissue proper, but they have very different structural and functional characteristics.
- 2. Fluid connective tissues have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. The only two types are *blood* and *lymph*.
- 3. **Supporting connective tissues** differ from connective tissue proper in having a less diverse cell population and a matrix containing much more densely packed fibers. Supporting connective tissues protect soft tissues and support the weight of part or all of the body. The two types of supporting connective tissues are *cartilage* and *bone*. The matrix of cartilage is a gel with characteristics that vary with the predominant type of fiber. The matrix of bone is **calcified**, because it contains mineral deposits (primarily calcium salts) that provide rigidity.

Connective Tissue Proper

Connective tissue proper contains a varied cell population, extracellular fibers, and a viscous (syrupy) ground substance (Figure 4–8). The number of cells and cell types in a tissue at any moment varies with local conditions.

Some cells function in local maintenance, repair, and energy storage. They include *fibroblasts, fibrocytes, adipocytes,* and *mesenchymal cells.* These cells are permanent residents of the connective tissue. Other cells defend and repair damaged tissues. These cells are more mobile and include *macrophages, mast cells, lymphocytes, plasma cells,* and *microphages.* They are not permanent residents. Instead they migrate through healthy connective tissues and collect at sites of tissue injury. **Figure 4–8** The Cells and Fibers of Connective Tissue Proper. A diagrammatic view of the cell types and fibers of connective tissue proper. (Microphages, not shown, are common only in damaged or abnormal tissues.)

Connective Tissue Proper Cell Populations

- **Fibrocytes** (FĪ-brō-sīts) are the second most abundant fixed cell in connective tissue proper. They differentiate from fibroblasts. Fibrocytes are spindle-shaped cells that maintain the connective tissue fibers of connective tissue proper.
- Adipocytes (AD-i-pō-sīts) are also known as fat cells. A typical adipocyte contains a single, enormous lipid droplet. The nucleus, other organelles, and cytoplasm are squeezed to one side, making a sectional view of the cell resemble a class ring. The number of adipocytes varies from one type of connective tissue to another, from one region of the body to another, and among individuals.
- **Mesenchymal cells** are stem cells that are present in many connective tissues. These cells respond to local injury or

infection by dividing to produce daughter cells that differentiate into fibroblasts, macrophages, or other connective tissue cells.

Macrophages (MAK-rō-fā-jez) are large phagocytic cells scattered throughout the matrix. These scavengers engulf damaged cells or pathogens that enter the tissue. (The name literally means "big eater.") Although not abundant, macrophages are important in mobilizing the body's defenses. When stimulated, they release chemicals that activate the immune system and attract large numbers of additional macrophages and other cells involved in tissue defense.

Macrophages are either *fixed macrophages*, which spend long periods in a tissue, or *free macrophages*, which migrate rapidly through tissues. In

effect, fixed macrophages provide a "frontline" defense that can be reinforced by the arrival of free macrophages and other specialized cells.

- Mast cells are small, mobile connective tissue cells that are common near blood vessels. The cytoplasm of a mast cell is filled with granules containing histamine (HIS-tuh-mēn) and heparin (HEP-uh-rin). Histamine, released after injury or infection, stimulates local inflammation. (You are probably familiar with the inflammatory effects of histamine if you've had a cold. People often take antihistamines to reduce cold symptoms.) *Basophils*, blood cells that enter damaged tissues and enhance the inflammation process, also contain granules of histamine and heparin. Heparin levels in the blood are normally low. It is an anticoagulant that enhances local blood flow during inflammation and reduces the development of blood clots in areas of slow-moving blood.
- Lymphocytes (LIM-fō-sīts) migrate throughout the body, traveling through connective tissues and other tissues. Their numbers increase markedly wherever tissue damage occurs. Some lymphocytes may develop into plasma cells, which produce *antibodies*—proteins involved in defending the body against disease.
- Microphages (*neutrophils* and *eosinophils*) are phagocytic blood cells that normally move through connective tissues in small numbers. They are attracted to the site of an infection or injury by chemicals released by macrophages and mast cells.

Melanocytes (me-LAN-ō-sīts) synthesize and store the brown pigment melanin (MEL-a-nin), which gives tissues a dark color. Melanocytes are common in the epithelium of the skin, where they play a major role in determining skin color. Melanocytes are also abundant in connective tissues of the eye and the dermis of the skin, although the number present differs by body region and among individuals.

Connective Tissue Fibers. Three types of fibers occur in connective tissue: *collagen, reticular,* and *elastic* fibers. Fibroblasts form all three by secreting protein subunits that interact in the matrix. Fibrocytes then maintain these fibers.

- 1. **Collagen fibers** are the most common fibers in connective tissue proper. They are long, straight, and unbranched. Each collagen fiber consists of a bundle of fibrous protein subunits wound together like the strands of a rope. A collagen fiber is flexible like a rope, but it is stronger than steel when pulled from either end. *Tendons*, which connect skeletal muscles to bones, consist almost entirely of collagen fibers. Typical *ligaments* are similar to tendons, but they connect one bone to another bone. Tendons and ligaments can withstand tremendous forces. Uncontrolled muscle contractions or skeletal movements are more likely to break a bone than to snap a tendon or a ligament.
- 2. Reticular fibers (*reticulum*, network) contain the same protein subunits as do collagen fibers, but they are arranged differently. Thinner than collagen fibers, reticular fibers form a branching, interwoven framework that is tough, yet flexible. Reticular fibers resist forces applied from many directions because they form a network rather than share a common alignment. This interwoven network, called a *stroma*, stabilizes the relative positions of the functional cells, or **parenchyma** (pa-RENG-ki-ma), of organs such as the liver. Reticular fibers also stabilize the positions of an organ's blood vessels, nerves, and other structures, despite changing positions and the pull of gravity.
- **3. Elastic fibers** contain the protein *elastin*. Elastic fibers are branched and wavy. After stretching, they return to their original length. **Elastic ligaments**, which are dominated by elastic fibers, are rare but have important functions, such as interconnecting vertebrae.

Ground Substance. Ground substance fills the spaces between cells and surrounds connective tissue fibers (Figure 4–8). In connective tissue proper, ground substance is clear, colorless, and viscous (due to the presence of proteoglycans and glycoproteins). \supset p. 56 Ground substance is viscous enough that

bacteria have trouble moving through it—imagine swimming in molasses. This viscosity slows the spread of pathogens and makes them easier for phagocytes to catch.

Embryonic Connective Tissues

Mesenchyme, or *embryonic connective tissue*, is the first connective tissue to appear in a developing embryo. Mesenchyme contains an abundance of star-shaped stem cells (mesenchymal cells) separated by a matrix with very fine protein filaments (Figure 4–9a). Mesenchyme gives rise to all other

Figure 4–9 Embryonic Connective Tissues.

b This sample was taken from the umbilical cord of a fetus.

connective tissues. **Mucous connective tissue (Figure 4–9b)**, or *Wharton's jelly*, is a loose connective tissue found in many parts of the embryo, including the umbilical cord.

Adults have neither form of embryonic connective tissue. Instead, many adult connective tissues contain scattered mesenchymal stem cells that can assist in tissue repair after an injury.

Loose Connective Tissues

Loose connective tissues are the "packing materials" of the body. They fill spaces between organs, cushion and stabilize specialized cells in many organs, and support epithelia. These tissues surround and support blood vessels and nerves, store lipids, and provide a route for the diffusion of materials. Loose connective tissues include mucous connective tissue in embryos and *areolar tissue, adipose tissue*, and *reticular tissue* in adults.

Areolar Tissue. Areolar tissue (*areola*, little space) is the least specialized connective tissue in adults. It may contain all the cells and fibers of any connective tissue proper in a very loosely organized array (Figure 4–10a). Areolar tissue has an open framework. A viscous ground substance provides most of its volume and absorbs shocks. Areolar tissue can distort without damage because its fibers are loosely organized. Elastic fibers make it resilient, so areolar tissue returns to its original shape after external pressure is relieved.

Areolar tissue forms a layer that separates the skin from deeper structures. In addition to providing padding, the elastic properties of this layer allow a considerable amount of independent movement. For this reason, if you pinch the skin of your arm, you will not affect the underlying muscle. Conversely, contractions of the underlying muscle do not pull against your skin: As the muscle bulges, the areolar tissue stretches. The areolar tissue layer under the skin is a common injection site for drugs because it has an extensive blood supply.

The capillaries (thin-walled blood vessels) in areolar tissue deliver oxygen and nutrients and remove carbon dioxide and waste products. They also carry wandering cells to and from the tissue. Epithelia commonly cover areolar tissue, and fibrocytes maintain the dense layer of the basement membrane that separates the two kinds of tissue. The epithelial cells rely on the oxygen and nutrients that diffuse across the basement membrane from capillaries in the underlying connective tissue.

Adipose Tissue. The distinction between areolar tissue and fat, or **adipose tissue**, is somewhat arbitrary. Adipocytes (fat cells) account for most of the volume of adipose tissue (**Figure 4–10b**), but only a fraction of the volume of areolar tissue. Adipose tissue provides padding, absorbs shocks, acts

Clinical Note

Marfan's Syndrome Marfan's syndrome is an inherited condition caused by the production of an abnormally weak form of *fibrillin*, a glycoprotein that gives strength and elasticity to connective tissues. The effects of this defect are widespread because most organs contain connective tissues. The most visible sign of Marfan's syndrome involves the skeleton. Most individuals with the condition are tall and have abnormally long limbs and fingers. The most serious consequences involve the cardiovascular system. About 90 percent of people with Marfan's syndrome have structural abnormalities in their cardiovascular system. The most dangerous possibility is that the weakened elastic connective tissues in the walls of major arteries, such as the aorta, may burst, causing a sudden, fatal loss of blood.

as an insulator to slow heat loss through the skin, and serves as packing or filler around structures. Adipose tissue is common under the skin of the flanks (between the last rib and the hips), buttocks, and breasts. It fills the bony sockets behind the eyes and surrounds the kidneys. It is also common beneath the mesothelial lining of the pericardial and peritoneal cavities.

Most of the adipose tissue in the body is called white fat, because it has a pale, yellow-white color. In infants and young children, however, the adipose tissue between the shoulder blades, around the neck, and possibly elsewhere in the upper body is highly vascularized, and the individual adipocytes contain numerous mitochondria. Together, these characteristics give the tissue a deep, rich color that gives it the name brown fat. When these cells are stimulated by the nervous system, lipid breakdown speeds up. The cells do not capture the energy that is released. Instead, the surrounding tissues absorb it as heat. The heat warms the circulating blood, which distributes the heat throughout the body. In this way, an infant can double its metabolic heat generation very quickly. It had been thought that adults had little, if any, active brown fat tissue. Recent evidence has indicated its presence in adults, and that its absence may be connected to obesity.

Adipocytes are not simply storage bins. Instead, they are metabolically active cells. Their lipids are constantly being broken down and replaced. When nutrients are scarce, adipocytes deflate like collapsing balloons as their lipids are broken down and the fatty acids released to support metabolism.

What happens if nutrients become plentiful again? The lost weight can easily be regained in the same areas of the body because the cells are not killed but merely reduced in

Figure 4–10 Loose Connective Tissues.

Adipose Tissue

Reticular Tissue

size. In adults, adipocytes cannot divide. The number of fat cells in peripheral tissues is established in the first few weeks of a newborn's life, perhaps in response to the amount of fats in the diet. However, that is not the end of the story, because loose connective tissues also contain mesenchymal cells. If circulating lipid levels are chronically elevated, the mesenchymal cells will divide, giving rise to cells that differentiate into fat cells. As a result, areas of areolar tissue can become adipose tissue in times of nutritional plenty, even in adults.

Liposuction is a cosmetic surgical procedure that removes excess or unwanted adipose tissue. It turns out that liposuction provides only a temporary and potentially risky solution to the problem of excess weight. Once again, the reason is that adipose tissue can regenerate through the differentiation of mesenchymal cells.

Reticular Tissue. As mentioned earlier, organs such as the spleen and liver contain **reticular tissue**, in which reticular fibers form a complex three-dimensional stroma (Figure 4–10c). The stroma supports the functional cells, or parenchyma, of these organs. This fibrous framework is also found in the lymph nodes and bone marrow. Fixed macrophages, fibroblasts, and fibrocytes are associated with the reticular fibers, but these cells are seldom visible, because specialized cells with other functions dominate the organs.

Dense Connective Tissues

Fibers create most of the volume of **dense connective tissues**. These tissues are often called **collagenous** (ko-LAJ-enus) **tissues**, because collagen fibers are the dominant type of fiber in them. The body has two types of dense connective tissues: dense regular connective tissue and dense irregular connective tissue.

In **dense regular connective tissue**, the collagen fibers are parallel to each other, packed tightly, and aligned with the forces applied to the tissue. **Tendons** are cords of dense regular connective tissue that attach skeletal muscles to bones (Figure 4–11a). The collagen fibers run longitudinally along the tendon and transfer the pull of the contracting muscle to the bone. **Ligaments** resemble tendons, but connect one bone to another or stabilize the positions of internal organs.

An **aponeurosis** (AP-ō-noo-RŌ-sis; plural, *aponeuroses*) is a tendinous sheet that attaches a broad, flat muscle to another muscle or to several bones of the skeleton. It can also stabilize the positions of tendons and ligaments. Aponeuroses are associated with large muscles of the skull, lower back, and abdomen, and with the tendons and ligaments of the palms of the hands and the soles of the feet. Large numbers of fibroblasts are scattered among the collagen fibers of tendons, ligaments, and aponeuroses. In contrast, the fibers in **dense irregular connective tissue** form an interwoven meshwork in no consistent pattern (Figure 4–11b). These tissues strengthen and support areas subjected to stresses from many directions. A layer of dense irregular connective tissue gives skin its strength. Cured leather (animal skin) is an excellent example of the interwoven nature of this tissue. Except at joints, dense irregular connective tissue forms a sheath around cartilages (the *perichondrium*) and bones (the *periosteum*). Dense irregular connective tissue also forms a thick fibrous layer called a **capsule**, which surrounds internal organs such as the liver, kidneys, and spleen and encloses the cavities of joints.

Dense regular and dense irregular connective tissues contain variable amounts of elastic fibers. When elastic fibers outnumber collagen fibers, the tissue has a springy, resilient nature that allows it to tolerate cycles of extension and recoil. Abundant elastic fibers are present in the connective tissue that supports transitional epithelia, in the walls of large blood vessels such as the aorta, and around the respiratory passageways.

Elastic tissue is a dense regular connective tissue made up mainly of elastic fibers. Elastic ligaments are almost completely dominated by elastic fibers. They help stabilize the positions of the vertebrae of the spinal column (Figure 4–11c).

Fluid Connective Tissues

Blood and *lymph* are connective tissues with distinctive collections of cells. The fluid matrix that surrounds the cells also includes many types of suspended proteins that do not form insoluble fibers under normal conditions.

In **blood**, the watery matrix is called **plasma**. Plasma contains blood cells and fragments of cells, collectively known as *formed elements*. There are three types of formed elements: red blood cells, white blood cells, and platelets (Figure 4–12).

Recall from Chapter 3 that the human body contains a large volume of extracellular fluid. This fluid includes three major subdivisions: *plasma, interstitial fluid,* and *lymph.* Plasma is normally confined to the vessels of the cardiovascular system. Contractions of the heart keep it in motion. **Arteries** carry blood away from the heart and into the tissues of the body. In those tissues, blood pressure forces water and small solutes out of the bloodstream across the walls of **capillaries**, the smallest blood vessels. This process is the origin of the interstitial fluid that bathes the body's cells. The remaining blood flows from the capillaries into **veins** that return it to the heart.

Lymph forms as interstitial fluid enters **lymphatic vessels**. As fluid passes along the lymphatic vessels, cells of the immune system monitor its composition and respond to signs of injury or infection. The lymphatic vessels ultimately return the lymph to large veins near the heart. This recirculation of fluid—from the cardiovascular system, through the

132 UNIT 1 Levels of Organization

interstitial fluid, to the lymph, and then back to the cardiovascular system—is a continuous process that is essential to homeostasis. It helps eliminate local differences in the levels of nutrients, wastes, or toxins; maintains blood volume; and alerts the immune system to infections that may be under way in peripheral tissues.

CHECKPOINT

- 15. Identify several functions of connective tissues.
- 16. List the three categories of connective tissues.
- 17. Identify the cells found in connective tissue proper.
- **18**. Lack of vitamin C in the diet interferes with the ability of fibroblasts to produce collagen. What effect might this interference have on connective tissue?
- 19. Many allergy sufferers take antihistamines to relieve their allergy symptoms. Which cells produce the molecule that this medication blocks?
- 20. Which type of connective tissue contains primarily triglycerides?
- 21. Which two types of connective tissue have a fluid matrix?
- See the blue Answers tab at the back of the book.

4–5 Cartilage and bone provide a strong supporting framework

Learning Outcome Describe how cartilage and bone function as a supporting connective tissue.

Cartilage and *bone* are called supporting connective tissues because they provide a strong framework that supports the rest of the body. In these connective tissues, the matrix contains numerous fibers. In bone, it also contains deposits of insoluble calcium salts.

Cartilage

The matrix of **cartilage** is a firm gel that contains polysaccharide derivatives called **chondroitin sulfates** (kon-DROY-tin; *chondros*, cartilage). Chondroitin sulfates form complexes with proteins in the ground substance, producing proteoglycans. Cartilage cells, or **chondrocytes** (KON-drō-sīts), are the only cells in the cartilage matrix. They occupy small chambers known as **lacunae** (la-KOO-nē; *lacus*, lake). The physical properties of cartilage depend on the proteoglycans of the matrix, and on the type and abundance of extracellular fibers.

Unlike other connective tissues, cartilage is avascular, so all exchange of nutrients and waste products must take place by diffusion through the matrix. Blood vessels do not grow into cartilage because chondrocytes produce a chemical that discourages their formation. This chemical inhibitor of new blood vessel formation is called antiangiogenesis factor (anti-, against + angeion, vessel + genesis, production). Other angiogenesis inhibitors have also been identified in the body or developed as drugs. Various inhibitors are now used in cancer treatments to discourage the formation of new blood vessels to tumors, thereby slowing their growth. Cartilage is generally set apart from surrounding tissues by a fibrous **peri**chondrium (per-i-KON-drē-um; peri-, around). The perichondrium contains two distinct layers: an outer, fibrous region of dense irregular connective tissue, and an inner, cellular layer. The fibrous layer gives mechanical support and protection and attaches the cartilage to other structures. The cellular layer is important to the growth and maintenance of the cartilage. Blood vessels in the perichondrium provide oxygen and nutrients to the underlying chondrocytes.

Cartilage Growth

Cartilage grows by two mechanisms: *interstitial growth* and *appositional growth* (Figure 4–13).

4

Figure 4–13 The Growth of Cartilage.

Interstitial growth enlarges the cartilage from within. Chondrocytes in the cartilage matrix divide, and the daughter cells produce additional matrix (Figure 4–13a). Interstitial growth is most important during development. It begins early in embryonic development and continues through adolescence.

Appositional growth adds new layers of cartilage to the surface (Figure 4–13b). In this process, cells of the inner layer of the perichondrium divide repeatedly and become chondroblasts (immature chondrocytes). These cells begin producing cartilage matrix. As they become surrounded by and embedded in new matrix, they differentiate into mature chondrocytes. Appositional growth gradually increases the size of the cartilage by adding to its outer surface.

Both interstitial and appositional growth take place during development, but interstitial growth contributes more to the mass of the adult cartilage. Neither interstitial nor appositional growth takes place in the cartilages of normal adults. However, appositional growth may occur in unusual circumstances, such as after cartilage has been damaged or excessively stimulated by *growth hormone* from the pituitary gland. Minor damage to cartilage can be repaired by appositional growth at the damaged surface. After more severe damage, a dense fibrous patch will replace the injured portion of the cartilage.

Types of Cartilage

The body contains three major types of cartilage: hyaline cartilage, elastic cartilage, and fibrocartilage.

- Hyaline cartilage (HĪ-uh-lin; *hyalos*, glass) is the most common type of cartilage. Except inside joint cavities, a dense perichondrium surrounds hyaline cartilages. Hyaline cartilage is tough but somewhat flexible because its matrix contains closely packed collagen fibers. Because these fibers are not in large bundles and do not stain darkly, they are not always apparent in light microscopy (Figure 4–14a). Examples in adults include the connections between the ribs and the sternum; the nasal cartilages and the supporting cartilages along the conducting passageways of the respiratory tract; and the *articular cartilages*, which cover opposing bone surfaces within many joints, such as the elbow and knee.
- 2. Elastic cartilage (Figure 4–14b) is extremely resilient and flexible because it contains numerous elastic fibers. These cartilages usually have a yellowish color on gross dissection. Elastic cartilage forms the external flap (the *auricle*, or *pinna*) of the outer ear; the epiglottis, which prevents food and liquids from entering the windpipe when swallowing; a passageway to the middle ear cavity (the *auditory tube*); and small cartilages (the *cuneiform cartilages*) in the larynx, or voice box.

Figure 4–14 Types of Cartilage.

Hyaline Cartilage

Elastic Cartilage

Fibrocartilage

3. Fibrocartilage is extremely durable and tough because it has little ground substance and its matrix is dominated by densely interwoven collagen fibers (Figure 4–14c). Pads of fibrocartilage called intervertebral discs lie between the spinal vertebrae, between the pubic bones of the pelvis, and around tendons and within or around joints. In these positions, fibrocartilage resists compression, absorbs shocks, and prevents damaging bone-to-bone contact. Cartilage heals poorly. Damaged fibrocartilage in joints such as the knee can interfere with normal movements.

Several complex joints, including the knee, contain both hyaline cartilage and fibrocartilage. The hyaline cartilage covers bony surfaces, and fibrocartilage pads in the joint prevent contact between bones during movement. Injuries to these pads do not heal. After repeated or severe damage, joint mobility is severely reduced. Surgery generally produces only a temporary or incomplete repair.

Bone

Here we focus only on significant differences between cartilage and bone. We will examine the detailed histology of **bone**, or **osseous** (OS-ē-us; *os*, bone) **tissue**, in Chapter 6. The volume of ground substance in bone is very small. About two-thirds of the matrix of bone consists of a mixture of calcium salts primarily calcium phosphate, with lesser amounts of calcium carbonate. The rest of the matrix is dominated by collagen fibers. This combination gives bone truly remarkable properties. By themselves, calcium salts are hard but rather brittle, whereas collagen fibers are strong but relatively flexible. In bone, the presence of the minerals surrounding the collagen fibers produces a strong, somewhat flexible combination that is highly resistant to shattering. In its overall properties, bone can compete with the best steel-reinforced concrete. In essence, the collagen fibers in bone act like the steel reinforcing rods, and the mineralized matrix acts like the concrete.

Figure 4–15 shows the general organization of osseous tissue. Lacunae in the matrix contain **osteocytes** (OS-tēō-sīts), or bone cells. The lacunae are typically organized around blood vessels that branch through the bony matrix. Diffusion cannot take place through the hard matrix, but osteocytes communicate with the blood vessels and with one another by means of slender cytoplasmic extensions. These extensions run through long, slender passageways in the matrix called **canaliculi** (kan-a-LIK-ū-lē; little canals). These passageways form a branching network for the exchange of materials between blood vessels, interstitial fluid, and osteocytes.

Except in joint cavities, where a layer of hyaline cartilage covers bone, the surfaces are sheathed by a **periosteum** (per-ē-OS-tē-um), a covering composed of fibrous (outer) and cellular (inner) layers. The periosteum helps to attach a bone to surrounding tissues and to associated tendons and ligaments. The cellular layer takes part in appositional bone growth and helps in repairs after an injury.

Unlike cartilage, bone undergoes extensive remodeling throughout life. Complete repairs can be made even after severe damage. Bones also respond to the stresses placed on them. They grow thicker and stronger with exercise and become thin and brittle with inactivity.

Figure 4–15 Bone. The osteocytes in bone are generally organized in groups around a central space that contains blood vessels. Bone dust produced during preparation of the section fills the lacunae and the central canal, making them appear dark in the micrograph.

Table 4–2	A Comparison of Ca	artilage and Bone			
Characteristic		Cartilage	Bone		
STRUCTURAL FEATURES					
Cells		Chondrocytes in lacunae	Osteocytes in lacunae		
Ground substance		Chondroitin sulfate (in proteoglycans) and water	A small volume of liquid surrounding insoluble crystals of calcium salts (calcium phosphate and calcium carbonate)		
Fibers		Collagen, elastic, and reticular fibers (proportions vary)	Collagen fibers predominate		
Vascularity		None	Extensive		
Covering		Perichondrium (two layers)	Periosteum (two layers)		
Strength		Limited: bends easily, but hard to break	Strong: resists distortion until breaking point		
METABOLIC FEAT	TURES				
Oxygen demand	ls	Low	High		
Nutrient deliver	у	By diffusion through matrix	By diffusion through cytoplasm and interstitial fluid in canaliculi		
Growth		Interstitial and appositional	Appositional only		
Repair capabiliti	ies	Limited	Extensive		

Table 4–2 summarizes the similarities and differences between cartilage and bone.

CHECKPOINT

- 22. Identify the two types of supporting connective tissue.
- 23. Why does bone heal faster than cartilage?
- 24. If a person has a herniated intervertebral disc, characterized by displacement of the pad of cartilage between the vertebrae, which type of cartilage has been damaged?

See the blue Answers tab at the back of the book.

4-6 Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial

Learning Outcome Explain how epithelial and connective tissues combine to form four types of tissue membranes, and specify the functions of each.

A tissue membrane forms a physical barrier. There are many different types of anatomical membranes. You encountered plasma membranes that enclose cells in Chapter 3, and you will find many other kinds of membranes in later chapters. Here we are concerned with the membranes that line or cover body surfaces. Each consists of an epithelium supported by connective tissue. Four such membrane types are found in the body: (1) *mucous membranes,* (2) *serous membranes,* (3) the *cutaneous membrane,* and (4) *synovial membranes* (Figure 4–16).

Mucous Membranes

Mucous membranes, or **mucosae** (mū-KŌ-sē), line, passageways and chambers that communicate with the exterior, including those in the digestive, respiratory, reproductive, and urinary tracts (**Figure 4–16a**). The epithelial surfaces of these passageways must be kept moist to reduce friction and, in many cases, to facilitate absorption or secretion. The epithelial surfaces are lubricated either by mucus produced by mucous cells or multicellular glands, or by fluids, such as urine or semen. The areolar tissue component of a mucous membrane is called the **lamina propria** (PRŌ-prē-uh). We will look at the organization of specific mucous membranes in greater detail in later chapters.

Many mucous membranes contain simple epithelia that perform absorptive or secretory functions, such as the simple columnar epithelium of the digestive tract. However, other types of epithelia may be involved. For example, a stratified squamous epithelium is part of the mucous membrane of the mouth, and the mucous membrane along most of the urinary tract contains a transitional epithelium.

Serous Membranes

Serous membranes line the sealed, internal cavities of the trunk—cavities that are not open to the exterior. These membranes consist of a mesothelium supported by areolar tissue (**Figure 4–16b**). As you may recall from Chapter 1, the three types of serous membranes are (1) the *pleura*, which lines the pleural cavities and covers the lungs; (2) the *pericardium*,

which lines the pericardial cavity and covers the heart; and (3) the *peritoneum*, which lines the peritoneal cavity and covers the surfaces of the enclosed organs. \supset p. 22 Serous membranes are very thin, but they are firmly attached to the body wall and to the organs they cover. When looking at an organ such as the heart or stomach, you are really seeing the tissues of the organ through a transparent serous membrane.

The primary function of any serous membrane is to minimize friction between the surfaces that it covers. Each serous membrane can be divided into a *parietal portion*, which lines the inner surface of the cavity, and an opposing *visceral portion*, or **serosa**, which covers the outer surfaces of visceral organs. These organs often move or change shape as they carry out their various functions, and the parietal and visceral surfaces of a serous membrane are in close contact at all times. Friction between these surfaces is kept to a minimum because mesothelia are very thin and permeable, and tissue fluids continuously diffuse onto the exposed surfaces, keeping them moist and slippery.

The fluid secreted by the mesothelium of a serous membrane is called *serous fluid*. Serous fluid prevents friction between the cavity walls and the surfaces of internal organs. However, after an injury or in certain disease states where there is an imbalance of hydrostatic and osmotic forces, the volume of serous fluid, now called *transudate* may increase dramatically. This change may complicate existing medical problems or produce new ones.

The Cutaneous Membrane

The **cutaneous membrane** is the skin that covers the surface of your body. It consists of a stratified squamous epithelium and a layer of areolar tissue reinforced by underlying dense irregular connective tissue (Figure 4–16c). In contrast to serous and mucous membranes, the cutaneous membrane is thick, relatively waterproof, and usually dry. We will take a closer look at the cutaneous membrane in Chapter 5.

Synovial Membranes

Adjacent bones often interact at joints, or *articulations*. There the two articulating bones are very close together or in contact. Joints that permit significant amounts of movement are complex structures. Such a joint is surrounded by a fibrous capsule, and the ends of the articulating bones lie within a *joint cavity* filled with **synovial** (si-NŌ-vē-ul) **fluid** (Figure 4–16d). The synovial fluid is produced by a **synovial membrane**, which lines the joint cavity. A synovial membrane consists of an extensive area of areolar tissue containing a matrix of interwoven collagen fibers, proteoglycans, and glycoproteins. An incomplete layer, or sheet, of macrophages and specialized fibroblasts overlies and separates the areolar tissue from the joint cavity. These cells regulate the composition of the synovial fluid.

This incomplete layer of cells is often called an epithelium, but it differs from true epithelia in four respects: (1) It develops within a connective tissue; (2) no basement membrane is present; (3) gaps of up to 1 mm may separate adjacent cells; and (4) fluid and solutes are continuously exchanged between the synovial fluid and capillaries in the underlying connective tissue.

Even though a smooth layer of articular cartilage covers the ends of the bones, the surfaces must be lubricated to keep friction from damaging the opposing surfaces. Synovial fluid provides the much-needed lubrication. This fluid is similar in composition to the ground substance in loose connective tissues. Synovial fluid circulates from the areolar tissue into the joint cavity and percolates through the articular cartilages, supplying oxygen and nutrients to the chondrocytes. Joint movement is important in stimulating the formation and circulation of synovial fluid: If a synovial joint is immobilized for long periods, the articular cartilages and the synovial membrane undergo degenerative changes.

CHECKPOINT

- 25. Identify the four types of tissue membranes found in the body.
- 26. Which cavities in the body are lined by serous membranes?
- 27. The lining of the nasal cavity is normally moist, contains numerous mucous cells, and rests on a layer of connective tissue called the lamina propria. Which type of membrane is this?
- See the blue Answers tab at the back of the book.

4–7 Connective tissue creates the internal framework of the body

Learning Outcome Describe how connective tissue establishes the framework of the body.

Connective tissue provides the internal structure of the body. Layers of connective tissue surround and support the organs within the trunk cavities and connect them to the rest of the body. These layers (1) provide strength and stability, (2) maintain the relative positions of internal organs, and (3) supply a route for the distribution of blood vessels, lymphatic vessels, and nerves.

Fasciae (FASH-ē-ē; singular, *fascia*) are connective tissue layers and wrappings that support and surround organs. We can divide the fasciae into three types of layers: the superficial fascia, the deep fascia, and the subserous fascia (Figure 4–17).

- The superficial fascia (FASH-ē-uh) is also called the hypodermis (hypo, below + dermis, skin) or subcutaneous tissue. This layer of areolar tissue and fat separates the skin from underlying tissues and organs. It also provides insulation and padding, and lets the skin and underlying structures move independently.
- 2. The **deep fascia** consists of dense irregular connective tissue. The organization of the fibers is like that of plywood: In each layer all the fibers run in the same direction, but the orientation of the fibers changes from layer to layer. This arrangement helps the tissue resist forces coming from many directions. The tough capsules that surround most organs, including the kidneys and the organs enclosed by the thoracic and peritoneal cavities, are bound to the deep fascia. The perichondrium around cartilages, the periosteum around bones and the ligaments that interconnect them, and the connective tissues of muscle (including tendons) are also connected to the deep fascia.

The dense connective tissue components are interwoven. For example, the deep fascia around a muscle blends into the tendon, whose fibers intermingle with those of the

periosteum. This arrangement creates a strong, fibrous network and binds structural elements together.

3. The **subserous fascia** is a layer of areolar tissue that lies between the deep fascia and the serous membranes that line body cavities. Because this layer separates the serous membranes from the deep fascia, movements of muscles or muscular organs do not severely distort the delicate body cavity linings.

CHECKPOINT

- 28. A sheet of tissue has many layers of collagen fibers that run in different directions in successive layers. Which type of tissue is this?
- See the blue Answers tab at the back of the book.

4-8 The three types of muscle tissue are skeletal, cardiac, and smooth

Learning Outcome Describe the three types of muscle tissue and the special structural features of each type.

As we have seen, epithelia cover surfaces and line passageways, and connective tissues support and interconnect parts of the body. Together, these tissues provide a strong, interwoven framework within which the organs of the body can function. Several vital functions involve movement of one kind or another—materials move along the digestive tract, blood flows within the vessels of the cardiovascular system, and the body itself moves from place to place. **Muscle tissue**, which is specialized for contraction, produces movement. Muscle cells have organelles and properties distinct from those of other cells.

There are three types of muscle tissue: (1) *skeletal muscle*, which forms the large muscles that produce gross body movements; (2) *cardiac muscle*, found in the heart, is responsible for circulating the blood; and (3) *smooth muscle*, found in the walls of visceral organs and a variety of other locations, where it provides elasticity, contractility, and support. The contraction mechanism is similar in all three types of muscle tissue, but the muscle cells differ in internal organization. We will examine only general characteristics at this point and then discuss each type of muscle more fully in Chapter 10.

Skeletal Muscle Tissue

Skeletal muscle tissue contains very large muscle cells—up to 0.3 m (1 ft) or more in length. The individual muscle cells are usually called **muscle fibers** because they are relatively long and slender. Each muscle fiber has several hundred nuclei just inside the plasma membrane (Figure 4–18a). For this reason, the fibers are described as *multinucleate*.

Figure 4–18 Types of Muscle Tissue.

Cardiac Muscle Tissue

Smooth Muscle Tissue

Skeletal muscle fibers are incapable of dividing. New muscle fibers are produced instead through the divisions of **myosatellite cells** (*satellite cells*), stem cells that persist in adult skeletal muscle tissue. As a result, skeletal muscle tissue can at least partially repair itself after an injury.

As noted in Chapter 3, the cytoskeleton contains actin and myosin filaments. \bigcirc pp. 71, 73 In skeletal muscle fibers, however, these filaments are organized into repeating patterns that give the cells a *striated*, or banded, appearance. The *striations*, or bands, are easy to see in light micrographs. Skeletal muscle fibers do not usually contract unless stimulated by nerves, and the nervous system provides voluntary control over their activities. Thus, skeletal muscle is called **striated voluntary muscle**.

TIPS & TRICKS

Associate the sound of the word **stri**ated with the sound of the word **stri**ped.

A *skeletal muscle* is an organ of the muscular system. Muscle tissue predominates, but the muscle contains all four types of body tissue. Within a skeletal muscle, adjacent skeletal muscle fibers are tied together by collagen and elastic fibers that blend into the attached tendon or aponeurosis. The tendon or aponeurosis conducts the force of contraction, often to a bone of the skeleton. When the muscles contract, they pull on the attached bone, producing movement.

Cardiac Muscle Tissue

Cardiac muscle tissue is found in the heart. A typical cardiac muscle cell, also known as a **cardiocyte**, is smaller than a skeletal muscle cell (**Figure 4–18b**). A typical cardiac muscle cell has one centrally positioned nucleus, but some cardiocytes have as many as five. Prominent striations resemble those of skeletal muscle because the actin and myosin filaments are arranged the same way in the cells of both tissue types.

Cardiac muscle tissue consists of a branching network of interconnected cardiac muscle cells. The cells are connected at specialized regions known as **intercalated discs**. There the membranes are locked together by desmosomes, proteoglycans, and gap junctions. Ion movement through gap junctions helps synchronize the contractions of the cardiac muscle cells, and the desmosomes and proteoglycans lock the cells together during a contraction.

Cardiac muscle tissue has a very limited ability to repair itself. Some cardiac muscle cells do divide after an injury to the heart, but the repairs are incomplete. Some heart function is usually lost.

Cardiac muscle cells do not rely on nerve activity to start a contraction. Instead, specialized cardiac muscle cells called *pacemaker cells* set a regular rate of contraction. The nervous system can alter the rate of pacemaker cell activity, but it does not provide voluntary control over individual cardiac muscle cells. For this reason, cardiac muscle is called **striated involuntary muscle**.

Smooth Muscle Tissue

Smooth muscle tissue is found in the walls of blood vessels, around hollow organs such as the urinary bladder, and in layers around the respiratory, cardiovascular, digestive, and reproductive tracts. A smooth muscle cell is small and spindle-shaped, with tapering ends and a single, oval nucleus (Figure 4–18c). These cells can divide, so smooth muscle tissue can regenerate after an injury.

The actin and myosin filaments in smooth muscle cells are organized differently from those of skeletal and cardiac muscles. One result is that smooth muscle tissue has no striations.

Smooth muscle cells may contract on their own, with gap junctions between adjacent cells coordinating the contractions of individual cells. The contraction of some smooth muscle tissue can be controlled by the nervous system, but contractile activity is not under voluntary control. (Imagine the effort you would need to exert conscious control over the smooth muscles along the 8 m [26 ft.] of digestive tract, not to mention the miles of blood vessels!) Smooth muscle is known as **nonstriated involuntary muscle** because of its appearance and the fact that the nervous system usually does not voluntarily control smooth muscle contractions.

CHECKPOINT

- 29. Identify the three types of muscle tissue in the body.
- **30**. Which type of muscle tissue has small, tapering cells with single nuclei and no obvious striations?
- **31**. If skeletal muscle cells in adults are incapable of dividing, how is skeletal muscle repaired?
- See the blue Answers tab at the back of the book.

4-9 Neural tissue responds to stimuli and propagates electrical impulses throughout the body

Learning Outcome Discuss the basic structure and role of neural tissue.

Neural tissue, also known as *nervous tissue* or *nerve tissue*, is specialized for the propagation (movement) of electrical impulses from one region of the body to another. Ninety-eight percent of the neural tissue in the body is in the brain and spinal cord, which are the control centers of the nervous system.

Figure 4–19 Neural Tissue.

Neural tissue contains two basic types of cells: (1) **neurons** (NOOR-onz; *neuro*, nerve) and (2) several kinds of supporting cells, collectively called **neuroglia** (nū-ROG-lē-uh), or *glial cells* (*glia*, glue). Our conscious and unconscious thought processes reflect the communication among neurons in the brain. Such communication involves the propagation of electrical impulses, in the form of reversible changes in the membrane potential. \bigcirc **p**. 100 The frequency and the pattern of the impulses convey information. Neuroglia support and repair neural tissue and supply nutrients to neurons.

Neurons are the longest cells in your body. Many are as long as a meter (39 in.)! Most neurons cannot divide under normal circumstances, so they have a very limited ability to repair themselves after injury. A typical neuron has a large **cell body** with a large nucleus and a prominent nucleolus (Figure 4–19). Extending from the cell body are many branching processes (projections or outgrowths) termed **dendrites** (DEN-drīts; *dendron*, a tree), and one **axon**. The dendrites receive information, typically from other neurons. The axon conducts that information to other cells. Because axons tend to be very long and slender, they are also called **nerve fibers**. In Chapter 12 we will examine the properties of neural tissue more closely.

TIPS & TRICKS

To remember the direction of information flow in a neuron, associate the "t" in dendrite with "to" and the "a" in **a**xon with "**a**way."

CHECKPOINT

32. A tissue contains irregularly shaped cells with many fibrous projections, some several centimeters long. These are probably which type of cell?

See the blue Answers tab at the back of the book.

4–10 The response to tissue injury involves inflammation and regeneration

Learning Outcome Describe how injuries affect the tissues of the body.

Now let's consider what happens after an injury, focusing on the interaction among different tissues. Our example includes connective tissue (blood), an epithelium (the endothelia of blood vessels), a muscle tissue (smooth muscle in the vessel walls), and neural tissue (sensory nerve endings). **Inflammation**, or the **inflammatory response**, isolates the injured area while damaged cells, tissue components, and any dangerous microorganisms, which could cause infection, are cleaned up. **Regeneration** is the repair process that restores normal function after inflammation has subsided. In later chapters, especially Chapters 5 and 22, we will consider inflammation and regeneration in more detail.

Inflammation

Impact, abrasion, distortion, chemical irritation, infection by pathogenic organisms (such as bacteria or viruses), and extreme temperatures (hot or cold) are all stimuli that can produce inflammation. Each of these stimuli kills cells, damages fibers, or injures the tissue in some way. Such changes alter the chemical composition of the interstitial fluid: Damaged cells release prostaglandins, proteins, and potassium ions, and the injury itself may have introduced foreign proteins or pathogens into the body. Damaged connective tissue activates mast cells, which release chemicals that stimulate the inflammatory response.

Tissue conditions soon become even more abnormal. **Necrosis** (ne-KR \overline{O} -sis) is the tissue destruction that takes place after cells have been damaged or killed. It begins several hours after the original injury. Lysosomal enzymes cause the damage. Through widespread autolysis, lysosomes release enzymes that first destroy the injured cells and then attack surrounding tissues. \bigcirc **p**. 76 The result may be **pus**, a collection of debris, fluid, dead and dying cells, and necrotic tissue components. An **abscess** is an accumulation of pus in an enclosed tissue space.

Regeneration

Each organ has a different ability to regenerate after injury. This ability is directly linked to the pattern of tissue organization in the injured organ. Epithelia, connective tissues (except cartilage), and smooth muscle tissue usually regenerate well, but skeletal and cardiac muscle tissues and neural tissue regenerate relatively poorly, if at all. The skin, which is dominated by epithelia and connective tissues, regenerates rapidly and completely after injury. (We will consider the process in Chapter 5.) In contrast, damage to the heart is much more serious. The connective tissues of the heart can be repaired, but the majority of damaged cardiac muscle cells are replaced only

by fibrous tissue. The permanent replacement of normal tissue by fibrous tissue is called *fibrosis* (fī-BRŌ-sis). Fibrosis is in muscle and other tissues may occur in response to injury, disease, or aging. **Spotlight Figure 4–20** shows the tissue response to injury and the process of tissue regeneration.

CHECKPOINT

- 33. Identify the two phases in the response to tissue injury.
- 34. List the four common signs of inflammation.
- See the blue Answers tab at the back of the book.

4–11 With advancing age, tissue repair declines and cancer rates increase

Learning Outcome Describe how aging affects the tissues of the body.

Aging has two important effects on tissues. The body's ability to repair damage to tissues decreases, and cancer is more likely to occur.

Aging and Tissue Structure

Tissues change with age, and the speed and effectiveness of tissue repairs decrease. Repair and maintenance activities throughout the body slow down, and the rate of energy consumption in general declines. All these changes reflect various hormonal alterations that take place with age, often coupled with reduced physical activity and a more sedentary lifestyle. These factors combine to alter the structure and chemical composition of many tissues.

Epithelia get thinner and connective tissues more fragile. Individuals bruise easily and bones become brittle. Joint pain and broken bones are common in the elderly. Because cardiac muscle cells and neurons are not normally replaced, cumulative damage can eventually cause major health problems, such as cardiovascular disease or deterioration in mental functioning.

In later chapters, we will consider the effects of aging on specific organs and systems. Some of these effects are genetically programmed. For example, the chondrocytes of older individuals produce a slightly different form of proteoglycan than do the chondrocytes of younger people. This difference probably accounts for the thinner and less resilient cartilage of older people.

In some cases, the tissue degeneration can be temporarily slowed or even reversed. Age-related reduction in bone strength, a condition called *osteoporosis*, typically results from a combination of inactivity, low dietary calcium levels, and a reduction in circulating sex hormones. A program of exercise that includes weight-bearing activity, calcium supplements, and in some cases medication can generally maintain healthy bone structure for many years.

SPOTLIGHT Figure 4–20 Inflammation and Regeneration

Tissues are not isolated, and they combine to form organs with diverse functions. Therefore, any injury affects several types of tissue simultaneously. To preserve homeostasis, the tissues must respond in a coordinated way. The restoration of homeostasis involves two related processes: inflammation and regeneration.

Exposure to Pathogens and Toxins

Injured tissue contains an abnormal concentration of pathogens, toxins,

wastes, and the chemicals from

iniured cells.

When a tissue is injured, a general defense mechanism is activated.

stimulates

Increased Local

Temperature

Mast Cell Activation

When an injury damages connective tissue, mast cells release a variety of chemicals. This process, called mast cell activation, stimulates inflammation.

> Histamine Heparin Prostaglandins

Removal of Toxins

and Wastes

INFLAMMATION

Inflammation produces several familiar indications of injury, including swelling, redness, heat (warmth), pain, and sometimes loss of function. Inflammation may also result from the presence of pathogens, such as harmful bacteria, within the tissues. The presence of these pathogens constitutes an infection.

Increased Blood Flow	Increased Vessel Permeability	Pain			
In response to the released chemicals, blood vessels dilate, increasing blood flow through the damaged tissue.	Vessel dilation is accompanied by an increase in the permeability of the capillary walls. Plasma now diffuses into the injured tissue, so the area becomes swollen.	The abnormal conditions within the tissue and the chemicals released by mast cells stimulate nerve endings that produce the sensation of pain.			

Increased

Phagocytosis

Increased Oxygen

and Nutrients

The increased Vessel dilation, Phagocytes in Enhanced circulation blood flow and increased blood flow, the tissue are carries away toxins permeability activated, and and increased vessel and wastes, distributing causes the tissue permeability result in they begin them to the kidneys to become warm enhanced delivery of engulfing tissue for excretion, or to the and red. oxygen and nutrients. debris and liver for inactivation. pathogens. Toxins and wastes Regeneration **Regeneration** is the repair that occurs

after the damaged tissue has been stabilized and the inflammation has subsided. Fibroblasts move into the area, laying down a collagenous framework known as scar tissue. Over time, scar tissue is usually "remodeled" and gradually assumes a more normal appearance.

Inflammation Subsides

Over a period of hours to days, the cleanup process generally succeeds in eliminating the inflammatory stimuli.

Aging and Cancer Incidence

Cancer rates increase with age, and about 25 percent of all people in the United States develop cancer at some point in their lives. It has been estimated that 70–80 percent of cancer cases result from chemical exposure, environmental factors, or some combination of the two, and 40 percent of those cancers are caused by cigarette smoke. Each year in the United States, more than 500,000 individuals die of cancer, making it second only to heart disease as a cause of death. We discussed the development and growth of cancer in Chapter 3. \bigcirc p. 106

With this chapter, you have concluded the introductory portion of this text. In combination, the four basic tissue types described here form all of the organs and systems we will discuss in subsequent chapters.

CHECKPOINT

- **35**. Identify some age-related factors that affect tissue repair and structure.
- **36**. What would account for the observed increase in cancer rates with age?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

- **autopsy:** An examination of a dead body to discover the cause of death or the extent of disease.
- **biopsy:** An examination of tissue removed from a living body to discover the presence, cause, or extent of disease.
- **cachexia:** Weakness and wasting of the body due to severe chronic illness.
- **carcinoma:** A cancer arising in the epithelial tissue of the skin or of the lining of the internal organs.
- **immunotherapy:** The prevention or treatment of disease with substances that stimulate the immune response.
- **lesion:** A region in an organ or tissue that has suffered damage from injury or disease; a wound, ulcer, abscess, or tumor, for example.
- **metaplasia:** A reversible structural change that alters the character of a tissue.
- **pathologist:** A physician who specializes in the study of disease processes in tissues and body fluids.
- **remission:** Abatement, ending, or lessening in severity of the signs and symptoms of a disease.

- **sarcoma:** A malignant tumor of connective or other nonepithelial tissue.
- **tissue engineering:** Tissue is either grown in or outside of a body to be transplanted into a patient or used for testing.
- **tissue rejection:** Occurs when a transplant recipient's immune system attacks a transplanted organ or tissue.
- **tissue transplantation:** Moving tissues (or organs) from one body and placing them into another body by medical procedures for the purpose of replacing the recipient's damaged or failing tissue (or organ).
- **tumor grading:** A system used to classify cancer cells in terms of how abnormal they look under a microscope and how quickly the tumor is likely to grow and spread.
- **tumor staging:** Defining at what point the patient is in the development of the malignant disease when the diagnosis is made.
- **xenotransplant:** The process of grafting or transplanting organs or tissues between members of different species.

- An Introduction to the Tissue Level of Organization p. 114
 - 1. Tissues are structures with discrete structural and functional properties that combine to form organs.
- **4-1** The four tissue types are epithelial, connective, muscle, and neural p. 114
- **2. Tissues** are collections of specialized cells and cell products that perform a relatively limited number of functions. The four *tissue types* are *epithelial tissue, connective tissue, muscle tissue,* and *neural tissue.*
- 3. Histology is the study of tissues.
- 4-2 Epithelial tissue covers body surfaces, lines cavities and tubular structures, and serves essential functions p. 114
- 4. Epithelial tissue includes epithelia and glands. An epithelium is an avascular layer of cells that forms a barrier that provides protection and regulates permeability. Glands are

secretory structures derived from epithelia. Epithelial cells may show **polarity**, the presence of structural and functional differences between their exposed (apical) and attached (basal) surfaces.

- 5. A **basement membrane (basal lamina)** attaches epithelia to underlying connective tissues.
- 6. Epithelia provide physical protection, control permeability, provide sensation, and produce specialized secretions. Gland cells are epithelial cells that produce secretions. In glandular epithelia, most cells produce secretions.
- 7. Epithelial cells are specialized to perform secretory or transport functions and to maintain the physical integrity of the epithelium. (*Figure 4–1*)
- 8. Many epithelial cells have microvilli.
- 9. The coordinated beating of the cilia on a **ciliated epithelium** moves materials across the epithelial surface.
- 10. Cells can attach to other cells or to extracellular protein fibers by means of cell adhesion molecules (CAMs) or at specialized attachment sites called cell junctions. The three major types of cell junctions are tight junctions, gap junctions, and desmosomes. (*Figure 4–2*)
- **11.** The inner surface of each epithelium is connected to a two-part basement membrane consisting of a *clear layer* and a *dense layer*. Divisions by **germinative cells** (a kind of stem cell) continually replace the short-lived epithelial cells.

4-3 Cell shape and number of layers determine the classification of epithelia p. 118

- **12.** Epithelia are classified on the basis of the number of cell layers and the shape of the cells at the apical surface.
- **13.** A **simple epithelium** has a single layer of cells covering the basement membrane; a **stratified epithelium** has several layers. The cells in a **squamous epithelium** are thin and flat. Cells in a **cuboidal epithelium** resemble hexagonal boxes; those in a **columnar epithelium** are taller and more slender. (*Table 4–1; Figures 4–3 to 4–5*)
- 14. Epithelial cells (or structures derived from epithelial cells) that produce secretions are called *glands*. **Exocrine glands** discharge secretions onto the body surface or into **ducts**, which communicate with the exterior. *Hormones*, the secretions of **endocrine glands**, are released by gland cells into the surrounding interstitial fluid.
- **15.** A glandular epithelial cell may release its secretions by merocrine, apocrine, or holocrine secretory modes. In **merocrine secretion**, the most common mode, the product is released through exocytosis. **Apocrine secretion** involves the loss of both the secretory product and cytoplasm. Unlike the other two methods, **holocrine secretion** destroys the gland cell, which becomes packed with secretions and then bursts. (*Figure 4–6*)
- **16.** In epithelia that contain scattered gland cells, individual secretory cells are called **unicellular glands**. **Multicellular glands** are organs that contain glandular epithelia that produce exocrine or endocrine secretions.
- 17. Exocrine glands can be classified on the basis of structure as unicellular exocrine glands (mucous or goblet cells) or as multicellular exocrine glands. Multicellular exocrine glands can be further classified according to structure. (*Figure 4–7*)

4-4 Connective tissue provides a protective structural framework for other tissue types p. 126

18. Connective tissues are internal tissues with many important functions: establishing a structural framework; transporting fluids and dissolved materials; protecting delicate organs;

supporting, surrounding, and interconnecting tissues; storing energy reserves; and defending the body from microorganisms.

- **19.** All connective tissues contain specialized cells and a **matrix**, composed of extracellular protein fibers and a **ground substance**.
- **20.** Connective tissue proper is connective tissue that contains varied cell populations and fiber types surrounded by a syrupy ground substance. (*Figure 4–8*)
- **21.** Fluid connective tissues have distinctive populations of cells suspended in a watery matrix that contains dissolved proteins. The two types of fluid connective tissues are *blood* and *lymph*.
- **22. Supporting connective tissues** have a less diverse cell population than connective tissue proper and a dense matrix with closely packed fibers. The two types of supporting connective tissues are *cartilage* and *bone*.
- 23. Connective tissue proper contains fibers, a viscous ground substance, and a varied population of cells, including fibroblasts, fibrocytes, macrophages, adipocytes, mesenchymal cells, melanocytes, mast cells, lymphocytes, and microphages.
- 24. The three types of fibers in connective tissue are **collagen fibers**, **reticular fibers**, and **elastic fibers**.
- 25. The first connective tissue to appear in an embryo is **mesen-***chyme*, or *embryonic connective tissue*.
- 26. Connective tissue proper is classified as either loose connective tissue or dense connective tissue. Loose connective tissues are mesenchyme and mucous connective tissues in the embryo; areolar tissue; adipose tissue, including white fat and brown fat; and reticular tissue. Most of the volume in dense connective tissue consists of fibers. The two types of dense connective tissue are dense regular connective tissue is a dense regular connective tissue. (*Figures 4–9 to 4–11*)
- 27. Blood and lymph are connective tissues that contain distinctive collections of cells in a fluid matrix.
- **28.** Blood contains formed elements: red blood cells (*erythrocytes*), white blood cells (*leukocytes*), and platelets. The watery matrix of blood is called plasma. (*Figure 4–12*)
- **29. Arteries** carry blood away from the heart and toward **capillaries**, where water and small solutes move into the interstitial fluid of surrounding tissues. **Veins** return blood to the heart.
- **30.** Lymph forms as interstitial fluid enters the **lymphatic vessels**, which return lymph to the cardiovascular system.
- 4-5 Cartilage and bone provide a strong supporting framework p. 133
- **31.** Cartilage and bone are called supporting connective tissues because they support the rest of the body.
- **32.** Chondrocytes, or cartilage cells, rely on diffusion through the avascular matrix to obtain nutrients.
- **33.** Cartilage grows by two mechanisms: interstitial growth and appositional growth. (*Figure 4–13*)
- 34. The matrix of cartilage is a firm gel that contains **chondroitin sulfates** (used to form proteoglycans) and chondrocytes. Chondrocytes occupy chambers called **lacunae**. A fibrous **perichondrium** separates cartilage from surrounding tissues. The three types of cartilage are **hyaline cartilage**, **elastic cartilage**, and **fibrocartilage**. (*Figure 4–14*)
- **35.** Bone, or osseous tissue, consists of osteocytes, little ground substance, and a dense, mineralized matrix. Osteocytes are situated in lacunae. The matrix consists of calcium salts and collagen fibers, giving it unique properties. (*Figure 4–15; Table 4–2*)

4

- **36.** Osteocytes depend on diffusion within **canaliculi** for nutrient intake.
- **37.** Each bone is surrounded by a **periosteum** with fibrous and cellular layers.
- **4-6** Tissue membranes are physical barriers of four types: mucous, serous, cutaneous, and synovial p. 137
- **38.** Membranes form a barrier or interface. Epithelia and connective tissues combine to form membranes that cover and protect other structures and tissues. (*Figure 4–16*)
- **39.** Mucous membranes line cavities that communicate with the exterior. They contain areolar tissue called the lamina propria.
- **40. Serous membranes** line the body's sealed internal cavities of the trunk. They secrete a fluid called a *transudate*.
- 41. The cutaneous membrane, or skin, covers the body surface.
- **42. Synovial membranes** form an incomplete lining within the cavities of synovial joints.
- 4-7 Connective tissues create the internal framework of the body p. 139
- 43. A network of connective tissue proper ties internal organs and systems together. This network consists of the **superficial fascia** (the **hypodermis**, or subcutaneous tissue, separating the skin from underlying tissues and organs), the **deep fascia** (dense connective tissue), and the **subserous fascia** (the layer between the deep fascia and the serous membranes that line true body cavities). (*Figure 4–17*)
- 4-8 The three types of muscle tissue are skeletal, cardiac, and smooth p. 140
- 44. Muscle tissue is specialized for contraction. (Figure 4–18)
- **45.** The cells of **skeletal muscle tissue** are *multinucleate*. Skeletal muscle, or **striated voluntary muscle**, produces new fibers by the division of **myosatellite cells**, a kind of stem cell.
- **46.** Cardiocytes, the cells of cardiac muscle tissue, occur only in the heart. Cardiac muscle, or striated involuntary muscle, relies on *pacemaker cells* to stimulate regular contraction.

- **47. Smooth muscle tissue**, or **nonstriated involuntary muscle**, is not striated. Smooth muscle cells can divide and therefore regenerate after injury.
- 4-9 Neural tissue responds to stimuli and conducts electrical impulses throughout the body p. 142
- **48. Neural tissue** conducts electrical impulses, which convey information from one area of the body to another.
- 49. Cells in neural tissue are either neurons or neuroglia. Neurons transmit information as electrical impulses. Several kinds of neuroglia exist, and their basic functions include supporting neural tissue and helping supply nutrients to neurons. (*Figure 4–19*)
- **50.** A typical neuron has a **cell body**, **dendrites**, and an **axon**, or **nerve fiber**. The axon carries information to other cells.
- **4-10** The response to tissue injury involves inflammation and regeneration p. 144
- **51.** Any injury affects several types of tissue simultaneously, and they respond in a coordinated manner. Homeostasis is restored by two processes: inflammation and regeneration.
- **52. Inflammation**, or the **inflammatory response**, isolates the injured area while damaged cells, tissue components, and any dangerous microorganisms (which could cause **infection**) are cleaned up. **Regeneration** is the repair process that restores normal function. (*Spotlight Figure 4–20*)
- 4-11 With advancing age, tissue repair declines and cancer rates increase p. 144
- **53.** Tissues change with age. Repair and maintenance become less efficient, and the structure and chemical composition of many tissues are altered.
- **54.** The incidence of cancer increases with age, with roughly threequarters of all cases caused by exposure to chemicals or by other environmental factors, such as cigarette smoke.

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the six categories of epithelial tissue shown in the drawing below.

Collections of specialized cells and cell products that perform a relatively limited number of functions are called (a) cellular aggregates, (b) tissues, (c) organs, (d) organ systems, (e) organisms.

See the blue Answers tab at the back of the book.

- Tissue that is specialized for contraction is (a) epithelial tissue,
 (b) muscle tissue, (c) connective tissue, (d) neural tissue.
- 4. A type of cell junction common in cardiac and smooth muscle tissues is the (a) hemidesmosome, (b) basal junction, (c) tight junction, (d) gap junction.
- The most abundant connections between cells in the superficial layers of the skin are (a) connexons, (b) gap junctions, (c) desmosomes, (d) tight junctions.
- A ______ membrane has an epithelium that is stratified and supported by dense connective tissue. (a) synovial, (b) serous, (c) cutaneous, (d) mucous.
- Mucous secretions that coat the passageways of the digestive and respiratory tracts result from ______ secretion. (a) apocrine, (b) merocrine, (c) holocrine, (d) endocrine.
- Matrix is a characteristic of which type of tissue? (a) epithelial,
 (b) neural, (c) muscle, (d) connective.
- Functions of connective tissue include (a) establishing a structural framework for the body, (b) storing energy reserves, (c) providing protection for delicate organs, (d) all of these, (e) a and c only.

- 10. Which of the following epithelia most easily permits diffusion?(a) stratified squamous, (b) simple squamous, (c) transitional,(d) simple columnar.
- The three major types of cartilage in the body are (a) collagen, reticular, and elastic, (b) areolar, adipose, and reticular, (c) hyaline, elastic, and fibrous, (d) tendons, reticular, and elastic.
- 12. The primary function of serous membranes in the body is to(a) minimize friction between opposing surfaces, (b) line cavities that communicate with the exterior, (c) perform absorptive and secretory functions, (d) cover the surface of the body.
- 13. The type of cartilage growth characterized by adding new layers of cartilage to the surface is (a) interstitial growth, (b) appositional growth, (c) intramembranous growth, (d) longitudinal growth.
- 14. Tissue changes with age can result from (a) hormonal changes,(b) increased need for sleep, (c) improper nutrition, (d) all of these,(e) a and c only.
- 15. Axons, dendrites, and a cell body are characteristic of cells located in(a) neural tissue, (b) muscle tissue, (c) connective tissue, (d) epithelial tissue.
- The repair process necessary to restore normal function after inflammation subsides in damaged tissues is (a) isolation, (b) regeneration, (c) reconstruction, (d) all of these.
- 17. What are the four essential functions of epithelial tissue?
- 18. Differentiate between endocrine and exocrine glands.
- **19.** By what three methods do various glandular epithelial cells release their secretions?
- 20. List three basic components of connective tissues.
- **21.** What are the four kinds of membranes composed of epithelial and connective tissue that cover and protect other structures and tissues in the body?
- **22.** What two cell populations make up neural tissue? What is the function of each?

LEVEL 2 Reviewing Concepts

23. What is the difference between an exocrine secretion and an endocrine secretion?

- **24.** A significant structural feature in the digestive system is the presence of tight junctions near the exposed surfaces of cells lining the digestive tract. Why are these junctions so important?
- **25.** Describe the fluid connective tissues in the human body. What are the main differences between fluid connective tissues and supporting connective tissues?
- **26.** Why are infections always a serious threat after a severe burn or abrasion?
- 27. A layer of glycoproteins and a network of fine protein filaments that prevents the movement of proteins and other large molecules from the connective tissue to the epithelium describes (a) interfacial canals, (b) the basement membrane, (c) the reticular lamina, (d) areolar tissue, (e) squamous epithelium.
- 28. Why does damaged cartilage heal slowly? (a) Chondrocytes cannot be replaced if killed, and other cell types must take their place,
 (b) Cartilage is avascular, so nutrients and other molecules must diffuse to the site of injury, (c) Damaged cartilage becomes calcified, thus blocking the movement of materials required for healing,
 (d) Chondrocytes divide more slowly than other cell types, delaying the healing process, (e) Damaged collagen cannot be quickly replaced, thereby slowing the healing process.
- **29.** List the similarities and differences among the three types of muscle tissue.

LEVEL 3 Critical Thinking and Clinical Applications

- **30.** Assuming that you had the necessary materials to perform a detailed chemical analysis of body secretions, how could you determine whether a secretion was merocrine or apocrine?
- **31.** During a lab practical, a student examines a tissue that is composed of densely packed protein fibers that are running parallel and form a cord. There are no striations, but small nuclei are visible. The student identifies the tissue as skeletal muscle. Why is the student's choice wrong, and what tissue is he probably observing?
- **32.** While in a chemistry lab, Jim accidentally spills a small amount of a caustic (burning) chemical on his arm. What changes in the characteristics of the skin would you expect to observe, and what would cause these changes?

CLINICAL CASE Wrap-Up

The Rubber Girl

Anne Marie suffers from a variant of Ehlers-Danlos syndrome—a rare inherited disorder of connective tissue. Specifically, the collagen fibers in the matrix of connective tissue are defective. Because connective tissue and collagen occur throughout the body, many tissues are involved, particularly the joints and skin.

Anne Marie's loose joints and dislocations are due to deficient dense connective tissue. Because of abnormal collagen fibers, both her ligaments (which connect bone to bone) and her tendons (which connect muscle to bone) are abnormally loose and heal poorly when overstretched. When she twists her knee and feels as if her kneecap is dislocating, it is, indeed, sliding out of its groove. The ligaments that protect her ankles have been repeatedly sprained. Thin, translucent skin that is soft, velvety, and stretchy is also typical of Ehlers-Danlos syndrome. Scars appear wide, fragile, and abnormal. Bruises and skin tears occur easily.

- 1. Connective tissues are made up of specialized cells and a matrix of extracellular protein fibers and a fluid known as ground substance. What part of connective tissue proper is defective in Ehlers-Danlos syndrome?
- 2. Do you think this genetic syndrome affects just Anne Marie's joints and skin or would you suspect other tisses are affected as well?

See the blue Answers tab at the back of the book.

The Integumentary System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 5-1 Describe the main structural features of the epidermis, and explain the functional significance of each.
- 5-2 Explain what accounts for individual differences in skin color, and discuss the response of melanocytes to sunlight exposure.
- **5-3** Describe the interaction between sunlight and vitamin D_3 production.
- **5-4** Describe the roles of epidermal growth factor.
- **5-5** Describe the structure and functions of the dermis.
- **5-6** Describe the structure and functions of the hypodermis.
- 5-7 Describe the mechanisms that produce hair, and explain the structural basis for hair texture and color.
- **5-8** Discuss the various kinds of glands in the skin, and list the secretions of those glands.
- 5-9 Describe the anatomical structure of nails, and explain how they are formed.
- 5-10 Explain how the skin responds to injury and repairs itself.
- 5-11 Summarize the effects of aging on the skin.

Skin Cells in Overdrive

Harold is a 50-year-old, overweight, diabetic, hardworking father of three. He has a 15-year smoking

addiction. He isn't crazy about his job and has a habit of scratching his head while sitting at his desk. For the past several months he has noticed dandruff-like flakes falling onto his paperwork. He assumed this was due to dandruff and has been using a dandruff shampoo, with no improvement. Harold has also noticed that his fingernails are pitted and discolored.

Today he is itching around his belt line. This is nearly as distracting as the itchy, scaly patches on his anterior knees and the posterior surfaces of his elbows. These round patches are raised, reddened, and scaly with silvery plaques. They are tender and have been enlarging and worsening for the past few weeks.

Harold is so concerned about these skin lesions that he consults a dermatologist (skin doctor), who performs a skin biopsy. The dermatologist comments that, under the microscope, the tissue looks like epidermis in "overdrive."

An Introduction to the Integumentary System

You are probably more familiar with the skin than with any other organ system. No other organ system is as accessible, large, and underappreciated as the *integumentary system*. Often referred to simply as the **integument** (in-TEG- \bar{u} -ment), this system makes up about 16 percent of your total body weight. Its surface, 1.5–2 m² (16.1–21.5 sq ft) in area, is continually abraded, attacked by microorganisms, irradiated by sunlight,

and exposed to environmental chemicals. The integumentary system is your body's first line of defense against an often hostile environment. It's the place where you and the outside world meet.

The integumentary system has two major parts: the **cu-taneous membrane** or skin, and the **accessory structures** (Figure 5–1).

1. The cutaneous membrane has two components: the **epidermis** (*epi-*, above) or superficial epithelium, and the **dermis**, an underlying area of connective tissues.

152 UNIT 2 Support and Movement

2. The accessory structures include hair, exocrine glands, and nails. They are located primarily in the dermis and pro-trude through the epidermis to the skin surface.

The integument does not function in isolation. An extensive network of blood vessels branches through the dermis. Sensory receptors monitor touch, pressure, temperature, and pain, providing valuable information to the central nervous system about the state of the body.

Deep to the dermis is the loose connective tissue of the **hypodermis**, also known as the superficial fascia or *subcutaneous layer*. The hypodermis separates the integument from the deep fascia around other organs, such as muscles and bones. \bigcirc **p**. 139 Although the hypodermis is often considered separate from the integument, we will consider it in this chapter because its connective tissue fibers are interwoven with those of the dermis.

The general functions of the integumentary system are summarized in Figure 5–2 and include:

 Protection of underlying tissues and organs against impact, abrasion, fluid loss, and chemical attack.

- *Excretion* of salts, water, and organic wastes by integumentary glands.
- *Maintenance* of normal body temperature through either insulation or evaporative cooling, as needed.
- *Production* of melanin, which protects underlying tissue from ultraviolet radiation.
- *Production* of keratin, which protects against abrasion and serves as a water repellent.
- Synthesis of vitamin D₃, a steroid that is converted to calcitriol, a hormone important to normal calcium metabolism.
- *Storage* of lipids in adipocytes in the dermis and in adipose tissue in the hypodermis (subcutaneous layer).
- Detection of touch, pressure, pain, vibration, and temperature stimuli and the relaying of that information to the nervous system. (We will consider these general senses, which provide information about the external environment, in Chapter 15.)
- *Coordination* of immune response to pathogens and cancers in the skin.

5-1 The epidermis is composed of layers with various functions

Learning Outcome Describe the main structural features of the epidermis, and explain the functional significance of each.

The epidermis is a stratified squamous epithelium. Recall from Chapter 4 that such an epithelium provides physical protection and helps keep microorganisms outside the body. \bigcirc p. 120

Like all other epithelia, the epidermis is avascular. Because there are no local blood vessels, epidermal cells rely on the diffusion of nutrients and oxygen from capillaries within the dermis. As a result, the epidermal cells with the highest metabolic demands are found close to the basement membrane, where the diffusion distance is short. The superficial cells, far removed from the source of nutrients, are dead. **Spotlight Figure 5–3** describes the epidermal layers and functions.

Keratinocytes (ke-RAT-i-nō-sīts), the body's most abundant epithelial cells, dominate the epidermis. These cells form several layers, or *strata*, and contain large amounts of the protein *keratin* (discussed shortly). **Thin skin** covers most of the body surface. **Thick skin** is found on the palms of the hands and the soles of the feet. Note that the terms *thick* and *thin* refer to the relative thickness of the epidermis, not to the cutaneous membrane as a whole.

Spotlight Figure 5–3 shows the five layers of keratinocytes in a section of the epidermis in an area of thick skin. The boundaries between the layers are often difficult to see in a standard light micrograph. Notice that the various layers have Latin names. The word *stratum* (plural, *strata*) means "layer," and the rest of the name refers to the function or appearance of the layer. The strata, in order from the basement membrane toward the free surface, are the *stratum basale*, the *stratum spinosum*, the *stratum granulosum*, the *stratum lucidum*, and the *stratum corneum*.

Stratum Basale

The deepest layer of the epidermis is the **stratum basale** (STRA-tum buh-SAHL-āy) or *stratum germinativum* (STRA-tum jer-mi-na-TĒ-vum). Hemidesmosomes attach the cells of this layer to the basement membrane that separates the epidermis from the areolar tissue of the dermis. \supset p. 117 The stratum basale and the underlying dermis interlock, increasing the strength of the bond between the epidermis and dermis. The stratum basale forms **epidermal ridges**, which extend into the dermis and are adjacent to dermal projections called **dermal papillae** (singular, *papilla*; a nipple-shaped mound) that project into the epidermis (**Spotlight Figure 5–3**). These ridges and papillae are important because the strength of the basement membrane. In other words, the more numerous and deeper the folds, the larger the surface area becomes.

The contours of the skin surface follow the ridge patterns, which vary from small conical pegs (in thin skin) to the complex whorls seen on the thick skin of the palms and soles. Ridges on the palms and soles increase the surface area of the skin and increase friction, ensuring a secure grip. The ridge patterns on the tips of the fingers are the basis of fingerprints. These ridge shapes are determined partially by the interaction of genes and partially by the intrauterine environment. That is, during fetal development our genes determine general characteristics, but the contact with amniotic fluid, another fetus (in the case of twins), or the uterine wall affect the ultimate pattern of a fetus's fingerprints. So, identical twins do not have identical fingerprints. However, the pattern of your epidermal ridges is unique and does not change after birth and during your lifetime. Basal cells, or germinative cells, dominate the stratum basale. Basal cells are stem cells that divide to replace the more superficial keratinocytes that are shed at the epithelial surface.

Skin surfaces that lack hair also contain specialized epithelial tactile cells known as *Merkel cells* scattered among the cells of the stratum basale. Each Merkel cell together with a sensory nerve terminal is called a **tactile disc**. The tactile cells are sensitive to touch and when compressed release chemicals that stimulate their associated sensory nerve endings. (The skin contains many other kinds of sensory receptors, as we will see in later sections.)

The brown tones of skin result from the synthesis of pigment by cells called *melanocytes*. \bigcirc **p**. **128** These pigment cells are distributed throughout the stratum basale, with cell processes extending into more superficial layers.

Stratum Spinosum

Each time a stem cell divides, one of the daughter cells is pushed superficial to the stratum basale into the **stratum spinosum**. This stratum consists of 8 to 10 layers of keratinocytes bound together by desmosomes. \bigcirc **p**. **116** The name *stratum spinosum*, which means "spiny layer," refers to the fact that the cells look like miniature pincushions in standard histological sections. They look that way because the keratinocytes were processed with chemicals that shrank the cytoplasm but left the cytoskeletal elements and desmosomes intact. Some of the cells entering this layer from the stratum basale continue to divide, further increasing the thickness of the epithelium.

The stratum spinosum also contains cells that participate in the immune response. Called *dendritic cells* (*dendron*, tree) because of their branching projections, they are also known as *Langerhans cells*. They stimulate defense against (1) microorganisms that manage to penetrate the superficial layers of the epidermis and (2) superficial skin cancers. We will consider dendritic cells and other cells of the immune response in Chapter 22.

SPOTLIGHT Figure 5-3 The Epidermis

BASIC ORGANIZATION OF THE EPIDERMIS

The epidermis consists of stratified squamous epithelium. It is separated from the dermis by a basement membrane. The stratum basale and the underlying dermis interlock,

strengthening the bond between the two. The epidermis forms epidermal ridges, which extend into the dermis and are adjacent to dermal papillae that project into the epidermis.

LAYERS OF THE EPIDERMIS

The layers of the epidermis are best shown in a sectional view of thick skin. Thick skin contains a fifth layer, the stratum lucidum. Because thick skin also has a much thicker superficial layer (the stratum corneum), it is about as thick as a standard paper towel (about 0.5 mm).

Stratum corneum Basement membrane Dermis Thin skin $LM \times 200$

> Thin skin contains four layers of keratinocytes, and is about as thick as the wall of a plastic sandwich bag (about 0.08 mm).

		-	- Surface	Epidermis	Characteristics
				Stratum corneum	 Multiple layers of flattened, dead, interlocking keratinocytes Water resistant but not waterproof Permits slow water loss by insensible perspiration
Stratum -				Stratum lucidum	Appears as a glassy layer in thick skin only
comcum				Stratum granulosum	 Keratinocytes produce keratohyalin and keratin Keratin fibers develop as cells become thinner and flatter Gradually the plasma membranes thicken, the organelles disintegrate, and the cells die
Stratum - lucidum		÷		Stratum spinosum	 Keratinocytes are bound together by desmosomes

EPIDERMAL RIDGES OF THICK SKIN

Fingerprints reveal the pattern of epidermal ridges. This scanning electron micrograph shows the ridges on a fingertip.

Superficial to the stratum spinosum is the **stratum granulosum**, or "grainy layer." It consists of three to five layers of keratinocytes derived from the stratum spinosum. By the time cells are pushed into this layer, most have stopped dividing and have started making large amounts of the proteins **keratin** (KER-a-tin; *keros*, horn) and **keratohyalin** (ker-a-tō-HĪ-a-lin). Keratin is a tough, fibrous protein. It is the basic structural component of hair and nails in humans. \bigcirc **p**. **120** As keratin fibers accumulate, the cells grow thinner and flatter, and their plasma membranes thicken and become less permeable. Keratohyalin forms dense cytoplasmic granules that promote dehydration of the cell as well as aggregation and cross-linking of the keratin fibers. The nuclei and other organelles then disintegrate, and the cells die. Further dehydration creates a tightly interlocked layer of cells that consists of keratin fibers surrounded by keratohyalin.

Stratum Lucidum

In the thick skin of the palms and soles, a glassy **stratum lucidum** ("clear layer") covers the stratum granulosum. The cells in the stratum lucidum are flattened, densely packed, largely without organelles, and filled with keratin.

Stratum Corneum

At the exposed surface of both thick skin and thin skin is the **stratum corneum** (KOR-nē-um; *corneus*, horny). It normally contains 15 to 30 layers of keratinized cells. **Keratinization**, or *cornification*, is the formation of protective, superficial layers of cells filled with keratin. This process takes place on all exposed skin surfaces except the anterior surfaces of the eyes. The dead cells in each layer of the stratum corneum remain tightly interconnected by desmosomes. The connections are so secure that keratinized cells are generally shed in large groups or sheets rather than individually.

It takes 7 to 10 days for a cell to move from the stratum basale to the stratum corneum. The dead cells generally remain in the exposed stratum corneum for an additional two weeks before they are shed or washed away. This arrangement places the deeper portions of the epithelium and underlying tissues beneath a protective barrier of dead, durable, and expendable cells. Normally, the surface of the stratum corneum is relatively dry, so it is unsuitable for the growth of many microorganisms. Lipid secretions from sebaceous glands coat the surface, helping to maintain this barrier against water loss or entry.

The stratum corneum is water resistant, but not waterproof. Water from interstitial fluids slowly penetrates to the surface and evaporates into the surrounding air. You lose about 500 mL (about 1 pt) of water in this way each day. The process is called **insensible perspiration**, because you are unable to see or feel (sense) the water loss. In contrast, you are usually very aware of the **sensible perspiration** produced by active sweat glands. Damage to the epidermis can increase the rate of insensible perspiration. If the damage breaks connections between superficial and deeper layers of the epidermis, fluid accumulates in pockets, or *blisters*, within the epidermis. (Blisters also form between the epidermis and dermis if the basement membrane is damaged.) If damage to the stratum corneum makes it less effective as a water barrier, the rate of insensible perspiration skyrockets, and a potentially dangerous fluid loss occurs. This loss is a serious consequence of severe burns and a complication in the condition known as *xerosis* (excessively dry skin).

Why do wrinkles form in the skin on the fingers and toes after a long soak in the bath? Previously, it was common to explain this effect as the osmotic movement of water across the epithelium. That is, the fingertips absorb water and swell, making the skin wrinkle. However, such a process failed to explain why wrinkling did not occur if there was nerve damage in the fingers. It turns out that the fingertips do not swell in water, but they actually shrink when they wrinkle, an effect caused by the constriction of underlying blood vessels. The effect is due to the autonomic nervous system, which functions mostly outside our awareness and controls blood vessel diameter. Is there any benefit to having wrinkled fingertips? Recent studies have shown that the wrinkles improve the ability to grip wet or submerged objects, much like the treads of a tire improve traction on a wet road.

CHECKPOINT

- 1. Identify the layers of the epidermis.
- 2. Dandruff is caused by excessive shedding of cells from the outer layer of skin in the scalp. So dandruff is composed of cells from which epidermal layer?
- 3. A splinter that penetrates to the third layer of the epidermis of the palm is lodged in which layer?
- 4. Why does taking a bath cause wrinkly fingertips and toes?
- 5. Some criminals sand the tips of their fingers so as not to leave recognizable fingerprints. Would this practice permanently remove fingerprints? Why or why not?
- See the blue Answers tab at the back of the book.

5-2 Factors influencing skin color are epidermal pigmentation and dermal circulation

Learning Outcome Explain what accounts for individual differences in skin color, and discuss the response of melanocytes to sunlight exposure.

One of the most obvious distinguishing characteristics among humans is skin color. What gives skin its various colors? In this section we examine how pigments in the epidermis and blood flow in the dermis influence skin color. We also discuss clinical implications of changes in skin color.

The Role of Epidermal Pigmentation

The epidermis contains variable quantities of two pigments: carotene and melanin. **Carotene** (KAR-uh-tēn) is an orangeyellow pigment that normally accumulates in epidermal cells. It is most apparent in cells of the stratum corneum of light-skinned individuals, but it also accumulates in fatty tissues in the deep dermis and subcutaneous layer. Carotene is found in a variety of orange vegetables, such as carrots and squashes. The skin of someone who eats lots of carrots can actually turn orange from an overabundance of carotene. The color change is very striking in pale-skinned individuals, but less obvious in people with darker skin pigmentation. Carotene can be converted to vitamin A, which is required for both the normal maintenance of epithelia and the synthesis of photoreceptor pigments in the eye.

Melanin is a pigment produced by melanocytes, pigmentproducing cells, introduced in Chapter 4. There are two types of melanin, a red-yellow form (pheomelanin) and a brown-black form (eumelanin). The melanocytes involved are located in the stratum basale, squeezed between or deep to the epithelial cells (Figure 5-4). Melanocytes manufacture both types of melanin from the amino acid tyrosine and package it into intracellular vesicles called melanosomes. These vesicles, which contain either pheomelanin or eumelanin, travel within the processes of melanocytes and are transferred intact to about 40 basal keratinocytes. The transfer of pigmentation colors the keratinocyte temporarily, until the melanosomes are destroyed by fusion with lysosomes. In individuals with pale skin, this transfer takes place in the stratum basale and stratum spinosum, and the cells of more superficial layers lose their pigmentation. In dark-skinned people, the melanosomes are larger and more numerous, and the transfer may occur in the stratum granulosum as well, making skin pigmentation darker and more persistent.

The ratio of melanocytes to basal cells ranges between 1:4 and 1:20, depending on the region of the body. The skin covering most areas of the body has about 1000 melanocytes per square millimeter. The cheeks and forehead, the nipples, and the genital region (the scrotum of males and the labia majora of females) have higher concentrations (about 2000 per square millimeter). The differences in skin pigmentation among individuals do not reflect different numbers of melanocytes, but rather, different levels of melanin synthesis. A deficiency or absence of melanin production leads to a disorder known as *albinism*. Individuals with this condition have a normal distribution of melanocytes, but the cells are incapable of producing melanin.

There can also be localized differences in the rates of melanin production by your melanocytes. *Freckles* are small, pigmented areas on relatively pale skin. These spots typically have an irregular border. They represent the areas serviced by melanocytes that are producing larger-than-average amounts of melanin. Freckles tend to be most abundant on **Figure 5–4** Melanocytes. The micrograph and accompanying drawing indicate the location and orientation of melanocytes in the stratum basale of a dark-skinned person.

b Melanocytes produce and store melanin.

surfaces such as the face, probably due to its greater exposure to the sun. *Lentigos* are similar to freckles but have regular borders and contain abnormal melanocytes. *Senile lentigos*, or *liver spots*, are variably pigmented areas that develop on sunexposed skin in older individuals with pale skin.

The melanin in keratinocytes protects your epidermis and dermis from the harmful effects of sunlight, which contains significant amounts of **ultraviolet (UV) radiation**. A small amount of UV radiation is beneficial, because it stimulates the epidermis to produce a compound required for calcium ion homeostasis (a process discussed in a later section). However, UV radiation can also damage DNA, causing mutations and promoting the development of cancer. Within keratinocytes, melanosomes become concentrated in the region around the nucleus, where the melanin pigments act like a sunshade to provide some UV protection for the DNA in those cells.

UV radiation can also produce some immediate effects, such as burns. If severe, sunburns can damage both the epidermis and the dermis. Thus, the pigment layers in the epidermis help protect both epidermal and dermal tissues. However, even though melanocytes respond to UV exposure by increasing their activity, the response is not rapid enough to prevent sunburn the first day you spend at the beach. Melanin synthesis accelerates slowly, peaking about 10 days after the initial exposure. Individuals of any skin color can suffer sun damage to the skin, but dark-skinned individuals have greater initial protection.

Over time, cumulative UV damage to the skin can harm fibroblasts, impairing maintenance of the dermis. The result is premature wrinkling. In addition, skin cancers can develop from chromosomal damage in basal cells or melanocytes. One of the major consequences of the global depletion of the ozone layer in Earth's upper atmosphere is likely to be a sharp increase in the rates of skin cancers (such as *malignant melanoma*). In recent years such increased cancer rates have been reported in Australia, which has already experienced a significant loss of ozone, as well as in the United States, Canada, and parts of Europe, which have had a more moderate ozone loss. For this reason, it makes sense to limit your UV exposure through wearing protective clothing and sunscreens during outdoor activities.

The Role of Dermal Circulation

Blood contains red blood cells filled with the pigment *hemo-globin*, which binds and transports oxygen in the bloodstream. When bound to oxygen, hemoglobin is bright red, giving capillaries in the dermis a reddish tint that is most apparent in lightly pigmented individuals. If those vessels are dilated, the red tones become much more pronounced. For example, your skin becomes flushed and red when your body temperature rises because the superficial blood vessels dilate so that the skin can act like a radiator and lose heat. $\supset p$. 11

The skin becomes relatively pale when its blood supply is temporarily reduced. A light-skinned person who is frightened may "turn white" due to a sudden drop in blood supply to the skin. During a sustained reduction in circulatory supply, the oxygen levels in the tissues decline. Under these conditions, hemoglobin releases oxygen and turns a much darker red. Seen from the surface, the skin then takes on a bluish coloration called **cyanosis** (sī-uh-NŌ-sis; *kyanos*, blue). In individuals of any skin color, cyanosis is easiest to see in areas of very thin skin, such as the lips or beneath the nails. It can occur in response to extreme

cold or as a result of cardiovascular or respiratory disorders, such as heart failure or severe asthma.

Because the skin is easy to observe, changes in the skin's appearance can be useful in diagnosing diseases that primarily affect other body systems. Several diseases can produce secondary effects on skin color and pigmentation:

- In *jaundice* (JAWN-dis), the liver is unable to excrete bile, so a yellowish pigment accumulates in body fluids. In advanced stages, the skin and whites of the eyes turn yellow.
- Some tumors affecting the pituitary gland result in the secretion of large amounts of *melanocyte-stimulating hormone* (*MSH*). This hormone causes a darkening of the skin, as if the individual has an extremely deep bronze tan.
- In *Addison's disease*, the pituitary gland secretes large quantities of *adrenocorticotropic hormone (ACTH)*, which is structurally similar to MSH. The effect of ACTH on skin color is similar to that of MSH.
- In vitiligo (vit-i-LĪ-gō), individuals lose their melanocytes, causing white patches on otherwise normal skin (Figure 5–5). The condition develops in about 1 percent of the population. Its incidence increases among individuals with thyroid gland disorders, Addison's disease, or several other disorders. It is suspected that vitiligo develops when the immune defenses malfunction and antibodies attack normal melanocytes. The primary problem with vitiligo is cosmetic, especially for individuals with darkly pigmented skin.

Figure 5–5 Vitiligo.

CHECKPOINT

- 6. Name the two major pigments in the epidermis.
- 7. Why does exposure to sunlight darken skin?
- 8. Why does the skin of a fair-skinned person appear red during exercise in hot weather?
- See the blue Answers tab at the back of the book.

Clinical Note

Skin Cancer Almost everyone has several benign tumors of the skin. Moles and warts are common examples. However, **skin cancers**, which are more dangerous, are the most common form of cancer.

An *actinic keratosis* is a premalignant scaly area on the skin. It is an indication that sun damage has occurred. In a small proportion of untreated individuals, it can lead to squamous cell carcinoma. In contrast, basal cell carcinoma, a cancer that originates in the stratum basale, is the most common skin cancer (Photo a). About two-thirds of these cancers appear in body areas subjected to chronic UV exposure. Researchers have identified genetic factors that predispose people to this condition. Squamous cell carcinomas are less common, but almost totally restricted to areas of sun-exposed skin. Metastasis (spread to distant sites) seldom occurs in treated squamous cell carcinomas and basal cell carcinomas, and most people survive these cancers. The usual treatment involves the surgical removal of the tumor, and 95 percent of patients survive for five years or longer after treatment. (This statistic, the 5-year survival rate, is a common method of reporting long-term outcomes.)

Unlike these common and seldom life-threatening cancers, *malignant melanomas* (mel-a-NŌ-muz) are extremely dangerous (Photo b). In this condition, cancerous melanocytes grow rapidly and metastasize through the lymphatic system. The outlook for long-term survival is in many cases determined by how early the condition is diagnosed. If the

b Melanoma

cancer is detected early, while it is still localized, the 5-year survival rate is 99 percent. If it is not detected until extensive metastasis has occurred, the survival rate drops to 14 percent.

To detect melanoma at an early stage, you must examine your skin, and you must know what to look for. The mnemonic ABCD makes it easy to remember this cancer's key characteristics:

- A is for *asymmetry*: Melanomas tend to be irregular in shape. Typically, they are raised; they may also ooze or bleed.
- **B** is for *border*: The border of a melanoma is generally irregular, and in some cases notched.
- **C** is for *color*: A melanoma is generally mottled, with any combination of tan, brown, black, red, pink, white, and blue tones.
- D is for *diameter*: Any skin growth more than about 5 mm (0.2 in.) in diameter, or approximately the area covered by the eraser on a pencil, is dangerous.

Fair-skinned individuals who live in the tropics are most susceptible to all forms of skin cancer, because their melanocytes are unable to shield them from UV radiation.

Prevent sun damage by avoiding exposure to the sun during the middle of the day and by using a sunscreen (not a tanning oil) before any sun exposure. This practice also delays the cosmetic problems of aging and wrinkling. Everyone who spends any time out in the sun should choose a broad-spectrum sunscreen with a sun protection factor (SPF) of at least 15. Blondes, redheads, and people with very pale skin are better off with an SPF of 20 to 30. (The risks are the same for those who spend time in a tanning salon or tanning bed.) The protection offered by these "sunscreens" comes both from organic molecules that absorb UV radiation and from inorganic pigments that absorb, scatter, and reflect UV rays. The higher the SPF, the more of these chemicals the product contains, and the fewer UV rays are able to penetrate to the skin's surface. Wearing a hat with a brim and panels to shield the neck and face, long pants, and long-sleeved shirts provides added protection.

The use of sunscreens will be even more important as the ozone gas in the upper atmosphere is further destroyed by our industrial emissions. Ozone absorbs UV radiation before it reaches Earth's surface. In doing so, ozone assists the melanocytes in preventing skin cancer. Australia, the continent that is most affected by the depletion of ozone above the South Pole (the "ozone hole"), is already reporting an increased incidence of skin cancers.

5–3 Sunlight causes epidermal cells to convert a steroid into vitamin D₃

Learning Outcome Describe the interaction between sunlight and vitamin D_3 production.

Too much sunlight can damage epithelial cells and deeper tissues, but limited exposure to sunlight is beneficial. When exposed to ultraviolet radiation, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid into **cholecalciferol** ($k\bar{o}$ -le-kal-SIF-er-ol), or **vitamin D**₃. The liver then converts cholecalciferol into an intermediary product used by the kidneys to synthesize the hormone **calcitriol** (Figure 5-6) (kal-si-TRĪ-ol). Calcitriol is essential for the normal absorption of calcium and phosphorus in the

Figure 5–6 Sources of Vitamin D₃.

small intestine. An inadequate supply leads to impaired bone maintenance and growth.

The term *vitamin* is usually reserved for essential organic nutrients that we must get from the diet because the body either cannot make them or makes them in insufficient amounts. Cholecalciferol can be absorbed by the digestive tract, and if the skin cannot make enough cholecalciferol, a dietary supply (from foods such as egg yolks, fish oil, and fortified milk) will maintain normal bone development. Under these circumstances, dietary cholecalciferol acts like a vitamin. For this reason, cholecalciferol is also called *vitamin* D_3 .

If cholecalciferol cannot be produced by the skin and is not included in the diet, bone development is abnormal and bone maintenance is inadequate. For example, children who live in areas with overcast skies and whose diet lacks cholecalciferol can have abnormal bone development. This condition, called **rickets** (Figure 5–7), has largely been eliminated in the United States because dairy companies are required to add cholecalciferol, usually identified as "vitamin D," to the milk sold in grocery stores. In Chapter 6, we will consider the hormonal control of bone growth in greater detail. Figure 5–7 Rickets. Rickets, a disease caused by vitamin D_3 deficiency, results in the bending of abnormally weak and flexible bones under the weight of the body, plus other structural changes.

CHECKPOINT

- 9. Explain the relationship between sunlight exposure and vitamin D_3 synthesis.
- In some cultures, women must be covered completely, except for their eyes, when they go out in public. Explain why these women may develop bone problems later in life.
- See the blue Answers tab at the back of the book.

5-4 Epidermal growth factor has several effects on the epidermis and epithelia

Learning Outcome Describe the roles of epidermal growth factor.

Epidermal growth factor (EGF) is one of the peptide growth factors introduced in Chapter 3. \bigcirc p. 103 It was named for its effects on the epidermis, but we now know that EGF has wide-spread effects on epithelia throughout the body. EGF is produced by the salivary glands and glands of the duodenum (initial segment of the small intestine). Here are some roles of EGF:

- Promoting the divisions of basal cells in the stratum basale and stratum spinosum
- Accelerating the production of keratin in differentiating keratinocytes
- Stimulating epidermal development and epidermal repair after injury
- Stimulating synthetic activity and secretion by epithelial glands

In the procedure known as tissue culture, cells are grown under laboratory conditions for experimental or therapeutic use. Epidermal growth factor has such a pronounced effect that it can be used in tissue culture to stimulate the growth and division of epidermal cells (or other epithelial cells). Using human epidermal growth factor (hEGF) produced through recombinant DNA technology, it is now possible to grow sheets of epidermal cells for use in treating severe or extensive burns. The burned areas can be covered by epidermal sheets "grown" from a small sample of intact skin from another part of the burn victim's body. (We will consider this treatment later in the chapter when we discuss burns.)

CHECKPOINT

- 11. Name the sources of epidermal growth factor in the body.
- **12**. Identify some roles of epidermal growth factor pertaining to the epidermis.

See the blue Answers tab at the back of the book.

5–5 The dermis is the tissue layer that supports the epidermis

Learning Outcome Describe the structure and functions of the dermis.

The dermis lies between the epidermis and the hypodermis (Figure 5–1). The dermis has two major components: (1) a superficial *papillary layer* and (2) a deeper *reticular layer*.

The **papillary layer** consists of areolar tissue. It contains the capillaries, lymphatic vessels, and sensory neurons that supply the surface of the skin. The papillary layer gets its name from the dermal papillae that project between the epidermal ridges (Spotlight Figure 5–3).

The **reticular layer** lies deep to the papillary layer. It consists of an interwoven meshwork of dense irregular connective tissue containing both collagen and elastic fibers (Figure 5–8, p. 131). Bundles of collagen fibers extend superficially beyond the reticular layer to blend into those of the papillary layer, so the boundary between the two layers is indistinct. Collagen fibers of the reticular layer also extend into the deeper hypodermis. In addition to extracellular protein fibers, the dermis contains all the cells of connective tissue proper. \supset p. 127

Accessory structures of epidermal origin, such as hair follicles and sweat glands, extend into the dermis. In addition, the reticular and papillary layers of the dermis contain networks of blood vessels and nerve fibers (Figure 5–1).

Because of the abundance of sensory receptors in the skin, regional infection or inflammation can be very painful. **Dermatitis** (der-muh-TĪ-tis) is an inflammation of the skin that primarily involves the papillary layer. The inflammation typically begins in a part of the skin exposed to infection or

irritated by chemicals, radiation, or mechanical stimuli. Dermatitis may cause no discomfort, or it may produce an annoying itch, as in poison ivy. Other forms of the condition can be quite painful, and the inflammation can spread rapidly across the entire integument.

Dermal Strength and Elasticity

Collagen and elastic fibers give the dermis strength and elasticity. *Collagen fibers* are very strong and resist stretching, but they are easily bent or twisted. *Elastic fibers* permit stretching and then recoil to their original length. The elastic fibers provide flexibility, and the collagen fibers limit that flexibility to prevent damage to the tissue.

The water content of the skin also helps maintain its flexibility and resilience. These properties are collectively known as *skin turgor*. One of the signs of dehydration is the loss of skin turgor, revealed by pinching the skin on the back of the hand. A dehydrated dermis will remain peaked when pinched, but hydrated skin will flatten out.

Aging, hormones, and the destructive effects of ultraviolet radiation permanently reduce the amount of elastin in the dermis. Wrinkles and sagging skin result. The extensive distortion of the dermis that occurs over the abdomen during pregnancy or after substantial weight gain can exceed the elastic limits of the skin. The resulting damage to the dermis prevents it from recoiling to its original size after delivery or weight loss. The skin then wrinkles and creases, creating a network of **stretch marks**.

Tretinoin (Retin-A) is a derivative of vitamin A that can be applied to the skin as a cream or gel. This drug was originally developed to treat acne, but it also increases blood flow to the dermis and stimulates dermal repair. As a result, the rate of wrinkle formation decreases, and existing wrinkles become smaller. The degree of improvement varies among individuals.

Figure 5–8 Reticular Layer of Dermis.

Cleavage Lines

Most of the collagen and elastic fibers at any location are arranged in parallel bundles oriented to resist the forces applied to the skin during normal movement. The resulting pattern of fiber bundles in the skin establishes **cleavage lines**. Cleavage lines are also called *tension lines* and *Langer lines*. Cleavage lines are clinically significant. A cut parallel to a cleavage line will usually remain closed and heal with little scarring. A cut at right angles to a cleavage line will be pulled open as severed elastic fibers recoil, resulting in greater scarring. For these reasons, surgeons choose to make incisions parallel to cleavage lines (Figure 5–9).

The Dermal Blood Supply

Arteries supplying the skin lie deep within the hypodermis. Branches of these arteries form two networks, or *plexuses*, in

Figure 5–9 Cleavage Lines of the Skin. Cleavage lines follow the pattern of collagen fiber bundles in the dermis of the skin.

Clinical Note

Decubitis Ulcers Problems with dermal circulation affect both the epidermis and the dermis. An *ulcer* is a localized shedding of an epithelium. *Decubitis ulcers*, or *bedsores*, affect patients whose circulation is restricted, especially when

a splint, a cast, or lying in bed continuously compresses superficial blood vessels. Such sores most commonly affect the skin covering joints or bony prominences, where dermal blood vessels

are pressed against deeper structures. The chronic lack of circulation kills epidermal cells, removing a barrier to bacterial infection. Eventually, dermal tissues deteriorate as well. (Cell death and tissue destruction, or *necrosis*, can occur in any tissue deprived of adequate blood flow.) Bedsores can be prevented or treated by frequently changing the position of the body or by placing patients in specially designed beds containing deflating and inflating air coils. Both approaches vary the pressures applied to local blood vessels.

the dermis. The deeper network lies along the border of the hypodermis with the reticular layer of the dermis. This network is called the *cutaneous plexus* (Figure 5–10). Tributaries of these arteries supply both the adipose tissues of the subcutaneous layer and the tissues of the integument. As small arteries travel toward the epidermis, branches supply the hair follicles, sweat glands, and other structures in the dermis.

On reaching the papillary layer, the small arteries form another branching network, the *subpapillary plexus* (Figure 5–10). It provides arterial blood to capillary loops that follow the contours of the epidermis–dermis boundary. These capillaries empty into small veins of the subpapillary plexus, which drain into veins accompanying the arteries of the cutaneous plexus. This network in turn connects to larger veins in the hypodermis.

Trauma to the skin often results in a *contusion*, or bruise. When dermal blood vessels rupture, blood leaks into the dermis, and the area develops the familiar "black and blue" color.

Innervation of the Skin

The integument is filled with sensory receptors. Anything that comes in contact with the skin—from the lightest touch of a

mosquito to the weight of a loaded backpack—initiates a nerve impulse that can reach our conscious awareness. Nerve fibers in the skin control blood flow, adjust gland secretion rates, and monitor sensory receptors in the dermis and the deeper layers of the epidermis.

We have already noted that the deeper layers of the epidermis contain tactile discs. They are fine touch and pressure receptors. The epidermis also contains the extensions of sensory neurons that provide sensations of pain and temperature. The dermis contains similar receptors, as well as other, more specialized receptors. Examples shown in **Figure 5–1** include receptors sensitive to light touch—*tactile (Meissner's) corpuscles*, located in dermal papillae—and receptors sensitive to deep pressure and vibration—*lamellated (pacinian) corpuscles*, in the reticular layer.

Even this partial list of the receptors in the skin is enough to highlight the importance of the integument as a sensory structure. We will return to this topic in Chapter 15, where we consider not only what receptors are present, but how they function.

CHECKPOINT

- **13**. Describe the location of the dermis.
- 14. Where are the capillaries and sensory neurons that supply the epidermis located?
- **15**. What accounts for the ability of the dermis to undergo repeated stretching?
- See the blue Answers tab at the back of the book.

5-6 The hypodermis connects the dermis to underlying tissues

Learning Outcome Describe the structure and functions of the hypodermis.

The **hypodermis** or *subcutaneous layer* lies deep to the dermis (Figure 5–1). The boundary between the two is generally indistinct because the connective tissue fibers of the reticular layer are extensively interwoven with those of the hypodermis. The hypodermis is not a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues, such as skeletal muscles or other organs, while permitting independent movement.

The hypodermis is quite elastic. It consists of areolar tissue and adipose tissue (also known as subcutaneous fat) (Figure 5-11). Subcutaneous fat makes up about 80 percent of all body fat. The remaining amount is visceral fat that is associated with visceral organs. Only its superficial region contains large arteries and veins. The venous circulation of this region contains a substantial amount of blood, and much of this volume will shift to the general circulation if these veins constrict. For that reason, we often describe the skin as a *blood reservoir*. The rest of the hypodermis contains a limited number of capillaries and no vital organs. This last characteristic makes **subcutaneous injection**—by means of a **hypodermic needle**—a useful method of administering drugs.

Most infants and small children have extensive "baby fat," which provides insulation and helps reduce heat loss. This subcutaneous fat also serves as a substantial energy reserve and as a shock absorber for the rough-and-tumble activities of our early years.

As we grow, the distribution of subcutaneous fat changes. The greatest changes take place in response to circulating

Figure 5–11 Hypodermis.

Adipocytes

Clinical Note

Liposuction The accumulation of excessive amounts of adipose tissue increases a person's risks of diabetes, stroke, and other serious conditions. Dietary restrictions and increased activity levels often promote weight loss and reduce these risks. However, a surgical procedure called liposuction or lipoplasty often promises a "quick fix." In this procedure, subcutaneous adipose tissue is removed through a tube inserted deep to the skin. Adipose tissue tears relatively easily, and suction applied to the tube rips chunks of adipose tissue from the body. After liposuction, the skin is loose fitting. Until it recoils, a tight-fitting garment is usually worn. Liposuction is relatively common and is increasing in popularity. According to the American Society of Plastic Surgeons, 325,332 liposuction procedures were performed in 2011 (the most recent year for which data are available).

Liposuction might sound like an easy way to remove unwanted fat, but in practice, it can be dangerous. There are risks from anesthesia, bleeding (adipose tissue is guite vascular), sensory loss, infection, and fluid loss. The death rate from liposuction procedures is 1 in 5000. That rate is very high for what is basically cosmetic surgery that provides only a temporary solution to a chronic problem. As noted in Chapter 4, unless there are changes in diet and lifestyle, the damaged adipose tissue will repair itself, and areas of areolar tissue will convert to adipose tissue. Over time, the surgery will have to be repeated.

sex hormones. Beginning at puberty, men accumulate subcutaneous fat at the neck, on the arms, along the lower back, and over the buttocks. In contrast, women accumulate subcutaneous fat at the breasts, buttocks, hips, and thighs. In adults of either gender, the subcutaneous layer of the backs of the hands and the upper surfaces of the feet contains few fat cells, but distressing amounts of adipose tissue can accumulate in the abdominal region, producing a "potbelly." An excessive amount of such abdominal fat, also called central adiposity, is strongly correlated with cardiovascular disease.

CHECKPOINT

- 16. List the two terms for the tissue that connects the dermis to underlying tissues.
- 17. Describe the hypodermis.
- 18. Identify several functions of subcutaneous fat.

See the blue Answers tab at the back of the book.

5-7 Hair is composed of keratinized dead cells that have been pushed to the surface

Learning Outcome Describe the mechanisms that produce hair. and explain the structural basis for hair texture and color.

Hair and several other structures-hair follicles, sebaceous and sweat glands, and nails-are considered accessory structures of the integument. During embryological development, these structures originate from the epidermis, so they are also known as epidermal derivatives. Although located in the dermis, they project to the surface of the skin. ATLAS: Embryology Summary 5: The Development of the Integumentary System

Hairs project above the surface of the skin almost everywhere, except over the sides and soles of the feet, the palms of the hands, the sides of the fingers and toes, the lips, and portions of the external genitalia. The human body has about 2.5 million hairs, and 75 percent of them are on the general body surface, not on the head. Hairs are nonliving structures produced in organs called hair follicles.

The hairs and hair follicles on your body have important functions. The 500,000 or so hairs on your head protect your scalp from ultraviolet radiation, help cushion light impacts to the head, and insulate the skull. The hairs guarding the entrances to your nostrils and external ear canals help keep out foreign particles and insects. Your eyelashes do the same for the surface of the eye. Eyebrows are important because they help keep sweat out of your eyes. Hairs are also extremely important as sensory receptors.

Figure 5–12 illustrates important details about the structure of hairs and hair follicles. Each hair follicle opens onto the surface of the epidermis but extends deep into the dermis and usually into the hypodermis. Deep to the epidermis, each follicle is wrapped in a dense connective tissue sheath. A root hair plexus of sensory nerves surrounds the base of each hair follicle (Figure 5–12a). As a result, you can feel the movement of the shaft of even a single hair. This sensitivity provides an earlywarning system that may help prevent injury. For example, you may be able to swat a mosquito before it reaches your skin.

A bundle of smooth muscle cells forms the **arrector pili** (a-REK-tor PI-le) muscle. It extends from the papillary layer of the dermis to the connective tissue sheath surrounding the hair follicle. When stimulated, the arrector pili muscle contracts, pulling on the follicle and forcing the hair to stand erect. Contraction may be the result of emotional states, such as fear or rage, or a response to cold, producing "goose bumps." In a furry mammal, this action increases the thickness of its insulating coat. Humans do not receive any comparable insulating benefits, but the response persists.

5

Figure 5–12 Hair Follicles and Hairs.

c Histological section along the longitudinal axis of hair follicles Each hair is a long, cylindrical structure that extends outward, past the epidermal surface (Figure 5–12a,c,d). The **hair root** is the portion that anchors the hair into the skin. The root begins at the base of the hair, at the *hair bulb*, and extends distally to the point at which the internal organization of the hair is complete, about halfway to the skin surface. The **hair shaft** extends from this halfway point to the exposed tip of the hair. The hair we see is the protruding part of the hair shaft.

Hair Production

Hair production begins at the bulging base of a hair follicle, a region called the **hair bulb** (Figure 5–12c,d). The hair bulb surrounds a small **hair papilla**, a peg of connective tissue containing capillaries and nerves. A layer of epithelial cells at the base of the hair bulb in contact with the hair papilla produces the hair. This layer is called the **hair matrix**. Basal cells of the hair matrix divide, producing daughter cells that are gradually pushed toward the surface. Daughter cells closest to the center of the matrix form the **medulla**, or core, of the hair (Figure 5–12b,c,d). Daughter cells farther from the center of the hair matrix form the **cortex**, an intermediate layer. Those at the edges of the hair matrix form the **cuticle**, which will be the surface of the hair.

As cell divisions continue at the hair matrix, the daughter cells are pushed toward the surface of the skin, and the hair gets longer. Keratinization is completed by the time these cells approach the surface. At the level that corresponds to the start of the hair shaft, the cells of the medulla, cortex, and cuticle are dead, and the keratinization process is at an end.

The epithelial cells of the follicle walls are organized into several concentric layers. Moving outward from the hair cuticle, these layers include the internal root sheath, the external root sheath, and the glassy membrane (Figure 5–12b,c,d).

The Hair Growth Cycle

Hairs grow and are shed according to a **hair growth cycle**. A hair in the scalp grows for two to five years, at a rate of about 0.33 mm per day. Variations in the growth rate and in the duration of the hair growth cycle account for individual differences in the length of uncut hair.

While hair is growing, the cells of the hair root absorb nutrients and incorporate them into the hair structure. As a result, clipping or collecting hair for analysis can be helpful in diagnosing several disorders. For example, hairs of individuals with lead poisoning or other heavy-metal poisoning contain high levels of those metal ions. Hair samples containing nucleated cells can also be used for identification purposes through DNA fingerprinting. \bigcirc p. 84

As a hair grows, the root is firmly attached to the matrix of the follicle. At the end of the growth cycle, the follicle becomes inactive. The hair is now termed a **club hair**. The follicle gets smaller, and over time the connections between the hair matrix and the club hair root break down. When another cycle begins, the follicle produces a new hair. The old club hair is pushed to the surface and is shed.

Healthy adults with a full head of hair typically lose about 100 head hairs each day. Sustained losses of more than 100 hairs per day generally indicate that a net loss of hairs is underway, and hair loss will eventually be noticeable. Temporary increases in hair loss can result from drugs, dietary factors, radiation, an excess of vitamin A, high fever, stress, or hormonal factors related to pregnancy.

In males, changes in the level of the sex hormones circulating in the blood can affect the scalp, causing a shift in the type of hair produced (discussed shortly), beginning at the temples and the crown of the head. This alteration is called *male pattern baldness*. Some cases of male pattern baldness respond to drug therapies, such as the topical application of *minoxidil (Rogaine)*.

Types of Hairs

Hairs first appear after about three months of embryonic development. These hairs, collectively known as *lanugo* (la- $N\overline{U}$ - $g\overline{o}$), are extremely fine and unpigmented. Most lanugo hairs are shed before birth. They are replaced by one of two types of hairs in the adult integument: vellus hairs or terminal hairs. **Vellus hairs** are the fine "peach fuzz" hairs located over much of the body surface. **Terminal hairs** are heavy, more deeply pigmented, and sometimes curly. The hairs on your head, including your eyebrows and eyelashes, are terminal hairs that are present throughout life. Hair follicles may alter the structure of the hairs in response to circulating hormones. For example, vellus hairs are present at the armpits, pubic area, and limbs until puberty. After puberty, the follicles produce terminal hairs, in response to circulating sex hormones.

What makes hair curly or straight? The cross-sectional shape of the hair shaft and its hair follicle determine whether hairs are curly or straight. A curly hair and its follicle are oval; a straight hair and its follicle are round.

TIPS & TRICKS

Associate the word vellus ("peach fuzz") with "velvet."

Hair Color

What gives your hair its color? Variations in hair color reflect differences in structure and variations in the pigment produced by melanocytes at the hair matrix. Different forms and amounts of melanin give a dark brown, yellow-brown, or red color to the hair. Genes determine these structural and biochemical characteristics, but hormonal and environmental factors also influence the condition of your hair. As pigment production decreases with age, hair color lightens. White hair results from the combination of a lack of pigment and the presence of air bubbles in the medulla of the hair shaft. As the proportion of white hairs increases, the person's overall hair color is described as gray. Because hair itself is dead and inert, any changes in its coloration are gradual.

What happens when we dye our hair? We are able to change our hair color by using chemicals that disrupt the cuticle and permit dyes to enter and stain the cortex and medulla. These color treatments damage the hair's protective cuticle layer and dehydrate and weaken the hair shaft. As a result, the hair becomes thin and brittle. Conditioners and oil treatments attempt to reduce the effects of this structural damage by rehydrating and recoating the shaft.

CHECKPOINT

- 19. Describe a typical strand of hair.
- 20. What happens when the arrector pili muscle contracts?
- **21**. Once a burn on the forearm that destroys the epidermis and extensive areas of the deep dermis heals, will hair grow again in the affected area?

See the blue Answers tab at the back of the book.

5-8 Sebaceous glands and sweat glands are exocrine glands found in the skin

Learning Outcome Discuss the various kinds of glands in the skin, and list the secretions of those glands.

As we have seen, the integumentary system contains various accessory structures that produce exocrine secretions. In this section we will focus on the structure and function of sebaceous glands and sweat glands.

Sebaceous Glands

Sebaceous (se-BĀ-shus) **glands**, or *oil glands*, are holocrine glands that discharge an oily lipid secretion into hair follicles (Figure 5–13). The gland cells produce large quantities of lipids as they mature. They release the lipid product through holocrine secretion, a process that involves the rupture of the secretory cells. \bigcirc p. 123 Sebaceous glands that communicate with a single hair follicle share a duct and thus are classified as simple branched alveolar glands. \bigcirc p. 125

The lipids released from gland cells enter the lumen (open passageway) of the gland. The arrector pili muscles that erect the hair then contract, squeezing the sebaceous gland and forcing the lipids into the hair follicle and onto the surface of the skin. The secreted lipid product, called **sebum** (SĒ-bum), is a mixture of triglycerides, cholesterol, proteins, and electrolytes. Sebum inhibits the growth of bacteria, lubricates and protects the keratin of the hair shaft, and conditions the surrounding skin. Keratin is a tough protein, but dead, keratinized cells become dry and brittle once exposed to the environment. Interestingly, when we shampoo and wash, we remove the oily secretions of sebaceous glands, only to add other lipids to our hair in the form of conditioners, and to our skin in the form of creams and lotions.

Sebaceous follicles are large sebaceous glands that are not associated with hair follicles. Instead, their ducts discharge sebum directly onto the epidermis (Figure 5–13). We have sebaceous follicles on the face, back, chest, nipples, and external genitalia.

Surprisingly, sebaceous glands are very active during the last few months of fetal development. Their secretions, mixed with shed epidermal cells, form a protective superficial layer—the *vernix caseosa*—that coats the skin surface. Sebaceous gland activity all but stops after birth, but it increases again at puberty in response to rising levels of sex hormones.

Figure 5–13 The Structure of Sebaceous Glands and Sebaceous Follicles.

Seborrheic dermatitis is an inflammation around abnormally active sebaceous glands, most often in the scalp. The affected area becomes red and oily, with increased epidermal scaling. In infants, mild cases are called *cradle cap*. Seborrheic dermatitis is a common cause of dandruff in adults. Anxiety, stress, and fungal or bacterial infections can aggravate the problem.

Sweat Glands

The skin contains two types of sweat glands, or **sudoriferous glands** (*sudor*, sweat): *apocrine sweat glands* and *merocrine sweat glands* (Figure 5–14).

Apocrine Sweat Glands

In the armpits (axillae), around the nipples, and in the pubic region, **apocrine sweat glands** secrete their products into hair follicles (Figure 5–14a). These coiled, tubular glands produce a sticky, cloudy, and potentially odorous secretion. The name *apocrine* was originally chosen because it was thought the gland cells used an apocrine method of secretion. \bigcirc p. 123 We now know that they rely on merocrine secretion, but the name has not changed.

Apocrine sweat glands begin secreting at puberty. This sweat is a nutrient source for bacteria, whose growth and breakdown intensify its odor. Surrounding the secretory cells in these glands are special **myoepithelial cells** that contract and squeeze the gland, causing the accumulated sweat to discharge into the hair follicles. The secretory activities of the gland cells and the contractions of myoepithelial cells are controlled by the nervous system and by circulating hormones.

Merocrine Sweat Glands

Merocrine sweat glands are also known as eccrine (EK-rin) sweat glands. These coiled, tubular glands discharge their secretions directly onto the surface of the skin (Figure 5–14b). Merocrine sweat glands are far more numerous and widely distributed than apocrine sweat glands. The adult integument contains 2–5 million merocrine sweat glands, which are smaller than apocrine sweat glands and do not extend as deeply into the dermis. The palms and soles have the highest numbers. The palms have an estimated 500 merocrine sweat glands per square centimeter (3000 per square inch).

As noted earlier, the sweat from merocrine sweat glands is called sensible perspiration. Sweat is 99 percent water, but it also contains some electrolytes (chiefly sodium chloride), a number of organic nutrients, a peptide with antibiotic properties, and various waste products. It has a pH range of 4.0–6.8. Sodium chloride gives sweat a salty taste. (See the

Figure 5–14 Sweat Glands.

Appendix for a complete analysis of the composition of normal sweat.)

The functions of merocrine sweat gland activity include:

- Cooling the Surface of the Skin to Reduce Body Temperature. This is the primary function of sensible perspiration (p. 155). The degree of secretory activity is regulated by neural and hormonal mechanisms. When all the merocrine sweat glands are working at their maximum, we can perspire more than a gallon per hour, and dangerous fluid and electrolyte losses can occur. For this reason, athletes in endurance sports must drink fluids at regular intervals.
- *Excreting Water and Electrolytes.* Water, salts (mostly sodium chloride), and a number of metabolized drugs are excreted.
- Providing Protection from Environmental Hazards. Sweat dilutes harmful chemicals in contact with the skin. It also discourages the growth of microorganisms in two ways:

 by either flushing them from the surface or making it difficult for them to adhere to the epidermal surface and
 through the action of *dermicidin*, a small peptide with powerful antibiotic properties.

The underarms, or armpits, provide consistent heat and moisture, ideal conditions for bacterial growth on the body surface. Deodorants and antiperspirants, singly or in combination, are commonly used to combat underarm bacteria and odor. Deodorants work by temporarily reducing bacteria numbers and by masking the body odor they produce. Antiperspirants target the sweat glands. Antiperspirants contain aluminum compounds that reduce the amount of moisture available to bacteria in two ways: (1) they interact with sweat to plug up sweat gland ducts, and (2) they cause the sweat gland pores to constrict. However, the plugs are eventually lost through the normal shedding of cells at the surface of the skin.

Other Integumentary Glands

As we have seen, merocrine sweat glands are widely distributed across the body surface, sebaceous glands are located wherever there are hair follicles, and apocrine sweat glands are located in relatively restricted areas. The skin also contains a variety of specialized glands that are restricted to specific locations. Here are two important examples:

1. The **mammary glands** of the breasts are anatomically related to apocrine sweat glands. A complex interaction between sex hormones and pituitary hormones controls their development and secretion. We will discuss mammary gland structure and function in Chapter 28.

2. Ceruminous (se-RŪ-mi-nus) glands are modified sweat glands in the passageway of the external ear. Their secretions combine with those of nearby sebaceous glands, forming a mixture called **cerumen**, or earwax. Together with tiny hairs along the ear canal, earwax helps trap foreign particles, preventing them from reaching the eardrum.

Control of Glandular Secretions and the Homeostatic Role of the Integument

The autonomic nervous system (ANS) is the portion of the nervous system that adjusts our basic life support systems without our conscious control (Chapter 16). It controls the activation and deactivation of sebaceous glands and apocrine sweat glands at the subconscious level. Regional control is not possible. The commands from the ANS affect all the glands of that type, everywhere on the body surface.

Merocrine sweat glands are much more precisely controlled, and the amount of secretion and the area of the body involved can vary independently. For example, when you are nervously awaiting an anatomy and physiology exam, only your palms may begin to sweat.

As we noted earlier, the primary function of sensible perspiration is to cool the surface of the skin and to reduce body temperature. When the environmental temperature is high, this is a key component of thermoregulation, the process of maintaining temperature homeostasis. When you sweat in the hot sun, all your merocrine glands are working together. The blood vessels beneath your epidermis are dilated and filled with blood, your skin reddens, and the surface of your skin is warm and wet. As the moisture evaporates, your skin cools. If your body temperature then falls below normal, sensible perspiration stops, blood flow to the skin is reduced, and the skin surface cools and dries, releasing little heat into the environment. Chapter 1 introduced the negative feedback mechanisms of thermoregulation. $\supset p$. 10 We will provide additional details in Chapter 25.

CHECKPOINT

- 22. Identify two types of exocrine glands found in the skin.
- 23. What are the functions of sebaceous secretions?
- 24. Deodorants are used to mask the effects of secretions from which type of skin gland?
- **25**. Which type of skin gland is most affected by the hormonal changes that occur during puberty?
- See the blue Answers tab at the back of the book.

5-9 Nails are keratinized epidermal cells that protect the tips of fingers and toes

Learning Outcome Describe the anatomical structure of nails, and explain how they are formed.

Nails protect the exposed dorsal surfaces of the tips of the fingers and toes (**Figure 5–15a**). They also help limit distortion of the digits from mechanical stress—for example, when you run or grasp objects. The **nail body**, the visible portion of the nail, covers an area of epidermis called the **nail bed** (**Figure 5–15b**). The nail body is recessed deep to the level of the surrounding epithelium and is bordered on either side by **lateral nail grooves** (depressions) and **lateral nail folds**. The **free edge** of the nail—the distal portion that continues past the nail bed—extends over the **hyponychium** (hī-pō-NIK-ē-um), an area of thickened stratum corneum (**Figure 5–15c**).

Figure 5–15 The Structure of a Nail.

Nail production takes place at the **nail root**, an epidermal fold not visible from the surface. The deepest portion of the nail root lies very close to the bone of the fingertip. A portion of the stratum corneum of the nail root extends over the exposed nail, forming the **eponychium** (ep- \bar{o} -NIK- \bar{e} -um; *epi-*, over + *onyx*, nail), or **cuticle**. Underlying blood vessels give the nail its characteristic pink color. Near the root, these vessels may be obscured, leaving a pale crescent known as the **lunula** (L \bar{U} -n \bar{u} -la; *luna*, moon) (Figure 5–15a).

The body of the nail consists of dead, tightly compressed cells packed with keratin. The cells producing the nails can be affected by conditions that alter body metabolism, so changes in the shape, structure, or appearance of the nails can provide useful diagnostic information. For example, the nails may turn yellow in individuals who have chronic respiratory disorders, thyroid gland disorders, or AIDS. Nails may become pitted and distorted as a result of *psoriasis* (a condition marked by rapid stem cell division in the stratum basale), and concave as a result of some blood disorders.

CHECKPOINT

- **26**. What substance makes fingernails hard?
- 27. What term is used to describe the thickened stratum corneum underlying the free edge of a nail?
- 28. Where does nail growth occur?
- See the blue Answers tab at the back of the book.

5-10 Several phases are involved in repairing the integument following an injury

Learning Outcome Explain how the skin responds to injury and repairs itself.

The integumentary system can function independently. It often responds directly and automatically to local influences without the involvement of the nervous or endocrine systems. For example, when the skin is continually subjected to mechanical stresses, stem cells in the stratum basale divide more rapidly, and the depth of the epithelium increases. That is why calluses form on your palms when you perform work with your hands.

A more dramatic display of local regulation can be seen after an injury to the skin. The skin can regenerate effectively, even after considerable damage, because stem cells persist in both the epithelial and connective tissue. Basal cell divisions replace lost epidermal cells, and mesenchymal cell divisions replace lost dermal cells.

The process can be slow. When large surface areas are involved, infection and fluid loss complicate the situation. The speed and effectiveness of skin repair vary with the type of wound. A slender, straight cut, or *incision*, may heal fairly quickly compared with a deep scrape, or *abrasion*, which involves a much greater surface area to be repaired.

Figure 5–16 illustrates the four phases in the regeneration of the skin after an injury:

When damage extends through the epidermis and into the dermis, bleeding, along with swelling, redness, and pain occur. This is the *inflammatory phase* **1**.

A blood clot, or **scab**, forms at the surface as part of the *migratory phase* **2**. The scab temporarily restores the integrity of the epidermis and restricts the entry of additional microorganisms into the area.

The bulk of the clot consists of an insoluble network of *fibrin*, a fibrous protein that forms from blood proteins during the clotting response. The clot's color is due to trapped red blood cells.

If the wound occupies an extensive area or involves a region covered by thin skin, dermal repairs must be underway before epithelial cells can cover the surface. Divisions by fibroblasts and mesenchymal cells produce mobile cells that invade the deeper areas of injury. Endothelial cells of damaged blood vessels also begin to divide, and capillaries follow the fibroblasts, enhancing circulation. The combination of blood clot, fibroblasts, and an extensive capillary network at the base of a wound is called **granulation tissue**.

Over time, deeper portions of the clot dissolve, and the number of capillaries declines in the *proliferation phase* 3. The repairs do not restore the integument to its original condition, however, because the dermis will contain an abnormally large number of collagen fibers and a few blood vessels. Severely damaged hair follicles, sebaceous or sweat glands, muscle cells, and nerves are seldom repaired. They, too, are replaced by fibrous tissue.

In the *scarring phase*, the formation of rather inflexible, fibrous, noncellular **scar tissue** completes the repair process, but without restoring the tissue to its original condition **4**.

We do not know what regulates the extent of scar tissue formation, and the process is highly variable. For example, surgical procedures performed on a fetus do not leave scars, perhaps because damaged fetal tissues do not produce the same types of growth factors that adult tissues do. In some adults, most often those with dark skin, scar tissue formation may continue beyond the requirements of tissue repair. The result is a thickened mass of scar tissue that begins at the site of injury and grows

Figure 5–16 Repair of Injury to the Integument.

Clinical Note

Burns and Grafts Burns are significant injuries. They can damage the integrity of large areas of the skin and compromise many essential functions. Burns result from the exposure of skin to heat, friction, radiation, electrical shock, or strong chemical agents. The severity of the burn depends on the depth of penetration and the total area affected.

First-degree and second-degree burns are also called *partial-thickness burns*, because damage is restricted to the superficial layers of the skin. Only the surface of the epidermis is affected by a *first-degree burn*. In this type of burn, which includes most sunburns, the skin reddens and can be painful. The redness, a sign called **erythema** (er-i-THĒ-muh), results from inflammation of the sun-damaged tissues. In a *second-degree burn*, the entire epidermis and perhaps some of the dermis are damaged. Accessory structures such as hair follicles and glands are generally not affected, but blistering, pain, and swelling occur. If the blisters rupture at the surface, infection can easily develop. Healing typically takes one to two weeks. Some scar tissue may form.

Full-thickness burns, or *third-degree burns*, destroy the epidermis and dermis, extending into the hypodermis. Despite swelling, these burns are less painful than second-degree burns, because sensory nerves are destroyed. Extensive third-degree burns cannot repair themselves, because granulation tissue cannot form and epithelial cells are unable to cover the injury. As a result, the affected area remains open to infection. Extensive third-degree burns often require skin grafts, discussed shortly.

Each year in the United States, roughly 4000 people die from fires and burns. There is a standard reference for calculating the percentage of total surface area damaged. Burns that cover more than 20 percent of the skin surface threaten life, because they affect the following functions:

- Fluid and Electrolyte Balance. Even areas with partial-thickness burns lose their effectiveness as barriers to fluid and electrolyte losses. In full-thickness burns, the rate of fluid loss through the skin may reach five times the normal level.
- Thermoregulation. Increased fluid loss means increased evaporative cooling. As a result, more energy must be expended to keep body temperature within acceptable limits.
- Protection from Infection. The dampness of the epidermal surface, resulting from uncontrolled fluid loss, encourages bacterial growth. If the skin is broken, infection is likely.
 Widespread bacterial infection, or **sepsis** (*sepsis*, rotting), is the leading cause of death in burn victims.

Effective treatment of full-thickness burns focuses on four procedures:

- 1. Replacing lost fluids and electrolytes.
- **2.** Providing sufficient nutrients to meet increased metabolic demands for thermoregulation and healing.

- **3.** Preventing infection by cleaning and covering the burn while administering antibiotic drugs.
- 4. Assisting tissue repair.

This illustration shows a simple method of estimating the surface area affected by burns. This method is called the **rule of nines**, because the surface area in adults is divided into multiples of 9. The rule must be modified for children, because their proportions are quite different.

Because large full-thickness burns cannot heal unaided, surgical procedures are necessary to encourage healing. In a **skin graft**, areas of intact skin are transplanted to cover the site of the burn. A *split-thickness graft* involves a transfer of the epidermis and superficial portions of the dermis. A *fullthickness graft* involves the epidermis and both layers of the dermis.

With fluid-replacement therapies, infection control methods, and grafting techniques, young patients with burns over 80 percent of the body have about a 50 percent chance of recovery. Recent advances in cell culturing may improve survival rates. After a postage-stamp-sized section of undamaged epidermis is removed and grown in the laboratory, basal cell divisions produce large sheets of epidermal cells—up to several square meters in area. These sheets can be transplanted to cover the burn area. Although questions remain about the strength and flexibility of the repairs, skin cultivation is a breakthrough in the treatment of serious burns.

Figure 5–17 A Keloid. Keloids are areas of raised fibrous scar tissue.

into the surrounding dermis. This thick, raised area of scar tissue, called a **keloid** (KĒ-loyd), is covered by a shiny, smooth epidermal surface (Figure 5–17). Keloids can develop anywhere on the body where the tissue has been injured, including as a result of surgeries. They are harmless and considered by some to be a cosmetic problem. However, some keloids are intentional and some cultures produce keloids as a form of body decoration.

People in societies around the world adorn the skin with culturally significant markings of one kind or another. Tattoos, piercings, keloids and other scar patterns, and even high-fashion makeup are all used to "enhance" the appearance of the integument. Several African cultures perform scarification, creating a series of complex, raised scars on the skin. Polynesian cultures have long used tattoos as a sign of status and beauty. A dark pigment is inserted deep within the dermis of the skin by tapping on a needle, shark tooth, or bit of bone. Because the pigment is inert, the markings remain for life, clearly visible through the overlying epidermis. American popular culture has recently rediscovered tattoos as a fashionable way of adorning the body. Some of the risks associated with tattooing include allergic reactions, blood-borne infections from the use of contaminated equipment, and skin infections.

Tattoos can now be partially or completely removed by laser surgery. The removal process takes time (10 or more sessions may be required to remove a large tattoo), and scars often remain. To remove the tattoo, an intense, narrow beam of light from a laser breaks down the ink molecules in the dermis. Each blast of the laser that destroys the ink also burns the surrounding dermal tissue. Although the burns are minor, they accumulate and result in the formation of localized scar tissue.

Clinical Note

Skin Abnormalities Because the skin is the most visible organ of the body, abnormalities are easy to recognize. Changes in skin color, tone, and overall condition commonly accompany disease. They can assist in the diagnosis of conditions involving other systems. A bruise, for example, is a swollen, discolored area where blood has leaked through vessel walls. Extensive bruising without any obvious cause may indicate a blood-clotting disorder. Yellowish skin and mucous membranes may signify *jaundice*, which generally indicates some type of liver disorder. The general condition of the skin can also be significant. In addition to color changes, changes in the flexibility, elasticity, dryness, or sensitivity of the skin commonly follow malfunctions in other organ systems.

CHECKPOINT

- **29**. What term describes the combination of fibrin clots, fibroblasts, and the extensive network of capillaries in healing tissue?
- **30**. Why can skin regenerate effectively even after considerable damage?
- See the blue Answers tab at the back of the book.

5–11 Effects of aging include skin thinning, wrinkling, and reduced melanocyte activity

Learning Outcome Summarize the effects of aging on the skin.

Aging affects all the components of the integumentary system:

- The epidermis thins as basal cell activity declines. The connections between the epidermis and dermis weaken, making older people more prone to injury, skin tears, and skin infections.
- The number of dendritic cells (Langerhans cells) decreases to about 50 percent of levels seen at maturity (about age 21). This decrease may reduce the sensitivity of the immune system and further encourage skin damage and infection.
- Vitamin D₃ production declines by about 75 percent. The result can be reduced calcium and phosphate absorption, eventually leading to muscle weakness and a reduction in bone strength and density.

- Melanocyte activity declines. In light-skinned individuals the skin becomes very pale. With less melanin in the skin, people become more sensitive to sunlight and more likely to experience sunburn.
- Glandular activity declines. The skin becomes dry and often scaly, because sebum production is reduced. Merocrine sweat glands are also less active. With impaired perspiration, older people cannot lose heat as fast as younger people can. So, the elderly are at greater risk of overheating in warm environments.
- The blood supply to the dermis is reduced. Reduction in blood flow makes the skin become cool, which in turn can stimulate thermoreceptors, making a person feel cold even in a warm room. However, reduced circulation and sweat gland function in the elderly lessens their ability to lose body heat. For this reason, overexertion or exposure to high temperatures (such as those in a sauna or hot tub) can cause body temperatures to soar dangerously high.
- Hair follicles stop functioning or produce thinner, finer hairs. With decreased melanocyte activity, these hairs are gray or white.
- The dermis thins, and the elastic fiber network decreases in size. As a result, the integument becomes weaker and less resilient, and sagging and wrinkling occur. These effects are

most noticeable in areas of the body that have been exposed to the sun.

- With changes in levels of sex hormones, secondary sexual characteristics in hair and body fat distribution begin to fade.
- Skin repairs proceed more slowly. Repairs to an uninfected blister might take three to four weeks in a young adult, but the same repairs could take six to eight weeks at age 65–75. Because healing takes place more slowly, recurring infections may result.

The **System Integrator** (Figure 5–18) reviews the integumentary system. System Integrators will appear after each body system has been covered to help build your understanding of the interconnections among all other body systems. Since we have covered only one body system thus far, Figure 5–18 does not include references to body systems to be discussed in upcoming chapters.

CHECKPOINT

- **31**. Older individuals do not tolerate the summer heat as well as they did when they were young, and they are more prone to heat-related illness. What accounts for these changes?
- 32. Why does hair turn white or gray with age?
- See the blue Answers tab at the back of the book.

SYSTEM INTEGRATOR

The INTEGUMENTARY System

The integumentary system provides physical protection against environmental hazards. It forms the external surface of the body and protects it from dehydration, environmental chemicals, and external forces. The integument (skin) is separated and insulated from the rest of the body by the subcutaneous layer, but it is interconnected with the rest of the body by an extensive circulatory network of blood vessels and lymphatic vessels. As a result, although the protective mechanical functions of the skin can be discussed independently, its physiological activities are always closely integrated with those of other systems.

ABOUT THE SYSTEM INTEGRATORS

Since each body system interacts with every other body system, no one system can be completely understood in isolation. The integration of the various systems allows the human body to function seamlessly, and when disease or injury strikes, multiple systems must respond to heal it.

These charts will introduce the body systems one by one. In so doing, you will see how previously studied systems interact with each other and contribute to overall body homeostasis. As we progress through the organ systems, the complementary nature of these interactions will become clear. Homeostasis depends on the thorough integration of all the body systems working as one.

Related Clinical Terms

- **carbuncle:** A skin infection that often involves a group of hair follicles. The infected material forms a lump, which occurs deep in the skin; the medical term for multiple boils.
- **cold sore:** A lesion that typically occurs in or around the mouth and is caused by a dormant herpes simplex virus that may be reactivated by factors such as stress, fever, or sunburn. Also called *fever blister*.
- **comedo:** The primary sign of acne consisting of an enlarged pore filled with skin debris, bacteria, and sebum (oil); the medical term for a blackhead.
- **dermatology:** The branch of medicine concerned with the diagnosis, treatment, and prevention of diseases of the skin, hair, and nails.
- eczema: Rash characterized by inflamed, itchy, dry, scaly, or irritated skin.
- **frostbite:** Injury to body tissues caused by exposure to belowfreezing temperatures, typically affecting the nose, fingers, or toes and sometimes resulting in gangrene.
- **furuncle:** A skin infection involving an entire hair follicle and nearby skin tissue; the medical term for a boil.
- **gangrene:** A term that describes dead or dying body tissue that occurs because the local blood supply to the tissue is either lost or is inadequate to keep the tissue alive.

- impetigo: An infection of the surface of the skin, caused by staphylococcus ("staph") and streptococcus ("strep") bacteria. nevus: A benign pigmented spot on the skin such as a mole.
- **onycholysis:** A nail disorder characterized by a spontaneous separation of the nail bed starting at the distal free margin and progressing proximally.
- **pallor:** An unhealthy pale appearance.
- **porphyria:** A rare hereditary disease in which the blood pigment hemoglobin is abnormally metabolized. Porphyrins are excreted in the urine, which becomes dark; other symptoms include mental disturbances and extreme sensitivity of the skin to light.
- **rosacea:** A condition in which certain facial blood vessels enlarge, giving the cheeks and nose a flushed appearance.
- **scleroderma:** An idiopathic chronic autoimmune disease characterized by hardening and contraction of the skin and connective tissue, either locally or throughout the body.

tinea: A skin infection caused by a fungus; also called ringworm.

urticaria: Skin condition characterized by red, itchy, raised areas that appear in varying shapes and sizes; commonly called hives.

An Introduction to the Integumentary System p. 151

- 1. The integument, or integumentary system, consists of the cutaneous membrane, or *skin* (which includes the epidermis and the dermis) and the accessory structures. Beneath the dermis lies the hypodermis, or subcutaneous layer. (*Figures* 5–1, 5–2)
- 2. Functions of the integument include protection, excretion, temperature maintenance, vitamin D_3 synthesis, nutrient storage, sensory detection, and coordination of the immune response. (Figure 5–2)

5-1 The epidermis is composed of layers with various functions p. 153

3. Thin skin, consisting of four layers of keratinocytes, covers most of the body. Heavily abraded body surfaces may be covered by thick skin containing five layers of keratinocytes. (*Spotlight Figure 5–3*)

- 4. The epidermis provides physical protection, prevents fluid loss, and helps keep microorganisms out of the body.
- 5. Cell divisions in the **stratum basale**, the deepest epidermal layer, replace more superficial cells. (*Spotlight Figure 5–3*)
- 6. As epidermal cells age, they pass through the stratum basale, the **stratum spinosum**, the **stratum granulosum**, the **stratum lucidum** (in thick skin), and the **stratum corneum**. In the process, they accumulate large amounts of **keratin**. Ultimately, the cells are shed. (*Spotlight Figure 5–3*)
- 7. The epidermis and dermis are bonded together by **epidermal ridges** interlocked with **dermal papillae**. (*Spotlight Figure 5–3*)
- 8. *Dendritic (Langerhans) cells* in the stratum spinosum are part of the immune system. *Tactile (Merkel) cells* in the stratum basale provide sensory information about objects that touch the skin.

5-2 Factors influencing skin color are epidermal pigmentation and dermal circulation p. 155

- **9.** The color of the epidermis depends on two factors: epidermal pigmentation and dermal blood supply.
- The epidermis contains the pigments carotene and melanin. Melanocytes, which produce melanin, protect us from ultraviolet (UV) radiation. Vitiligo is the appearance of nonpigmented white patches of various sizes on otherwise normallypigmented skin. (*Figures 5–4, 5–5*)
- **11.** Interruptions of the dermal blood supply or poor oxygenation in the lungs can lead to **cyanosis**.

5-3 Sunlight causes epidermal cells to convert a steroid into vitamin D₃ p. 158

12. Epidermal cells synthesize vitamin D_3 , or cholecalciferol, when exposed to the UV radiation in sunlight. Rickets is a disease caused by vitamin D_3 deficiency. (*Figures 5–6, 5–7*)

5-4 Epidermal growth factor has several effects on the epidermis and epithelia p. 159

13. Epidermal growth factor (EGF) promotes growth, division, and repair of the epidermis and epithelial gland synthetic activity and secretion.

5-5 The dermis is the tissue layer that supports the epidermis p. 160

- 14. The dermis consists of the superficial **papillary layer** and the deeper **reticular layer**. (*Figures 5–1, 5–2, and 5–8*)
- **15.** The papillary layer of the dermis contains blood vessels, lymphatics, and sensory nerves that supply the epidermis. The reticular layer consists of a meshwork of collagen and elastic fibers oriented to resist tension in the skin.
- 16. Extensive distension of the dermis can cause stretch marks.
- 17. The pattern of collagen and elastic fiber bundles forms **cleav**age lines. (*Figure 5–9*)
- **18.** Arteries to the skin form the **cutaneous plexus** in the hypodermis. The **subpapillary plexus** is at the base of the papillary layer of the dermis. (*Figure 5–10*)
- **19.** Integumentary sensory receptors detect both light touch and pressure.
- 5-6 The hypodermis connects the dermis to underlying tissues p. 162
- **20.** The **hypodermis**, or subcutaneous layer, stabilizes the skin's position against underlying organs and tissues. (*Figure 5–1, 5–11*)
- 5-7 Hair is composed of keratinized dead cells that have been pushed to the surface p. 163
- 21. Hairs originate in complex organs called hair follicles. Each hair has a root and a shaft. At the base of the root are a hair papilla, surrounded by a hair bulb, and a root hair plexus of sensory nerves. Hairs have a medulla, or core of soft keratin, surrounded by a cortex of hard keratin. The cuticle is a superficial layer of dead cells that protects the hair. (*Figure 5–12*)
- 22. Our bodies have both **vellus hairs** ("peach fuzz") and heavy **terminal hairs**. A hair that has stopped growing is called a **club hair**. A curly hair and its follicle are oval; a straight hair and its follicle are round.
- 23. Each arrector pili muscle can erect a single hair. (Figure 5-12)

b

24. Our hairs grow and are shed according to the **hair growth cycle**. A typical hair on the head grows for two to five years and is then shed.

5-8 Sebaceous glands and sweat glands are exocrine glands found in the skin **p. 166**

- **25.** A typical **sebaceous gland** discharges waxy **sebum** into a lumen and, ultimately, into a hair follicle. **Sebaceous follicles** are large sebaceous glands that discharge sebum directly onto the epidermis. (*Figure 5–13*)
- **26.** The two types of sweat glands, or **sudoriferous glands**, are apocrine and merocrine sweat glands. **Apocrine sweat glands** produce an odorous secretion. The more numerous **merocrine sweat glands** produce a watery secretion known as sensible perspiration. (*Figure 5–14*)
- 27. Mammary glands of the breasts are structurally similar to apocrine sweat glands. Ceruminous glands in the ear produce a waxy substance called cerumen.

5-9 Nails are keratinized epidermal cells that protect the tips of fingers and toes p. 169

28. The **nail body** of a **nail** covers the **nail bed**. Nail production occurs at the **nail root**, which is covered by the **cuticle**, or **eponychium**. The **free edge** of the nail extends over the **hyponychium**. (*Figure 5–15*)

5-10 Several phases are involved in repairing the integument following an injury p. 169

- **29.** Based on the division of stem cells, the skin can regenerate effectively even after considerable damage. The process begins with bleeding and inflammation *(inflammatory phase)*, the formation of a **scab** and **granulation tissue** *(migratory phase)*, loss of granulation tissue and undermining of the scab (*proliferation phase*), and ends with the creation of **scar tissue** *(scarring phase)*. (Figure 5–16)
- **30.** Keloids are raised areas of fibrous scar tissue. (*Figure 5–17*)

5-11 Effects of aging include skin thinning, wrinkling, and reduced melanocyte activity p. 172

- **31.** With aging, the integument thins, blood flow decreases, cellular activity decreases, and repairs take place more slowly.
- **32.** The integumentary system provides physical protection for all other body systems. (*Figure 5-18*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- Identify the different portions (a-d) of the cutaneous membrane and the underlying layer of loose connective tissue (e) in the diagram to the right.
 - (a) _____
 - (b) _____
 - (c) _____ (d) _____
 - (u) _____
- The two major components of the integumentary system are (a) the cutaneous membrane and the accessory structures, (b) the epidermis and the hypodermis, (c) the hair and the nails, (d) the dermis and the hypodermis.
- 3. Beginning at the basement membrane and traveling toward the free surface,

See the blue Answers tab at the back of the book.

the epidermis includes the following strata: (a) corneum, lucidum, granulosum, spinosum, basale, (b) granulosum, lucidum, spinosum, basale, corneum, (c) basale, spinosum, granulosum, lucidum, corneum, (d) lucidum, granulosum, spinosum, basale, corneum.

- 4. Each of the following is a function of the integumentary system, *except*(a) protection of underlying tissue, (b) excretion of salts and wastes,
 (c) maintenance of body temperature, (d) synthesis of vitamin C,
 (e) storage of nutrients.
- 5. Exposure of the skin to ultraviolet (UV) radiation (a) can result in increased numbers of melanocytes forming in the skin, (b) can result in decreased melanin production in melanocytes, (c) can cause destruction of vitamin D_3 , (d) can result in damage to the DNA of cells in the stratum basale, (e) has no effect on the skin cells.
- 6. The two major components of the dermis are the (a) superficial fascia and cutaneous membrane, (b) epidermis and hypodermis, (c) papillary layer and reticular layer, (d) stratum basale and stratum corneum.
- 7. The cutaneous plexus and subpapillary plexus consist of (a) blood vessels providing the dermal blood supply, (b) a network of nerves

providing dermal sensations, (c) specialized cells for cutaneous sensations, (d) gland cells that release cutaneous secretions.

- 8. The accessory structures of the integument include the (a) blood vessels, glands, muscles, and nerves, (b) tactile discs, lamellated corpuscles, and tactile corpuscles, (c) hair, skin, and nails, (d) hair follicles, nails, sebaceous glands, and sweat glands.
- The portion of the hair follicle where cell divisions occur is the (a) shaft, (b) matrix, (c) root hair plexus, (d) cuticle.
- The two types of exocrine glands in the skin are (a) merocrine and sweat glands, (b) sebaceous and sweat glands, (c) apocrine and sweat glands, (d) eccrine and sweat glands.
- Apocrine sweat glands can be controlled by (a) the autonomic nervous system, (b) regional control mechanisms, (c) the endocrine system, (d) both a and c.
- The primary function of sensible perspiration is to: (a) get rid of wastes, (b) protect the skin from dryness, (c) maintain electrolyte balance, (d) reduce body temperature.
- 13. The stratum corneum of the nail root, which extends over the exposed nail, is called the (a) hyponychium, (b) eponychium, (c) lunula, (d) cerumen.
- 14. Muscle weakness and a reduction in bone strength in the elderly result from decreased (a) vitamin D_3 production, (b) melanin production, (c) sebum production, (d) dermal blood supply.
- 15. In which layer(s) of the epidermis does cell division occur?
- 16. What is the function of the arrector pili muscles?
- 17. What widespread effects does epidermal growth factor (EGF) have on the integument?
- **18.** What two major layers constitute the dermis, and what components are in each layer?
- 19. List the four phases in the regeneration of the skin after an injury.

LEVEL 2 Reviewing Concepts

- 20. Contrast insensible perspiration and sensible perspiration.
- **21.** In clinical practice, drugs can be delivered by diffusion across the skin. This delivery method is called transdermal administration. Why are fat-soluble drugs more suitable for transdermal administration than drugs that are water soluble?
- 22. In our society, a tanned body is associated with good health. However, medical research constantly warns about the dangers of excessive

exposure to the sun. Describe how a tan develops and cite a benefit of minimal sun exposure.

- **23.** Why is it important for a surgeon to choose an incision pattern according to the cleavage lines of the skin?
- 24. The fibrous protein that is responsible for the strength and water resistance of the skin surface is (a) collagen, (b) eleidin, (c) keratin, (d) elastin, (e) keratohyalin.
- 25. The darker an individual's skin color (a) the more melanocytes she has in her skin, (b) the more layers she has in her epidermis, (c) the more melanin her melanocytes produce, (d) the more superficial her blood vessels.
- 26. In order for bacteria on the skin to cause an infection in the skin, they must accomplish all of the following, *except* (a) survive the bactericidal components of sebum, (b) avoid being flushed from the surface of the skin by sweat, (c) penetrate the stratum corneum, (d) penetrate to the level of the capillaries, (e) escape the dendritic cells.

LEVEL 3 Critical Thinking and Clinical Applications

- 27. In the elderly, blood supply to the dermis is reduced and sweat glands are less active. This combination of factors would most affect (a) the ability to thermoregulate, (b) the ability to heal injured skin, (c) the ease with which the skin is injured, (d) the physical characteristics of the skin, (e) the ability to grow hair.
- **28.** Two patients are brought to the emergency room. One has cut his finger with a knife; the other has stepped on a nail. Which wound has a greater chance of becoming infected? Why?
- 29. Exposure to optimum amounts of sunlight is necessary for proper bone maintenance and growth in children. (a) What does sunlight do to promote bone maintenance and growth? (b) If a child lives in an area where exposure to sunlight is rare because of pollution or overcast skies, what can be done to minimize impaired maintenance and growth of bone?
- **30.** One of the factors to which lie detectors respond is an increase in electrical skin conductance due to the presence of moisture. Explain the physiological basis for the use of this indicator.
- **31.** Many people change the natural appearance of their hair, either by coloring it or by altering the degree of curl in it. Which layers of the hair do you suppose are affected by the chemicals added during these procedures? Why are the effects of the procedures not permanent?

CLINICAL CASE

Skin Cells in Overdrive

Harold is suffering from psoriasis, a rather common skin disorder that speeds up the life cycle of

skin cells. Instead of the keratinocytes maturing and migrating from the stratum basale to the epidermal surface in a normal amount of time, the process takes place too rapidly. Dead skin cells build up on the epidermal surface in scaly patches.

Nearly 10 million Americans suffer from psoriasis. Like nearly half of them, Harold has a family history of the disease. Other risk factors for developing psoriasis include obesity, smoking, and some medications. And, like one-third of psoriasis patients, Harold has a chance of developing psoriatic arthritis, an inflammatory joint disorder that can affect the large and small joints of the head, neck, and trunk as well as the arms and legs.

Wrap-Up

Psoriasis is a chronic, or longterm, condition. Harold's dermatologist offered him a variety of treatments. One is phototherapy,

which uses ultraviolet light to treat psoriasis. Others include lotions, creams, and shampoos. Still other treatments involve pills and injections aimed at controlling inflammation.

- 1. What layer of the cutaneous membrane is affected by psoriasis?
- 2. What is the underlying problem, as seen in the microscope, in psoriasis?

See the blue Answers tab at the back of the book.

Osseous Tissue and Bone Structure

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 6-1 Describe the primary functions of the skeletal system.
- **6-2** Classify bones according to shape and internal organization, giving examples of each type, and explain the functional significance of each of the major types of bone markings.
- 6-3 Identify the cell types in bone, and list their major functions.
- **6-4** Compare the structures and functions of compact bone and spongy bone.
- **6-5** Compare the mechanisms of endochondral ossification and intramembranous ossification.
- **6-6** Describe the remodeling and homeostatic mechanisms of the skeletal system.
- 6-7 Discuss the effects of exercise, hormones, and nutrition on bone development and on the skeletal system.
- 6-8 Explain the role of calcium as it relates to the skeletal system.
- 6-9 Describe the types of fractures, and explain how fractures heal.
- **6-10** Summarize the effects of the aging process on the skeletal system.

SPOTLIGHTS

• Endochondral Ossification pp. 190–191

CLINICAL CASE

• A Case of Child Abuse? p. 179

Clinical Notes

- Heterotopic Bone Formation p. 188
- Abnormal Bone Development p. 196

CLINICAL CASE

A Case of Child Abuse?

Alex's mom has been waiting in the emergency room for over two hours since her son was

wheeled off to x-ray. Poor Alex had been carried home from third-grade soccer practice. The coach said she had not witnessed the injury, but it seemed like Alex had twisted and fallen without even having contact with another player. He was unable to bear weight on his left lower leg.

A handsome young man, *not* wearing a white coat, approaches her. "Mrs. Otero, I am the hospital social worker. I am here to speak with you about your son, Alex. Alex has an acute fracture of his tibia and fibula—the bones in his lower leg—but he also has two healed rib fractures and a healing fracture of his upper arm as well. We fear he has been the victim of child abuse, so he is being admitted until we can investigate further."

Mrs. Otero is dumbfounded by the suggestion of child abuse. She knows that no one at home has hurt him. Alex had complained about shoulder pain after playing on the monkey bars a few weeks ago, but she had not suspected his upper arm was broken. She considered Alex to be a

lot like her. Both were somewhat fragile and prone to breaking bones, although she had not had any more fractures since she was married. They both had soft, discolored teeth. And, oddly enough, the whites of their eyes had a blue tint. If Alex is not a victim of child abuse, what else could explain his multiple fractures? To find out, turn to the Clinical Case Wrap-Up on p. 205.

An Introduction to the Skeletal System

In this chapter we expand on the introduction to bone, presented in Chapter 4, by examining the mechanisms involved with the growth, remodeling, and repair of the skeleton. The bones of the skeleton are more than just racks from which muscles hang. They have a variety of vital functions. In addition to supporting the weight of the body, bones work with muscles to maintain body position and to produce controlled, precise movements. Without the skeleton to pull against, contracting muscle fibers could not make us sit, stand, walk, or run.

6-1 The skeletal system has five primary functions

Learning Outcome Describe the primary functions of the skeletal system.

Your skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or interconnect the bones. This system has five primary functions:

- 1. *Support.* The skeletal system provides structural support for the entire body. Individual bones or groups of bones provide a framework for the attachment of soft tissues and organs.
- 2. Storage of Minerals and Lipids. Minerals are inorganic ions that contribute to the osmotic concentration of body fluids, as you will learn in Chapter 25. Minerals also take part in various physiological processes, and several are important as enzyme cofactors. Calcium is the most abundant mineral in the human body. The calcium salts of bone are a valuable mineral reserve that maintains normal

concentrations of calcium and phosphate ions in body fluids. In addition, the bones of the skeleton store energy as lipids in areas filled with *yellow bone marrow*.

- **3.** *Blood Cell Production.* Red blood cells, white blood cells, and other blood elements are produced in *red bone marrow*, which fills the internal cavities of many bones. We will describe blood cell formation when we examine the cardio-vascular and lymphatic systems (Chapters 19 and 22).
- 4. *Protection.* Skeletal structures surround many soft tissues and organs. The ribs protect the heart and lungs, the skull encloses the brain, the vertebrae shield the spinal cord, and the pelvis cradles digestive and reproductive organs.
- 5. *Leverage*. Many bones function as levers that can change the magnitude and direction of the forces generated by skeletal muscles. The movements produced range from the precise motion of a fingertip to changes in the position of the entire body.

Chapters 6–9 describe the structure and function of the skeletal system. We begin by describing bone, or osseous tissue, a supporting connective tissue introduced in Chapter 4. \bigcirc **p. 136** All of the features and properties of the skeletal system ultimately depend on the unique and dynamic properties of bone. The bone specimens that you study in lab or that you may have seen in the skeletons of dead animals are only the dry remains of this living tissue. They have the same relationship to the bone in a living organism as a kiln-dried 2-by-4 board has to a living oak tree.

CHECKPOINT

- 1. Name the five primary functions of the skeletal system.
- See the blue Answers tab at the back of the book.

6-2 Bones are classified according to shape and structure, and they have a variety of surface markings

Learning Outcome Classify bones according to shape and internal organization, giving examples of each type, and explain the functional significance of each of the major types of bone markings.

We can classify a bone by its general shape or by its internal tissue organization. Before we consider specific bones of the skeleton, let's look at the classification schemes.

Bone Shapes

The adult skeleton typically contains 206 major bones. We can divide these into six broad categories according to their individual shapes (Figure 6–1):

- Sutural bones, or Wormian bones, are small, flat, irregularly shaped bones between the flat bones of the skull (Figure 6–1a). There are individual variations in the number, shape, and position of the sutural bones.
- 2. Irregular bones have complex shapes (Figure 6-1b).
- **3. Short bones** are small and boxy, with approximately equal dimensions. (Figure 6–1c).
- 4. Flat bones have a thin, flattened shape.
- 5. **Long bones** are elongated and consist of a shaft (diaphysis) with two ends (epiphyses) that are wider than the shaft (Figure 6–1e).
- 6. **Sesamoid bones** are small, flat, and shaped somewhat like a sesame seed (Figure 6–1f). Except for the patellae (kneecaps), there are individual variations in the location and number of sesamoid bones. These variations, along

Figure 6–1 A Classification of Bones by Shape.

with varying numbers of sutural bones, account for individual differences in the total number of bones in the skeleton. (Sesamoid bones may form in at least 26 locations.)

Bone Markings

The surfaces of each bone in your body have characteristic features. Elevations or projections form where tendons and ligaments attach, and where adjacent bones articulate (that is, at joints). Depressions, grooves, and tunnels in bone are sites where blood vessels or nerves lie alongside or penetrate the bone. Detailed examination of these **bone markings**, or *surface features*, can yield an abundance of anatomical information. For example, anthropologists, criminologists, and pathologists can often determine the size, age, sex, and general appearance of an individual on the basis of incomplete skeletal remains.

Figure 6–2 introduces the prominent bone markings. It uses specific anatomical terms for the various projections,

depressions, and openings. These markings provide fixed landmarks that can help us determine the position of the softtissue components of other organ systems.

Bone Structure

Figure 6–3a introduces the anatomy of the femur, the long bone of the thigh. This representative long bone has an extended tubular shaft, or **diaphysis** (dī-AF-i-sis). At each end is an expanded area known as the **epiphysis** (ē-PIF-i-sis). The diaphysis is connected to each epiphysis at a narrow zone known as the **metaphysis** (me-TAF-i-sis; *meta*, between).

6

The wall of the diaphysis consists of a layer of compact bone. **Compact bone**, or *dense bone*, is relatively solid. It forms a sturdy protective layer that surrounds a central space called the **medullary cavity** (*medulla*, innermost part), or *marrow cavity*.

Figure 6–3 Bone Structure.

The epiphyses consist largely of spongy bone. **Spongy bone**, also called *cancellous* (KAN-se-lus) or *trabecular bone*, consists of an open network of struts and plates that resembles latticework. The spongy bone of each epiphysis is covered by a thin layer of compact bone, also called *cortical bone*.

Figure 6–3b shows the structure of a flat bone from the skull, such as one of the *parietal bones*. A flat bone resembles a spongy bone sandwich, with layers of compact bone covering a core of spongy bone. Within the cranium, the layer of spongy bone between the layers of compact bone is called the *diploë* (DIP-lō-ē; *diplous*, twofold). Red bone marrow is present within the spongy bone, but there is no large medullary cavity as in the diaphysis of a long bone.

Many people think the skeleton is rather dull and boring. This is far from the truth. Our bones are complex, dynamic organs that constantly change to adapt to the demands we place on them. We will now consider the histology of a typical bone.

- CHECKPOINT

- 2. Identify the six broad categories for classifying a bone according to shape.
- **3**. Define bone marking.
- See the blue Answers tab at the back of the book.

6-3 Bone is composed of matrix and several types of cells: osteocytes, osteoblasts, osteogenic cells, and osteoclasts

Learning Outcome Identify the cell types in bone, and list their major functions.

Osseous tissue is a supporting connective tissue. (You may review the sections on dense connective tissues, cartilage, and bone in Chapter 4.) \bigcirc pp. 131–137 Like other connective

tissues, it contains specialized cells and a matrix consisting of extracellular protein fibers and a ground substance. The matrix of bone tissue is solid and sturdy, due to deposits of calcium salts around the protein fibers.

Recall these characteristics of bone from Chapter 4:

- The matrix of bone is very dense and contains deposits of calcium salts.
- The matrix contains bone cells, or *osteocytes*, within pockets called *lacunae*. (The same term is used for the spaces that chondrocytes occupy in cartilage. ⊃ p. 133) The lacunae of bone are typically organized around blood vessels that branch through the bony matrix.
- Canaliculi, narrow passageways through the matrix, extend between the lacunae and nearby blood vessels, forming a branching network for the exchange of nutrients, wastes, and gases.
- Except at joints, a periosteum covers the outer surfaces of bones. It consists of an outer fibrous layer and an inner cellular layer.

We now take a closer look at the organization of the matrix and cells of bone.

Bone Matrix

Calcium phosphate, $Ca_3(PO_4)_2$, makes up almost two-thirds of the weight of bone. Calcium phosphate interacts with calcium hydroxide, $Ca(OH)_2$, to form crystals of **hydroxyapatite** (hī-drok-sē-AP-a-tīt), $Ca_{10}(PO_4)_6(OH)_2$. As these crystals form, they incorporate other calcium salts, such as calcium carbonate (CaCO₃), and ions such as sodium, magnesium, and fluoride. Approximately one-third of the weight of bone is collagen fibers. Cells make up only 2 percent of the mass of a typical bone.

Calcium phosphate crystals are very hard, but relatively inflexible and quite brittle. They can withstand compression but are likely to shatter when exposed to bending, twisting, or sudden impacts. Collagen fibers, by contrast, are remarkably strong. When subjected to tension (pull), they are stronger than steel. They are flexible as well as tough and can easily tolerate twisting and bending, but offer little resistance to compression. When compressed, they simply bend out of the way.

The composition of the matrix in compact bone is the same as that in spongy bone. The collagen fibers provide an organic framework on which hydroxyapatite crystals can form. These crystals form small plates and rods that are locked into the collagen fibers at regular angles. The result is a protein-crystal combination that has the flexibility of collagen and the compressive strength of hydroxyapatite crystals. The protein-crystal interactions allow bone to be strong, somewhat flexible, and highly resistant to shattering.

In its overall properties, bone is on a par with the best steelreinforced concrete. In fact, bone is far superior to concrete, because it can undergo remodeling (cycles of bone formation and resorption) as needed and can repair itself after injury.

Bone Cells

Bone contains four types of cells: osteocytes, osteoblasts, osteogenic cells, and osteoclasts (Figure 6–4).

Osteocytes (OS-tē- \bar{o} -sīts) (*osteo-*, bone + -*cyte*, cell) are mature bone cells that make up most of the cell population. Each

Figure 6–4 Types of Bone Cells.

osteocyte occupies a lacuna, a pocket sandwiched between layers of matrix. The layers are called **lamellae** (lah-MEL-lē; singular, *lamella*, a thin plate). Osteocytes cannot divide, and a lacuna never contains more than one osteocyte. Narrow passageways called **canaliculi** penetrate the lamellae, radiating through the matrix and connecting lacunae with one another and with sources of nutrients, supplied by blood vessels in the central canal.

Canaliculi contain cytoplasmic extensions of osteocytes. Neighboring osteocytes are linked by gap junctions, which permit the cells to exchange ions and small molecules, including nutrients and hormones. The interstitial fluid that surrounds the osteocytes and their extensions is an additional route for the diffusion of nutrients and waste products.

Osteocytes have two major functions:

- 1. Osteocytes maintain the protein and mineral content of the surrounding matrix. There is continual turnover of matrix components. Osteocytes secrete chemicals that dissolve the adjacent matrix, and the minerals released enter the circulation. Osteocytes then rebuild the matrix, stimulating the deposition of new hydroxyapatite crystals. The turnover rate varies from bone to bone. We will consider this process further in a later section.
- 2. Osteocytes take part in the repair of damaged bone. If released from their lacunae, osteocytes can convert to a less specialized type of cell, such as an osteoblast or an osteogenic cell.

Osteoblasts (OS-tē-ō-blasts; *-blast*, immature precursor cell) produce new bone matrix in a process called **ossification**, or **osteogenesis** (os-tē-ō-JEN-e-sis; *genesis*, production). Osteoblasts make and release the proteins and other organic components of the matrix. Before calcium salts are deposited, this organic matrix is called **osteoid** (OS-tē-oyd). Osteoblasts also help increase local concentrations of calcium phosphate above its solubility limit, triggering the deposition of calcium salts in the organic matrix. This process converts osteoid to bone. Osteocytes develop from osteoblasts that have become completely surrounded by bone matrix.

Bone contains small numbers of mesenchymal cells called **osteogenic** (os-tē-ō-JEN-ik) **cells** or *osteoprogenitor* (os-tē-ō-prō-JEN-i-tor) *cells*. These squamous stem cells divide to produce daughter cells that differentiate into osteoblasts. Osteogenic cells maintain populations of osteoblasts and are important in the repair of a *fracture* (a break or a crack in a bone). Osteogenic cells are found in the inner, cellular layer of the periosteum. They are also found in an inner layer, or *endosteum*, that lines medullary cavities and passageways for blood vessels penetrating the matrix of compact bone.

Osteoclasts (OS-tē-ō-clasts; *klastos*, broken) are cells that absorb and remove bone matrix. They are large cells with 50

or more nuclei. Osteoclasts are not related to osteogenic cells or their descendants. Instead, they are derived from the same stem cells that produce monocytes and macrophages, which are cells involved in the body's defense mechanisms. Acids and protein-digesting enzymes secreted by osteoclasts dissolve the matrix and release the stored minerals. This erosion process is called **osteolysis** (os-tē-OL-i-sis; *osteo-*, bone + *lysis*, a loosening) or *resorption*. It is important in the regulation of calcium and phosphate concentrations in body fluids.

In living bone, osteoclasts are constantly removing matrix, and osteoblasts are always adding to it. The homeostatic balance between the opposing activities of osteoblasts and osteoclasts is very important. When osteoclasts remove calcium salts faster than osteoblasts deposit them, bones weaken. When osteoblast activity predominates, bones become stronger and more massive. This opposition causes some interesting differences in bone structure among individuals. People who subject their bones to muscular stress through weight training or strenuous exercise develop not only stronger muscles, but also stronger bones. Alternatively, declining muscular activity due to immobility leads to reduced bone mass at sites of muscle attachment. We will look at this phenomenon further in a later section of the chapter.

- CHECKPOINT

- Mature bone cells are known as _____, bone-building cells are called _____, and _____ are bone-resorbing cells.
- 5. How would the compressive strength of a bone be affected if the ratio of collagen to hydroxyapatite increased?
- 6. If the activity of osteoclasts exceeds the activity of osteoblasts in a bone, how will the mass of the bone be affected?

See the blue Answers tab at the back of the book.

6-4 Compact bone contains parallel osteons, and spongy bone contains trabeculae

Learning Outcome Compare the structures and functions of compact bone and spongy bone.

Compact bone functions to protect, support, and resist stress. Spongy bone provides some support and stores marrow. In this section, we examine in detail the structures of compact and spongy bone, which allow these types of bone to perform their functions. We also look at the outer and inner coverings of bone, called the periosteum and endosteum, respectively.

Compact Bone Structure

The basic functional unit of mature compact bone is the **osteon** (OS-tē-on), or *Haversian system*. In an osteon, the osteocytes are arranged in concentric layers around a vascular **central canal**, or *Haversian canal* (Figure 6–5). This canal contains one or more blood vessels (normally a capillary and a *venule*, a very small vein) that carry blood to and from the osteon (Figure 6–6a). Central canals generally run parallel to the surface of the bone. Other passageways, known as **perforating canals** or *Volkmann's canals*, extend perpendicular to the surface. Blood vessels in these canals supply blood to osteons deeper in the bone and to tissues of the medullary cavity.

The lamellae of each osteon form a series of nested cylinders around the central canal. In transverse section, these *concentric lamellae* create a targetlike pattern, with the central canal as the bull's-eye. Collagen fibers within each lamella form a spiral pattern that adds strength and resiliency (Figure 6–6b).

Canaliculi radiating through the lamellae interconnect the lacunae of the osteons with one another and with the central canal. *Interstitial lamellae* fill in the spaces between the osteons in compact bone. These lamellae are remnants of osteons whose matrix components have been almost completely recycled by osteoclasts. *Circumferential lamellae (circum-, around + ferre, to bear)* are found at the outer and inner surfaces of the bone, where they are covered by the periosteum and

endosteum, respectively (Figure 6–6a,b). These lamellae are produced during the growth of the bone, as we will describe in a later section.

TIPS&TRICKS

To understand the relationship of collagen fibers to bone matrix, think about the reinforcing steel rods (rebar) in concrete. Like the rebar in concrete, collagen adds strength to bone.

Compact bone is thickest where stresses arrive from a limited range of directions. All osteons in compact bone are aligned the same, making such bones very strong when stressed along the axis of alignment. You might think of a single osteon as a drinking straw with very thick walls. When you try to push the ends of the straw together or to pull them apart, the straw is quite strong. But if you hold the ends and push from the side, the straw will easily bend at a sharp angle.

The osteons in the diaphysis of a long bone are parallel to the long axis of the shaft. For this reason, the shaft does not bend, even when extreme forces are applied to either end. (The femur can withstand 10–15 times the body's weight without breaking.) Yet a much smaller force applied to the side of the shaft can break the femur. A sudden sideways force, as in a fall or auto accident, causes the majority of breaks in this bone.

black due to the presence of bone dust.

Figure 6–5 The Histology of Compact Bone.

Spongy Bone Structure

In spongy bone, lamellae are not arranged in osteons. The matrix in spongy bone forms a meshwork of supporting bundles of fibers called **trabeculae** (tra-BEK-ū-lē) (Figure 6–7). These thin trabeculae branch, creating an open network. There are no capillaries or venules in the matrix of spongy bone. Nutrients reach the osteocytes by diffusion along canaliculi that open onto the surfaces of trabeculae. Red bone marrow is found between the trabeculae of spongy bone. Blood vessels within this tissue deliver nutrients to the trabeculae and remove wastes generated by the osteocytes.

Spongy bone is found where bones are not heavily stressed or where stresses arrive from many directions. The trabeculae are oriented along stress lines and extensively cross-braced.

In addition to being able to withstand stresses applied from many directions, spongy bone is much lighter than compact bone. Spongy bone reduces the weight of the skeleton, making it easier for muscles to move the bones.

Finally, the framework of trabeculae supports and protects the cells of the bone marrow. Spongy bone within the epiphyses of long bones, such as the femur, and the interior of other large bones such as the sternum and ilium (a large bone of the pelvis), contains **red bone marrow**, which forms blood

Endosteum Lamellae

cells. At other sites, spongy bone may contain **yellow bone marrow**—adipose tissue important as an energy reserve.

How do compact bone and spongy bone work together to support the body's weight? **Figure 6–8** shows the distribution of forces applied to the femur at the hip joint, and illustrates the functional relationship between compact bone and spongy bone. The head of the femur articulates with a socket on the lateral surface of the pelvis. At the proximal epiphysis of the femur, trabeculae transfer forces from the pelvis to the compact bone of the femoral shaft, across the hip joint. At the distal epiphysis, trabeculae transfer weight from the shaft to the leg, across the knee joint. The femoral

Figure 6–8 The Distribution of Forces on a Long Bone. The femur, or thigh bone, has a diaphysis (shaft) with walls of compact bone and epiphyses filled with spongy bone. The body weight is transferred to the femur at the hip joint. Because the hip joint is off center relative to the axis of the shaft, the body weight is distributed along the bone in a way that compresses the medial (inner) portion of the shaft and stretches the lateral (outer) portion.

head projects medially, and the body weight compresses the medial side of the shaft. However, because the force is applied off center, the bone must also resist the tendency to bend into a lateral bow. So while the medial portion of the shaft is under compression, the lateral portion of the shaft, which resists this bending, is placed under a stretching load, or *tension*. The medullary cavity does not reduce the bone's strength because the center of the bone is not subjected to compression or tension.

The Periosteum and Endosteum

Except within joint cavities, the superficial layer of compact bone that covers all bones is wrapped by a **periosteum**, a membrane with a fibrous outer layer and a cellular inner layer (**Figure 6–9a**). The periosteum (1) isolates the bone from surrounding tissues, (2) provides a route for the blood vessels and nerves, and (3) takes part in bone growth and repair.

Near joints, the periosteum becomes continuous with the connective tissues that hold the bones in place. At a joint that permits significant amounts of movement, called a *synovial joint*, the periosteum is continuous with the joint capsule. The fibers of the periosteum are also interwoven with those of the tendons attached to the bone. As the bone grows, these tendon fibers are cemented into the circumferential lamellae by osteoblasts from the cellular layer of the periosteum. Collagen fibers incorporated into bone tissue from tendons and ligaments, as well as from the superficial periosteum, are called *perforating (Sharpey's) fibers*.

This method of attachment bonds the tendons and ligaments into the general structure of the bone, providing a much stronger attachment than would otherwise be possible. An extremely powerful pull on a tendon or ligament will usually break a bone rather than snap the collagen fibers at the bone surface.

The **endosteum**, an incomplete cellular layer, lines the medullary cavity (Figure 6–9b). This layer is active during bone growth, repair, and remodeling. It covers the trabeculae of spongy bone and lines the inner surfaces of the central canals of compact bone. The endosteum consists of a simple flattened layer of osteogenic cells that covers the bone matrix, generally without any intervening connective tissue fibers. Where the cellular layer is not complete, the matrix is exposed. At these exposed sites, osteoclasts and osteoblasts can remove or deposit matrix components. The osteoclasts generally occur in shallow depressions called *osteoclastic crypts* (*Howship's lacunae*) that they have eroded into the matrix.

CHECKPOINT

- 7. Compare the structures and functions of compact bone and spongy bone.
- 8. A sample of bone has lamellae, which are not arranged in osteons. Is the sample most likely taken from the epiphysis or diaphysis?

See the blue Answers tab at the back of the book.

Clinical Note

Heterotopic Bone Formation Bones sometimes form where they do not belong. In response to abnormal stresses, bone may form anywhere in the dermis or within tendons, around joints, in the kidneys, or in skeletal muscles. Dermal bones forming in abnormal locations are called *heterotopic bones* (*hetero-*, different + *topos*, place). These bones can form in very odd places, such as the testes or the whites of the eyes. Physical or chemical events can stimulate the abnormal development of osteoblasts in normal connective tissues, such as sesamoid bones developing within tendons or near points of friction and pressure. Bone can also form within a large blood clot, at an injury site, or within portions of the dermis subjected to overuse.

Persons with the rare genetic disease *fibrodysplasia ossificans progressiva* (FOP) form bone around skeletal muscles and provide the most dramatic demonstrations of heterotopic bone formation. Bone gradually replaces the muscles of the back, neck, and upper limbs. The extent of the conversion can be seen in the photos on the right. Photo a shows an adult male with FOP. Photo b shows the skeleton of an adult male with advanced FOP. Several of the vertebrae have fused into a solid mass, and major muscles of the back, shoulders, and hips have undergone extensive ossification. Treatment can be problematic, because any surgical excision may trigger more ossification.

b The skeleton of a man with advanced FOP

6–5 Bones form through ossification and enlarge through appositional growth and remodeling

Learning Outcome Compare the mechanisms of endochondral ossification and intramembranous ossification.

The growth of the skeleton determines the size and proportions of your body. The bony skeleton begins to form about six weeks after fertilization, when the embryo is approximately 12 mm (0.5 in.) long. (At this stage, the existing skeletal elements are made of cartilage.) During subsequent development, the bones undergo a tremendous increase in size. Bone growth continues through adolescence, and portions of the skeleton generally do not stop growing until about age 25.

In this section, we consider the physical process of bone formation, or *ossification*, and bone growth. Ossification or osteogenesis refers specifically to the formation of bone. The process of **calcification**—the deposition of calcium salts takes place during ossification, but it can also occur in other tissues. When calcification occurs in tissues other than bone, the result is a calcified tissue (such as calcified cartilage) that does not resemble bone.

Two major forms of ossification exist: endochondral and intramembranous. In *endochondral ossification*, bone replaces existing cartilage. In *intramembranous ossification*, bone develops directly from mesenchyme (loosely organized embryonic connective tissue) or fibrous connective tissue.

Endochondral Ossification

During development, most bones originate as hyaline cartilages that are miniature models of the corresponding bones of the adult skeleton. These cartilage models are gradually replaced by bone through the process of **endochondral** (en-dō-KON-drul) **ossification** (*endo-*, inside + *chondros*, cartilage). The steps in limb bone development provide a good example of this process (**Spotlight Figure 6–11**).

The timing of endochondral ossification can be monitored by comparing the width of the epiphyseal cartilages in successive x-rays. In adults, the former location of this cartilage can often be seen in x-rays as a narrow *epiphyseal line*, which remains after epiphyseal growth has ended (Figure 6–10). The completion of epiphyseal growth is called *epiphyseal closure*.

Appositional Growth

A superficial layer of bone, or bone collar, forms early in endochondral ossification (**Spotlight Figure 6–11**). After that, the developing bone increases in diameter through **appositional growth** at the outer surface. In this process, cells of the inner layer of the periosteum differentiate into osteoblasts and deposit superficial layers of bone matrix. Eventually, these osteoblasts become surrounded by matrix and differentiate into osteocytes.

Over much of the surface, appositional growth adds a series of layers that form circumferential lamellae. In time, the deepest circumferential lamellae are recycled and replaced by osteons typical of compact bone. However, blood vessels and collagen fibers of the periosteum can sometimes become enclosed within the matrix produced by osteoblasts. Osteons may then form around the smaller vessels. While bone matrix is being added to the outer surface of the growing bone, osteoclasts are removing bone matrix at the inner surface, but at a slower rate. As a result, the medullary cavity gradually enlarges as the bone gets larger in diameter.

Figure 6–10 Bone Growth at an Epiphyseal Cartilage.

a An x-ray of growing epiphyseal cartilages (arrows)

b Epiphyseal lines in an adult (arrows)

SPOTLIGHT Figure 6–11 Endochondral Ossification

Endochondral ossification begins with the formation of a hyaline cartilage model. This model serves as the pattern for almost all bone development. Limb bone development is a good example of this process. By the time an embryo is six weeks old, the proximal bones of the limbs, the humerus (upper limb) and femur (lower limb), have formed, but they are composed entirely of cartilage. These cartilage models continue to grow by expansion of the cartilage matrix (interstitial growth) and the production of more cartilage at the outer surface (appositional growth).

Initiation of Ossification in the Developing Bone (Steps 1–4)

2

As the cartilage enlarges, chondrocytes near the center of the shaft increase greatly in size. The matrix is reduced to a series of small struts that soon begin to calcify. The enlarged chondrocytes then die and disintegrate, leaving cavities within the cartilage.

Blood vessels grow around the edges of the cartilage, and the cells of the perichondrium convert to osteoblasts. The shaft of the cartilage then becomes ensheathed in a superficial layer of bone.

Blood vessels penetrate the cartilage and invade the central region. **Fibroblasts migrating** with the blood vessels differentiate into osteoblasts and begin producing spongy bone at a primary ossification center. Bone formation then spreads along the shaft toward both ends of the former cartilage model.

Remodeling occurs as growth continues, creating a medullary cavity. The osseous tissue of the shaft becomes thicker, and the cartilage near each epiphysis is replaced by shafts of bone. Further growth involves increases in length and diameter.

Enlarging chondrocytes within calcifying matrix

Disintegrating chondrocytes of the cartilage mode

Medullary cavity Metaphysis

Increasing the Length of a Developing Long Bone (Steps 5–7)

During the initial stages of ossification, osteoblasts move away from the primary ossification center toward the epiphyses. But they do not complete the ossification of the model immediately, because the cartilages of the epiphyses continue to grow. The region where the cartilage is being replaced by bone lies at the metaphysis, the junction between the diaphysis and an epiphysis. On the diaphyseal (shaft) side of the metaphysis, osteoblasts continually invade the cartilage and replace it with bone, while on the epiphyseal side, new cartilage is produced at the same rate. The situation is like a pair of joggers, one in front of the other. As long as they are running at the same speed, they can run for miles without colliding. In this case, the osteoblasts and the epiphysis are both "running away" from the primary ossification center. As a result, the osteoblasts never catch up with the epiphysis, and the bone continues to grow longer and longer.

Intramembranous Ossification

Intramembranous (in-tra-MEM-bra-nus) **ossification** begins when osteoblasts differentiate within a mesenchymal or fibrous connective tissue. This type of ossification is also called *dermal ossification* because it normally takes place in the deeper layers of the dermis. The bones that result are called dermal bones. Examples of dermal bones are the flat bones of the skull, the mandible (lower jaw), and the clavicles (collarbones). The steps of intramembranous ossification are summarized in Figure 6–12.

The Blood and Nerve Supplies to Bone

6

In order for bones to grow and be maintained, they require an extensive blood supply. For this reason, osseous tissue is highly vascular. In a typical bone such as the humerus, three major sets of blood vessels develop (Figure 6–13):

- 1. *The Nutrient Artery and Vein.* The blood vessels that supply the diaphysis form by invading the cartilage model as endochondral ossification begins. Most bones have only one *nutrient artery* and one *nutrient vein*, but a few bones, including the femur, have more than one of each. The vessels enter the bone through one or more round passageways called *nutrient foramina* in the diaphysis. Branches of these large vessels form smaller perforating canals and extend along the length of the shaft into the osteons of the surrounding compact bone.
- **2.** *Metaphyseal Vessels.* The *metaphyseal vessels* supply blood to the inner (diaphyseal) surface of each epiphyseal cartilage, where that cartilage is being replaced by bone.
- **3.** *Periosteal Vessels.* Blood vessels from the periosteum provide blood to the superficial osteons of the shaft. During endochondral bone formation, branches of periosteal vessels also enter the epiphyses, providing blood to the secondary ossification centers.

Following the closure of the epiphyses, all three sets of vessels become extensively interconnected.

The periosteum also contains a network of lymphatic vessels (lymphatics) and sensory nerves. The lymphatics collect lymph from branches that enter the bone and reach individual osteons by the perforating canals. The sensory nerves penetrate the compact bone with the nutrient artery to innervate the endosteum, medullary cavity, and epiphyses. Because of the rich sensory innervation, injuries to bones are usually very painful.

In the next section, we examine the maintenance and replacement of mineral reserves in the adult skeleton.

- CHECKPOINT

- 9. In endochondral ossification, what is the original source of osteoblasts?
- **10**. During intramembranous ossification, which type of tissue is replaced by bone?
- 11. How could x-rays of the femur be used to determine whether a person has reached full height?
- See the blue Answers tab at the back of the book.

6-6 Bone growth and development depend on a balance between bone formation and bone resorption

Learning Outcome Describe the remodeling and homeostatic mechanisms of the skeletal system.

The process of **remodeling** continuously recycles and renews the organic and mineral components of the bone matrix. Bone remodeling goes on throughout life, as part of normal bone maintenance. Remodeling can replace the matrix but leave the bone as a whole unchanged, or it may change the shape, internal architecture, or mineral content of the bone. Through remodeling, older mineral deposits are removed from bone and released into the circulation at the same time that circulating minerals are being absorbed and deposited.

Bone remodeling involves interplay among the activities of osteocytes, osteoblasts, and osteoclasts. In adults, osteocytes are continuously removing and replacing the surrounding calcium salts. Osteoclasts and osteoblasts also remain active, even after the epiphyseal cartilages have closed. Normally, their activities are balanced: As quickly as osteoblasts form one osteon, osteoclasts remove another by osteolysis.

The turnover rate of bone is quite high. In young adults, almost one-fifth of the skeleton is recycled and replaced each year. Not every part of every bone is affected equally. The rate of turnover differs regionally and even locally. For example, the spongy bone in the head of the femur may be replaced two or three times each year, but the compact bone along the shaft remains largely unchanged.

Because of their biochemical similarity to calcium, heavymetal ions such as lead, strontium, cobalt, or radioactive uranium or plutonium can be incorporated into the matrix of bone. Osteoblasts do not differentiate between these heavymetal ions and calcium. This means that any heavy-metal ions present in the bloodstream will be deposited into the bone matrix. Some of these ions are potentially dangerous, and the turnover of bone matrix can have detrimental health effects as ions that are absorbed and accumulated are released into the circulation over a period of years. This was one of the major

......

6

Figure 6–12 Intramembranous Ossification.

Intramembranous ossification starts about the eighth week of embryonic development. This type of ossification occurs in the deeper layers of the dermis, forming **dermal bones**. Mesenchymal cells cluster together, differentiate into osteoblasts, and start to secrete the organic components of the matrix. The resulting osteoid then becomes mineralized with calcium salts forming bone matrix.

As ossification proceeds, some osteoblasts are trapped inside bony pockets where they differentiate into osteocytes. The developing bone grows outward from the ossification center in small struts called **spicules**.

2

3

Blood vessels begin to branch within the region and grow between the spicules. The rate of bone growth accelerates with oxygen and a reliable supply of nutrients. As spicules interconnect, they trap blood vessels within the bone.

complications in the aftermath of the Chernobyl nuclear reactor incident in 1986. Radioactive compounds released in the meltdown of the reactor were deposited into the bones of exposed individuals. Over time, the radiation released by their own bones has caused thyroid cancers, leukemia (cancer of the blood cells, which starts in the red bone marrow), and other potentially fatal cancers.

CHECKPOINT

- 12. Describe bone remodeling.
- **13**. Explain how heavy-metal ions could be incorporated into bone matrix.
- See the blue Answers tab at the back of the book.

6-7 Exercise, hormones, and nutrition affect bone development and the skeletal system

Learning Outcome Discuss the effects of exercise, hormones, and nutrition on bone development and on the skeletal system.

What factors have the most important effects on the processes of bone remodeling? Exercise, nutrition, and hormones are key.

The Effects of Exercise on Bone

The turnover and recycling of minerals give each bone the ability to adapt to new stresses. The sensitivity of osteoblasts to electrical events has been theorized as the mechanism that controls the internal organization and structure of bone. Whenever a bone is stressed, the mineral crystals generate minute electrical fields. Osteoblasts are apparently attracted to these electrical fields and, once in the area, begin to produce bone. This finding has led to the successful use of small electric fields in stimulating bone healing.

Because of their adaptability, bone shapes reflect the forces applied to them. For example, bumps and ridges on the surface of a bone mark the sites where tendons are attached. If muscles become more powerful, the corresponding bumps and ridges enlarge to withstand the increased forces. Heavily stressed bones become thicker and stronger, and bones that are not subjected to ordinary stresses become thin and brittle. For this reason, regular exercise is an important stimulus for maintaining normal bone structure. Champion weight lifters typically have massive bones with thick, prominent ridges. In nonathletes (especially "couch potatoes"), moderate amounts of physical activity and weight-bearing activities are essential for stimulating normal bone maintenance and maintaining adequate bone strength.

Degenerative changes in the skeleton take place after relatively brief periods of inactivity. For example, you may use a crutch to take weight off an injured leg while you wear a cast. After a few weeks, your unstressed bones can lose up to a third of their mass. The bones rebuild just as quickly when you resume normal weight loading. However, the removal of calcium salts can be a serious health hazard both for astronauts remaining in a weightless environment and for bedridden or paralyzed patients who spend months or years without stressing their skeleton.

Nutritional and Hormonal Effects on Bone

Normal bone growth and maintenance depend on a combination of nutritional and hormonal factors, such as:

Table 6–1	Hormones Involved in Bone Growth and M	es Involved in Bone Growth and Maintenance		
Hormone	Primary Source	Effect on Skeletal System		
Calcitriol	Kidneys	Promotes calcium and phosphate ion absorption along the digestive tract		
Growth hormon	e Pituitary gland	Stimulates osteoblast activity and the synthesis of bone matrix		
Thyroxine	Thyroid gland (follicle cells)	With growth hormone, stimulates osteoblast activity and the synthesis of bone matrix		
Sex hormones	Ovaries (estrogens) Testes (androgens)	Stimulate osteoblast activity and the synthesis of bone matrix; estrogens stimulate epiphyseal closure earlier than androgens		
Parathyroid hor	none Parathyroid glands	Stimulates osteoclast (and osteoblast) activity; increases blood calcium ion concentrations		
Calcitonin	Thyroid gland (C cells)	Inhibits osteoclast activity; promotes calcium loss by kidneys; decreases blood calcium ion concentrations		

- Minerals. Normal bone growth and maintenance cannot take place without a constant dietary source of calcium and phosphate salts. Lesser amounts of other minerals, such as magnesium, fluoride, iron, and manganese, are also required.
- *Calcitriol and vitamin* D_3 . The hormone *calcitriol*, synthesized in the kidneys, is essential for normal calcium and phosphate ion absorption in the digestive tract. Calcitriol is synthesized from a related steroid, *cholecalciferol* (vitamin D_3), which may be produced in the skin or absorbed from the diet. \supset p. 158
- Vitamin C. Adequate levels of vitamin C must be present in the diet. This vitamin, which is required for certain key enzymatic reactions in collagen synthesis, also stimulates osteoblast differentiation. One of the signs of vitamin C deficiency—a condition called *scurvy*—is a loss of bone mass and strength.
- Vitamins A, K, and B₁₂. Three other vitamins have significant effects on bone structure. Vitamin A, which stimulates osteoblast activity, is particularly important for normal bone growth in children. Vitamins K and B₁₂ are required for the synthesis of proteins in normal bone.
- Growth hormone and thyroxine. Growth hormone, produced by the pituitary gland, and thyroxine, from the thyroid gland, stimulate bone growth. Growth hormone stimulates protein synthesis and the rates of cell division and cell growth throughout the body. Thyroxine stimulates cell metabolism and increases the rate of osteoblast activity. In proper balance, these hormones maintain normal activity at the epiphyseal cartilages until puberty.
- *Sex hormones.* At puberty, rising levels of sex hormones (*estrogens* in females and *androgens* in males) stimulate osteoblasts to produce bone faster than the rate at which epiphyseal cartilage expands. Over time, the epiphyseal cartilages narrow and eventually close. The timing of epiphyseal closure differs from bone to bone and from individual to

individual. The toes may complete ossification by age 11, but parts of the pelvis or the wrist may continue to enlarge until about age 25.

Differences in male and female sex hormones account for significant variations in body size and proportions. Because estrogens cause faster epiphyseal closure than do androgens, women are generally shorter than men at maturity.

 Calcitonin and parathyroid hormone. Two other hormones calcitonin (kal-si-TŌ-nin), from the thyroid gland, and parathyroid hormone, from the parathyroid gland—have important effects on bone. They are involved in the homeostatic control of calcium and phosphate levels in body fluids, as we will see in the next section.

The major hormones affecting the growth and maintenance of the skeletal system are summarized in Table 6–1.

The skeletal system is unique in that it persists after life, providing hints to the gender, lifestyle, and environmental conditions experienced by the individual. Not only do the bones reflect the physical stresses placed on the body, but they also provide clues about a person's health and diet. By using the appearance, strength, and composition of bone, forensic scientists and physical anthropologists can detect features characteristic of hormonal deficiencies. Combining the physical clues from the skeleton with modern molecular techniques, such as DNA fingerprinting, a wealth of information can be learned.

CHECKPOINT

- 14. Why would you expect the arm bones of a weight lifter to be thicker and heavier than those of a jogger?
- **15**. A child who enters puberty several years later than the average age is generally taller than average as an adult. Why?
- 16. A 7-year-old child has a pituitary gland tumor involving the cells that secrete growth hormone (GH), resulting in increased levels of GH. How will this condition affect the child's growth?

See the blue Answers tab at the back of the book.

Clinical Note

Abnormal Bone Development A variety of endocrine or metabolic problems can result in characteristic skeletal changes. In pituitary dwarfism, inadequate production of growth hormone leads to reduced epiphyseal cartilage activity and abnormally short bones. This condition is becoming increasingly rare in the United States, because children can be treated with synthetic human growth hormone.

6

Gigantism (also known as *giantism*) results from an overproduction of growth hormone before puberty (Photo a). (The world record for height is 272 cm, or 8 ft, 11 in. It was reached by Robert Wadlow, of Alton, Illinois, who died at age 22 in 1940. Wadlow weighed 216 kg, or 475 lb.) If growth hormone levels rise abnormally after epiphyseal cartilages close, the skeleton does not grow longer. Instead, bones get thicker, especially in the face, jaw, and hands. Cartilage growth and alterations in soft-tissue structure lead to changes in physical features, such as the contours of the face. These physical changes take place in the disorder called **acromegaly**.

Several inherited metabolic conditions that affect many systems influence the growth and development of the skeletal system. These conditions produce characteristic variations in body proportions. For example, many individuals with **Marfan's syndrome** are very tall and have long, slender limbs (Photo b). The cause is excessive cartilage formation at the epiphyseal cartilages. These body proportions are not in themselves dangerous. However, the underlying mutation affects the structure of connective tissue throughout the body and commonly causes life-threatening cardiovascular problems.

a Gigantism

b Marfan's syndrome

6-8 Calcium plays a critical role in bone physiology

Learning Outcome Explain the role of calcium as it relates to the skeletal system.

A dynamic relationship exists between calcium and the skeletal system, and hormones influence calcium balance in the body.

The Skeleton as a Calcium Reserve

A chemical analysis of bone reveals its importance as a mineral reserve (Figure 6–14). For the moment, we will focus on the homeostatic regulation of calcium ion concentration in body fluids. (We will consider other minerals in later chapters.) Calcium is the most abundant mineral in the human body. The typical human body contains 1-2 kg (2.2-4.4 lb) of calcium, with nearly 99 percent of it deposited in the skeleton.

Calcium ions play a role in a variety of physiological processes, so the body must tightly control calcium ion concentrations in order to prevent damage to essential physiological systems. Even small variations from the normal concentration affect cellular operations. Larger changes can cause a clinical crisis. Calcium ions are particularly important to both the plasma membranes and the intracellular activities of neurons and muscle cells, especially cardiac muscle cells. If the calcium concentration of body fluids increases by 30 percent, neurons and muscle cells become unresponsive. If calcium levels decrease by 35 percent, neurons become so excitable that convulsions can occur. A 50 percent reduction in calcium concentration is so closely regulated, however, that daily fluctuations of more than 10 percent are highly unusual.

Hormones and Calcium Balance

Two hormones with opposing effects maintain calcium ion homeostasis. These hormones, parathyroid hormone and calcitonin, coordinate the storage, absorption, and excretion of calcium ions. Three target sites and functions are involved: (1) the bones (storage), (2) the digestive tract (absorption), and (3) the kidneys (excretion).

Figure 6–15a indicates factors that raise calcium levels in the blood. When calcium ion concentrations in the blood fall below normal, cells of the **parathyroid glands**, embedded in the thyroid gland in the neck, release **parathyroid hormone**

Figure 6–14 A Chemical Analysis of Bone.

(PTH) into the bloodstream. Parathyroid hormone has three major effects, all of which *increase* blood calcium levels:

- 1. *Stimulating osteoclast activity (indirectly)*. Osteoclasts do not have PTH receptors, so PTH binds to adjacent osteoblasts. This binding causes the osteoblasts to release an osteoclast differentiation factor called RANKL (receptor activator of nuclear factor-kB). RANKL activates receptors on preosteoclast cells, which in turn causes them to differentiate into mature osteoclasts. These mature osteoclasts release enzymes that promote bone resorption, thereby releasing calcium ions into the bloodstream.
- 2. Increasing the rate of intestinal absorption of calcium ions by enhancing the action of calcitriol. Under normal circumstances, calcitriol is always present, and parathyroid hormone controls its effect on the intestinal epithelium.
- 3. Decreasing the rate of excretion of calcium ions by the kidneys.

Under these conditions, *more* calcium ions *enter* body fluids, and *fewer* are *lost*. The calcium ion concentration increases to normal levels, and homeostasis is restored.

Figure 6–15b indicates factors that lower blood calcium levels. If the calcium ion concentration of the blood rises above normal, *parafollicular cells (C cells)* in the thyroid gland secrete **calcitonin**. This hormone has two major functions, which together act to *decrease* calcium ion concentrations in the blood:

- 1. Inhibiting osteoclast activity.
- 2. Increasing the rate of excretion of calcium ions by the kidneys.

Under these conditions, *less* calcium *enters* the blood because osteoclasts leave the mineral matrix of bone alone. *More* calcium *leaves* the blood because osteoblasts continue to produce new bone matrix while calcium ion excretion by the kidneys increases. Lower levels of PTH (and calcitriol) also reduce the intestinal absorption of calcium. The net result is a decline in the calcium ion concentration in the blood, restoring homeostasis. By providing a calcium reserve, the skeleton plays the primary role in the homeostatic maintenance of normal blood calcium ion concentrations. This function can have a direct effect on the shape and strength of the bones in the skeleton. When large numbers of calcium ions are released from the bones, the bones become weaker. When calcium salts are deposited, the bones become denser and stronger.

Changes in mineral content do not necessarily affect the shape of the bone because the bone matrix contains protein fibers as well as mineral deposits. In osteomalacia (os-tē-ō-ma-LA-shē-uh; malakia, softness), the bones appear normal, although they are weak and flexible due to poor mineralization. Rickets, a form of osteomalacia affecting children, generally results from a vitamin D₃ deficiency caused by inadequate skin exposure to sunlight and an inadequate dietary supply of the vitamin. \bigcirc p. 159 The bones of children with rickets are so poorly mineralized that they become very flexible. The bones bend laterally and affected individuals develop a bowlegged appearance because the walls of each femur can no longer resist the tension and compression forces applied by the body weight (Figure 6–8). In the United States, homogenized milk is fortified with vitamin D specifically to prevent rickets.

CHECKPOINT

- 17. Identify the hormones involved in stimulating and inhibiting the release of calcium ions from bone matrix.
- 18. Why does a child who has rickets have difficulty walking?
- **19**. What effect would increased PTH secretion have on blood calcium levels?
- **20**. How does calcitonin help lower the calcium ion concentration of blood?
- See the blue Answers tab at the back of the book.

6

6-9 A fracture is a crack or break in a bone

Learning Outcome Describe the types of fractures, and explain how fractures heal.

Despite its mineral strength, bone can crack or even break if subjected to extreme loads, sudden impacts, or stresses from unusual directions. The damage is called a **fracture**. Most fractures heal even after severe damage, if the blood supply and the cellular components of the endosteum and periosteum survive. **Spotlight Figure 6–16** on pp. 200–201 illustrates the different types of fractures and the repair process.

CHECKPOINT

- **21**. List the four steps involved in fracture repair, beginning at the onset of the bone break.
- 22. At which point in fracture repair would you find an external callus?
- See the blue Answers tab at the back of the book.

6

6-10 Osteopenia has a widespread effect on aging skeletal tissue

Learning Outcome Summarize the effects of the aging process on the skeletal system.

The bones of the skeleton become thinner and weaker as a normal part of the aging process. Inadequate ossification is called **osteo-penia** (os-tē-ō-PĒ-nē-uh; *penia*, lacking). All of us become slightly osteopenic as we age. This reduction in bone mass begins between ages 30 and 40. During that time, osteoblast activity begins to decrease, while osteoclast activity continues at previous levels. Once

the reduction begins, women lose about 8 percent of their skeletal mass every decade. Men lose less—about 3 percent per decade. Not all parts of the skeleton are equally affected. Epiphyses, vertebrae, and the jaws lose more mass than other sites, resulting in fragile limbs, reduction in height, and loss of teeth.

When the reduction in bone mass is sufficient to compromise normal function, the condition is known as **osteoporosis** (os-tē- \bar{o} -po-R \bar{O} -sis; *porosus*, porous). The fragile bones that result are likely to break when exposed to stresses that younger individuals could easily tolerate. For example, a hip fracture can occur when a 90-year-old person simply tries to stand. Any

SPOTLIGHT

Figure 6–16 Types of Fractures and Steps in Repair

TYPES OF FRACTURES

Fractures are named according to their external appearance, their location, and the nature of the crack or break in the bone. Important types of fractures are illustrated here by representative x-rays. The broadest general categories are closed fractures and open fractures. Closed, or simple, fractures are completely internal. They can be seen only on x-rays, because they do not involve a break in the skin. **Open**, or compound, fractures project through the skin. These fractures, which are obvious on inspection, are more dangerous than closed fractures, due to the possibility of infection or uncontrolled bleeding. Many fractures fall into more than one category, because the terms overlap.

Transverse fractures, such as this fracture of the ulna, break a bone shaft across its long axis. Displaced fractures produce new and abnormal bone arrangements. Nondisplaced fractures retain the normal alignment of the bones or fragments. **Compression fractures** occur in vertebrae subjected to extreme stresses, such as those produced by the forces that arise when you land on your seat in a fall. Compression fractures are often associated with osteoporosis.

Spiral fractures, such as this fracture of the tibia, are produced by twisting stresses that spread along the length of the bone.

Cartilage of

external callus

1 Fracture hematoma formation. Immediately after the fracture, extensive bleeding occurs. A large blood clot, or fracture hematoma, soon closes off the injured vessels and leaves a fibrous meshwork in the damaged area. The disruption of circulation kills local osteocytes, broadening the area affected. Dead bone soon extends along the shaft in either direction.

Spongy bone of

internal callus

Spongy bone of external callus

Periosteum

2 Callus formation. The cells of the intact endosteum and periosteum undergo rapid cycles of cell division, and the daughter cells migrate into the fracture zone. An internal callus forms as a network of spongy bone unites the inner edges of the fracture. An external callus of cartilage and bone encircles and stabilizes the outer edges of the fracture.

Comminuted fracture

Epiphyseal fractures, such as this fracture of the femur, tend to occur where the bone matrix is undergoing calcification and chondrocytes are dying. A clean transverse fracture along this line generally heals well. Unless carefully treated, fractures between the epiphysis and the epiphyseal cartilage can permanently stop growth at this site.

Comminuted fractures, such as this fracture of the femur, shatter the affected area into a multitude of bony fragments.

In a greenstick fracture,

such as this fracture of the radius, only one side of the shaft is broken, and the other is bent. This type of fracture generally occurs in children, whose long bones have yet to ossify fully. A **Colles fracture**, a break in the distal portion of the radius, is typically the result of reaching out to cushion a fall. A **Pott's fracture**, also called a bimalleolar fracture, occurs at the ankle and affects both the medial malleolus of the distal tibia and the lateral malleolus of the distal fibula.

Internal callus

External callus

3 **Spongy bone formation**. As the repair continues, osteoblasts replace the central cartilage of the external callus with spongy bone, which then unites the broken ends. Fragments of dead bone and the areas of bone closest to the break are resorbed and replaced. The ends of the fracture are now held firmly in place and can withstand normal stresses from muscle contractions.

Compact bone formation. A swelling initially marks the location of the fracture. Over time, this region will be remodeled by osteoblasts and osteoclasts, and little evidence of the fracture will remain. The repair may be "good as new" or the bone may be slightly thicker and stronger than normal at the fracture site. Under comparable stresses, a second fracture will generally occur at a different site.

Normal spongy bone

 $SEM \times 25$

Spongy bone in osteoporosis

fractures in aged individuals lead to a loss of independence and an immobility that further weakens the skeleton. The extent of the loss of spongy bone mass due to osteoporosis is shown in Figure 6–17. The reduction in compact bone mass is equally severe.

Sex hormones are important in maintaining normal rates of bone deposition. Over age 45, an estimated 29 percent of women and 18 percent of men have osteoporosis. In women, the condition accelerates after menopause, due to a decline in circulating estrogens. Severe osteoporosis is less common in men under age 60 than in women of that same age group because men continue to produce androgens until late in life.

Osteoporosis can also develop as a secondary effect of many cancers. Cancers of the bone marrow, breast, or other tissues release a chemical known as osteoclast-activating factor. It increases both the number and activity of osteoclasts and produces severe osteoporosis.

CHECKPOINT

- 23. Define osteopenia.
- 24. Why is osteoporosis more common in older women than in older men?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

- achondroplasia: A disorder of bone growth that causes the most common type of dwarfism.
- bone marrow transplant: Transferring healthy bone marrow stem cells from one person into another, replacing bone marrow that is either dysfunctional or has been destroyed by chemotherapy or radiation.
- bone mineral density test (BMD): A test to predict the risk of bone fractures by measuring how much calcium and other types of minerals are present in the patient's bones.
- bone scan: A nuclear scanning test that identifies new areas of bone growth or breakdown. Used to evaluate damage, find

cancer in the bones, and/or monitor the bone's conditions (including infection and trauma).

- closed reduction: The correction of a bone fracture by manipulation without incision into the skin.
- dual energy x-ray absorptiometry (DEXA): Procedure that uses very small amounts of radiation to measure changes in bone density as small as 1 percent; the test monitors bone density in osteoporosis and osteopenia.
- open reduction: The correction of a bone fracture by making an incision into the skin and rejoining the fractured bone parts, often by mechanical means such as a rod, plate, or screw.

- **orthopedics:** The branch of medicine dealing with the correction of deformities of bones or muscles.
- **osteogenesis imperfecta (OI):** An inherited (genetic) disorder characterized by extreme fragility of the bones; also called brittle bone disease.

osteomyelitis: An acute or chronic bone infection.

- **osteopetrosis:** A rare hereditary bone disorder in which the bones become overly dense; it presents in one of three forms: osteopetrosis tarda, osteopetrosis congenita, and "marble bone" disease.
- **osteosarcoma:** A type of cancer that starts in the bones; also called osteogenic sarcoma.
- **Paget's disease:** A chronic disorder that can result in enlarged and misshapen bones due to abnormal bone destruction and regrowth.
- **traction:** The application of a sustained pull on a limb or muscle in order to maintain the position of a fractured bone until healing occurs or to correct a deformity.

An Introduction to the Skeletal System p. 179

- 1. The skeletal system has a variety of purposes, such as providing a framework for body posture and allowing for precise movements.
- **6-1** The skeletal system has five primary functions p. 179
- 2. The skeletal system includes the bones of the skeleton and the cartilages, ligaments, and other connective tissues that stabilize or connect the bones. The functions of the skeletal system include support, storage of minerals and lipids, blood cell production, protection, and leverage.
- 6-2 Bones are classified according to shape and structure, and they have a variety of surface markings p. 180
- 3. Bones may be categorized as **sutural bones**, (*Wormian bones*) **irregular bones**, **short bones**, **flat bones**, **long bones**, and **sesamoid bones**. (*Figure 6–1*)
- 4. Each bone has characteristic **bone markings**, including elevations, projections, depressions, grooves, and tunnels. (*Figure 6–2*)
- 5. The two types of bone tissue are compact (*dense*) bone and spongy (*cancellous*) bone.
- 6. A representative long bone has a **diaphysis**, **epiphyses**, **metaphyses**, and a **medullary cavity**. (*Figure 6–3*)
- 7. The medullary cavity and spaces within spongy bone contain either **red bone marrow** (for blood cell formation) or **yellow bone marrow** (for lipid storage).

- 6-3 Bone is composed of matrix and several types of cells: osteocytes, osteoblasts, osteogenic cells, and osteoclasts p. 182
- 8. Osseous tissue is a supporting connective tissue with a solid matrix and is ensheathed by a *periosteum*.
- 9. Bone matrix consists largely of crystals of **hydroxyapatite**; the minerals are deposited in **lamellae**.
- 10. Osteocytes, located in *lacunae*, are mature bone cells. Adjacent osteocytes are interconnected by canaliculi. Osteoblasts synthesize the bony matrix by ossification, or osteogenesis. Osteoclasts dissolve the bony matrix through osteolysis. Osteogenic cells differentiate into osteoblasts. (*Figure 6-4*)
- 6-4 Compact bone contains parallel osteons, and spongy bone contains trabeculae p. 184
- 11. The basic functional unit of compact bone is the osteon, containing osteocytes arranged around a central canal.
 Perforating canals extend perpendicularly to the bone surface. (*Figures 6–5, 6–6*)
- **12.** Compact bone is located where stresses come from a limited range of directions, such as along the diaphysis of long bones.
- **13.** Spongy bone contains **trabeculae**, typically in an open network. (*Figure 6–7*)
- Spongy bone is located where stresses are few or come from many directions, such as at the epiphyses of long bones. (*Figure 6–8*)
- **15.** A bone is covered by a **periosteum** and lined with an **endosteum**. (*Figure 6–9*)
- 6-5 Bones form through ossification and enlarge through appositional growth and remodeling p. 189
- **16.** Ossification (or osteogenesis) is the process of bone formation. Calcification is the process of depositing calcium salts within a tissue.
- **17.** Endochondral ossification begins with a cartilage model that is gradually replaced by bone at the metaphysis. In this way, bone length increases. (*Spotlight Figure 6–11*)
- **18.** The ends of the cartilage model remain as **articular cartilages**. *(Spotlight Figure 6–11)*

- 19. The timing of epiphyseal closure of the epiphyseal cartilage and the formation of an epiphyseal line differs among bones and among individuals. (Figure 6-10, Spotlight Figure 6-11)
- 20. Bone diameter increases through appositional growth.
- 21. Intramembranous ossification begins when osteoblasts differentiate within connective tissue. The process produces dermal bones. Such ossification begins at an ossification center. (Figure 6-12)
- 22. Three major sets of blood vessels provide an extensive supply of blood to bone. (Figure 6–13)
- 6-6 Bone growth and development depend on a balance between bone formation and bone resorption p. 192
- 23. The organic and mineral components of bone are continuously recycled and renewed through remodeling, which involves interplay among the activities of osteocytes, osteoblasts, and osteoclasts.
- 6-7 Exercise, hormones, and nutrition affect bone development and the skeletal system p. 194
- 24. The shapes and thicknesses of bones reflect the stresses applied to them. For this reason, regular exercise is important in maintaining normal bone structure.
- 25. Normal ossification requires a reliable source of minerals, vitamins, and hormones.

26. Growth hormone and thyroxine stimulate bone growth. Calcitonin and parathyroid hormone control blood calcium levels. (Table 6-1)

6-8 Calcium plays a critical role in bone physiology p. 196

- 27. Calcium is the most abundant mineral in the human body; about 99 percent of it is located in the skeleton. (Figure 6-14)
- 28. Interactions among the bones, digestive tract, and kidneys affect the calcium ion concentration. (Figure 6–15)
- 29. Two hormones, calcitonin and parathyroid hormone (PTH), regulate calcium ion homeostasis. Calcitonin leads to a decrease in the calcium ion concentration in blood, whereas parathyroid hormone increases the calcium ion concentration in blood. (Figure 6–15)

6-9 A fracture is a crack or break in a bone p. 198

- **30.** A break or crack in a bone is a **fracture**. The repair of a fracture involves the formation of a fracture hematoma, an external callus, and an internal callus. (Spotlight Figure 6-16)
- 6-10 Osteopenia has a widespread effect on aging skeletal tissue p. 199
- 31. The effects of aging on the skeleton include osteopenia and osteoporosis. (Figure 6-17)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- 1. Blood cell formation occurs in (a) yellow bone marrow, (b) red bone marrow, (c) the matrix of bone tissue, (d) the ground substance of bones.
- 2. Two-thirds of the weight of bone is accounted for by (a) crystals of calcium phosphate, (b) collagen fibers, (c) osteocytes, (d) calcium carbonate
- The membrane found wrapping the bones, except within the joint cav-3. ity, is the (a) periosteum, (b) endosteum, (c) perforating fibers, (d) a, b, and c are correct.
- 4. The basic functional unit of compact bone is the Haversian system or (a) osteocyte, (b) osteoclast, (c) osteon, (d) osseous matrix, (e) osseous lamellae.
- The vitamins essential for normal adult bone maintenance and repair 5 are (a) A and E_i (b) C and D_{3i} (c) B and E_i (d) B complex and K.
- 6. The hormones that coordinate the storage, absorption, and excretion of calcium ions are (a) growth hormone and thyroxine, (b) calcitonin and parathyroid hormone, (c) calcitriol and cholecalciferol, (d) estrogens and androgens.
- 7. Classify the bones in the following diagram according to their shape.

(e)

See the blue Answers tab at the back of the book.

- 8. The presence of an epiphyseal line indicates (a) epiphyseal growth has ended, (b) epiphyseal growth is just beginning, (c) growth of bone diameter is just beginning, (d) the bone is fractured at the location, (e) no particular event.
- 9. The primary reason that osteoporosis accelerates after menopause in women is (a) reduced levels of circulating estrogens, (b) reduced levels of vitamin C, (c) diminished osteoclast activity, (d) increased osteoblast activity.
- 10. The nonpathologic loss of bone that occurs with aging is called (a) osteomyelitis, (b) osteoporosis, (c) osteopenia, (d) osteitis, (e) osteomalacia.
- 11. What are the five primary functions of the skeletal system?
- 12. List the four distinctive cell populations of osseous tissue.
- 13. What are the primary parts of a typical long bone?
- 14. What is the primary difference between endochondral ossification and intramembranous ossification?
- 15. List the organic and inorganic components of bone matrix.
- 16. (a) What nutritional factors are essential for normal bone growth and maintenance? (b) What hormonal factors are necessary for normal bone growth and maintenance?
- 17. Which three organs or tissues interact to assist in the regulation of calcium ion concentration in body fluids?
- 18. What major effects of parathyroid hormone oppose those of calcitonin?

LEVEL 2 Reviewing Concepts

- 19. If spongy bone has no osteons, how do nutrients reach the osteocytes?
- 20. Why are stresses or impacts to the side of the shaft in a long bone more dangerous than stress applied to the long axis of the shaft?
- 21. Why do extended periods of inactivity cause degenerative changes in the skeleton?
- 22. What are the functional relationships between the skeleton, on the one hand, and the digestive and urinary systems, on the other?

- 23. Why would a physician concerned about the growth patterns of a young child request an x-ray of the hand?
- Why does a second fracture in the same bone tend to occur at a site 24. different from that of the first fracture?
- 25. The process of bone growth at the epiphyseal cartilage is similar to (a) intramembranous ossification, (b) endochondral ossification, (c) the process of osteopenia, (d) the process of healing a fracture, (e) the process of calcification.
- 26. How might bone markings be useful in identifying the remains of an individual who was shot and killed years ago?

LEVEL 3 Critical Thinking and Clinical Applications

- 27. While playing on her swing set, 10-year-old Sally falls and breaks her right leg. At the emergency room, the doctor tells her parents that the proximal end of the tibia where the epiphysis meets the diaphysis is fractured. The fracture is properly set and eventually heals. During a routine physical when she is 18, Sally learns that her right leg is 2 cm shorter than her left, probably because of her accident. What might account for this difference?
- 28. Which of the following conditions would you possibly observe in a child who is suffering from rickets? (a) abnormally short limbs, (b) abnormally long limbs, (c) oversized facial bones, (d) bowed legs, (e) weak, brittle bones
- 29. Frank does not begin puberty until he is 16. What effect would you predict this will have on his stature? (a) Frank will probably be taller than if he had started puberty earlier, (b) Frank will probably be shorter than if he had started puberty earlier, (c) Frank will probably be a dwarf, (d) Frank will have bones that are heavier than normal, (e) The late onset of puberty will have no effect on Frank's stature
- 30. In physical anthropology, cultural conclusions can be drawn from a thorough examination of the skeletons of ancient peoples. What sorts of clues might bones provide as to the lifestyles of those individuals?

CLINICAL CASE

A Case of Child Abuse?

Alex and his mother both suffer from osteogenesis imperfecta (OI), which means the imperfect formation of bone. Osteogenesis imperfecta is the most commonly inherited connective tissue disorder in the United States. The inherited defective gene codes for collagen that is made by osteoblasts and released into the bone matrix. This collagen is critical for bone strength and also important in forming teeth, ligaments, and the whites of the eyes. There are several types of OI with varying severities, but the Otero family suffers from the most common, relatively mild type.

Without enough normal collagen in the bone matrix, the bones are brittle and fracture easily, often with minimal trauma. In more severe cases, the skeleton is not strong enough to support the body's weight. Patients with OI have a characteristic heart-shaped face, and the whites of their eyes have a blue tint. They often suffer hearing loss.

Wrap-Up

Osteogenesis imperfecta seems to have affected people throughout history. An Egyptian mummy dating from 1000 BC has been found with evidence of osteogenesis imperfecta.

Because of the way that this bone disorder is inherited, each of Alex's children will have a 50 percent chance of inheriting osteogenesis imperfecta. At least Alex will be aware of the problem and hopefully will never be accused of child abuse.

- 1. Why do you think the emergency department personnel suspected child abuse?
- 2. Do you think Alex should continue to play soccer?

See the blue Answers tab at the back of the book.

The Axial Skeleton

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 7-1 Identify the bones of the axial skeleton, and specify their functions.
- 7-2 Identify the bones, foramina, and fissures of the cranium and face, and explain the significance of the markings on the individual bones.
- **7-3** Describe the structure and functions of the orbital complex, nasal complex, and paranasal sinuses.
- 7-4 Describe the key structural differences among the skulls of infants, children, and adults.
- 7-5 Identify and describe the curvatures of the spinal column, and indicate the function of each.
- **7-6** Identify the five vertebral regions, and describe the distinctive structural and functional characteristics of vertebrae in each region.
- 7-7 Explain the significance of the articulations between the thoracic vertebrae and the ribs, and between the ribs and sternum.

CLINICAL CASE

Knocked Out

Dr. Deb Grady, a member of the American Board of Ringside Medicine, is covering a Golden

Gloves boxing event as the ringside physician. She is closely watching a match between two older teenage boys. Up to the third round the fighters seem to be evenly matched. Suddenly, Dr. Grady witnesses a crushing blow delivered to the face of one fighter, knocking him out cold.

Dr. Grady jumps into the ring and carefully rolls the fighter over. She sees immediate and alarming swelling and bruising of the soft tissues around his left eye and profuse bleeding from a cut over the eye. As the young boxer regains consciousness, he sputters and coughs. Dr. Grady feels crackling subcutaneous air (like popping bubble wrap) in the expanding soft tissues around his eye. "How many fingers am I holding up?" she asks the fighter, holding up her index finger. "Two," the confused fighter answers. He is seeing double. "Follow my finger," she instructs, moving her finger up to the level of his forehead. The fighter can track her finger with his right eye, but his injured left eye remains looking straight ahead.

Dr. Grady calls the fight and accompanies the young boxer to the closest emergency room. What has happened to the boxer's left eye? To find out, turn to the Clinical Case Wrap-Up on p. 240.

An Introduction to the Axial Skeleton

In this chapter, we turn our attention to the functional anatomy of the bones that form the longitudinal axis of the body.

7-1 ■ The 80 bones of the head and trunk make up the axial skeleton

Learning Outcome Identify the bones of the axial skeleton, and specify their functions.

The **axial skeleton** forms the longitudinal axis of the body (Figure 7–1). The axial skeleton has 80 bones, about 40 percent of the bones in the human body:

- The skull (8 cranial bones and 14 facial bones).
- Bones associated with the skull (6 *auditory ossicles* and the *hyoid bone*).
- The vertebral column (24 vertebrae, the sacrum, and the coccyx).
- The thoracic cage (the sternum and 24 ribs).

The axial skeleton provides a framework that supports and protects the brain, the spinal cord, and the thoracic and abdominal organs. It also provides an extensive surface area for the attachment of muscles that (1) adjust the positions of the head, neck, and trunk; (2) perform respiratory movements; and (3) stabilize or position parts of the **appendicular skeleton**, which supports the limbs. The joints of the axial skeleton allow limited movement, but they are very strong and heavily reinforced with ligaments.

- CHECKPOINT

- 1. Identify the bones of the axial skeleton.
- 2. List the primary functions of the axial skeleton.

See the blue Answers tab at the back of the book.

7-2 The skull is composed of 8 cranial bones and 14 facial bones

Learning Outcome Identify the bones, foramina, and fissures of the cranium and face, and explain the significance of the markings on the individual bones.

The **skull** contains 22 bones: 8 form the **cranium**, or *braincase*, and 14 are associated with the face (Figure 7–2).

Seven additional bones are associated with the skull; six auditory ossicles, involved with hearing, and the hyoid bone that supports the voicebox.

The cranium consists of 8 **cranial bones** that enclose the **cranial cavity**, a chamber that supports the brain. Blood vessels, nerves, and membranes that stabilize the position of the brain are attached to the inner surface of the cranium. Its outer surface provides an extensive area for the attachment of muscles that move the eyes, jaws, and head.

Joints, or *articulations*, form where two bones connect. A joint between the occipital bone of the skull and the first vertebra of the neck stabilizes the positions of the brain and spinal cord. The joints between the vertebrae of the neck permit a wide range of head movements.

If you think of the cranium as the house where the brain resides, then the *facial complex* is the front porch (Figure 7–2).

The nine superficial facial bones serve as attachment sites for muscles that control facial expressions and assist in manipulating food.

The five deeper facial bones help separate the oral and nasal cavities, increase the surface area of the nasal cavities, or help form the **nasal septum** (*septum*, wall), which divides the nasal cavity into left and right halves.

Several bones of the skull contain air-filled chambers called **sinuses** (Figures 7-3, 7-4). Sinuses have three major functions: (1) They lessen the weight of the bone; (2) the

mucous membrane lining them produces mucus that moistens and cleans the air in and adjacent to the sinus; and (3) they serve as resonating chambers in speech production. We will consider the sinuses as we discuss specific bones (Figures 7-5 to 7-12).

The connections between the skull bones of adults are immovable joints called **sutures** (except where the mandible contacts the cranium). At a suture, bones are tied firmly together with dense fibrous connective tissue. Each suture of the skull has a name. These are the four major sutures:

- Lambdoid Suture. The lambdoid (LAM-doyd) suture (Greek lambda + eidos, shape) arches across the posterior surface of the skull (Figure 7–3a). This suture connects the occipital bone with the two parietal bones. One or more sutural bones (Wormian bones) may be present along the lambdoid suture. ⊃ p. 180
- Coronal Suture. The coronal suture attaches the frontal bone to the parietal bones of either side (Figure 7–3b). The occipital, parietal, and frontal bones form the calvaria (kal-VA-rē-uh), or skullcap. A cut through the body that parallels the coronal suture produces a *frontal section*, or *coronal section* (Figure 1–8, ⊃ p. 18).
- **3.** *Sagittal Suture*. The **sagittal suture** extends from the lambdoid suture to the coronal suture, between the parietal bones (Figure 7–3b). A cut along the midline of this suture produces a *midsagittal section*. A slice that parallels the sagittal suture produces a *parasagittal section*. ⊃ p. 18
- Squamous Sutures. A squamous (SKWA⁻-mus) suture on each side of the skull joins the temporal bone and the parietal bone of that side. Figure 7–3a shows the intersection between the squamous sutures and the lambdoid suture. Figure 7–3c shows the path of the squamous suture on the right side of the skull.

FOCUS The Individual Bones of the Skull

We can explore the surface features of these bones further, using the related images in the *Atlas*. Foramina and fissures create passages for vessels and nerves. The vessels are detailed in Chapter 21. The nerves are shown in the Focus on cranial nerves in Chapter 14.

Cranial Bones

The Occipital Bone (Figure 7–5a)

General Functions: The **occipital bone** forms much of the posterior and inferior surfaces of the cranium.

Articulations: The occipital bone articulates with the parietal bones, the temporal bones, the sphenoid, and the first cervical vertebra (the atlas) (Figure 7–3a–c,e and Spotlight Figure 7–4).

Regions/Markings (Figure 7–5a): The **external occipital protuberance** is a small bump at the midline on the inferior surface.

The **external occipital crest** begins at the external occipital protuberance. This crest marks the attachment of a ligament that helps stabilize the vertebrae of the neck.

The **occipital condyles** are the site of articulation between the skull and the first vertebra of the neck.

The *inferior* and *superior nuchal* (NŪ-kul) *lines* are ridges that intersect the occipital crest. They mark the attachment sites of muscles and ligaments that stabilize the articulation at the occipital condyles and balance the weight of the head over the vertebrae of the neck.

The concave internal surface of the occipital bone (Spotlight Figure 7–4a) closely follows the contours of the brain. The grooves follow the paths of major blood vessels, and the ridges mark the attachment sites of membranes that stabilize the position of the brain.

Foramina: The foramen magnum (Spotlight Figure 7-4b)

connects the cranial cavity with the vertebral canal, which is enclosed by the vertebral column. This foramen surrounds the connection between the brain and spinal cord.

The **jugular foramen** lies between the occipital bone and the temporal bone (Figure 7–3e). The *internal jugular vein* passes through this foramen, carrying venous blood from the brain.

The **hypoglossal canals** (Spotlight Figure 7–4b) begin at the lateral base of each occipital condyle and end on the inner surface of the occipital bone near the foramen magnum. The *hypoglossal nerves*, cranial nerves that control the tongue muscles, pass through these canals.

The Parietal Bones (Figure 7-5b)

General Functions: The **parietal bones** form part of the superior and lateral surfaces of the cranium.

Articulations: The parietal bones articulate with one another and with the occipital, temporal, frontal, and sphenoid bones (Figure 7–3a–d and Spotlight Figure 7–4).

Regions/Markings: The *superior* and *inferior temporal lines* are low ridges that mark the attachment sites of the *temporalis muscle*, a large muscle that closes the mouth (Figure 7–5b).

Grooves on the inner surface of the parietal bones mark the paths of cranial blood vessels (Spotlight Figure 7–4a).

Figure 7–5 The Occipital and Parietal Bones.

The Frontal Bone (Figure 7–6a,b)

General Functions: The **frontal bone** forms the anterior portion of the cranium and the roof of the *orbits* (eye sockets). Mucus from the *frontal sinuses* within this bone helps flush the surfaces of the nasal cavities.

Articulations: The frontal bone articulates with the parietal, sphenoid, ethmoid, nasal, lacrimal, maxillary, and zygomatic bones (Figure 7–3b–e and Spotlight Figure 7–4).

Regions/Markings: The **frons**, or forehead, forms the anterior, superior portion of the cranium. It provides surface area for the attachment of facial muscles. The *superior temporal line* is continuous with the superior temporal line of the parietal bone.

The **supraorbital margin** is a thickening of the frontal bone that helps protect the eye. The **glabella** (*glabellus*, hairless) is the area between the supraorbital margins and superior to the nasal bones. It marks the most forward projection of the frontal bone.

The **lacrimal fossa** on the superior and lateral surface of the orbit is a shallow depression that marks the location of the *lacrimal* (tear) *gland*. Tears from this gland lubricate the surface of the eye.

The **frontal sinuses** are extremely variable in size and time of appearance. They generally appear after age 6, but some people never develop them. We will describe the frontal sinuses and other sinuses of the cranium and face in a later section.

Foramina: The **supraorbital foramen** provides passage for blood vessels that supply the eyebrow, eyelids, and frontal sinuses.

In some cases, this foramen is incomplete. In that case, the vessels then cross the orbital rim within a **supraorbital notch**.

Remarks: During development, the bones of the cranium form by the fusion of separate centers of ossification. At birth, the fusions are not yet complete: Two frontal bones articulate along the *frontal (metopic) suture*. The suture generally disappears by age 8 as the bones fuse, but the adult skull commonly retains traces of the suture line. This suture, or what remains of it, runs down the center of the frons.

The Temporal Bones (Figure 7–7a,b)

General Functions: The **temporal bones** (1) form part of both the lateral walls of the cranium and the *zygomatic arches*, (2) form the only articulations with the mandible, (3) surround and protect the sense organs of the internal ear, and (4) are attachment sites for muscles that close the jaws and move the head.

Articulations: The temporal bones articulate with the zygomatic, sphenoid, parietal, and occipital bones of the cranium and with the mandible (Figure 7–3 and Spotlight Figure 7–4).

Regions/Markings: The **squamous part** of the temporal bone is the lateral portion that borders the squamous suture. The concave, internal surface parallels the surface of the brain and is called the *cerebral surface*.

The **zygomatic process**, inferior to the temporal squamous part, articulates with the *temporal process* of the zygomatic bone.

Figure 7–6 The Frontal Bone.

Together, these processes form the **zygomatic arch**, or cheekbone (Figure 7–3c,e).

The **mandibular fossa** on the inferior surface marks the site of articulation with the mandible.

The **mastoid process** (Figure 7–7b,c) is an attachment site for muscles that rotate or extend the head. It contains *mastoid cells* (also called mastoid air cells), small interconnected cavities that connect to the middle ear cavity. If pathogens invade the mastoid cells, *mastoiditis* develops. Signs and symptoms include severe earaches, fever, and swelling behind the ear.

The **styloid** (STĪ-loyd; *stylos,* pillar) **process**, near the base of the mastoid process, is attached to ligaments that support the hyoid bone and to the tendons of several muscles associated with the hyoid bone, the tongue, and the pharynx.

The **petrous part** of the temporal bone, located on its internal surface, encloses the structures of the *internal ear*—sense organs that provide information about hearing and balance.

The **auditory ossicles** are located in the *tympanic cavity*, or *middle ear*, a cavity within the petrous part. These tiny bones—three on each side—transfer sound vibrations from the delicate

tympanic membrane, or eardrum, to the internal ear. (We will discuss these bones and their functions in Chapter 17.)

Foramina (Figure 7–3e): The *jugular foramen*, between the temporal and occipital bones, provides passage for the internal jugular vein.

The **carotid canal** provides passage for the internal carotid artery, a major artery to the brain. As it leaves the carotid canal, the internal carotid artery passes through the anterior portion of the foramen lacerum.

The **foramen lacerum** (LA-se-rum; *lacerare*, to tear) is a jagged slit extending between the sphenoid and the petrous part of the temporal bone. This slit contains hyaline cartilage and small arteries that supply the inner surface of the cranium.

The *auditory tube* is an air-filled passageway that connects the pharynx (throat) to the tympanic cavity. This tube passes through the posterior portion of the foramen lacerum.

The **external acoustic meatus**, or *auditory canal*,¹ on the lateral surface ends at the tympanic membrane (which disintegrates during the preparation of a dried skull).

The **stylomastoid foramen** lies posterior to the base of the styloid process. The *facial nerve* passes through this foramen to control the facial muscles.

Figure 7–7 The Temporal Bones.

The **internal acoustic meatus**, or *internal auditory meatus*,¹ begins on the medial surface of the petrous part of the temporal bone. It carries blood vessels and nerves to the internal ear and conveys the facial nerve to the stylomastoid foramen.

¹The names for these passageways vary widely; the terms *acoustic* and *auditory* are used interchangeably, as are *meatus* and *canal*.

The Sphenoid (Figure 7–8a,b)

General Functions: The **sphenoid** forms part of the floor of the cranium, unites the cranial and facial bones, and acts as a cross-brace that strengthens the sides of the skull. Mucus from the *sphenoidal sinuses* within this bone helps clean the surfaces of the nasal cavities. **Articulations:** The sphenoid articulates with the ethmoid and the frontal, occipital, parietal, and temporal bones of the cranium and the palatine bones, zygomatic bones, maxillae, and vomer of the face (Figure 7–3c–e and Spotlight Figure 7–4).

Regions/Markings (Spotlight Figure 7–4 and **Figure 7–8**):

The shape of the sphenoid has been compared to a bat with its wings extended. This bone is relatively large, but more superficial bones hide much of it.

The **body** forms the central axis of the sphenoid.

The **sella turcica** (TUR-si-kuh), or Turkish saddle, is a bony, saddle-shaped enclosure on the superior surface of the body. Within the sella turcica is a depression known as the **hypophyseal** (hī-pō-FIZ-ē-ul) **fossa** (**Spotlight Figure 7–4a**). This fossa contains the *pituitary gland*.

Figure 7–8 The Sphenoid.

The **sphenoidal sinuses** (Spotlight Figure 7–4a and Figure 7–8b) are on either side of the body, inferior to the sella turcica.

The **lesser wings** extend horizontally anterior to the sella turcica. The **greater wings** extend laterally from the body and form part of the cranial floor. A sharp *sphenoidal spine* lies at the posterior, lateral corner of each greater wing. Anteriorly, each greater wing contributes to the posterior wall of the orbit.

The **pterygoid** (TER-i-goyd; *pterygion*, wing) **processes** are vertical projections that originate on either side of the body. Each pterygoid process forms a pair of *pterygoid plates*, which are attachment sites for muscles that move the mandible and soft palate.

Foramina (Spotlight Figure 7–4b and Figure 7–8): The optic canals permit passage of the optic nerves from the eyes to the brain.

Penetrating each greater wing are a **superior orbital fissure**, **foramen rotundum, foramen ovale** (ō-VAH-lē), and **foramen spinosum.** These passages carry blood vessels and nerves to the orbit, face, jaws, and membranes of the cranial cavity, respectively.

The Ethmoid (Figure 7–9a,b)

General Functions: The **ethmoid**, or *ethmoid bone*, forms the anteromedial floor of the cranium, the roof of the nasal cavity,

and part of the nasal septum (which subdivides the nasal cavity) and medial orbital wall. Mucus from a network of sinuses, or *ethmoid air cells*, within this bone flushes the surfaces of the nasal cavities.

Articulations: The ethmoid articulates with the frontal bone and sphenoid of the cranium and with the nasal, lacrimal, palatine, and maxillary bones and the inferior nasal conchae and vomer of the face (Figure 7–3c,d and Spotlight Figure 7–4).

Regions/Markings: The ethmoid has three parts: (1) the cribriform plate, (2) the paired lateral masses, and (3) the perpendicular plate.

The **cribriform plate** (*cribrum*, sieve) forms the anteromedial floor of the cranium and the roof of the nasal cavity. The **crista galli** (*crista*, crest + *gallus*, rooster, cock; cock's comb) is a bony ridge that projects superior to the cribriform plate. A membrane that stabilizes the position of the brain, the *falx cerebri*, attaches to this ridge.

The **lateral masses** contain the **ethmoidal labyrinth**, which consists of the interconnected **ethmoid air cells** that open into the nasal cavity on each side. The **superior nasal conchae** (KONG-kē; singular, *concha*, a snail shell) and the **middle nasal conchae** are delicate projections of the lateral masses.

Figure 7–9 The Ethmoid.

The **perpendicular plate** forms part of the nasal septum, along with the vomer and a piece of hyaline cartilage.

Foramina: The **olfactory foramina** in the cribriform plate permit passage of the olfactory nerves, which provide the sense of smell.

Remarks: Olfactory (smell) receptors are located in the epithelium that covers the inferior surfaces of the cribriform plate, the medial surfaces of the superior nasal conchae, and the superior portion of the perpendicular plate.

The nasal conchae break up the airflow in the nasal cavity. They create swirls, turbulence, and eddies that have three major functions: (1) Particles in the air are thrown against the sticky mucus that covers the walls of the nasal cavity; (2) air movement is slowed, providing time for warming, humidification, and dust removal before the air reaches more delicate portions of the respiratory tract; and (3) air is directed toward the superior portion of the nasal cavity, adjacent to the cribriform plate, where the olfactory receptors are located.

Facial Bones The Maxillae (Figure 7–10a,b)

General Functions: The **maxillae**, or *upper jawbones*, support the upper teeth and form the inferior orbital rim, the lateral margins of the external nares, the upper jaw, and most of the hard palate. The *maxillary sinuses* in these bones produce mucus that flushes the inferior surfaces of the nasal cavities. The maxillae are the largest facial bones, and the maxillary sinuses are the largest sinuses.

Articulations: The maxillae articulate with the frontal bones and ethmoid, with one another, and with all the other facial bones except the mandible (Figure 7–3c–e and Spotlight Figure 7–4a).

Regions/Markings: The **orbital rim** protects the eye and other structures in the orbit. The *anterior nasal spine* is found at the anterior portion of the maxilla, at its articulation with the maxilla of the other side. It is an attachment point for the cartilaginous anterior portion of the nasal septum.

Figure 7–10 The Maxillae and Palatine Bones. ATLAS: Plates 8a–d; 12d

The **alveolar process** of the maxilla supports the upper teeth.

The **palatine processes** form most of the **hard palate**, or bony roof of the mouth. One type of *cleft palate*, a developmental disorder, results when the maxillae fail to meet along the midline of the hard palate. ATLAS: Embryology Summary 6: The Development of the Skull

The **maxillary sinuses** lighten the portion of the maxillae superior to the teeth.

The **nasolacrimal canal** is formed by a maxilla and lacrimal bone. It protects the *lacrimal sac* and the *nasolacrimal duct*, which carries tears from the orbit to the nasal cavity.

Foramina: The **infraorbital foramen** marks the path of a major sensory nerve that reaches the brain by the foramen rotundum of the sphenoid.

The **inferior orbital fissure** (Figure 7–3d) lies between the maxilla and the sphenoid. It permits passage of cranial nerves and blood vessels.

The Palatine Bones (Figure 7–10b,c)

General Functions: The **palatine bones** form the posterior portion of the hard palate. They also contribute to the floor of each orbit.

Articulations: The palatine bones articulate with one another, with the maxillae, with the sphenoid and ethmoid, with the

inferior nasal conchae, and with the vomer (Figure 7–3e and Spotlight Figure 7–4a).

Regions/Markings: The palatine bones are L-shaped. The **horizontal plate** forms the posterior part of the hard palate. The **perpendicular plate** extends from the horizontal plate to the **orbital process**, which forms part of the floor of the orbit. This process contains a small sinus that normally opens into the sphenoidal sinus.

Foramina: Small blood vessels and nerves supplying the roof of the mouth penetrate the lateral portion of the horizontal plate.

The Nasal Bones (Figure 7–11)

General Functions: The paired **nasal bones** support the superior portion of the bridge of the nose. They are connected to cartilages that support the distal portions of the nose. These flexible cartilages, and associated soft tissues, extend to the superior border of the **external nares** (NA-rēz; singular, *naris*), the entrances to the nasal cavity.

Articulations: The paired nasal bones articulate with one another, with the ethmoid, and with the frontal bone and maxillae (Figure 7–3b–d and Spotlight Figure 7–4a).

The Vomer (Figure 7–11)

General Functions: The **vomer** forms the inferior portion of the bony nasal septum.

Figure 7–11 The Smaller Bones of the Face.

Articulations: The vomer articulates with the maxillae, sphenoid, ethmoid, and palatine bones, and with the cartilaginous part of the nasal septum, which extends into the fleshy part of the nose (Figure 7–3d,e and Spotlight Figure 7–4a).

The Inferior Nasal Conchae (Figure 7–11)

General Functions: The **inferior nasal conchae** create turbulence in air passing through the nasal cavity. They also increase the epithelial surface area to promote warming and humidification of inhaled air.

Articulations: The inferior nasal conchae articulate with the maxillae, ethmoid, palatine, and lacrimal bones (Figure 7–3d).

The Zygomatic Bones (Figure 7–11)

General Functions: The **zygomatic bones** contribute to the rim and lateral wall of the orbit and form part of the zygomatic arch.

Articulations: The zygomatic bones articulate with the maxillae, and the sphenoid, frontal, and temporal bones (Figure 7–3b–e).

Regions/Markings: The **temporal process** curves posteriorly to meet the zygomatic process of the temporal bone.

Foramina: The **zygomaticofacial foramen** on the anterior surface of each zygomatic bone carries a sensory nerve that innervates the cheek.

The Lacrimal Bones (Figure 7–11)

General Functions: The **lacrimal bones** form part of the medial wall of the orbit.

Articulations: The lacrimal bones are the smallest facial bones. They articulate with the frontal bone and maxillae, and with the ethmoid (Figure 7–3c,d).

Regions/Markings: The **lacrimal sulcus**, a groove along the anterior, lateral surface of the lacrimal bone, marks the location of the lacrimal sac. The lacrimal sulcus leads to the nasolacrimal canal, which begins at the orbit and opens into the nasal cavity. As noted earlier, the lacrimal bone and the maxilla form this canal.

The Mandible (Figure 7–12a,b)

General Functions: The mandible forms the lower jaw.

Articulations: The mandible articulates with the mandibular fossae of the temporal bones (Figures 7–3c,e and 7–7b).

Figure 7–12 The Mandible.

Regions/Markings: The **body** of the mandible is the horizontal portion of that bone.

The **alveolar process** of the mandible supports the lower teeth.

The *mental protuberance* (*mentalis,* chin) is the attachment site for several facial muscles.

A prominent depression on the medial surface marks the position of the *submandibular salivary gland*.

The *mylohyoid line* marks the insertion of the *mylohyoid muscle,* which supports the floor of the mouth.

The **ramus** of the mandible is the ascending part that begins at the *mandibular angle* on either side. On each ramus:

- 1. The **condylar process** articulates with the temporal bone at the *temporomandibular joint*.
- 2. The **coronoid** (KOR-ō-noyd) **process** is the insertion point for the *temporalis muscle*, a powerful muscle that closes the jaws.
- **3.** The **mandibular notch** is the depression that separates the condylar and coronoid processes.

Foramina: The **mental foramina** are openings for nerves that carry sensory information from the lips and chin to the brain.

The **mandibular foramen** is the entrance to the *mandibular canal*, a passageway for blood vessels and nerves that service the lower teeth. Dentists typically anesthetize the sensory nerve that enters this canal before they work on the lower teeth.

The Hyoid Bone (Figure 7–13)

General Functions: The **hyoid bone** supports the larynx and is the attachment site for muscles of the larynx, pharynx, and tongue.

Articulations: *Stylohyoid ligaments* connect the *lesser horns* to the styloid processes of the temporal bones.

Regions/Processes: The **body** of the hyoid is an attachment site for muscles of the larynx, tongue, and pharynx.

The **greater horns** help support the larynx and are attached to muscles that move the tongue.

The **lesser horns** are attached to the stylohyoid ligaments. From these ligaments, the hyoid and larynx hang beneath the skull like a child's swing from the limb of a tree.

Figure 7–13 An anterior view of the hyoid bone

An anterior view of the hyoid bone

Clinical Note

Temporomandibular Joint Syndrome The temporomandibular joint (TMJ), between each temporal bone and the mandible, is quite mobile. It allows your jaw to move while you chew or talk. The disadvantage of such mobility is that your jaw can easily be dislocated by forceful forward or lateral displacement. The connective tissue sheath, or capsule, that surrounds the joint is relatively loose. A pad of fibrocartilage separates the opposing bone surfaces. In TMJ syndrome, the mandible is pulled slightly out of alignment, generally by spasms in one of the jaw muscles. The individual has facial pain that radiates around the ear on the affected side and cannot open the mouth fully. TMJ syndrome is a repeating cycle of muscle spasm \rightarrow misalignment \rightarrow pain \rightarrow muscle spasm. It has been linked to involuntary behaviors, such as grinding the teeth during sleep (bruxism), and to emotional stress. Treatment focuses on breaking the cycle of muscle spasm and pain. When necessary, treatment includes emotional support. Applying heat to the affected joint, coupled with the use of anti-inflammatory drugs, local anesthetics, or both, may help. If teeth grinding is suspected, special mouth guards may be worn during sleep.

CHECKPOINT

- 3. In which bone is the foramen magnum located?
- Tomás suffers a blow to the skull that fractures the right 4. superior lateral surface of his cranium. Which bone is fractured?
- 5. Which bone contains the depression called the sella turcica? What is located in this depression?
- Identify the facial bones. 6.
- 7. Identify the bone containing the mental foramen, and list the structures using this passageway.
- 8 Identify the bone containing the optic canal, and cite the structures using this passageway.
- 9. Name the foramina found in the ethmoid bone.

See the blue Answers tab at the back of the book.

7-3 Each orbital complex contains an eye, and the nasal complex encloses the nasal cavities

Learning Outcome Describe the structure and functions of the orbital complex, nasal complex, and paranasal sinuses.

The facial bones not only protect and support the openings of the digestive and respiratory systems, but also protect the sense organs responsible for vision and smell. Together, certain cranial bones and facial bones form an orbital complex, which surrounds each eye, and the nasal complex, which surrounds the nasal cavities.

The Orbital Complexes

The orbits are the bony recesses that contain the eyes. Seven bones of the **orbital complex** form each orbit (Figure 7–14). The frontal bone forms the roof, and the maxilla provides most of the orbital floor. The orbital rim and the first portion of the medial wall are formed by the maxilla, the lacrimal bone, and the lateral mass of the ethmoid. The lateral mass articulates with the sphenoid and a small process of the palatine bone. Several prominent foramina and fissures penetrate the sphenoid or lie between it and the maxilla. Laterally, the sphenoid and maxilla articulate with the zygomatic bone, which forms the lateral wall and rim of the orbit.

The Nasal Complex

The nasal complex (Figure 7-15) includes the bones that enclose the nasal cavities and the paranasal sinuses, air-filled chambers connected to the nasal cavities. The frontal bone, sphenoid, and ethmoid form the superior wall of the nasal cavities. The lateral walls are formed by the maxillae and the lacrimal bones (not shown), the ethmoid (the superior and middle nasal conchae), and the inferior nasal conchae. The soft tissues of the nose form much of the anterior margin of the nasal cavity, but the maxillae and nasal bones support the bridge of the nose.

The sphenoid, ethmoid, frontal bone, and paired palatine bones and maxillae contain the paranasal sinuses. Figure 7-15a shows the locations of the frontal and sphenoid sinuses, ethmoid air cells, and maxillary sinuses. (The tiny palatine sinuses,

7
Figure 7–15 The Nasal Complex. ATLAS: Plates 11b; 12d; 13b,g

not shown, generally open into the sphenoidal sinuses.) The paranasal sinuses lighten the skull bones and provide an extensive area of mucous epithelium, which releases mucus into the nasal cavities. The ciliated epithelium moves the mucus back toward the throat, where it is eventually swallowed or expelled by coughing. Incoming air is humidified and warmed as it flows across this thick carpet of mucus. Foreign particulates, such as

and are then swallowed or expelled. This mechanism helps protect the more delicate portions of the respiratory tract.

dust or microorganisms, become trapped in the sticky mucus

CHECKPOINT

- **10**. Identify the bones of the orbital complex.
- 11. Identify the bones of the nasal complex.
- 12. Identify the bones containing the paranasal sinuses.

See the blue Answers tab at the back of the book.

7-4 Fontanelles are non-ossified areas between cranial bones that allow for brain growth in infants and small children

Learning Outcome Describe the key structural differences among the skulls of infants, children, and adults.

Many different centers of ossification are involved in forming the skull. As development proceeds, the centers fuse, producing a smaller number of composite bones. For example, the sphenoid begins as 14 separate ossification centers. At birth, fusion is not yet complete: There are two frontal bones, four occipital bones, and several sphenoid and temporal elements.

The skull organizes around the developing brain. As the time of birth approaches, the brain enlarges rapidly. The bones of the skull are also growing, but they fail to keep pace. At birth, the cranial bones are connected by areas of fibrous connective tissue (Figure 7–16). The connections are quite flexible, so the skull can be distorted without damage. Such distortion normally takes place during delivery, and the changes in head shape ease the passage of the infant through the birth canal. The largest fibrous areas between the cranial bones are known as **fontanelles** (fon-tuh-NELZ; sometimes spelled *fontanels*):

- The *anterior fontanelle* is the largest fontanelle. It lies at the intersection of the frontal, sagittal, and coronal sutures in the anterior portion of the skull.
- The *occipital fontanelle* is at the junction between the lambdoid and sagittal sutures.
- The *sphenoidal fontanelles* are at the junctions between the squamous sutures and the coronal suture.
- The *mastoid fontanelles* are at the junctions between the squamous sutures and the lambdoid suture.

The anterior fontanelle is often called the "soft spot" on newborns. It is usually the only fontanelle easily seen by new parents. The anterior fontanelle pulses as the heart beats because it is made of fibrous connective tissue and covers a

Clinical Note

Sinusitis When an irritant is introduced into the nasal passages, our bodies work to remove it. Large particles or strong chemical agents can cause us to sneeze, expelling a sizable amount of air quickly and forcefully. The sneeze often sweeps the offending particles or chemicals out with the air. Smaller particles or milder irritants trigger the production of mucus by the epithelium of the paranasal sinuses. The mucus stream flushes the nasal surfaces clean, often removing irritants such as pepper, pollen grains, or dust. In *allergic rhinitis*, an overactive immune response to an allergen, such as pollen or house dust mites, causes excessive mucosal swelling, mucus production, and sneezing.

A sinus infection, however, is another matter entirely. A viral, bacterial, or fungal infection produces an inflammation of the mucous membrane of the nasal cavity. As the membrane swells, the small passageways called *ostia* within the paranasal sinuses narrow. Mucus drains more slowly, the sinuses fill, and the individual has headaches and a feeling of pressure within the facial bones. This condition of sinus inflammation and congestion is called **sinusitis**. The maxillary sinuses are commonly involved. Because gravity does little to assist mucus drainage from these sinuses, the flushing action is less effective, and pressure on the sinus walls typically increases.

The relief of pain associated with sinusitis is the basis of a large over-the-counter (OTC) drug market in the United States. Every major pharmaceutical company has at least one product designed specifically to relieve sinus pressure. The active ingredients are compounds that dry the epithelial linings, reduce pain, and restrict further swelling. Antihistamines and vasoconstrictors, which reduce mucus production, combined with pain relievers such as acetaminophen or ibuprofen are often included.

Temporary sinus problems may follow when the mucous epithelium is exposed to chemical irritants or invading microorganisms. Chronic sinusitis may accompany chronic allergies. It may also occur as the result of a **deviated** (nasal) **septum**. In this condition, the nasal septum has a bend in it, generally at the junction between the bony and cartilaginous regions. Septal deviation often blocks the drainage of one or more sinuses, producing chronic cycles of infection and inflammation. A deviated septum can result from injuries to the nose. Many boxers and hockey players suffer from a deviated septum, because their sports subject them to numerous blows to the soft tissues of the nose. It can usually be corrected or improved by surgery.

major blood vessel. This fontanelle is sometimes used to determine whether an infant is dehydrated, as the surface becomes indented when blood volume is low.

The occipital, sphenoidal, and mastoid fontanelles disappear within a month or two after birth. The anterior fontanelle generally persists until the child is nearly 2 years old. Even after the fontanelles disappear, the bones of the skull remain separated by fibrous connections.

The skulls of infants and adults differ in terms of the shape and structure of cranial elements. This difference accounts for variations in proportions as well as in size. The cranium of a young child, compared with the skull as a whole, is relatively larger than that of an adult. The most significant growth in the skull takes place before age 5, because at that age the brain stops growing and the cranial sutures develop. The growth of the cranium is generally coordinated with the expansion of the brain. If one or more sutures form before the brain stops growing, the skull will be abnormal in shape, size, or both.

CHECKPOINT

- **13**. Define fontanelle, and identify the major fontanelles.
- 14. What purpose does a fontanelle serve?
- See the blue Answers tab at the back of the book.

7-5 The vertebral column has four spinal curves

Learning Outcome Identify and describe the curvatures of the spinal column, and indicate the function of each.

The rest of the axial skeleton consists of the vertebral column, ribs, and sternum. The adult **vertebral column**, or *spine*, consists of 26 bones: the **vertebrae** (24), the **sacrum** (1), and the **coccyx** (1) (KOK-siks), or tailbone. The vertebrae provide a

Clinical Note

Craniostenosis Unusual distortions of the skull result from *craniostenosis* (krā-nē-ō-sten-Ō-sis; *stenosis*, narrowing), the premature closure of one or more fontanelles. As the brain continues to enlarge, the rest of the skull distorts to accommodate it. A long and narrow head is produced by early closure of the sagittal suture. A very broad skull results if the coronal suture forms prematurely. Early closure of all cranial sutures restricts the development of the brain, and surgery must be performed to prevent brain damage. If brain enlargement stops due to genetic or developmental abnormalities, however, skull growth ceases as well. This condition, which results in an undersized head, is called *microcephaly* (mī-krō-SEF-uh-lē; *micro-*, small + *cephalon*, head).

column of support, bearing the weight of the head, neck, and trunk and ultimately transferring the weight to the appendicular skeleton of the lower limbs. The vertebrae also protect the spinal cord and help maintain an upright body position, as when we sit or stand. The total length of the vertebral column of an adult averages 71 cm (28 in.).

Spinal Curvature

The vertebral column is not straight and rigid. A lateral view shows four **spinal curves**: the (1) **cervical curve**, (2) **thoracic curve**, (3) **lumbar curve**, and (4) **sacral curve** (Figure 7–17).

You may have noticed that an infant's body axis forms a C-shape, with the back curving posteriorly. The C-shape results from the thoracic and sacral curves. These are called **primary curves**, because they appear late in fetal development. They are also called **accommodation curves**, because they accommodate the thoracic and abdominopelvic viscera (internal organs). The primary curves are present at birth.

The lumbar and cervical curves, known as **secondary curves**, appear several months after birth. They are also called **compensation curves**, because they help shift the weight to permit an upright posture. The cervical and lumbar secondary curves become accentuated as the toddler learns to walk and run. All four curves are fully developed by age 10.

When you stand, the weight of your body must be transmitted through the vertebral column to the hips and ultimately to the lower limbs. Yet most of your body weight lies anterior to the vertebral column. The various curves bring that weight in line with the body axis. Think about what you do automatically when standing with a heavy object hugged to your chest. You avoid toppling forward by exaggerating the lumbar curve and by keeping the weight back toward the body axis. This posture can lead to discomfort at the base of the spinal column. For example, many women in the last three months of pregnancy develop chronic back pain from the changes in lumbar curvature that adjust for the increasing weight of the fetus. In many parts of the world, people often carry heavy objects balanced on their head. This practice increases the load on the vertebral column but does not affect the spinal curves because the weight is aligned with the axis of the spine.

Vertebral Anatomy

Each vertebra consists of three basic parts: (1) a *vertebral body*, (2) a *vertebral arch*, and (3) *articular processes* (Figure 7–18a).

The **vertebral body** is the part of a vertebra that transfers weight along the axis of the vertebral column (Figure 7–18a,b,e). The bodies of adjacent vertebrae are interconnected by ligaments, but are separated by pads of fibrocartilage, the **intervertebral discs**.

The **vertebral arch** forms the posterior margin of each **vertebral foramen** (Figure 7–18a,c). The vertebral arch has walls, called **pedicles** (PED-i-kulz), and a roof, formed by flat layers called **laminae** (LAM-i-nē; singular, *lamina*, a thin plate). The pedicles arise along the posterior and lateral margins of the body. The laminae on either side extend dorsally and medially to

complete the roof. Together, the vertebral foramina of successive vertebrae form the **vertebral canal**, which encloses the spinal cord (Figure 7–18e).

A **spinous process** projects posteriorly from the point where the vertebral laminae fuse to complete the vertebral arch. You can see—and feel—the spinous processes through the skin of the back when the spine is flexed. **Transverse processes** project laterally or dorsolaterally on both sides from the point where the laminae join the pedicles. These processes are sites of muscle attachment, and they may also articulate with the ribs.

Like the transverse processes, the **articular processes** arise at the junction between the pedicles and the laminae. A **superior** and an **inferior articular process** lie on each side of the vertebra. The superior articular processes articulate with the inferior articular processes of a more superior vertebra (or the occipital condyles, in the case of the first cervical vertebra). The inferior articular processes articulate with the superior articular processes of a more inferior vertebra (or the sacrum, in

the case of the last lumbar vertebra). Each articular process has a smooth concave surface called an **articular facet**. The superior processes have articular facets on their dorsal surfaces, whereas the inferior processes articulate along their ventral surfaces.

Intervertebral discs separate adjacent vertebral bodies, and gaps separate the pedicles of successive vertebrae. These gaps, called **intervertebral foramina**, permit the passage of nerves running to or from the enclosed spinal cord (Figure 7–18e).

CHECKPOINT

- **15**. What is the importance of the secondary curves of the spine?
- 16. When you run your finger along a person's spine, what part of the vertebrae are you feeling just beneath the skin?

See the blue Answers tab at the back of the book.

7-6 The five vertebral regions are the cervical, thoracic, lumbar, sacral, and coccygeal regions

Learning Outcome Identify the vertebral regions, and describe the distinctive structural and functional characteristics of vertebrae in each region.

As **Figure 7–17** shows, the vertebral column is divided into cervical, thoracic, lumbar, sacral, and coccygeal regions. The cervical, thoracic, and lumbar regions consist of individual vertebrae. Seven **cervical vertebrae** (C_1-C_7) constitute the neck and

extend inferiorly to the trunk. Twelve **thoracic vertebrae** (T_1 - T_{12}) form the superior portion of the back. Each articulates with one or more pairs of ribs. Five **lumbar vertebrae** (L_1 - L_5) form the inferior portion of the back. The fifth articulates with the sacrum, which in turn articulates with the coccyx.

During development, the sacrum originates as a group of five vertebrae, and the coccyx begins as three to five very small vertebrae. In general, the vertebrae of the sacrum are completely fused by age 25–30. Ossification of the distal coccygeal vertebrae is not complete before puberty. Thereafter fusion takes place at a variable pace. ATLAS: Embryology Summary 7: The Development of the Vertebral Column

Clinical Note

Kyphosis, Lordosis, and Scoliosis The vertebral column must move, balance, and support the trunk and head. Conditions or events that damage the bones, muscles, and/or nerves can result in distorted shapes and impaired function. In **kyphosis** (kī-FŌ-sis; *kyphos*, humpbacked, bent), the normal thoracic curvature becomes exaggerated posteriorly, producing a "round-back" appearance (Photo a). This condition can be caused by (1) osteoporosis with compression fractures affecting the anterior portions of vertebral bodies, (2) chronic contractions in muscles that insert on the vertebrae, or (3) abnormal vertebral growth. In **lordosis** (lor-DŌ-sis; *lordosis*, a bending backward), or "swayback," both the abdomen and buttocks protrude abnormally (Photo b). The cause is an anterior exaggeration of the lumbar curvature. This may occur during pregnancy or result from abdominal obesity or weakness

in the muscles of the abdominal wall. **Scoliosis** (skō-lē-Ō-sis; *scoliosis*, crookedness) is an abnormal lateral curvature of the spine in one or more of the movable vertebrae (Photo c). Scoliosis is the most common distortion of the spinal curvature. This condition may result from developmental problems from damage to vertebral bodies, or from muscular paralysis affecting one side of the back (as in some cases of polio). In 4 out of 5 cases, the structural or functional cause of the abnormal spinal curvature is impossible to determine. This idiopathic (of no known cause) scoliosis generally appears in girls during adolescence, when periods of growth are most rapid. Small curves may later stabilize once growth is complete. For larger curves, bracing may prevent progression. Severe cases can be treated through surgical straightening with implanted metal rods or cables.

Note that when we refer to a specific vertebra, we use a capital letter for the vertebral region: C, T, L, S, and Co represent the cervical, thoracic, lumbar, sacral, and coccygeal regions, respectively. In addition, we use a numerical subscript to indicate the relative position of the vertebra within that region, with 1 indicating the vertebra closest to the skull. For example, C_1 is in contact with the skull and C_3 is the third cervical vertebra. Similarly, T_{12} is in contact with L_1 and L_4 is the fourth lumbar vertebra (Figure 7–17). We will use this shorthand throughout the text.

Each vertebra has characteristic markings and articulations, but we will focus on the general characteristics of each region. We will see how regional variations determine each vertebral group's function.

Cervical Vertebrae

Most mammals—whether giraffes, whales, mice, or humans have seven cervical vertebrae (Figure 7–19a). The cervical vertebrae are the smallest in the vertebral column. They extend from the occipital bone of the skull to the thorax. The body of a cervical vertebra is small compared with the size of the vertebral foramen (Figure 7–19b). At this level, the spinal cord still contains most of the axons that connect the brain to the rest of

the body. The diameter of the spinal cord decreases as you proceed caudally along the vertebral canal, and so does the diameter of the vertebral arch. However, cervical vertebrae support only the weight of the head, so the vertebral body can be relatively small and light. As you continue toward the sacrum, the loading increases and the vertebral bodies gradually enlarge.

In a typical cervical vertebra, the superior surface of the body is concave from side to side, and it slopes, with the anterior edge inferior to the posterior edge (Figure 7–19c). Vertebra C_1 has no spinous process. The spinous processes of the other cervical vertebrae are relatively stumpy, generally shorter than the diameter of the vertebral foramen. In the case of vertebrae C_2 – C_6 , the tip of each spinous process has a prominent

notch (Figure 7–19b). A notched spinous process is said to be **bifid** (BĪ-fid).

Laterally, the transverse processes are fused to the **costal processes**, which originate near the ventrolateral portion of the vertebral body. The costal and transverse processes encircle prominent, round **transverse foramina**. These passageways protect the *vertebral arteries* and *vertebral veins*. These important blood vessels service the brain.

The preceding description is adequate for identifying the cervical vertebrae C_3-C_6 . The first two cervical vertebrae are unique, and the seventh is modified. We will describe these vertebrae shortly. The interlocking bodies of articulated C_3-C_7 permit more flexibility than do those of other regions.

Table 7–1	Regiona	Differences in Vertebral Structure and Function				
			Type (Number)			
Feature		Cervical Vertebrae (7)	Thoracic Vertebrae (12)	Lumbar Vertebrae (5)		
Location		Neck	Chest	Inferior portion of back		
Body		Small, oval, curved faces	Medium, heart-shaped, flat faces; facets for rib articulations	Massive, oval, flat faces		
Vertebral foramen		Large	Medium	Small		
Spinous process	5	Long; split tip; points inferiorly	Long, slender; not split; points inferiorly	Blunt, broad; points posteriorly		
Transverse proc	esses	Have transverse foramina	All but two (T_{11}, T_{12}) have facets for rib articulations	Short; no articular facets or transverse foramina		
Functions		Support skull, stabilize relative positions of brain and spinal cord, and allow controlled head movement	Support weight of head, neck, upper limbs, and chest; articulate with ribs to allow changes in volume of thoracic cage	Support weight of head, neck, upper limbs, and trunk		

Typical appearance (superior view)

Table 7–1 includes a summary of the features of these cervical vertebrae.

Compared with the cervical vertebrae, your head is relatively massive. It sits atop the cervical vertebrae like a soup bowl on the tip of a finger. With this arrangement, small muscles can produce significant effects by tipping the balance one way or another. But if you change position suddenly, as in a fall or during rapid acceleration (a jet takeoff) or deceleration (a car crash), the balancing muscles are not strong enough to stabilize the head. A dangerous partial or complete dislocation of the cervical vertebrae can result, with injury to muscles and ligaments and potential injury to the spinal cord. We use the term **whiplash** to describe such an injury, because the movement of the head resembles the cracking of a whip.

The Atlas (C₁)

The **atlas**, cervical vertebra C_1 (Figure 7–19d), holds up the head. It articulates with the occipital condyles of the skull. This

vertebra is named after Atlas, who, according to Greek myth, holds the world on his shoulders. The articulation between the occipital condyles and the atlas is a joint that permits you to nod (such as when you indicate "yes"). The atlas can easily be distinguished from other vertebrae by (1) the lack of a body and spinous process and (2) the presence of a large, round vertebral foramen bounded by **anterior** and **posterior arches**.

The atlas articulates with the second cervical vertebra, the *axis.* This articulation permits rotation (as when you shake your head to indicate "no").

The Axis (C_2)

During development, the body of the atlas fuses to the body of the second cervical vertebra, called the **axis** (C_2) (Figure 7–19d). This fusion creates the prominent **dens** (DENZ; *dens*, tooth), or *odontoid* (\bar{o} -DON-toyd; *odontos*, tooth) *process*, of the axis. A transverse ligament binds the dens to the inner surface of the atlas, forming a pivot for rotation of the atlas and skull.

Important muscles controlling the position of the head and neck attach to the especially robust spinous process of the axis.

In children, the fusion between the dens and axis is incomplete. Impacts or even severe shaking can cause dislocation of the dens and severe damage to the spinal cord. In adults, a hit to the base of the skull can be equally dangerous, because a dislocation of the atlas–axis joint can force the dens into the base of the brain, with fatal results.

TIPS&TRICKS

To remember the difference between the atlas and the axis and their respective movements, consider Greek mythology and the Earth. In this case, the head (Earth) is held up by Atlas and is capable of nodding "yes" movements. The Earth rotates on its axis, and the axis allows for us to shake our heads in a "no" movement.

The Vertebra Prominens (C₇)

The transition from one vertebral region to another is not abrupt. The last vertebra of one region generally resembles the first vertebra of the next. The **vertebra prominens**, or seventh cervical vertebra (C_7), has a long, slender spinous process (Figure 7–19a) that ends in a broad tubercle that you can feel through the skin at the base of the neck. This vertebra is the interface between the cervical curve, which arches anteriorly, and the thoracic curve, which arches posteriorly (Figure 7–17). The transverse processes of C_7 are large, providing additional surface area for muscle attachment.

The **ligamentum nuchae** (lig-uh-MEN-tum-Nū-kē; *nucha*, nape), a stout elastic ligament, begins at the vertebra prominens and extends to an insertion (attachment site) along the occipital crest of the skull. Along the way, it attaches to the spinous processes of the other cervical vertebrae. When your head is upright, this ligament acts like the string on a bow, maintaining the cervical curvature without muscular effort. If you have bent your neck forward, the elasticity in the ligamentum nuchae helps return your head to an upright position.

Thoracic Vertebrae

There are 12 thoracic vertebrae (Figure 7–20a). A typical thoracic vertebra has a distinctive heart-shaped body that is more massive than that of a cervical vertebra (Figure 7–20b). The vertebral foramen is relatively smaller. The long, slender spinous processes projects posteriorly and inferiorly. The spinous processes of T_{10} , T_{11} , and T_{12} increasingly resemble those of the lumbar region as the transition between the thoracic and lumbar vertebrae carry so much weight, the transition between the thoracic and lumbar vertebrae carry so compression–dislocation fractures

from a hard fall tend to involve the last thoracic and first two lumbar vertebrae.

Each thoracic vertebra articulates with ribs along the dorsolateral surfaces of the body. The **costal facets** on the vertebral bodies articulate with the heads of the ribs. The location and structure of the articulations vary somewhat among thoracic vertebrae (Figure 7–20a). Vertebrae T_1-T_8 each articulate with two pairs of ribs, so their vertebral bodies have two costal facets (*superior* and *inferior*) on each side. Vertebrae T_9-T_{11} have a single costal facet on each side, and each vertebra articulates with a single pair of ribs.

The transverse processes of vertebrae T_1-T_{10} are relatively thick and contain **transverse costal facets** for rib articulation (Figure 7–20b,c). Thus, rib pairs 1 through 10 contact their vertebrae at two points: a costal facet and a transverse costal facet. Table 7–1 summarizes the features of thoracic vertebrae.

Lumbar Vertebrae

The five lumbar vertebrae are the largest vertebrae (Figure 7–21a). The body of a typical lumbar vertebra (Figure 7–21b,c) is thicker than that of a thoracic vertebra, and the superior and inferior surfaces are oval rather than heart shaped. Also note that (1) lumbar vertebrae do not have costal facets; (2) the slender transverse processes, which lack transverse costal facets, project dorsolaterally; (3) the vertebral foramen is triangular; (4) the stumpy spinous processes project dorsally; (5) the superior articular processes face medially ("up and in"); and (6) the inferior articular processes face laterally ("down and out").

The lumbar vertebrae withstand the most weight. Their massive spinous processes provide surface area for the attachment of lower back muscles that reinforce or adjust the lumbar curve. Table 7–1 summarizes the features of lumbar vertebrae.

TIPS&TRICKS

To remember the number of bones in the first three spinal curves, think about mealtimes. You eat breakfast at 7 a.m. (7 cervical vertebrae), lunch at 12 p.m. (12 thoracic vertebrae), and dinner at 5 p.m. (5 lumbar vertebrae).

The Sacrum

The sacrum consists of the fused components of five sacral vertebrae. These vertebrae begin fusing shortly after puberty. In general, they are completely fused at age 25–30. The sacrum protects the reproductive, digestive, and urinary organs. Through paired articulations, it attaches the axial skeleton to the paired hip bones, or pelvic girdle, of the appendicular skeleton (Figure 7–1a).

Figure 7–20 The Thoracic Vertebrae. Notice the characteristic features listed in Table 7–1 on p. 231. ATLAS: Plates 22a-c

The broad posterior surface of the sacrum (Figure 7–22a) provides an extensive area for the attachment of muscles, especially those that move the thigh. The superior articular processes of the first sacral vertebra articulate with the last lumbar vertebra. The **sacral canal** is a passageway that begins between these articular processes and extends the length of the sacrum. Nerves and membranes that line the vertebral canal in the spinal cord continue into the sacral canal.

Three sacral crests provide surface areas for the attachment of muscles. The **median sacral crest** is a ridge formed by the fused spinous processes of the sacral vertebrae. The laminae of the fifth sacral vertebra fail to contact one another at the midline. They form the **sacral cornua** (KOR-nū-uh; singular, *cornu; cornua*, horns). These ridges form the margins of the **sacral hiatus** (hī-Ā-tus), the opening at the inferior end of the sacral canal. This opening is covered by connective tissues. Four pairs of **sacral foramina** open on either side of the median sacral crest. The intervertebral foramina of the fused sacral vertebrae open into these passageways. Each **lateral sacral crest** is a ridge that represents the fused transverse processes of the sacral vertebrae. The sacrum is curved, with a convex posterior surface (**Figure 7–22b**). The degree of curvature is more pronounced in males than in females. The **auricular surface** is a thickened, flattened area lateral and anterior to the superior portion of the lateral sacral crest. The auricular surface is the site of articulation with the pelvic girdle (the *sacroiliac joint*).

c A superior view of the same vertebra shown in part b

The **sacral tuberosity** is a roughened area between the lateral sacral crest and the auricular surface. It marks the attachment site of ligaments that stabilize the sacroiliac joint.

The subdivisions of the sacrum are most clearly seen in anterior view (Figure 7–22c). The narrow, inferior portion is the sacral **apex**. The broad superior surface is the **base**. The **sacral promontory**, a prominent bulge at the anterior tip of the base, is an important landmark in females during pelvic examinations and during labor and delivery. Prominent *transverse lines* mark the former boundaries of individual vertebrae that fuse during the formation of the sacrum. At the base of the sacrum, a broad sacral **ala**, or *wing*, extends on either side. The anterior and superior surfaces of each ala provide an extensive area for muscle attachment. At the apex, a flattened area marks the site of articulation with the coccyx.

The Coccyx

The small coccyx consists of three to five (typically, four) coccygeal vertebrae that have generally begun fusing by age 26 (Figure 7–22). The coccyx provides an attachment site for a number of ligaments and for a muscle that constricts the anal opening. The first two coccygeal vertebrae have transverse processes and unfused vertebral arches. The prominent laminae of the first coccygeal vertebrae are known as the **coccygeal cornua**. These laminae curve to meet the sacral cornua. The coccygeal vertebrae do not fuse completely until late in adulthood. In very old persons, the coccyx may fuse with the sacrum.

CHECKPOINT

- **17**. Why does the vertebral column of an adult have fewer vertebrae than that of a newborn?
- **18**. Joe suffered a hairline fracture at the base of the dens. Which bone is fractured, and where is it located?
- 19. Examining a human vertebra, you notice that, in addition to the large foramen for the spinal cord, two smaller foramina are on either side of the bone in the region of the transverse processes. From which region of the vertebral column is this vertebra?
- 20. Why are the bodies of the lumbar vertebrae so large?

See the blue Answers tab at the back of the book.

7-7 The thoracic cage protects organs in the chest and provides sites for muscle attachment

Learning Outcome Explain the significance of the articulations between the thoracic vertebrae and the ribs, and between the ribs and sternum.

The skeleton of the chest, or **thoracic cage** (Figure 7–23), provides bony support to the walls of the thoracic cavity. It consists of the thoracic vertebrae, the ribs, and the sternum (breastbone). The ribs and the sternum form the *rib cage*,

whose movements are important in respiration. The thoracic cage as a whole serves two functions:

- 1. It protects the heart, lungs, thymus, and other structures in the thoracic cavity.
- It serves as an attachment point for muscles involved in (1) respiration, (2) maintenance of the position of the vertebral column, and (3) movements of the pectoral girdle (both clavicles and scapulae) and upper limbs.

The Ribs

Ribs, or *costae*, are long, curved, flattened bones that originate on or between the thoracic vertebrae and end in the wall of the thoracic cavity. Each of us, regardless of sex, has 12 pairs of ribs (**Figure 7–23**). The first seven pairs are called **true ribs**, or *vertebrosternal ribs*. They reach the anterior body wall and are connected to the sternum by separate cartilaginous extensions, the **costal cartilages**. Beginning with the first rib, the vertebrosternal ribs gradually increase in length and in radius of curvature.

Ribs 8–12 are called **false ribs**, because they do not attach directly to the sternum. The costal cartilages of ribs 8–10, the *vertebrochondral ribs*, fuse together and merge with the cartilages of rib pair 7 before they reach the sternum (Figure 7–23a). The last two pairs of ribs (11 and 12) are called *floating ribs* because they have no connection with the sternum. They are also called *vertebral ribs* because they are attached only to the vertebrae (Figure 7–23b) and muscles of the body wall.

Figure 7–24a shows the superior surface of a typical rib. The *vertebral end* of the rib articulates with the vertebral column at the **head**, or *capitulum* (ka-PIT-ū-lum). A ridge divides the articular surface of the head into superior and inferior articular facets (**Figure 7–24b**). From the head, a short **neck** leads to the **tubercle**, a small elevation that projects dorsally. The inferior portion of the tubercle contains an articular facet that contacts the transverse process of the thoracic vertebra.

Ribs 1 and 10 originate at costal facets on vertebrae T_1 and T_{10} , respectively, and their tubercular facets articulate with the transverse costal facets on those vertebrae. The heads of ribs 2–9 articulate with costal facets on two adjacent vertebrae. Their tubercular facets articulate with the transverse costal facets of the inferior member of the vertebral pair. Ribs 11 and 12, which originate at T_{11} and T_{12} , do not have tubercular facets and do not contact the transverse processes of T_{11} or T_{12} .

The bend, or *angle*, of the rib is the site where the tubular **body**, or *shaft*, begins curving toward the sternum (Figure 7–24b). The internal rib surface is concave, and a prominent *costal groove* along its inferior border marks the path of nerves and blood vessels. The superficial surface is convex and provides an attachment site for muscles of the pectoral girdle and trunk. The *intercostal muscles*, which move the ribs, are attached to the superior and inferior surfaces.

The ribs are quite mobile, due to their complex musculature, dual articulations at the vertebrae, and flexible connection to the sternum. Note how the ribs curve away from the vertebral column to angle inferiorly (Figure 7–23). Because of the curvature of the ribs, their movements during breathing changes the position of the sternum. Lowering the ribs pulls the sternum inward, and raising the ribs moves it outward. As a result, movements of the ribs change both the width and the depth of the thoracic cage, decreasing or increasing its volume accordingly as we breathe out or in. These movements are important in breathing, as we will see in detail in Chapter 23.

The ribs can bend and move to cushion shocks and absorb hits, but severe or sudden impacts can cause painful rib fractures. A cracked rib can heal without a cast or splint because the ribs are tightly bound in connective tissues. But compound fractures of the ribs can send bone splinters or fragments into the thoracic cavity, with potential damage to internal organs.

Surgery on the heart, lungs, or other organs in the thorax typically involves entering the thoracic cavity. The mobility of the

ribs and the cartilaginous connections with the sternum allow the ribs to be temporarily moved out of the way. "Rib spreaders" are used to push the ribs apart in much the same way that a jack lifts a car off the ground for a tire change. If more extensive access is required, the cartilages of the sternum can be cut and the entire sternum folded out of the way. Once the sternum is replaced, scar tissue reunites the cartilages, and the ribs heal fairly rapidly.

The Sternum

The adult **sternum**, or breastbone, is a flat bone that forms in the anterior midline of the thoracic wall (Figure 7–23a). The sternum has three parts:

1. The broad, triangular **manubrium** (ma-NU-brē-um) articulates with the *clavicles* (collarbones) and the cartilages of the first pair of ribs. The manubrium is the widest and most superior portion of the sternum. Only the first pair of ribs is attached by cartilage to this portion of the sternum. The **jugular notch**, located between the clavicular

Figure 7–24 The Ribs. ATLAS: Plates 22a,b

b A posterior view of the head of a representative rib from the right side (ribs 2–9)

articulations, is a shallow indentation on the superior surface of the manubrium.

- 2. The tongue-shaped **body** attaches to the inferior surface of the manubrium and extends inferiorly along the midline. Individual costal cartilages from rib pairs 2–7 are attached to this portion of the sternum.
- **3.** The **xiphoid** (ZI-foyd) **process** is the smallest part of the sternum. It is attached to the inferior surface of the body. The muscular *diaphragm* and *rectus abdominis muscles* attach to the xiphoid process.

Ossification of the sternum begins at 6 to 10 ossification centers, and fusion is not complete until at least age 25. Before that age, the sternal body consists of four separate bones. In adults, their boundaries appear as a series of transverse lines crossing the sternum. The xiphoid process is generally the last part to ossify and fuse. Its connection to the sternal body can be broken by impact or by strong pressure, creating a spear of bone that can severely damage the liver. The xiphoid process is used as a palpable landmark during the administration of cardiopulmonary resuscitation (CPR), and CPR training strongly emphasizes proper hand positioning to reduce the chances of breaking ribs or the xiphoid process.

CHECKPOINT

- 21. How are true ribs distinguished from false ribs?
- 22. Improper administration of cardiopulmonary resuscitation (CPR) can result in a fracture of which bones?
- **23**. What are the main differences between vertebrosternal ribs and vertebrochondral ribs?

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **craniotomy:** The surgical removal of a section of bone (bone flap) from the skull for the purpose of operating on the underlying tissues.
- **deviated nasal septum:** A bent nasal septum (cartilaginous structure dividing the left and right nasal cavities) that slows or prevents sinus drainage.
- **herniated disc:** A disc (fibrocartilage pad) between the vertebrae that slips out of place or ruptures; if it presses on a nerve, it can cause back pain or sciatica.
- **laminectomy:** A surgical operation to remove the posterior vertebral arch on a vertebra, usually to give access to the spinal cord or to relieve pressure on nerves.

spina bifida: A condition resulting from the failure of the vertebral laminae to unite during development; commonly associated with developmental abnormalities of the brain and spinal cord.

spinal fusion: A surgical procedure that stabilizes the spine by joining together (fusing) two or more vertebrae using bone grafts, metal rods, or screws.

7-1 The 80 bones of the head and trunk make up the axial skeleton p. 207

- The skeletal system consists of the axial skeleton and the appendicular skeleton. The axial skeleton can be divided into the skull, the auditory ossicles and hyoid bone, the vertebral column, and the thoracic cage. (*Figure 7–1*)
- 2. The **appendicular skeleton** includes the pectoral and pelvic girdles, which support the upper and lower limbs.
- 7-2 The skull is composed of 8 cranial bones and 14 facial bones p. 207
- **3.** The **skull** consists of the **cranium** and the bones of the face. The cranium, composed of **cranial bones**, encloses the **cranial cavity.** The **facial bones** protect and support the entrances to the digestive and respiratory tracts. (*Figure 7–2*)
- Prominent superficial landmarks on the skull include the lambdoid, coronal, sagittal, and squamous sutures. (*Figure 7–3*)
- 5. The bones of the cranium are the **occipital bone**, the two **parietal bones**, the **frontal bone**, the two **temporal bones**, the **sphenoid**, and the **ethmoid**. (*Figures* 7–2 to 7–9)
- 6. The occipital bone surrounds the **foramen magnum**. *(Figures 7–3 to 7–5)*
- 7. The frontal bone contains the **frontal sinuses**. (*Spotlight Figure* 7–4, *Figure* 7–6)
- 8. The **auditory ossicles** are located in a cavity within the temporal bone. (*Figure* 7–7)
- 9. The bones of the face are the maxillae, the palatine bones, the nasal bones, the vomer, the inferior nasal conchae, the zygomatic bones, the lacrimal bones, and the mandible. (*Figures 7–2 to Spotlight Figure 7–4, 7–10 to 7–12*)
- The left and right maxillae, or *maxillary bones*, are the largest facial bones; they form the upper jaw and most of the hard palate. (*Figures 7–3*, *Spotlight Figure 7–4*, 7–10)
- **11.** The palatine bones are small L-shaped bones that form the posterior portions of the hard palate and contribute to the floor of the orbital cavities. (*Figures 7–3, Spotlight Figure 7–4, 7–10*)
- **12.** The paired nasal bones extend to the superior border of the **external nares**. (*Figures 7–3, Spotlight Figure 7–4, 7–11*)

- **13.** The vomer forms the inferior portion of the **nasal septum.** (*Figures 7–3, Spotlight Figure 7–4, 7–11*)
- 14. The **temporal process** of the zygomatic bone articulates with the **zygomatic process** of the temporal bone to form the **zygomatic arch.** (*Figures 7–3, 7–7, 7–11*)
- **15.** The paired lacrimal bones, the smallest bones of the face, are situated medially in each **orbit.** (*Figures* 7–3, 7–11)
- **16.** The mandible is the bone of the lower jaw. (*Figures 7–3, Spotlight Figure 7–4, 7–12*)
- **17.** The **hyoid bone**, suspended by *stylohyoid ligaments*, supports the larynx. (*Figure 7–13*)
- **18.** The foramina and fissures of the adult skull are summarized in *Spotlight Figure 7–4*.
- 7-3 Each orbital complex contains an eye, and the nasal complex encloses the nasal cavities p. 223
- 19. Seven bones form each orbital complex. (Figure 7–14)
- **20.** The **nasal complex** includes the bones that enclose the nasal cavities and the **paranasal sinuses**, hollow airways that connect with the nasal passages. (*Figure 7–15*)
- 7-4 Fontanelles are non-ossified fibrous areas between cranial bones that allow for brain growth in infants and small children p. 224
- 21. Fibrous connective tissue **fontanelles** permit the skulls of infants and children to continue growing after birth. *(Figure 7–16)*
- 7-5 The vertebral column has four spinal curves p. 226
- 22. The **vertebral column** consists of the vertebrae, sacrum, and coccyx. We have 7 **cervical vertebrae** (the first articulates with the skull), 12 **thoracic vertebrae** (which articulate with the ribs), and 5 **lumbar vertebrae** (the last articulates with the sacrum). The **sacrum** and **coccyx** consist of fused vertebrae. (*Figure 7–17*)
- 23. The spinal column has four **spinal curves**. The **thoracic** and **sacral curves** are called **primary** or **accommodation curves**; the **lumbar** and **cervical curves** are known as **secondary** or **compensation curves**. (*Figure 7–17*)
- 24. A typical vertebra has a **vertebral body** and a **vertebral arch**, and articulates with adjacent vertebrae at the **superior** and **inferior articular processes**. (*Figure 7–18*)
- 25. **Intervertebral discs** separate adjacent vertebrae. Spaces between successive **pedicles** form the **intervertebral foramina.** (*Figure 7–18*)
- 7-6 The five vertebral regions are the cervical, thoracic, lumbar, sacral, and coccygeal regions p. 228
- **26.** Cervical vertebrae are distinguished by the shape of the body, the relative size of the vertebral foramen, the presence of **costal processes** with **transverse foramina**, and notched **spinous processes**. These vertebrae include the **atlas**, **axis**, and **vertebra prominens**. (*Figure 7–19*; *Table 7–1*)
- Thoracic vertebrae have a distinctive heart-shaped body; long, slender spinous processes; and articulations for the ribs. (*Figures 7–20, 7–23; Table 7–1*)

- **28.** The lumbar vertebrae are the most massive and least mobile of the vertebrae; they are subjected to the greatest strains. (*Figure 7–21; Table 7–1*)
- **29.** The sacrum protects reproductive, digestive, and urinary organs and articulates with the pelvic girdle and with the fused elements of the coccyx. (*Figure 7–22*)
- 7-7 The thoracic cage protects organs in the chest and provides sites for muscle attachment p. 235
- **30.** The skeleton of the **thoracic cage** consists of the thoracic vertebrae, the ribs, and the sternum. The **ribs** and **sternum** form the *rib cage.* (*Figure 7–23*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the cranial and facial bones in the diagram below.

Facial bones

(a)	 (b)	
(c)	 (d)	
(e)	 (f)	
(g)	 (h)	
(i)	 (j)	
(k)	 (1)	

- Which of the following lists contains *only* facial bones? (a) mandible, maxilla, nasal, zygomatic, (b) frontal, occipital, zygomatic, parietal, (c) occipital, sphenoid, temporal, lacrimal, (d) frontal, parietal, occipital, sphenoid.
- The unpaired facial bones include the (a) lacrimal and nasal,
 (b) vomer and mandible, (c) maxilla and mandible, (d) zygomatic and palatine.

- 31. Ribs 1–7 are true ribs, or *vertebrosternal ribs*. Ribs 8–12 are called false ribs; they include the *vertebrochondral ribs* (ribs 8–10) and two pairs of *floating (vertebral) ribs* (ribs 11–12). A typical rib has a head, or *capitulum*; a neck; a tubercle; an *angle*; and a body, or *shaft*. A *costal groove* marks the path of nerves and blood vessels. (*Figures 7–23, 7–24*)
- **32.** The sternum consists of the **manubrium**, **body**, and **xiphoid process**. (*Figure 7–23*)

See the blue Answers tab at the back of the book.

- 4. The boundaries between skull bones are immovable joints called(a) foramina, (b) fontanelles, (c) lacunae, (d) sutures.
- 5. The joint between the frontal and parietal bones is correctly called the ______ suture. (a) parietal, (b) lambdoid, (c) squamous, (d) coronal.
- Blood vessels that drain blood from the head pass through the (a) jugular foramina, (b) hypoglossal canals, (c) stylomastoid foramina, (d) mental foramina, (e) lateral canals.
- 7. For each of the following vertebrae, indicate its vertebral region.

- a. ______ b. _____ c. _____
 8. Cervical vertebrae can usually be distinguished from other vertebrae by the presence of (a) transverse processes, (b) transverse foramina, (c) demifacets on the body, (d) the vertebra prominens, (e) large spinous processes.
- 9. The lateral walls of the vertebral foramen are formed by the
 (a) body of the vertebra, (b) spinous process, (c) pedicles,
 (d) laminae, (e) transverse processes.
- 10. The part of the vertebra that transfers weight along the axis of the vertebral column is the (a) vertebral arch, (b) lamina, (c) pedicles, (d) body.
- 11. Which eight bones make up the cranium?
- 12. What seven bones constitute the orbital complex?
- 13. What is the primary function of the vomer?
- 14. In addition to the spinal curves, what skeletal element contributes to the flexibility of the vertebral column?

LEVEL 2 Reviewing Concepts

- 15. What is the relationship between the temporal bone and the ear?
- **16.** What is the relationship between the ethmoid bone and the nasal cavity?
- 17. Describe how movement of the ribs functions in breathing.
- **18.** Why is it important to keep your back straight when you lift a heavy object?
- 19. The atlas (C₁) can be distinguished from the other vertebrae by
 (a) the presence of anterior and posterior vertebral arches,
 (b) the lack of a body, (c) the presence of superior facets and inferior articular facets, (d) all of these.

240 UNIT 2 Support and Movement

- **20**. What purpose do the fontanelles serve during birth?
- 21. The secondary spinal curves (a) help position the body weight over the legs, (b) accommodate the thoracic and abdominopelvic viscera, (c) include the thoracic curvature, (d) do all of these, (e) do only a and c.
- 22. When you rotate your head to look to one side, (a) the atlas rotates on the occipital condyles, (b) C₁ and C₂ rotate on the other cervical vertebrae, (c) the atlas rotates on the dens of the axis, (d) the skull rotates the atlas, (e) all cervical vertebrae rotate.
- 23. Improper administration of CPR (cardiopulmonary resuscitation) can force the _____ into the liver. (a) floating ribs, (b) lumbar vertebrae, (c) manubrium of the sternum, (d) costal cartilage, (e) xiphoid process.

LEVEL 3 Critical Thinking and Clinical Applications

- 24. Jane has an upper respiratory infection and begins to feel pain in her teeth. This is a good indication that the infection is located in the (a) frontal sinuses, (b) sphenoid bone, (c) temporal bone, (d) maxillary sinuses, (e) zygomatic bones.
- **25.** While working at an excavation, an archaeologist finds several small skull bones. She examines the frontal, parietal, and occipital bones and concludes that the skulls are those of children not yet 1 year old. How can she tell their ages from an examination of these bones?
- **26.** Mary is in her last month of pregnancy and is suffering from lower back pains. Since she is carrying excess weight in front of her, she wonders why her back hurts. What would you tell her?

Q

CLINICAL CASE

Knocked Out

The young boxer has sustained a "blowout" fracture of his left orbital complex. The orbit that con-

tains the eye is formed by seven facial bones and is surrounded by four air-filled sinuses. The orbital rim is strong, composed of thick, protective bone. But the very thin medial wall and floor of the orbit were literally blown out by the intact eyeball itself when he was struck with such a forceful blow.

A computerized tomography (CT) scan reveals fractures of the ethmoid, lacrimal, palatine, and maxillary bones that make up the delicate medial wall and floor of the left orbit. Many tiny fracture fragments can be seen within the maxillary sinus.

The opening to the air-filled sinus allowed the air to escape into the soft tissues surrounding the eye when the fighter coughed, causing the subcutaneous air expansion around the eye. The muscles that move the eye had become entrapped within the fracture fragments, preventing the fighter from gazing upward and giving rise to his double vision.

Wrap-Up

The young boxer is taken to the operating room. A surgical repair of the orbital floor is performed, using an implant to support the eyeball until fracture healing is complete.

- 1. What are the seven bones that make up the orbital complex?
- 2. What are the four paranasal sinuses surrounding the orbital complex?

See the blue Answers tab at the back of the book.

The Appendicular Skeleton

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 8-1 Identify the bones that form the pectoral girdles, their functions, and their superficial features.
- 8-2 Identify the bones of the upper limbs, their functions, and their superficial features.
- 8-3 Identify the bones that form the pelvic girdle, their functions, and their superficial features.
- 8-4 Identify the bones of the lower limbs, their functions, and their superficial features.
- 8-5 Summarize sex differences and agerelated changes in the human skeleton.

SPOTLIGHT

• Sex Differences in the Human Skeleton p. 253

CLINICAL CASE

• The Orthopedic Surgeon's Nightmare p. 242

Clinical Notes

- Carpal Tunnel Syndrome p. 249
- Hip Fracture p. 254
- Runner's Knee p. 254
- Stress Fractures p. 258
- Congenital Talipes Equinovarus p. 258

CLINICAL CASE

The Orthopedic Surgeon's Nightmare

It is Caitlyn's first day of "big kids" school. She cries a little when she kisses her Mom good-bye and gets on the bus. She feels lost when she gets to school, but a kind kindergarten teacher meets her and leads her to her new classroom. The best part of her day is getting to go out to the playground.

Caitlyn has seen the climbing structure from outside the playground fence many times, but this is the first time she has the chance to climb all the way to the top. She feels very grown up, perched up so high. Suddenly her foot slips and she feels herself falling to the ground. She stretches out her right hand to break her fall just before she hits the ground. As she lands, she feels and hears a crack in her elbow. "Help!" Caitlyn cries.

The school nurse examines the child's deformed elbow, notices there is no pulse in her wrist, and springs into action. She splints Caitlyn's arm and calls the orthopedic surgeon. "Doc, we have a five-year-old who has an elbow injury following a fall on her outstretched hand, with no distal pulses."

"Oh no," groans the surgeon. Of all the playground fractures, this is likely to be the most difficult to treat. What has happened to Caitlyn's elbow? To find out, turn to the Clinical Case Wrap-Up on p. 262.

An Introduction to the Appendicular Skeleton

In this chapter we focus on the functional anatomy of the bones of the limbs and the bones that connect them to the body. In the previous chapter, we discussed the 80 bones of the axial skeleton. Remaining are 60 percent of the bones that make up the skeletal system. These bones are appended to the axial skeleton. The **appendicular skeleton** includes the bones of the limbs and the supporting bone (pectoral and pelvic) girdles that connect them to the trunk (Figure 8–1).

To appreciate the role of the appendicular skeleton in your life, make a mental list of all the things you have done with your arms or legs today. Standing, walking, writing, turning pages, eating, dressing, shaking hands, and texting—the list quickly becomes unwieldy. Your axial skeleton protects and supports internal organs and takes part in vital functions, such as breathing. But your appendicular skeleton lets you manipulate objects and move from place to place.

The appendicular skeleton is dominated by the long bones that support the limbs. $\supset p$. 180 Each long bone shares common features with other long bones. For example, one epiphysis is usually called the *head*, the diaphysis is called the *shaft*, and a *neck* normally separates the head and shaft. For simplicity, an illustration of a single bone will have labels that do not include the name of the bone. For example, a photo of the humerus will have the label *head* rather than *head of the humerus* or *humeral head*. When more than one bone is shown, the label will use the complete name to avoid confusion. In the descriptions in this chapter, we emphasize surface markings that either have functional importance (such as the attachment sites for skeletal muscles and the paths of major nerves and blood vessels) or provide markings that define areas and locate structures of the body.

8-1 The pectoral girdles—the clavicles and scapulae—attach the upper limbs to the axial skeleton

Learning Outcome Identify the bones that form the pectoral girdles, their functions, and their superficial features.

Each arm articulates (that is, forms a joint) with the trunk at a **pectoral girdle**, or *shoulder girdle* (Figure 8–1). The pectoral girdles consist of two S-shaped *clavicles* (KLAV-i-kulz; collarbones) and two broad, flat *scapulae* (SKAP- \bar{u} -l \bar{e} ; singular, *scapula*, SKAP- \bar{u} -luh; shoulder blades). The medial, anterior end of each clavicle articulates with the manubrium of the sternum. \bigcirc p. 236 These articulations are the *only* direct connections between the pectoral girdles and the axial skeleton. Skeletal muscles support and position the scapulae, which have no direct bony or ligamentous connections to the thoracic cage. As a result, the shoulders are extremely mobile, but not very strong.

Movements of the clavicles and scapulae position the shoulder joints and provide a base for arm movement. The shoulder joints are positioned and stabilized by skeletal muscles that extend between the axial skeleton and the pectoral girdles. Once the joints are in position, other skeletal muscles, including several that originate on the pectoral girdle, move the upper limbs.

The surfaces of the scapulae and clavicles are extremely important as sites for muscle attachment. Bony ridges and projections mark the attachment sites of major muscles. Other bone markings, such as sulci or foramina, indicate the positions of nerves that control the muscles or the passage of blood vessels that nourish the muscles and bones.

The Clavicles

The **clavicles** are S-shaped bones that originate at the superior, lateral border of the manubrium of the sternum, lateral to the jugular notch (**Figure 8–2a**). From the pyramid-shaped **sternal end**, each clavicle curves laterally and posteriorly for about half its length. It then forms a smooth posterior curve to articulate with a process of the scapula, the *acromion* (a-KRŌ-mē-on). The flat, **acromial end** of the clavicle is broader than the sternal end (**Figure 8–2b,c**).

The smooth, superior surface of the clavicle lies just beneath the skin. The acromial end has a rough inferior surface that has prominent lines and tubercles (Figure 8–2c). These surface markings are attachment sites for muscles and ligaments of the shoulder. The combination of the direction of curvature and the differences between superior and inferior surfaces makes it easy to distinguish a left clavicle from a right clavicle.

You can explore the connection between your own clavicles and sternum. With your fingers in your jugular notch (the depression just superior to the manubrium), locate the clavicle on either side and find the *sternoclavicular joints* where the sternum articulates with the clavicles. These are the only articulations between the pectoral girdles and the axial skeleton. When you move your shoulders, you can feel the sternal ends of the clavicles change their positions.

The clavicles are small and fragile. It's no surprise that fractures of the clavicle are fairly common. For example, a simple fall can fracture a clavicle if you land on your hand with your arm outstretched. Fortunately, most clavicular fractures heal rapidly with a simple clavicle strap.

The Scapulae

The anterior surface of the **body** of each **scapula** forms a broad triangle (Figure 8–3a). The three sides of the triangle are the **superior border**; the **medial border**, or *vertebral border*; and the **lateral border**, or *axillary border* (*axilla*, armpit). Muscles that position the scapula attach along these edges. The corners of the triangle are called the *superior angle*, the *inferior angle*, and the *lateral angle*.

The lateral angle, or *head* of the scapula, forms a broad process that supports the cup-shaped **glenoid cavity** (Figure 8–3b). At the glenoid cavity, the scapula articulates with the *humerus*, the proximal bone of the upper limb. This articulation is the shoulder joint, also known as the *glenohumeral joint*. The anterior surface of the body of the scapula is smooth and concave. The depression in the anterior surface is called the **subscapular fossa**.

Two large scapular processes extend beyond the margin of the glenoid cavity (**Figure 8–3b**) superior to the head of the humerus. The smaller, anterior projection is the **coracoid** (KOR-uh-koyd) **process**. The **acromion** is the larger, posterior process. If you run your fingers along the superior surface of the shoulder joint, you will feel this process. The acromion articulates with the clavicle at the *acromioclavicular joint*. Both the coracoid process and the acromion are attached to ligaments and tendons associated with the shoulder joint.

Figure 8–2 The Right Clavicle. ATLAS: Plates 26a,b

8

The acromion is continuous with the **scapular spine**, a ridge that crosses the posterior surface of the scapular body before ending at the medial border (**Figure 8–3c**). The scapular spine divides the convex posterior surface of the body into two regions. The area superior to this spine is the **supraspinous fossa** (*supra*, above). The region inferior to the spine is the **infraspinous fossa** (*infra*, beneath). Small ridges and lines mark the entire posterior surface where smaller muscles attach to the scapula.

CHECKPOINT

- 1. Name the bones of the pectoral girdles.
- 2. How would a broken clavicle affect the mobility of the scapula?
- 3. Which bone articulates with the scapula at the glenoid cavity?

See the blue Answers tab at the back of the book.

8-2 The upper limbs are adapted for free movement

Learning Outcome Identify the bones of the upper limbs, their functions, and their superficial features.

The skeleton of the upper limbs consists of the bones of the arms, forearms, wrists, and hands. Note that in anatomical descriptions, the term *arm* refers only to the proximal portion of

the upper limb (from shoulder to elbow), not to the entire limb. The distal portion of the upper limb (from elbow to wrist) is the *forearm*. Let's examine the bones of the right upper limb.

The Humerus

The arm, or *brachium*, contains only one bone, the **humerus**, which extends from the scapula to the elbow. At the proximal end of the humerus, the round **head** articulates with the scapula (Figure 8–4a,b). The prominent **greater tubercle** is a rounded projection on the lateral surface of the epiphysis, near the margin of the humeral head. The greater tubercle establishes the lateral contour of the shoulder. You can verify its position by feeling for a bump located a few centimeters from the tip of the acromion. The **lesser tubercle** is a smaller projection that lies on the anterior, medial surface of the epiphysis, separated from the greater tubercle by the **intertubercular groove**, or *intertubercular sulcus*. A large tendon runs along the groove. Both tubercles are important sites for muscle attachment.

The **anatomical neck** lies between the tubercles and the articular surface of the head. This neck marks the extent of the joint capsule. The narrower distal **surgical neck** corresponds to the metaphysis of the growing bone. The name reflects the fact that fractures typically occur at this site.

The proximal shaft of the humerus is round in section. The **deltoid tuberosity** is a large, rough elevation on the lateral

surface of the shaft, approximately halfway along its length. It is named after the *deltoid muscle*, which attaches to it.

On the posterior surface, the deltoid tuberosity ends at the **radial groove** (Figure 8–4b). This depression marks the path of the *radial nerve*, a large nerve that provides both sensory information from the posterior surface of the limb and motor control over the large muscles that straighten the elbow. Distal to the radial groove, the posterior surface of the humerus is fairly flat.

Near the distal articulation with the bones of the forearm, the shaft expands to either side at the **medial** and **lateral epicondyles**. *Epicondyles* are processes that develop proximal to an articulation. They provide additional surface area for muscle attachment.

The *ulnar nerve* crosses the posterior surface of the medial epicondyle. A hit at the posteromedial surface of the elbow joint can strike this nerve and produce a temporary numbness and paralysis of muscles on the anterior surface of the forearm. Because of the odd sensation, this area is sometimes called the *funny bone*.

At the **condyle**, the humerus articulates with the *radius* and the *ulna*, the bones of the forearm. The condyle is divided into two articular regions: the trochlea and the capitulum (Figure 8–4a). The **trochlea** is the spool-shaped medial portion of the condyle. It extends from the base of the **coronoid fossa** on the anterior surface to the **olecranon** (ō-LEK-ruh-non) fossa on the posterior surface. The rounded **capitulum** forms the lateral surface of the condyle (Figure 8–4a,c).

A shallow **radial fossa** superior to the capitulum accommodates a portion of the radial head as the forearm approaches the humerus (Figure 8–4a,c). Projections from the ulnar surface fit into the coronoid fossa and the olecranon fossa as the elbow approaches the limits of its range of motion (Figure 8–4d). The prominent medial head and the differences between the lateral and medial condyles make it easy to tell a left humerus from a right humerus.

The Ulna

The *ulna* and *radius* are parallel bones that support the forearm, or *antebrachium*. In the anatomical position, the **ulna** lies medial to the radius. The **olecranon**, the superior end of the ulna, is the point of the elbow (Figures 8–4d and 8–5a). On the anterior surface of the proximal epiphysis, the **trochlear notch** of the ulna (Figure 8–5b) articulates with the trochlea of the humerus at the elbow joint. Figure 8–5c shows the trochlear notch of the ulna in a lateral view.

TIPS&TRICKS

The memory tool for olecranon involves the letter "*I*": The knob you feel at the e**I**bow is the o**I**ecranon of the u**I**na. You can remember that the trochlear notch is a feature of the **u**Ina because this notch forms a U in lateral view.

The olecranon forms the superior lip of the trochlear notch. The **coronoid process** forms its inferior lip. At the limit of *extension*, movement that straightens the forearm and arm, the olecranon swings into the olecranon fossa on the posterior surface of the humerus (Figure 8–4d). At the limit of *flexion*, a movement that decreases the angle between the articulating bones, the arm and forearm form a tight V, and the coronoid process projects into the coronoid process, a smooth **radial notch** accommodates the head of the radius at the *proximal radioulnar joint* (Figure 8–5a).

Viewed in cross section, the shaft of the ulna is triangular. The **interosseous membrane**, a fibrous sheet, connects the lateral margin of the ulna to the radius (Figure 8–5a,b). Near the wrist, the shaft of the ulna narrows before ending at a disc-shaped **ulnar head**, or *head of the ulna*. The posterior, lateral surface of the ulnar head has a short **styloid process** (*stylos*, pillar). A triangular cartilage, the *articular disc*, attaches to the styloid process. This cartilage separates the ulnar head articulates with the distal end of the radius to form the *distal radioulnar joint* (Figure 8–5b).

The Radius

The **radius** is the lateral bone of the forearm (Figure 8–5). The discshaped **radial head**, or *head of the radius*, articulates with the capitulum of the humerus (Figure 8–4c). During flexion, the radial head swings into the radial fossa of the humerus. A narrow neck extends from the radial head to the **radial tuberosity** (Figure 8–5b). This tuberosity marks the attachment site of the *biceps brachii muscle*, a large muscle on the anterior surface of the arm.

The shaft of the radius curves along its length. It also enlarges, and the distal portion of the radius is considerably larger than the distal portion of the ulna. The **ulnar notch** on the medial surface of the distal end of the radius marks the site of articulation with the head of the ulna (Figure 8–5a).

The distal end of the radius articulates with the bones of the wrist. The **styloid process** on the lateral surface of the radius helps stabilize this joint (Figure 8–5a,b). If you are looking at an isolated radius or ulna, you can quickly identify whether it is left or right by finding the radial notch (ulna) or ulnar notch (radius) and remembering that the radius lies lateral to the ulna.

The Carpal Bones

The *carpus*, or wrist, contains eight **carpal bones**. These bones form two rows, one with four **proximal carpal bones** and the other with four **distal carpal bones**.

The proximal carpal bones are the scaphoid, lunate, triquetrum, and pisiform (Figure 8–6a,b).

The scaphoid (*skaphe*, boat) is the proximal carpal bone on the lateral border of the wrist. It is the carpal bone closest to the styloid process of the radius.

Figure 8–5 The Right Radius and Ulna. ATLAS: Plates 31; 35f; 36a,b

- The comma-shaped **lunate** (luna, moon) lies medial to the scaphoid. Like the scaphoid, it articulates with the radius.
- The **triquetrum** (trī-KWĒ-trum; *triquetrus*, three-cornered) is a small, pyramid-shaped bone medial to the lunate. The triquetrum articulates with the articular disc that separates the ulnar head from the wrist.
- The small, pea-shaped **pisiform** (PIS-i-form; *pisum*, pea) sits anterior to the triquetrum.

The distal carpal bones are the trapezium, trapezoid, capitate, and hamate (Figure 8-6a,b).

- The **trapezium** (*trapezion*, four-sided with no parallel sides) is the lateral bone of the distal row. Its proximal surface articulates with the scaphoid.
- The wedge-shaped **trapezoid** lies medial to the trapezium. Like the trapezium, it has a proximal articulation with the scaphoid.

- The **capitate** (*caput*, head) is the largest carpal bone. It sits between the trapezoid and the hamate.
- The **hamate** (*hamatum*, hooked) is the medial distal carpal bone.

$\mathsf{TIPS} \mathcal{R} \mathsf{TRICKS}$

It may help you to identify the eight carpal bones if you remember the sentence "Sam Likes To Push The Toy Car Hard." In lateral-to-medial order, the first four words stand for the proximal carpal bones (scaphoid, lunate, triquetrum, pisiform). The last four stand for the distal carpal bones (trapezium, trapezoid, capitate, hamate).

The Metacarpal Bones and Phalanges

Five metacarpal (met-uh-KAR-pul; metacarpus, hand) bones articulate with the distal carpal bones and support the

Figure 8–6 Bones of the Right Wrist and Hand. ATLAS: Plates 38a,b

hand (Figure 8–6). Roman numerals I–V identify the metacarpal bones, beginning with the lateral metacarpal bone, which articulates with the trapezium. For example, metacarpal I articulates with the proximal bone of the thumb.

Distally, the metacarpal bones articulate with the proximal finger bones. Each hand has 14 finger bones, or **phalanges** (fa-LANjēz; singular, *phalanx*). The first finger, known as the **pollex** (POLeks), or thumb, has two phalanges (*proximal* and *distal*). Each of the other four fingers has three phalanges (*proximal*, *middle*, and *distal*).

Carpal Tunnel Syndrome The carpal bones articulate with one another at joints that permit limited sliding and twisting. Ligaments interconnect the carpal bones and help stabilize the wrist joint. The tendons of muscles that flex the fingers pass across the anterior surface of the wrist. These tendons are sandwiched between the intercarpal ligaments and a broad, superficial transverse ligament called the *flexor retinaculum*. Inflammation of the connective tissues between the flexor retinaculum and the carpal bones can compress the tendons and the adjacent *median nerve*. The result is pain, weakness, and reduced wrist mobility. This condition is called *carpal tunnel syndrome*.

CHECKPOINT

- 4. List all the bones of an upper limb.
- 5. The rounded projections on either side of the elbow are parts of which bone?
- 6. Using the terms *lateral* and *medial*, describe the relationship between the forearm bones when a person is in the anatomical position.
- 7. Bill accidentally fractures his first distal phalanx with a hammer. Which finger is broken?

See the blue Answers tab at the back of the book.

8-3 The pelvic girdle—two hip bones—attaches the lower limbs to the axial skeleton

Learning Outcome Identify the bones that form the pelvic girdle, their functions, and their superficial features.

The bones of the **pelvic girdle** attach to the lower limbs and must withstand the stresses involved in weight bearing and mobility. For this reason, they are more massive than the bones of the pectoral girdle. For similar reasons, the bones of the lower limbs are more massive than those of the upper limbs.

In this section we first consider the pelvic girdle, which consists of the two hip bones. Then we examine the *pelvis*, a composite structure that includes the hip bones of the appendicular skeleton plus the sacrum and coccyx of the axial skeleton. \bigcirc pp. 232–235

The Pelvic Girdle

The pelvic girdle consists of the paired **hip bones**, also called the **coxal bones** or **pelvic bones**. Each hip bone forms by the fusion of three bones: an **ilium** (IL- \bar{e} -um; plural, *ilia*), an **ischium** (IS- $k\bar{e}$ -um; plural, *ischia*), and a **pubis** (PU-bis) (Figure 8–7). The ilia have a sturdy articulation with the auricular surfaces of the sacrum, attaching the pelvic girdle to the axial skeleton. \bigcirc **p**. 233 Anteriorly, the medial surfaces of the hip bones are connected by a pad of fibrocartilage at a joint called the *pubic symphysis* (Figure 8–7b).

On the lateral surface of each hip bone is an **acetabulum** (as-e-TAB-ū-lum; *acetabulum*, shallow vinegar cup), a concave socket that articulates with the head of the femur (Figure 8–7a). A ridge of bone forms the lateral and superior margins of the acetabulum, which has a diameter of about 5 cm (2 in.). The anterior and inferior portion of the ridge is incomplete, leaving a gap called the **acetabular notch**. The smooth, cup-shaped articular surface of the acetabulum is the **lunate surface**.

The ilium, ischium, and pubis meet inside the acetabulum, as though it were a pie sliced into three pieces. Superior to the acetabulum, the ilium forms a broad, curved surface that provides an extensive area for the attachment of muscles, tendons, and ligaments (Figure 8–7a). Bone markings along the margin of the ilium include the *iliac spines*, which mark the attachment sites of important muscles and ligaments; the *gluteal lines*, which mark the attachment of large hip muscles; and the greater sciatic (sī-AT-ik) notch, through which a major nerve (the *sciatic nerve*) reaches the lower limb.

The ischium forms the posterior, inferior portion of the acetabulum. Posterior to the acetabulum, the prominent **ischial spine** projects superior to the *lesser sciatic notch*. Blood vessels, nerves, and a small muscle pass through this notch. The **ischial tuberosity**, a roughened projection, is located at the posterior and lateral edge of the ischium. When you are sitting, the ischial tuberosities bear your body's weight.

The narrow **ischial ramus** continues until it meets the **inferior ramus** of the pubis. The inferior pubic ramus extends between the ischial ramus and the *pubic tubercle*, a small, elevated area anterior and lateral to the pubic symphysis. There the inferior pubic ramus meets the **superior ramus** of the pubis, which originates near the acetabulum. The *pectineal line*, a ridge that ends at the pubic tubercle, is found on the anterior, superior surface of the superior ramus (Figure 8–7b). The pubic ramus and ischial ramus encircle the **obturator** (OB-tū-rā-tor) **foramen** (Figure 8–7a). This space is closed by a sheet of collagen fibers whose inner and outer surfaces provide a firm base for the attachment of muscles of the hip.

The broadest part of the ilium extends between the **arcuate line**, which is continuous with the pectineal line, and the **iliac crest** (Figure 8–7b). These prominent ridges mark the attachments of ligaments and muscles. The area between the arcuate line and the iliac crest forms a shallow depression known as the **iliac fossa**. The concave surface of the iliac fossa helps support the abdominal organs. It also provides additional area for muscle attachment.

In a medial view of a hip bone, the anterior and medial surface of the pubis has a roughened area that marks the site of articulation with the pubis of the opposite side (Figure 8–7b). At this articulation—the **pubic symphysis**—the two pubic bones are attached to a median pad of fibrocartilage.

Posteriorly, the **auricular surface** of the ilium articulates with the auricular surface of the sacrum at the *sacroiliac joint*. **p. 233** Ligaments arising at the **iliac tuberosity**, a roughened area superior to the auricular surface, stabilize this joint.

The Pelvis

Figure 8–8 shows anterior and posterior views of the **pelvis**, which consists of the two hip bones, the sacrum, and the coccyx. An extensive network of ligaments connects the lateral borders of the sacrum with the iliac crest, the ischial tuberosity, the ischial spine, and the arcuate line. Other ligaments tie the ilia to the posterior lumbar vertebrae. These interconnections increase the stability of the pelvis.

Figure 8–7 The Right Hip Bone. The left and right hip bones make up the pelvic girdle.

The pelvis may be divided into the **true** (*lesser*) **pelvis** and the **false** (*greater*) **pelvis** (**Figure 8–9a,b**). The true pelvis encloses the *pelvic cavity*, a subdivision of the abdominopelvic cavity. \supset p. 22 The superior limit of the true pelvis is a line that extends from either side of the base of the sacrum, along the arcuate line and pectineal line to the pubic symphysis. The bony edge of the true pelvis is called the **pelvic brim**, or *linea terminalis*. The enclosed space is the **pelvic inlet**. The false pelvis consists of the expanded, bladelike portions of each ilium superior to the pelvic brim.

The **pelvic outlet** is the opening bounded by the coccyx, the ischial tuberosities, and the inferior border of the pubic symphysis (**Figure 8–9b,c**). The surface region bordered by the inferior edges of the pelvis is called the *perineum* (per-i-NĒ-um). Perineal muscles form the floor of the pelvic cavity and support the organs in the true pelvis.

The shape of the pelvis of a female is somewhat different from that of a male. Some of the differences are the result of variations in body size and muscle mass. For example, in females, the pelvis is generally smoother and lighter and has less-prominent markings. Other female pelvic variations appear to be adaptations for childbearing. These adaptations help support the weight of the developing fetus within the uterus, and the passage of the newborn through the pelvic outlet during delivery. In addition, the hormone *relaxin*, produced during pregnancy, loosens the pubic symphysis and sacroiliac ligaments. This loosening allows movement between the hip bones that can further increase the size of the pelvic inlet and outlet. **Spotlight Figure 8–10** compares some major overall differences between adult male and female skeletons.

Figure 8–8 The Pelvis of an Adult Male. (See Figure 7–22, p. 234, for a detailed view of the sacrum and coccyx.)

SPOTLIGHT Figure 8–10 Sex Differences in the Human Skeleton

The sex of an adult human skeleton can be determined by many of the details seen in the bones. The skull and pelvis are particularly helpful. Not every skeleton shows every feature in classic detail, but this chart gives the basic differences between the sexes.

MALE	SKULL	FEMALE
Heavier, rougher	General Appearance	Lighter, smoother
About 10% larger	Cranium	About 10% smaller
More sloping	Forehead	More vertical
Larger	Sinuses	Smaller
Larger	Teeth	Smaller
Larger, more robust	Mandible	Smaller, less robust
	PELVIS	
Narrower, rougher, more robust	General appearance	Broader, smoother, less robust
More vertical; extends farther superior to sacroiliac joint	llium	Less vertical; less extension
Long, narrow triangle with pronounced sacral curvature	Sacrum	Broad, short triangle — with less sacral curvature
Deeper	lliac fossa	Shallower
Narrower, heart shaped	Pelvic inlet	Open, circular shaped
Narrow	Pelvic outlet	Enlarged
Points anteriorly	Соссух	Points inferiorly
Directed laterally	Acetabulum	Faces slightly anteriorly
Oval	Obturator foramen	Triangular
Under 90°	Pubic angle	100° or more
	OTHER	
Heavier	Bone weight	Lighter
More prominent	Bone markings	Less prominent

CHECKPOINT

- 8. Name the bones of the pelvic girdle.
- 9. Which three bones make up a hip bone?
- 10. How is the pelvis of females adapted for childbearing?
- 11. When you are seated, which part of the pelvis supports your body's weight?

• See the blue Answers tab at the back of the book.

8-4 The lower limbs are adapted for movement and support

Learning Outcome Identify the bones of the lower limbs, their functions, and their superficial features.

The skeleton of each lower limb consists of a *femur* (thigh), a *pa-tella* (kneecap), a *tibia* and a *fibula* (leg), and the tarsal bones, meta-tarsal bones, and phalanges of the foot. Once again, anatomical terminology differs from common usage. In anatomical terms, *leg* refers only to the distal portion of the limb, not to the entire lower limb. We will use *thigh* and *leg*, rather than *upper leg* and *lower leg*.

The functional anatomy of the lower limbs differs from that of the upper limbs, primarily because the lower limbs transfer the body weight to the ground. We now examine the bones of the right lower limb.

Hip Fracture A *hip fracture,* or a "broken hip," actually involves the femur, not a hip bone. The two types of hip fractures are femoral neck fractures and intertrochanteric fractures. In a femoral neck fracture, the femoral head is separated from the femur (and its blood supply). There is no disconnection to the blood supply in an intertrochanteric fracture. As a result, such fractures may be repaired with a metal plate and screws.

The Femur

The **femur** is the longest and heaviest bone in the body (Figure 8–11). It articulates with the hip bone at the hip joint and with the tibia of the leg at the knee joint. The rounded epiphysis, or **femoral head**, articulates with the pelvis at the acetabulum. A ligament attaches the acetabulum to the femur at the **fovea capitis**, a small pit in the center of the femoral head. The **neck** of the femur joins the **shaft** at an angle of about 125°.

The **greater** and **lesser trochanters** are large, rough projections that originate at the junction of the neck and shaft. The greater trochanter projects laterally. The lesser trochanter projects posteriorly and medially. These trochanters develop where large tendons attach to the femur. On the anterior surface of the femur, the raised intertrochanteric (in-ter-trō-kan-TER-ik) line marks the edge of the articular capsule. This line continues around to the posterior surface as the **intertrochanteric crest**.

The **linea aspera** is a rough ridge that runs along the center of the posterior surface of the femur, marking the attachment site of powerful hip muscles (Figure 8–11b). As it approaches the knee joint, the linea aspera divides into a pair of ridges that continue to the **medial** and **lateral epicondyles** (Figure 8–11a,b). These smoothly rounded projections form superior to the **medial** and **lateral condyles**, which are part of the knee joint. The two condyles are separated by a deep **intercondylar fossa**.

The medial and lateral condyles extend across the inferior surface of the femur, but the intercondylar fossa does not reach the anterior surface (Figure 8–11a). The anterior and inferior surfaces of the two condyles are separated by the **patellar surface**, a smooth articular surface over which the patella glides.

The Patella

The **patella** is a large sesamoid bone that forms within the tendon of the *quadriceps femoris*, a group of muscles that extend (straighten) the knee. The patella has a rough, convex anterior surface and a broad **base** (Figure 8–12a). The roughened surface reflects the attachment of the quadriceps tendon (anterior and superior surfaces) and the *patellar ligament* (anterior and inferior surfaces). The patellar ligament connects the **apex** of the patella to the tibia.

The posterior patellar surface (Figure 8–12b) has two concave facets for articulation with the medial and lateral condyles of the femur (Figure 8–12c). The patellae are cartilaginous at birth. They start to ossify after the person begins walking, as thigh and leg movements become more powerful. Ossification usually begins at age 2 or 3 and ends around the time of puberty.

Normally, the patella glides across the patellar surface of the femur. Its direction of movement is superior–inferior (up and down), not medial–lateral (side to side).

Clinical Note

Runner's Knee *Runner's knee*, or *patellofemoral stress syndrome*, develops from improper tracking of the patella across the patellar surface. In this syndrome, the patella is forced outside its normal track, so that it shifts laterally. The movement is often associated with increased compression forces or with lateral muscles in the quadriceps group overpowering the medial muscles. Running on hard or slanted surfaces (such as the beach shore or the shoulder of a road) and inadequate arch support are often responsible. The misalignment puts lateral pressure on the knee, resulting in swelling and tenderness after exercise.

The Tibia

The **tibia** (TIB-ē-uh), or shinbone, is the large medial bone of the leg (**Figure 8–13a**). The medial and lateral condyles of the femur articulate with the **medial** and **lateral tibial condyles** at the proximal end of the tibia. The **intercondylar eminence** is a ridge that separates the condyles (**Figure 8–13b**). The anterior surface of the tibia near the condyles has a prominent, rough **tibial tuberosity**, which you can feel through the skin. This tuberosity marks the attachment of the patellar ligament.

8

The **anterior margin** is a ridge that begins at the tibial tuberosity and extends distally along the anterior tibial surface. You can also easily feel the anterior margin of the tibia through the skin. As it nears the ankle joint, the tibia broadens, and the medial border ends in the **medial malleolus** (ma-LĒō-lus; *malleolus*, hammer), a large process familiar to you as the medial bump at the ankle. The inferior surface of the tibia articulates with the proximal bone of the ankle. The medial malleolus supports this joint medially.

The Fibula

The slender **fibula** (FIB-ū-luh) parallels the lateral border of the tibia (**Figure 8–13a,b**). The head of the fibula articulates with the tibia. The articular facet is located on the anterior, inferior surface of the lateral tibial condyle. The medial border of the thin shaft is bound to the tibia by the **interosseous membrane**, which extends to the lateral margin of the tibia. This membrane helps stabilize the positions of the two bones. It also provides additional surface area for muscle attachment. A cross section of the tibia and fibula is shown in **Figure 8–13c**.

As its small diameter suggests, the fibula does not help transfer weight to the ankle and foot. In fact, it does not even articulate with the femur. However, the fibula is an important site for the attachment of muscles that move the foot and toes. In addition, the distal tip of the fibula extends lateral to the ankle joint. This fibular process, the **lateral malleolus**, gives lateral stability to the ankle. However, forceful movement of the foot

Figure 8–13 The Right Tibia and Fibula. ATLAS: Plates 32; 80a,b; 83a,b

TIPS&TRICKS

To remember how to distinguish the fibula from the tibia, consider the "fib" and "I" parts of the word *fibula*. To tell a small **l**ie is to **fib.** The **fib**ula is smaller than the tibia, and is **l**ateral to it.

The Tarsal Bones

The ankle, or *tarsus*, consists of seven **tarsal bones** (Figure 8–14). The large **talus** transmits the weight of the body from the tibia toward the toes. The articulation between the talus and the tibia occurs across the superior and medial surfaces of the **trochlea**, a spool- or pulley-shaped articular process. The lateral surface of the trochlea articulates with the lateral malleolus of the fibula.

TIPS&TRICKS

To remember where the talus is located, think that the **t**alus is on **t**op of the foot and articulates with the **t**ibia.

The **calcaneus** (kal-KĀ-nē-us), or heel bone, is the largest of the tarsal bones. When you stand normally, most of your weight is transmitted from the tibia, to the talus, to the calcaneus, and then to the ground. The posterior portion of the calcaneus is a rough, knob-shaped projection. This is the attachment site for the *calcaneal tendon* (*Achilles tendon*), which arises at the calf muscles. If you are standing, these strong muscles can lift the heel off the ground so that you stand on tiptoes. The superior and anterior surfaces of the calcaneus have smooth facets for articulation with other tarsal bones.

The **cuboid** articulates with the anterior surface of the calcaneus. The **navicular** is anterior to the talus, on the medial side of the ankle. It articulates with the talus and with the three *cuneiform* (kū-NĒ-i-form) *bones*. These are wedge-shaped bones arranged in a row, with articulations between them. They are named according to their position: **medial cuneiform**, **intermediate cuneiform**, and **lateral cuneiform**. Proximally, the cuneiform bones articulate with the anterior surface of the navicular. The lateral cuneiform also articulates with the medial surface of the cuboid. The distal surfaces of the cuboid and the cuneiform bones articulate with the metatarsal bones of the foot.

Figure 8–14 Bones of the Ankle and Foot. ATLAS: Plates 32; 85a; 86a,c; 87a–c; 88

TIPS & TRICKS

To remember the names of the tarsal bones in the order presented in this text, try the memory aid "Tom Can Control Not Much In Life."

The Metatarsal Bones and Phalanges

The **metatarsal bones** are five long bones that form the distal portion of the foot, or *metatarsus* (Figure 8–14). The metatarsal bones are identified by Roman numerals I–V, proceeding from medial to lateral across the sole. Proximally, metatarsal bones I–III articulate with the three cuneiform bones, and metatarsal bones IV and V articulate with the cuboid. Distally, each metatarsal bone articulates with a different proximal phalanx.

The **phalanges**, or toe bones (Figure 8–14), have the same anatomical organization as the fingers. The toes contain 14 phalanges. The **hallux**, or great toe, has two phalanges (*proximal* and *distal*). The other four toes have three phalanges apiece (*proximal*, *middle*, and *distal*).

Stress Fractures Running is beneficial to overall health but places the foot bones under more stress than does walking. *Stress fractures* are hairline fractures that develop in bones subjected to repeated shocks or impacts. Stress fractures of the foot usually involve one of the metatarsal bones. These fractures are caused either by improper placement of the foot while running or by poor arch support. In a fitness regime that includes street running, proper support for the bones of the foot is essential. An entire running-shoe market has arisen around the amateur and professional runner's need for good arch support.

Arches of the Foot

Weight transfer occurs along the **longitudinal arch** of the foot (Figure 8–14c). Ligaments and tendons maintain this arch by tying the calcaneus to the distal portions of the metatarsal bones. However, the lateral, or *calcaneal*, portion of the longitudinal arch has much less curvature than the medial, *talar* portion. Part of the reason is that the talar portion has more elasticity. As a result, the medial plantar surface of the foot remains elevated, so that the muscles, nerves, and blood vessels that supply the inferior surface are not squeezed between the metatarsal bones and the ground. In the condition known as *flatfeet*, normal arches are lost ("fall") or never form.

The elasticity of the talar portion of the longitudinal arch absorbs the shocks from sudden changes in weight loading. For example, the stresses that running or ballet dancing places on the toes are cushioned by the elasticity of this portion of the

Clinical Note

Congenital Talipes

Equinovarus The arches of the foot are usually present at birth. Sometimes, however, they fail to develop properly. In **congenital talipes equinovarus** (clubfoot), abnormal

muscle development distorts growing bones and joints. One or both feet may be involved. The condition can be mild, moderate, or severe. In most cases, the tibia, ankle, and foot are affected. The longitudinal arch is exaggerated, and the feet are turned medially and inverted. If both feet are involved, the soles face one another. This condition affects 1 in 1000 births and is twice as common in boys as girls. Prompt treatment with casts or other supports in infancy helps alleviate the problem. Fewer than half the cases require surgery.

arch. The **transverse arch** describes the degree of curvature change from the medial to the lateral borders of the foot.

When you stand normally, your body weight is distributed evenly between the calcaneus and the distal ends of the metatarsal bones. The amount of weight transferred forward depends on the position of the foot and the placement of your body weight. During *flexion* at the ankle, a movement also called *dorsiflexion*, all your body weight rests on the calcaneus—as when you "dig in your heels." During *extension* at the ankle, also known as *plantar flexion*, when you stand on tiptoe, the talus and calcaneus transfer your weight to the metatarsal bones and phalanges through the more anterior tarsal bones.

CHECKPOINT

- 12. Identify the bones of the lower limb.
- 13. The fibula neither participates in the knee joint nor bears weight. When it is fractured, however, walking becomes difficult. Why?
- 14. While jumping off the back steps at his house, 10-yearold Joey lands on his right heel and breaks his foot. Which foot bone is most likely broken?
- **15**. Which foot bone transmits the weight of the body from the tibia toward the toes?
- See the blue Answers tab at the back of the book.

8–5 Sex differences and age account for individual skeletal variation

Learning Outcome Summarize sex differences and age-related changes in the human skeleton.

A comprehensive study of a human skeleton can reveal important information about an individual. We can estimate

Table 8–1	Age-Related Changes in the Skeleton			
Region and Feature		Events	Age in Years	
GENERAL SKELET	ON			
Bony matrix		Reduction in mineral content; increased risk of osteoporosis	Begins at age 30–45; values differ for males versus females between ages 45 and 65; similar reductions occur in both sexes after age 65	
Bone markings		Reduction in size, roughness	Gradual reduction with increasing age and decreasing muscular strength and mass	
SKULL				
Fontanelles		Closure	Completed by age 2	
Frontal suture		Fusion	2-8	
Occipital bone		Fusion of ossification centers	1–4	
Styloid process		Fusion with temporal bone	12–16	
Hyoid bone		Complete ossification and fusion	25–30	
Teeth		Loss of "baby teeth"; appearance of secondary dentition; eruption of permanent molars	Detailed in Chapter 24 (digestive system)	
Mandible		Loss of teeth; reduction in bone mass; change in angle at mandibular notch	Accelerates in later years (60+)	
VERTEBRAE				
Curvature		Development of major curves	3 months-10 years

a person's muscular development and muscle mass from the appearance of various ridges and from the general bone mass. Details such as the condition of the teeth or the presence of healed fractures give an indication of the individual's medical history. Two important facts, sex and age, can be determined or closely estimated on the basis of measurements indicated in **Spotlight Figure 8–10** and **Table 8–1**. In some cases, the skeleton may provide clues about the individual's nutritional state, handedness, and even occupation. **ATLAS: Embryology Summary 8: The Development of the Appendicular Skeleton**

Spotlight Figure 8–10 (p. 253) identifies characteristic differences between the skeletons of males and females. However, not every skeleton shows every feature in classic detail. Many differences, including markings on the skull, cranial capacity, and general skeletal features, reflect differences in average body size, muscle mass, and muscular strength.

The general changes in the skeletal system that take place with age are summarized in Table 8–1. Note that these changes

begin at age 3 months and continue throughout life. The epiphyseal cartilages, for example, begin to fuse at about age 3. Degenerative changes in the normal skeletal system, such as a reduction in mineral content in the bony matrix, typically do not begin until age 30–45. The timing of epiphyseal closure is a key factor determining adult body size. Young people whose long bones are still growing should avoid heavy weight training, because they risk crushing the epiphyseal cartilages and thus shortening their stature (Spotlight Figure 6–11, p. 191).

CHECKPOINT

- Compare and contrast the bones of males and females with respect to weight and bone markings.
- 17. An anthropologist discovered several bones in a deep grave. After close visual inspection and careful measurements, what sort of information could the bones reveal?

- See the blue Answers tab at the back of the book.
Related Clinical Terms

bone graft: A surgical procedure that transplants bone tissue to repair and rebuild diseased or damaged bone.

pelvimetry: Measurement of the dimensions of the female pelvis.

genu valgum: Deformity in which the knees angle medially and touch one another while standing; commonly called knock-knee.

An Introduction to the Appendicular Skeleton p. 242

- 1. The **appendicular skeleton** includes the bones of the upper and lower limbs and the pectoral and pelvic girdles, which connect the limbs to the trunk. (*Figure 8–1*)
- 8-1 The pectoral girdles—the clavicles and scapulae attach the upper limbs to the axial skeleton p. 242
- 2. Each upper limb articulates with the trunk through a **pectoral girdle**, or *shoulder girdle*, which consists of a **scapula** and a **clavicle**.
- 3. On each side, a clavicle and scapula position the shoulder joint, help move the upper limb, and provide a base for muscle attachment. (*Figures* 8–2, 8–3)
- 4. Both the **coracoid process** and the **acromion** of the scapula have attached ligaments and tendons associated with the shoulder joint. (*Figure 8–3*)

8-2 The upper limbs are adapted for free movement p. 245

- 5. The scapula articulates with the **humerus** at the shoulder (*glenohumeral*) joint. The **greater** and **lesser tubercles** of the humerus are important sites of muscle attachment. (*Figure 8–4*)
- 6. The humerus articulates with the **radius** and **ulna**, the bones of the forearm, at the elbow joint. (*Figure 8–5*)
- 7. The **carpal bones** of the wrist, or *carpus*, form two rows. The distal row articulates with the five **metacarpal bones**. Four of the fingers contain three **phalanges**; the **pollex** (thumb) has only two phalanges. (*Figure 8–6*)

- 8-3 The pelvic girdle—two hip bones—attaches the lower limbs to the axial skeleton p. 250
- 8. The bones of the **pelvic girdle** are more massive than those of the pectoral girdle because of their role in weight bearing and locomotion.
- 9. The pelvic girdle consists of two hip bones, or coxal bones. Each hip bone forms through the fusion of an ilium, an ischium, and a pubis. (*Figure 8–7*)
- 10. The ilium is the largest component of the hip bone. Inside the acetabulum, the ilium is fused to the ischium (posteriorly) and the pubis (anteriorly). The *pubic symphysis* limits movement between the pubic bones of the left and right hip bones. (*Figures 8–7, 8–8*)
- 11. The **pelvis** consists of the hip bones, the sacrum, and the coccyx. It is subdivided into the **false** (*greater*) **pelvis** and the **true** (*lesser*) **pelvis**. (*Figures* 8–8, 8–9, Spotlight Figure 8–10)
- 8-4 The lower limbs are adapted for movement and support p. 254
- **12.** The **femur** is the longest and heaviest bone in the body. It articulates with the **tibia** at the knee joint. (*Figures 8–11, 8–13*)
- 13. The patella is a large sesamoid bone. (Figure 8-12)
- 14. The fibula parallels the tibia laterally. (Figure 8–13)
- 15. The tarsus, or ankle, has seven tarsal bones. (Figure 8-14)
- **16.** The basic organizational pattern of the **metatarsal bones** and **phalanges** of the foot resembles that of the hand. All the toes have three phalanges, except for the **hallux** (great toe), which has two. (*Figure 8–14*)
- 17. When a person stands normally, most of the body weight is transferred to the **calcaneus**, and the rest is passed on to the five metatarsal bones. Weight transfer occurs along the **longitudinal arch**. There is also a **transverse arch**. (*Figure 8–14*)

8-5 Sex differences and age account for individual skeletal variation p. 258

- **18.** Studying a human skeleton can reveal important information, such as the person's weight, sex, body size, muscle mass, and age. (*Spotlight Figure 8–10, Table 8–1*)
- **19.** Age-related changes take place in the skeletal system. These changes begin at about age 1 and continue throughout life. *(Table 8–1)*

See the blue Answers tab at the back of the book.

Review Questions

LEVEL 1 Reviewing Facts and Terms

 In the following photographs of the scapula, identify the three views (a-c) and the indicated bone markings (d-g).

- (g) ______
 2. Which of the following is primarily responsible for stabilizing, positioning, and bracing the pectoral girdles? (a) tendons, (b) ligaments, (c) the joint shape, (d) muscles, (e) the shape of the bones within the joint.
- 3. In the following drawing of the pelvis, label the structures indicated.

(c) _____ (d) _____ (e) _____ (f) ____

(a)

- 4. In anatomical position, the ulna lies (a) medial to the radius,
 (b) lateral to the radius, (c) inferior to the radius,
 (d) superior to the radius.
- The point of the elbow is actually the _____ of the ulna. (a) styloid process, (b) olecranon, (c) coronoid process, (d) trochlear notch.
- The bones of the hand articulate distally with the (a) carpal bones,
 (b) ulna and radius, (c) metacarpal bones, (d) phalanges.
- The epiphysis of the femur articulates with the pelvis at the

 (a) pubic symphysis,
 (b) acetabulum,
 (c) sciatic notch,
 (d) obturator foramen.
- 8. What is the name of the flexible sheet that interconnects the radius and ulna (and the tibia and fibula)?
- 9. Name the components of each hip bone.
- 10. Which seven bones make up the ankle (tarsus)?

LEVEL 2 Reviewing Concepts

- 11. The presence of tubercles on bones indicates the positions of(a) tendons and ligaments, (b) muscle attachment,(c) ridges and flanges, (d) a and b.
- **12.** At the glenoid cavity, the scapula articulates with the proximal end of the **(a)** humerus, **(b)** radius, **(c)** ulna, **(d)** femur.
- 13. All of the following are structural characteristics of the female pelvic girdle compared to the male pelvic girdle with either one or two exceptions. Identify the exception(s). (a) The female pelvis is adapted for childbearing, (b) The female pelvic girdle is generally lighter than the male pelvic girdle, (c) Relaxin produced by the male pelvic girdle loosens the pubic symphysis and sacroiliac joints, (d) The shape of the female pelvic girdle is the same as that of the male, (e) Answers c and d are exceptions.
- 14. The large foramen between the pubic ramus and ischial ramus is the(a) foramen magnum, (b) suborbital foramen, (c) acetabulum,(d) obturator foramen.
- 15. Which of the following skeletal characteristics is an adaption for childbearing? (a) inferior angle of 100° or more between the pubic bones, (b) a relatively broad, low pelvis, (c) less curvature of the sacrum and coccyx, (d) All of these are correct.
- 16. The fibula (a) forms an important part of the knee joint, (b) articulates with the femur, (c) helps to bear the weight of the body, (d) provides lateral stability to the ankle, (e) does (a) and (b).
- 17. The tarsal bone that accepts weight and distributes it to the heel or toes is the (a) cuneiform, (b) calcaneus, (c) talus, (d) navicular.
- **18.** What is the difference in skeletal structure between the pelvic girdle and the pelvis?
- Jack injures himself playing hockey, and the physician who examines him informs him that he has dislocated his pollex. What part of Jack's body did he injure? (a) his arm, (b) his leg, (c) his hip, (d) his thumb, (e) his shoulder.
- **20.** Why would a self-defense instructor advise a student to strike an assailant's clavicle?
- 21. The pelvis (a) protects the upper abdominal organs, (b) contains bones from both the axial and appendicular skeletons, (c) is composed of the coxal bones, sacrum, and coccyx, (d) does all of these, (e) does (b) and (c).
- **22.** Why is the tibia, but not the fibula, involved in the transfer of weight to the ankle and foot?
- 23. In determining the age of a skeleton, all of the following pieces of information would be helpful *except* (a) the number of cranial sutures, (b) the size and roughness of the markings of the bones, (c) the presence or absence of fontanelles, (d) the presence or absence of epiphyseal cartilages, (e) the types of minerals deposited in the bones.

LEVEL 3 Critical Thinking and Clinical Applications

- **24.** Why would a person suffering from osteoporosis be more likely to suffer a hip fracture than a broken shoulder?
- **25.** While Fred, a fireman, is fighting a fire in a building, part of the ceiling collapses, and a beam strikes him on his left shoulder. He is rescued, but has a great deal of pain in his shoulder. He cannot move his arm properly, especially in the anterior direction. His clavicle is not broken, and his humerus is intact. What is the probable nature of Fred's injury?
- **26.** Archaeologists find the pelvis of a primitive human and are able to identify the sex, the relative age, and some physical characteristics of the individual. How is this possible from only the pelvis?

CLINICAL CASE

The Orthopedic Surgeon's Nightmare

When Caitlyn arrives at the emergency room, she has no pulse distal to the injury in her arm. Many of the critical nerves and blood vessels to the forearm and hand run anterior to the humerus through the elbow. These structures have been impaled by the sharp fractured edge of the humeral shaft. This is a true surgical emergency.

Of all the orthopedic injuries a child can sustain in a "fall on the out stretched hand" (known as a FOOSH injury), a supracondylar distal humerus fracture is the most difficult to reduce (restore to anatomical position) and maintain in a reduced position during healing.

Just proximal to the humeral condyle (the trochlea and capitulum), at the site of the olecranon fossa posteriorly and the radial fossa anteriorly, the humerus is extremely thin. As the elbow extends, the olecranon is wedged into the olecranon fossa. With the force of the falling child's weight, the distal humerus can fracture through this thin bone.

Wrap-Up

Trying to reduce this fracture in an extremely swollen injured elbow is like trying to perch one razor blade

on top of another inside a watermelon. And the reduction is about as stable.

Caitlyn is taken to an operating room where the surgeon performs a closed reduction with the help of x-ray. Her pulse immediately returns. The fracture is held with pins and a long arm posterior splint is applied.

- 1. What skeletal structures are still attached to the distal humeral fracture fragment?
- 2. Why would the surgeon want to avoid a circular cast in the immediate post-fracture period and apply a posterior splint instead?

See the blue Answers tab at the back of the book.

Joints

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 9-1
 Contrast the major categories of joints, and explain the relationship between structure and function for each category.
- 9-2 Describe the basic structure of a synovial joint, and describe common synovial joint accessory structures and their functions.
- 9-3 Describe how the anatomical and functional properties of synovial joints permit movements of the skeleton.
- **9-4** Describe the joints between the vertebrae of the vertebral column.
- 9-5 Describe the structure and function of the shoulder joint and the elbow joint.
- **9-6** Describe the structure and function of the hip joint and the knee joint.
- 9-7 Describe the effects of aging on joints, and discuss the most common age-related clinical problems for joints.
- **9-8** Explain the functional relationships between the skeletal system and other body systems.

SPOTLIGHT

• Joint Movement pp. 270–271

CLINICAL CASE

• What's Ailing the Birthday Girl? p. 264

Clinical Notes

- Bursitis and Bunions p. 268
- Dislocation and Subluxation p. 268
- Damage to Intervertebral Discs p. 275
- Knee Injuries p. 283

What's Ailing the Birthday Girl?

Jessica just woke up from her nap at daycare. Earlier this morning the class celebrated her fourth birth-

day with cupcakes and singing. Now she feels like crying when she tries to roll over. She can't seem to get moving out of her little cot.

"Come on, Jessie, let's play tag," says her best friend. When Jessica finally gets to a sitting position on the side of the cot, she doesn't feel like taking a single step. When she stands, she feels slow and clumsy. She certainly cannot run after her classmates. She sits for a while at the coloring table. When she tries to reach across the table for crayons, she winces and withdraws her hand. Her teacher notices Jessica's lethargy and offers her a glass of juice. Even her favorite juice does not taste good to her.

When Jessica's mother comes to pick her up from daycare, the teacher pulls her aside for a quick conference. "Jessica has not been participating in any play activities

this whole week," reports the teacher. "Even today, on her birthday, she refused to play tag. She takes a really long time getting up from the floor after story circle. And she has been limping after naptime. I wonder what's going on?" What's ailing Jessica? To find out, turn to the Clinical Case Wrap-Up on p. 288.

An Introduction to Joints

In this chapter we consider the ways bones interact wherever they interconnect. In the last two chapters, you learned the individual bones of the skeleton. These bones provide strength, support, and protection for softer tissues of the body. However, your daily life demands more of the skeleton—it must also facilitate and adapt to body movements. Think of your activities in a typical day: You breathe, talk, walk, sit, stand, and change positions countless times. In each case, your skeleton is directly involved. Movements can occur only at **joints**, or **articulations**, where two bones meet, because the bones of the skeleton are fairly inflexible. The characteristic structure of a joint determines the type and amount of movement that may take place. Each joint reflects a compromise between the need for strength and the need for mobility.

In this chapter we compare the relationships between articular form and function. We consider several examples that range from relatively immobile but very strong joints (the intervertebral joints) to a highly mobile but relatively weak joint (the shoulder).

9-1 ■ Joints are categorized according to their range of motion or structure

Learning Outcome Contrast the major categories of joints, and explain the relationship between structure and function for each category.

We use two classification methods to categorize joints. The first is the one we will use in this chapter. It is a functional scheme because it is based on the amount of movement possible, a property known as the *range of motion* (ROM). Each functional group is further subdivided primarily on the basis of the anatomical structure of the joint (Table 9–1):

- An *immovable joint* is a **synarthrosis** (sin-ar-THRŌ-sis; *syn*, together + *arthros*, joint). A synarthrosis can be *fibrous* or *cartilaginous*, depending on the nature of the connection. Over time, the two bones may fuse.
- 2. A *slightly movable joint* is an **amphiarthrosis** (am-fē-ar-THRŌ-sis; *amphi*, on both sides). An amphiarthrosis is either *fibrous* or *cartilaginous*, depending on the nature of the connection between the opposing bones.
- A freely movable joint is a diarthrosis (dī-ar-THRŌ-sis; dia, through), or synovial joint. Diarthroses are subdivided according to the movement permitted.

The second classification scheme relies solely on the anatomy of the joint, without regard to the degree of movement permitted. Using this framework, we classify joints as *fibrous, cartilaginous, bony,* or *synovial*. Bony joints form when fibrous or cartilaginous joints ossify. The ossification may be normal or abnormal, and may occur at various times in life.

The two classification schemes are loosely correlated. We see many anatomical patterns among immovable or slightly movable joints, but there is only one type of freely movable joint—synovial joints. All synovial joints are diarthroses. We will use the functional classification rather than the anatomical one because our primary interest is how joints work.

Table 9–1 Functional and Structural Classifications of Joints					
Functional Category	Structural C	Category and Type	Description		
SYNARTHROSIS (no movement)					
At a synarthrosis, the bony edges are quite close together and may even interlock. These extremely strong joints are located where movement between the bones must be prevented.	Sutu	ire Contraction of the second s	A suture (<i>sutura</i> , a sewing together) is a synarthrotic joint located only between the bones of the skull. The edges of the bones are interlocked and bound together at the suture by dense fibrous connective tissue.		
	Gom	nphosis	A gomphosis (gom-FŌ-sis; <i>gomphos</i> , bolt) is a synarthrosis that binds the teeth to bony sockets in the maxillae and mandible. The fibrous connection between a tooth and its socket is a <i>periodontal</i> (per-ē-ō-DON- tal) <i>ligament</i> (<i>peri</i> , around + <i>odontos</i> , tooth).		
	Sync	chondrosis	A synchondrosis (sin-kon-DRŌ-sis; <i>syn</i> , together+ <i>chondros</i> , cartilage) is a rigid, cartilaginous bridge between two articulating bones. The cartilaginous connection between the ends of the first pair of vertebrosternal ribs and manubrium of the sternum is a synchondrosis. Another example is the epiphyseal cartilage, which connects the diaphysis to the epiphysis in a growing long bone.		
	Syno	ostosis	A synostosis (sin-os-TŌ-sis) is a totally rigid, immovable joint created when two bones fuse and the boundary between them disappears. The frontal (metopic) suture of the frontal bone, the fusion of an infant's left and right mandibular bones, and the epiphyseal lines of mature long bones are synostoses.		
AMPHIARTHROSIS (little movement)					
An amphiarthrosis permits more movement than a synarthrosis, but is much stronger than a freely movable joint. The articulating bones are connected by collagen fibers or cartilage.	Synd	desmosis	At a syndesmosis (sin-dez-MŌ-sis; <i>syndesmos</i> , ligament), bones are connected by a ligament. One example is the distal joint between the tibia and fibula.		
	Sym	physis	At a symphysis , the articulating bones are connected by a wedge or pad of fibrocartilage. The joint between the two pubic bones (the <i>pubic</i> <i>symphysis</i>) is an example of a symphysis.		
DIARTHROSIS (free movement)					
 Planes of Movement Monoaxial - movement in one plane; elbow, ankle Biaxial - movement in two planes; ribs and wrist Triaxial - movement in three planes; shoulder, hip 	SYNOVIAL		Synovial (si-NŌ-ve-ul) joints permit a wider range of motion than do other types of joints. They are typically located at the ends of long bones, such as those of the upper and lower limbs.		

CHECKPOINT

- 1. Name and describe the three types of joints as classified by their range of motion.
- 2. What characteristics do typical synarthrotic and amphiarthrotic joints share?
- 3. In a newborn, the large bones of the skull are joined by fibrous connective tissue. The bones later grow, interlock, and form immovable joints. Structurally, which type of joints are these?

See the blue Answers tab at the back of the book.

9-2 Synovial joints are freely movable joints containing synovial fluid

Learning Outcome Describe the basic structure of a synovial joint, and describe common synovial joint accessory structures and their functions.

Synovial joints are freely movable and classified as diarthroses. A two-layered **joint capsule**, also called an **articular capsule**, surrounds the synovial joint (**Figure 9–1**). The joint capsule contains an inner *synovial membrane* and an outer *fibrous capsule*. This membrane does not cover the articulating surfaces within the joint. Recall that a synovial membrane consists of areolar tissue covered by an incomplete epithelial layer. The synovial fluid that fills the joint cavity originates in the areolar tissue of

the synovial membrane. \bigcirc p. 139 Now let's consider the major features of synovial joints.

Articular Cartilage

Under normal conditions, the bony surfaces at a synovial joint cannot contact one another, because special **articular cartilage** covers the articulating surfaces. Articular cartilage resembles hyaline cartilage elsewhere in the body. ⊃ p. 134 However, articular cartilage has no perichondrium (the fibrous sheath described in Chapter 4), and the matrix contains more water than that of other cartilage.

The surface of articular cartilage is slick and smooth. This feature alone can reduce friction during movement at the joint. However, even when pressure is applied across a joint, the smooth articular cartilages do not touch one another because a thin film of synovial fluid within the joint cavity separates them (Figure 9–1a). This fluid acts as a lubricant, minimizing friction.

Synovial joints cannot function normally if the articular cartilages are damaged. When such damage occurs, the matrix may begin to break down. The exposed surface will then change from a slick, smooth-gliding surface to a rough abrasive surface of bristly collagen fibers. This abrasive surface drastically increases friction at the joint.

Figure 9–1 The Structure of a Synovial Joint.

a Synovial joint, sagittal section

Synovial Fluid

What is synovial fluid? It is a clear, viscous solution with the consistency of egg yolk or heavy molasses. **Synovial fluid** resembles interstitial fluid, but contains proteoglycans with a high concentration of hyaluronan (hyaluronic acid) secreted by fibroblasts of the synovial membrane. \bigcirc **p.** 139 Even in a large joint such as the knee, the total quantity of synovial fluid in a joint is small—normally less than 3 mL. The synovial fluid within a joint has three primary functions:

- 1. *Lubrication*. Articular cartilages act like sponges filled with synovial fluid. When part of an articular cartilage is compressed, some of the synovial fluid is squeezed out of the cartilage and into the space between the opposing surfaces. This thin layer of fluid greatly reduces friction between moving surfaces, just as a thin film of water makes a highway slick by reducing friction between a car's tires and the road. When the compression stops, synovial fluid is pulled back into the articular cartilage.
- 2. Nutrient Distribution. The synovial fluid in a joint must circulate continuously to provide nutrients and a waste disposal route for the chondrocytes of the avascular articular cartilage. It circulates whenever the joint moves. The compression and re-expansion of the articular cartilage pumps synovial fluid into and out of the cartilage matrix. As the synovial fluid flows through the areolar tissue of the synovial membrane, waste products are absorbed and additional nutrients are delivered by diffusion across capillary walls.
- 3. *Shock Absorption.* Synovial fluid cushions joints that are subjected to compression from shocks and sudden impacts. This occurs because the viscosity of synovial fluid increases with increased pressure. For example, your hip, knee, and ankle joints are compressed as you walk. They are even more severely compressed when you jog or run. When the pressure across a joint suddenly increases, the resulting shock is lessened as the viscosity of synovial fluid increases. As the pressure lessens, viscosity decreases and it regains its lubricating function across the articular surfaces.

Accessory Structures

Synovial joints may have a variety of accessory structures, including pads of cartilage or fat, ligaments, tendons, and bursae (Figure 9–1b).

Cartilages and Fat Pads

In several joints, including the knee (Figure 9–1b), menisci and fat pads may lie between the opposing articular surfaces. A **meniscus** (me-NIS-kus; a crescent; plural, *menisci*), also called an *articular disc*, is a pad of fibrocartilage located between opposing bones within a synovial joint. Menisci may subdivide a synovial cavity, channel the flow of synovial fluid, or allow for variations in the shapes of the articular surfaces.

Fat pads are localized masses of adipose tissue covered by a layer of synovial membrane. They are commonly superficial to the joint capsule (Figure 9–1b). Fat pads protect the articular cartilages and act as packing material for the joint. When the bones move, the fat pads fill in the spaces created as the joint cavity changes shape.

Ligaments

The capsule that surrounds the entire joint is continuous with the periostea of the articulating bones. **Accessory ligaments** support, strengthen, and reinforce synovial joints. *Capsular ligaments*, or *intrinsic ligaments*, are localized thickenings of the joint capsule. *Extrinsic ligaments* are separate from the joint capsule. These ligaments may be located either inside or outside the joint capsule, and are called *intracapsular* or *extracapsular* ligaments, respectively.

Ligaments are very strong. In a **sprain**, a ligament is stretched so much that some of the collagen fibers are torn, but the ligament as a whole survives and the joint is not damaged. With excessive force, one of the attached bones often breaks before the ligament tears. In general, a broken bone heals much more quickly and effectively than does a torn ligament. The reason is that ligaments have no direct blood supply and thus must obtain essential substances by diffusion.

Tendons

Tendons are not part of the joint itself, but tendons passing across or around a joint may limit the joint's range of motion and provide mechanical support for it. For example, tendons associated with the muscles of the arm help brace the shoulder joint.

Bursae

Bursae (BUR-sē; singular, *bursa*, a pouch) are small, thin, fluidfilled pockets in connective tissue. They contain synovial fluid and are lined by a synovial membrane. Bursae may be connected to the joint cavity or separate from it. They form where a tendon or ligament rubs against other tissues. Located around most synovial joints, including the shoulder joint, bursae reduce friction and act as shock absorbers. *Synovial tendon sheaths* are tubular bursae that surround tendons where they cross bony surfaces. Bursae may also appear deep to the skin, covering a bone or lying within other connective tissues exposed to friction or pressure. Bursae that develop in abnormal locations, or because of abnormal stresses, are called *adventitious bursae*.

Factors That Stabilize Synovial Joints

A joint cannot be both highly mobile and very strong. The greater the range of motion at a joint, the weaker it becomes.

A synarthrosis is the strongest type of joint, but it permits no movement. In contrast, a diarthrosis, such as the shoulder joint, is far weaker but has a broad range of motion.

Movement beyond its normal range of motion will damage any mobile diarthrosis. Several factors are responsible for limiting the range of motion, stabilizing the joint, and reducing the chance of injury:

- The collagen fibers of the joint capsule and any accessory, extracapsular, or intracapsular ligaments.
- The shapes of the articulating surfaces and menisci, which may prevent movement in specific directions.
- The presence of other bones, skeletal muscles, or fat pads around the joint.
- Tension in tendons attached to the articulating bones.

When a skeletal muscle contracts and pulls on a tendon, movement in a specific direction may be either encouraged or opposed. The pattern of stabilizing structures varies among joints. For example, the hip joint is stabilized by the shapes of the bones (the head of the femur projects into the acetabulum), a heavy capsule, intracapsular and extracapsular ligaments, tendons, and massive muscles. It is therefore very strong and stable. In contrast, the elbow is another stable

Clinical Note

Dislocation and Subluxation In general, the more stable the joint, the more restricted is its range of motion. The shoulder joint is the most mobile synovial joint, but it relies primarily on the surrounding ligaments, muscles, and tendons for stability. For this reason, it is fairly weak.

When reinforcing structures cannot protect a joint from extreme stresses, a **dislocation**, or **luxation** (luk-SĀ-shun), results. In a dislocation, the articulating surfaces are forced out of position. The displacement can damage the articular cartilages, tear ligaments, or distort the joint capsule. The *inside* of a joint has no pain receptors, but nerves that monitor the capsule, ligaments, and tendons are quite sensitive, so dislocations are very painful.

The damage accompanying a partial dislocation, or **subluxation** (sub-luk-SĀ-shun), is less severe. People who are "double jointed" have joints that are weakly stabilized. Their joints permit a greater range of motion than do those of other individuals, but they are more likely to suffer partial or complete dislocations.

Clinical Note

Bursitis and Bunions Bursae are normally flat and contain a small amount of synovial fluid. When injured, however, they become inflamed and swell with synovial fluid. This causes pain in the affected area whenever the tendon or ligament moves, resulting in a condition called **bursitis**. Inflammation can result from the friction due to repetitive motion, pressure over the joint, irritation by chemical stimuli, infection, or trauma. Bursitis associated with repetitive motion typically occurs at the shoulder. Musicians, golfers, baseball pitchers, and tennis players may develop bursitis there. The most common pressure-related bursitis is a **bunion**. Bunions may form over the base of the great toe as a result of friction and distortion of the first metatarsophalangeal joint from wearing tight shoes, especially narrow shoes with pointed toes.

We have special, older names for bursitis at other locations, indicating the occupations most often associated with them. In "housemaid's knee," which accompanies prolonged kneeling, the affected bursa lies between the patella and the skin. "Student's elbow" is a form of bursitis that can result from propping your head up with your arm on a desk while you read your anatomy and physiology textbook. joint, but it gains its stability from the interlocking shapes of the articulating bones. The capsule and associated ligaments provide additional support.

CHECKPOINT

- 4. Describe the components of a synovial joint, and identify the functions of each.
- 5. Why would improper circulation of synovial fluid lead to the degeneration of articular cartilages in the affected joint?
- **6**. Define subluxation.
- See the blue Answers tab at the back of the book.

9-3 ■ The structure and function of synovial joints enable various skeletal movements

Learning Outcome Describe how the anatomical and functional properties of synovial joints permit movements of the skeleton.

To *describe* human movement, we need a frame of reference that enables accurate and precise communication. In descriptions of movement at synovial joints, phrases such as "bend the leg" or "raise the arm" are not sufficiently precise. Anatomists use descriptive terms that have specific meanings. **Spotlight Figure 9–2** (pp. 270–271) considers these movements with reference to six basic categories of synovial joints.

Types of Movements at Synovial Joints

Gliding Movement

In gliding, two opposing surfaces slide past one another (Spotlight Figure 9–2). Gliding occurs between the surfaces of articulating carpal bones, between tarsal bones, and between the clavicles and the sternum. The movement can occur in almost any direction, but the amount of movement is slight, and rotation is generally prevented by the capsule and associated ligaments.

Angular Movement

Examples of angular movement include *flexion, extension, abduction, adduction,* and *circumduction* (Figure 9–3). Descriptions of these movements are based on reference to an individual in the anatomical position. \supset p. 14

Flexion and Extension. Flexion (FLEK-shun) is movement in the anterior–posterior plane that decreases the angle between articulating bones. **Extension** occurs in the same plane, but it increases the angle between articulating bones (**Figure 9–3a**).

Figure 9–3 Angular Movements. The red dots indicate the locations of the joints involved in the movements illustrated.

SPOTLIGHT Figure 9-2 Joint Movement

SIMPLE MODEL OF ARTICULAR MOTION

Take a pencil as your model and stand it upright on the surface of a desk. The pencil represents a bone, and the desk is an articular surface. A lot of twisting, pushing, and pulling will demonstrate that there are only three ways to move the pencil.

AXES OF MOTION

Superior-inferior axis

Movement of joints can also be described by the number of axes that they can rotate around. A joint that permits movement around one axis is called monaxial, a joint that permits movement around two axes is called **biaxial**, and one that permits movement around three axes is called **triaxial**.

Moving the Point

Linear motion

Possible movement 1 shows the pencil can move. If you hold the pencil upright, without securing the point, you can push the pencil across the surface. This kind of motion is called **gliding**. You could slide the point forward or backward, from side to side, or diagonally.

Changing the Shaft Angle

Angular motion

Possible movement 2 shows the pencil shaft can change its angle with the surface. With the tip held in position, you can move the eraser end of the pencil forward and backward, from side to side. or at some intermediate angle.

Circumduction

Possible movement 3 shows a complex angular movement. Grasp the pencil eraser and move the pencil in any direction until it is no longer vertical. Now, swing the eraser through a complete circle in a movement called circumduction.

Rotating the Shaft

Rotation

Possible movement 4 shows that the pencil shaft can rotate. If you keep the shaft vertical and the point at one location, you can still spin the pencil around its longitudinal axis in a movement called rotation. No joint can freely rotate because this would tangle blood vessels, nerves, and muscles as they crossed the joint.

CLASSIFICATION OF SYNOVIAL JOINTS

Synovial joints are freely movable diarthrotic joints, and they are classified by the type and range of motion permitted. Synovial joints are described as **gliding**, **hinge**, **condylar**, **saddle**, **pivot**, or **ball-and-socket** on the basis of the shapes of the articulating surfaces, which in turn determine the joint movement.

We usually apply these terms to the movements of the long bones of the limbs, but we can also use them to describe movements of the axial skeleton. For example, when you bring your head toward your chest, you flex the intervertebral joints of the neck. When you bend down to touch your toes, you flex the intervertebral joints of the spine. Extension reverses these movements, returning you to the anatomical position.

When a person is in the anatomical position, all of the major joints of the axial and appendicular skeletons (except the ankle) are at full extension. (Shortly we will introduce special terms to describe movements of the ankle joint.) Flexion of the shoulder joint or hip joint moves the limbs anteriorly, whereas extension moves them posteriorly. Flexion of the wrist joint moves the hand anteriorly, and extension moves it posteriorly.

In each of these examples, extension can be continued past the anatomical position. Extension past the anatomical position is called **hyperextension** (Figure 9–3a). When you hyperextend your neck, you can gaze at the ceiling. Ligaments, bony processes, or soft tissues prevent hyperextension of many joints, such as the elbow or the knee.

Abduction and Adduction. Abduction (*ab*, from) is movement *away* from the longitudinal axis of the body in the frontal plane (Figure 9–3b). For example, swinging the upper limb to the side is abduction of the limb. Moving it back to the anatomical position is **adduction** (*ad*, to). Adduction of the wrist moves the heel of the hand and fingers *toward* the body, whereas abduction moves them farther away. Spreading the fingers or toes apart abducts them, because they move *away from* a central digit (Figure 9–3c). Bringing them together is called adduction. (Fingers move toward or away from the middle finger; toes move toward or away from the second toe.) Abduction and adduction always refer to movements of the appendicular skeleton, not to those of the axial skeleton.

TIPS&TRICKS

When someone is **abduct**ed, they are taken away, just as **abduct**ion takes the limb away from the body. During **add**uction, the limb is **add**ed to the body.

Circumduction. Recall the special type of angular movement, circumduction, from our model. Moving your arm in a loop is circumduction, as when you draw a large circle on a whiteboard (**Figure 9–3d**). Your hand moves in a circle, but your arm does not rotate.

Rotation

We also describe rotational movements with reference to a person in the anatomical position. Rotation of the head may involve **left rotation** or **right rotation** (Figure 9–4a). We describe limb rotation by reference to the longitudinal axis of the

trunk. During medial rotation, also known as *internal rotation* or *inward rotation*, the anterior surface of a limb turns toward the long axis of the trunk (Figure 9–4a). The reverse movement is called **lateral rotation**, *external rotation*, or *outward rotation*.

The proximal joint between the radius and the ulna permits rotation of the radial head. As the shaft of the radius rotates, the distal epiphysis of the radius rolls across the anterior surface of the ulna. This movement, called **pronation**

(prō-NĀ-shun), turns the wrist and hand from palm facing front to palm facing back (Figure 9-4b). The opposing movement, in which the palm is turned anteriorly, is supination (soo-pi-NĀ-shun). The forearm is supinated in the anatomical position. This view makes it easier to follow the path of the blood vessels, nerves, and tendons, which rotate with the radius during pronation.

TIPS & TRICKS

In order to carry a bowl of soup, the hand must be supinated.

Special Movements

Several special terms apply to specific joints or unusual types of movement (Figure 9-5):

- **Inversion** (*in*, into + *vertere*, to turn) is a twisting movement of the foot that turns the sole inward, elevating the medial edge of the sole. The opposite movement is called eversion (ē-VER-zhun).
- **Dorsiflexion** is flexion at the ankle joint and elevation of the sole, as when you dig in your heel. Plantar flexion (plantaris, sole), the opposite movement, extends the ankle joint and elevates the heel, as when you stand on tiptoe. However, it is

also acceptable (and simpler) to use "flexion and extension at the ankle," rather than "dorsiflexion and plantar flexion."

- **Opposition** is movement of the thumb toward the surface of the palm or the pads of other fingers. Opposition enables you to grasp and hold objects between your thumb and palm. It involves movement at the first carpometacarpal and metacarpophalangeal joints. Flexion at the fifth metacarpophalangeal joint can assist this movement. **Reposition** is the movement that returns the thumb and fingers from opposition.
- **Protraction** is moving a body part anteriorly in the horizontal plane. **Retraction** is the reverse movement. You protract your jaw when you jut your chin forward, and you retract your jaw when you return it to its normal position.
- **Elevation** and **depression** take place when a structure moves in a superior or an inferior direction, respectively. You depress your mandible when you open your mouth, and you elevate your mandible as you close your mouth. Another familiar elevation takes place when you shrug your shoulders.
- Lateral flexion occurs when your vertebral column bends to the side. This movement is most pronounced in the cervical and thoracic regions.

274 UNIT 2 Support and Movement

CHECKPOINT

- 7. Identify the types of synovial joints based on the shapes of the articulating surfaces.
- 8. When you do jumping jacks, which lower limb movements are necessary?
- 9. Which movements are associated with hinge joints?

See the blue Answers tab at the back of the book.

9-4 Intervertebral discs and ligaments are structural components of intervertebral joints

Learning Outcome Describe the joints between the vertebrae of the vertebral column.

The articulations between the superior and inferior articular processes of adjacent vertebrae—called *intervertebral joints*—are gliding joints that permit small movements associated with flexion and rotation of the vertebral column (Figure 9–6). Little gliding occurs between adjacent vertebral bodies. From axis to sacrum, the vertebrae are separated and cushioned by pads of fibrocartilage called **intervertebral discs**. Thus, the bodies of vertebrae form symphyseal joints.

Intervertebral discs and symphyseal joints are not found in the sacrum or coccyx, where vertebrae have fused, or between the first and second cervical vertebrae. Recall that the first cervical vertebra has no vertebral body and no intervertebral disc. The only joint between the first two cervical vertebrae is a pivot joint that allows much more rotation than the symphyseal joints between other cervical vertebrae would allow.

Intervertebral Discs

Each intervertebral disc has a tough outer layer of fibrocartilage, the **anulus fibrosus** (AN-ū-lus fī-BRŌ-sus). The collagen fibers of this layer attach the disc to the bodies of adjacent vertebrae. The anulus fibrosus surrounds the **nucleus pulposus** (pul-PŌ-sus), a soft, elastic, gelatinous core. The nucleus pulposus gives the disc resiliency and enables it to absorb shocks. The superior and inferior surfaces of the disc are almost completely covered by thin **vertebral end plates**. These end plates are composed of hyaline cartilage and fibrocartilage (**Figure 9–6**).

a Anterior view

Movement of the vertebral column compresses the nucleus pulposus and displaces it in the opposite direction. This displacement permits smooth gliding movements between vertebrae while maintaining their alignment.

The discs make a significant contribution to an individual's height: They account for about one-quarter the length of the vertebral column superior to the sacrum. As we grow older, the water content of the nucleus pulposus in each disc decreases. The discs gradually become less effective as cushions, and the chances of vertebral injury increase. Water loss from the discs also causes the vertebral column to shorten, accounting for the characteristic decrease in height with advancing age.

Intervertebral Ligaments

Numerous ligaments are attached to the bodies and processes of all vertebrae, binding them together and stabilizing the vertebral column (Figure 9–6). Ligaments interconnecting adjacent vertebrae include the following:

• The *anterior longitudinal ligament*, which connects the anterior surfaces of adjacent vertebral bodies.

- The *posterior longitudinal ligament,* which parallels the anterior longitudinal ligament and connects the posterior surfaces of adjacent vertebral bodies.
- The *ligamentum flavum*, which connects the laminae of adjacent vertebrae.
- The *interspinous ligament*, which connects the spinous processes of adjacent vertebrae.
- The *supraspinous ligament*, which interconnects the tips of the spinous processes from C₇ to the sacrum. The *ligamentum nuchae*, which extends from vertebra C₇ to the base of the skull, is continuous with the supraspinous ligament. ⁽¹⁾ p. 232

TIPS&TRICKS

The inter**spinous** ligament and supra**spinous** ligament get their names because they are attached to the **spinous** processes of the vertebrae.

Vertebral Movements

The following movements can take place across the intervertebral joints of the vertebral column: (1) flexion, or bending

Damage to Intervertebral Discs If the posterior longitudinal ligaments are weakened, as often occurs as we age, intervertebral discs become more vulnerable to damage. The compressed nucleus pulposus of a disc may distort the anulus fibrosus, forcing it partway into the vertebral canal. This condition, seen here in lateral view, is called a **bulging disc** (Figure a). If the nucleus pulposus breaks through the anulus fibrosus, it too may protrude into the vertebral canal. This condition, shown here in superior view, is called a **herniated disc** (Figure b). When a disc herniates, it compresses spinal nerves and may cause pain.

anteriorly; (2) extension, or bending posteriorly; (3) lateral flexion, or bending laterally; and (4) rotation. Table 9–2 summarizes information about intervertebral and other joints of the axial skeleton.

CHECKPOINT

- 10. What types of movements can occur across intervertebral joints?
- 11. Which regions of the vertebral column lack intervertebral discs? Explain why the absence of discs is significant.
- 12. Which vertebral movements are involved in(a) bending forward, (b) bending to the side, and(c) moving the head to signify "no"?

See the blue Answers tab at the back of the book.

9-5 ■ The shoulder is a ball-andsocket joint, and the elbow is a hinge joint

Learning Outcome Describe the structure and function of the shoulder joint and the elbow joint.

In this section we consider the structure and function of two major joints in the upper limb: the shoulder joint and elbow joint.

The Shoulder Joint

The **shoulder joint**, or *glenohumeral joint*, permits the greatest range of motion of any joint. It is also the most frequently

Table 9–2	Joints of the Ax	nts of the Axial Skeleton				
Element		Joint	Type of Joint	Movement		
SKULL						
Cranial and facia	al bones of skull	Various	Synarthroses (suture or synostosis)	None		
Maxilla/teeth ar	nd mandible/teeth	Alveolar	Synarthrosis (gomphosis)	None		
Temporal bone/	mandible	Temporomandibular	Combined gliding joint and hinge diarthrosis	Elevation, depression, and lateral gliding		

VERTEBRAL COLUMN

Occipital bone/atlas	Atlantooccipital	Condylar diarthrosis	Flexion/extension
Atlas/axis	Atlantoaxial	Pivot diarthrosis	Rotation
Other vertebral elements	Intervertebral (between vertebral bodies)	Amphiarthrosis (symphysis)	Slight movement
	Intervertebral (between articular processes)	Gliding diarthrosis	Slight rotation and flexion/extension
L ₅ /sacrum	Between L_5 body and sacral body	Amphiarthrosis (symphysis)	Slight movement
	Between inferior articular processes of L ₅ and articular processes of sacrum	Gliding diarthrosis	Slight flexion/extension
Sacrum/ hip bone	Sacroiliac	Gliding diarthrosis	Slight movement
Sacrum/coccyx	Sacrococcygeal	Gliding diarthrosis (may become fused)	Slight movement
Coccygeal bones		Synarthrosis (synostosis)	No movement
THORACIC CAGE			
Bodies of T_1 - T_{12} and heads of ribs	Costovertebral	Gliding diarthrosis	Slight movement
Transverse processes of T ₁ -T ₁₀	Costovertebral	Gliding diarthrosis	Slight movement
Ribs and costal cartilages		Synarthrosis (synchondrosis)	No movement
Sternum and first costal cartilage	Sternocostal (1st)	Synarthrosis (synchondrosis)	No movement
Sternum and costal cartilages 2–7	Sternocostal (2nd–7th)	Gliding diarthrosis*	Slight movement

*Commonly converts to synchondrosis in elderly individuals.

Figure 9–7 The Shoulder Joint. ATLAS: Plate 27d

dislocated joint, demonstrating the principle that stability must be sacrificed to obtain mobility. The shoulder is a ball-andsocket diarthrosis formed by the articulation of the head of the humerus with the glenoid cavity of the scapula (Figure 9–7a).

The area of the glenoid cavity is increased by a fibrocartilaginous **glenoid labrum** (*labrum*, lip or edge), which continues beyond the bony rim and deepens the socket (**Figure 9–7b**). The relatively loose articular capsule extends from the scapula, proximal to the glenoid labrum, to the anatomical neck of the humerus. Somewhat oversized, the articular capsule permits an extensive range of motion. The bones of the pectoral girdle provide some stability to the superior surface, because the acromion and coracoid process project laterally superior to the head of the humerus. However, the surrounding skeletal muscles provide most of the stability at this joint, with help from their associated tendons and various ligaments. Bursae reduce friction between the tendons and other tissues at the joint.

The major ligaments that help stabilize the shoulder joint are the *glenohumeral, coracohumeral, coracoacromial, coracoclavicular,* and *acromioclavicular ligaments.* The acromioclavicular ligament reinforces the capsule of the acromioclavicular joint and supports the superior surface of the shoulder. A **shoulder separation** is a relatively common injury involving partial or complete dislocation of the acromioclavicular joint. This injury can result from a hit to the superior surface of the shoulder. The acromion is forcibly depressed while the clavicle is held back by strong muscles. A dislocation of the shoulder joint is different, and involves the glenohumeral joint.

The muscles that move the humerus do more to stabilize the shoulder joint than do all the ligaments and capsular fibers combined. Muscles originating on the trunk, pectoral girdle, and humerus cover the anterior, superior, and posterior surfaces of the capsule. The tendons of the *supraspinatus, infraspinatus, teres minor,* and *subscapularis muscles* reinforce the joint capsule and limit range of movement. These muscles, known as the muscles of the *rotator cuff,* are the primary mechanism for supporting the shoulder joint and limiting its range of movement. Damage to the rotator cuff typically occurs in sports that place severe strains on the shoulder. White-water kayakers, baseball pitchers, and quarterbacks are all at high risk for rotator cuff injuries.

TIPS&TRICKS

The rotator cuff muscles can be remembered by using the acronym **SITS**, for **s**upraspinatus, **i**nfraspinatus, **t**eres minor, and **s**ubscapularis.

The anterior, superior, and posterior surfaces of the shoulder joint are reinforced by ligaments, muscles, and tendons, but the inferior capsule is poorly reinforced. As a result, a dislocation caused by an impact or a violent muscle contraction is most likely to occur at this site. Such a dislocation can tear the inferior capsular wall and the glenoid labrum. The healing process typically leaves a weakness that increases the chances for future dislocations.

As at other joints, bursae at the shoulder reduce friction where large muscles and tendons pass across the joint capsule. The shoulder has several important bursae, such as the *subacromial bursa*, the *subdeltoid bursa*, the *subcoracoid bursa*, and the *subscapular bursa* (Figure 9–7a,b). A tendon of the biceps brachii muscle runs through the shoulder joint. As it passes through the articular capsule, it is surrounded by a tubular bursa that is continuous with the joint cavity. Inflammation of any of these extracapsular bursae can restrict motion and produce the painful symptoms of bursitis. \supset p. 267

The Elbow Joint

The elbow joint is a complex hinge joint that involves the humerus, radius, and ulna (Figure 9–8). The largest and strongest articulation at the elbow is the *humeroulnar joint*, where the trochlea of the humerus articulates with the trochlear notch of the ulna. This joint works like a door hinge, with physical limitations imposed on the range of motion. In the case of the elbow, the shape of the trochlear notch of the ulna determines the plane of movement, and the combination of the notch and the olecranon limits the degree of extension permitted. At the smaller *humeroradial joint*, the capitulum of the humerus articulates with the head of the radius.

Muscles that extend the elbow attach to the rough surface of the olecranon. These muscles are mainly under the control of the *radial nerve*, which passes along the radial groove of the humerus. \bigcirc p. 247

The large *biceps brachii muscle* covers the anterior surface of the arm. Its distal tendon is attached to the radius at the radial tuberosity. Contraction of this muscle produces supination of the forearm and flexion at the elbow.

The elbow joint is extremely stable because (1) the bony surfaces of the humerus and ulna interlock, (2) a single, thick articular capsule surrounds both the humeroulnar and proximal radioulnar joints, and (3) strong ligaments reinforce the articular capsule.

The *radial collateral ligament* stabilizes the lateral surface of the elbow joint (Figure 9–8a). It extends between the lateral epicondyle of the humerus and the *annular ligament*, which binds the head of the radius to the ulna. The *ulnar collateral ligament* stabilizes the medial surface of the elbow joint. This ligament extends from the medial epicondyle of the humerus anteriorly to the coronoid process of the ulna and posteriorly to the olecranon (Figure 9–8b).

Despite the strength of the capsule and ligaments, the elbow can be damaged by severe impacts or unusual stresses.

For example, if you fall on your hand with a partially flexed elbow, contractions of muscles that extend the elbow may break the ulna at the center of the trochlear notch. Less violent stresses can produce dislocations or other injuries to the elbow, especially if epiphyseal growth has not been completed. For example, parents in a rush may drag a toddler along behind them, exerting an upward, twisting pull on the elbow joint that can result in a partial dislocation of the radial head from the annular ligament known as *nursemaid's elbow*.

CHECKPOINT

- **13**. Which tissues or structures provide most of the stability for the shoulder joint?
- 14. Would a tennis player or a jogger be more likely to develop inflammation of the subscapular bursa? Why?
- **15**. A football player received a blow to the upper surface of his shoulder, causing a shoulder separation. What does this mean?
- 16. Terry suffers an injury to his forearm and elbow. After the injury, he notices an unusually large degree of motion between the radius and the ulna at the elbow. Which ligament did Terry most likely damage?

See the blue Answers tab at the back of the book.

9-6 ■ The hip is a ball-and-socket joint, and the knee is a hinge joint

Learning Outcome Describe the structure and function of the hip joint and the knee joint.

Next we examine two representative articulations in the lower limb: the hip joint and the knee joint.

The Hip Joint

The hip joint is a sturdy ball-and-socket diarthrosis that permits flexion, extension, adduction, abduction, circumduction, and rotation. Figure 9–9 introduces the structure of the hip joint.

The acetabulum, a deep fossa, accommodates the head of the femur. \bigcirc p. 250 Within the acetabulum, articular cartilage extends like a horseshoe to either side of the acetabular notch (Figure 9–9a). The *acetabular labrum*, a projecting rim of rubbery fibrocartilage, increases the depth of the joint cavity and helps to seal in synovial fluid.

The articular capsule of the hip joint is extremely dense and strong. It extends from the lateral and inferior surfaces of the pelvic girdle to the intertrochanteric line and intertrochanteric crest of the femur, enclosing both the head and neck of the femur. \bigcirc p. 254 This arrangement helps to keep the femoral head from moving too far from the acetabulum.

Four broad ligaments reinforce the articular capsule (Figure 9–9). Three of them—the *iliofemoral, pubofemoral,* and *ischiofemoral ligaments*—are regional thickenings of the capsule. The *transverse acetabular ligament* crosses the acetabular notch, filling in the gap in the inferior border of the acetabulum. A fifth ligament, the *ligament of the femoral head,* or *ligamentum teres* (*teres,* long and round), originates along the transverse acetabular ligament (Figure 9–9a) and attaches to the fovea capitis, a small pit at the center of the femoral head. \bigcirc p. 254 This ligament tenses only when the hip is flexed and the thigh is undergoing lateral rotation.

Much more important stabilization is provided by the bulk of the surrounding muscles, aided by ligaments and capsular fibers. The combination of an almost complete bony socket, a strong articular capsule, supporting ligaments, and muscular padding makes the hip joint extremely stable. The head of the femur is well supported, but the ball-and-socket joint is not directly aligned with the weight distribution along the shaft. Stress must be transferred at an angle from the joint, along the thin femoral neck to the length of the femur. $\Box p$. 187 Hip fractures (fractures of the femoral neck or between the greater and lesser trochanters of the femur) are more common than hip dislocations. As we noted in Chapter 6, femoral fractures at the hip are common in elderly individuals with severe osteoporosis. $\Box p$. 199

The Knee Joint

The hip joint passes weight to the femur, and then the knee joint transfers the weight from the femur to the tibia. The shoulder is mobile; the hip, stable; and the knee . . . ? If you had to choose one word, it would probably be "complicated." The knee joint functions as a hinge, but the joint is far more complex than the elbow or even the ankle. The rounded condyles of the femur roll across the superior surface of the tibia, so the points of contact are constantly changing. The joint permits flexion, extension, and very limited rotation.

The knee joint contains three separate articulations. Two are between the femur and tibia (medial condyle to medial condyle, and lateral condyle to lateral condyle). One is between the patella and the patellar surface of the femur (Figure 9–10).

The Articular Capsule and Joint Cavity

The articular capsule at the knee joint is thin and in some areas incomplete, but various ligaments and tendons of associated muscles strengthen it. A pair of fibrocartilage pads, the medial and lateral menisci, lies between the femoral and tibial surfaces (Figures 9–1b and 9–10b,d). The menisci (1) act as cushions, (2) conform to the shape of the articulating surfaces as the femur changes position, and (3) provide lateral stability to the joint. Prominent fat pads cushion the margins of the joint. These fat pads also assist the many bursae in reducing friction between the patella and other tissues.

Supporting Ligaments

A complete dislocation of the knee is very rare, mainly because seven major ligaments stabilize the knee joint:

- The tendon from the *quadriceps femoris* muscles responsible for extending the knee passes over the anterior surface of the joint. The patella is embedded in this tendon, and the *patellar ligament* continues to its attachment on the anterior surface of the tibia (Figure 9–10a). The patellar ligament and two ligamentous bands known as the *patellar retinaculae* support the anterior surface of the knee joint.
- **2,3.** Two *popliteal ligaments* extend between the femur and the heads of the tibia and fibula (Figure 9–10c). These ligaments reinforce the knee joint's posterior surface.
- 4,5. Inside the joint capsule, the *anterior cruciate ligament* (*ACL*) and *posterior cruciate ligament* (*PCL*) attach the intercondylar area of the tibia to the condyles of the femur (Figure 9–10b,d). *Anterior* and *posterior* refer to the sites of origin of these ligaments on the tibia. They cross one another as they proceed to their destinations on the femur. (The term *cruciate* is derived from the Latin word *crucialis*, meaning a cross.) The ACL and the PCL limit the anterior and posterior movement of the tibia and maintain the alignment of the femoral and tibial condyles.
- **6,7.** The *tibial collateral ligament*, also called the *medial collateral ligament (MCL)*, reinforces the medial surface of the knee joint, and the *fibular collateral ligament*, also called the *lateral collateral ligament (LCL)*, reinforces the lateral surface (Figure 9–10). These ligaments tighten only at full extension, the position in which they stabilize the joint.

At full extension, a slight lateral rotation of the tibia tightens the anterior cruciate ligament and jams the lateral meniscus between the tibia and femur. The knee joint is essentially locked in the extended position. With the joint locked, a person can stand for prolonged periods without using (and tiring) the muscles that extend the knee. Unlocking the knee joint requires muscular contractions that medially rotate the tibia or laterally rotate the femur. If the locked knee is struck from the side, the

Figure 9–10 The Right Knee Joint. ATLAS: Plates 78a-i; 79a,b; 80a,b

lateral meniscus can tear and the supporting ligaments can be seriously damaged.

The knee joint is structurally complex and is subjected to severe stresses in the course of normal activities. Painful knee injuries are all too familiar to both amateur and professional athletes. Treatment is often costly and prolonged, and repairs seldom make the joint "good as new."

 Table 9–3 summarizes information about the joints of the appendicular skeleton.

Table 9–3	le 9–3 Joints of the Appendicular Skeleton				
Articulating Bone	s	Joint	Type of Joint	Movement

*A "double-gliding joint," with two joint cavities separated by an articular cartilage.

[†]During pregnancy, hormones weaken the pubic symphysis and permit movement important to childbirth; see Chapter 29.

Clinical Note

Knee Injuries Athletes place tremendous stresses on their knees. Ordinarily, the medial and lateral menisci move as the position of the femur changes. The knee is most stable when it is not bent. Placing a lot of weight on the knee while it is partially flexed can trap a meniscus between the tibia and femur, resulting in a break or tear in the cartilage. In the most common injury, the lateral surface of the leg is driven medially, tearing the medial meniscus. In addition to being quite painful, the torn cartilage may restrict movement at the joint. It can also lead to chronic problems and the development of a "trick knee"—a knee that feels unstable. Sometimes the meniscus can be heard and felt popping in and out of position when the knee is extended.

Other knee injuries involve tearing one or more stabilizing ligaments or damaging the patella. Torn ligaments can be difficult to correct surgically, and healing is slow. Rupture of the anterior cruciate ligament (ACL) is a common sports injury that affects women two to five times more often than men. ACL injuries are frequently caused by twisting an extended weightbearing knee. This movement is common in sports such as football, basketball, and skiing. Nonsurgical treatment with

exercise and braces is possible, but requires a change in activity patterns. Reconstructive surgery using part of the patellar tendon or a graft from a cadaver tendon may allow a return to active sports. A strong hit or force to the lateral surface of the knee, as in a football tackle or flying hockey puck, may damage both the ACL and the medial collateral ligament (MCL).

The patella can be injured in a number of ways. If the leg is immobilized (as it might be in a football pileup) while you try to extend the knee, the muscles are powerful enough to pull the patella apart. Impacts to the anterior surface of the knee can also shatter the patella. Knee injuries may lead to chronic painful arthritis that impairs walking. Total knee replacement surgery is rarely performed on young people, but it is becoming increasingly common among elderly patients with severe arthritis.

CHECKPOINT

- 17. Name the bones making up the shoulder joint and knee joint, respectively.
- 18. At what site are the iliofemoral ligament, pubofemoral ligament, and ischiofemoral ligament located?
- 19. What signs and symptoms would you expect in a person who has damaged the menisci of the knee joint?
- 20. Why is "clergyman's knee" (a type of bursitis) common among carpet layers and roofers?

See the blue Answers tab at the back of the book.

9-7 ■ With advancing age, arthritis and other degenerative changes impair joint mobility

Learning Outcome Describe the effects of aging on joints, and discuss the most common age-related clinical problems for joints.

Joints are subjected to heavy wear and tear throughout our lifetimes. Problems with joint function are common, especially in older individuals. **Rheumatism** (ROO-muh-tiz-um) is a general term for pain and stiffness affecting the *musculoskeletal system* (bones, muscles, and joints). **Arthritis** (ar-THRĪ-tis) means *joint inflammation*, and encompasses all the rheumatic diseases that affect synovial joints. Many types of arthritis are recognized.

Arthritis always involves damage to the articular cartilages, but the specific cause can vary. For example, arthritis can result from bacterial or viral infection, injury to the joint, decreased viscosity or lack of synovial fluid, metabolic problems, or severe physical stresses. The most common type of arthritis is *osteoarthritis* (os-tē-ō-ar-THRĪ-tis), also known as *degenerative arthritis* or *degenerative joint disease (DJD)*. It generally affects people age 60 or older. Osteoarthritis can result from cumulative wear and tear at the joint surfaces or from genetic factors affecting collagen formation. In the U.S. population, 25 percent of women and 15 percent of men over age 60 show signs of this disease.

Rheumatoid arthritis is an inflammatory condition that affects about 0.5–1.0 percent of the adult population, generally those between 40 and 60, and women more than men. Rheumatoid arthritis occurs when the immune response mistakenly attacks the joint tissues. Such a condition, in which the body attacks its own tissues, is called an *autoimmune disease*. Allergies, bacteria, viruses, and genetic factors have all been proposed as contributing to or triggering the destructive inflammation.

In *gouty arthritis*, or *crystal arthritis*, crystals of uric acid form within the synovial fluid of joints. The accumulation of

crystals of uric acid over time eventually interferes with normal movement. This form of arthritis is named after the metabolic disorder known as *gout*, discussed further in Chapter 25. In gout, the crystals are derived from uric acid (a metabolic waste product), and the joint most often affected is the metatarsal–phalangeal joint of the great toe. Gout is relatively rare, but other forms of gouty arthritis are much more common. Some degree of calcium salt deposition occurs in the joints in 30–60 percent of those over age 85. The cause is unknown, but the condition appears to be linked to age-related changes in the articular cartilages.

Regular exercise, physical therapy, and drugs that reduce inflammation (such as aspirin) can often slow the progress of osteoarthritis. Surgical procedures can realign or redesign the affected joint. In extreme cases involving the hip, knee, elbow, or shoulder, the defective joint can be replaced by an artificial one.

Degenerative changes comparable to those seen in arthritis may result from joint immobilization. When motion ceases, so does the circulation of synovial fluid, and the cartilages begin to degenerate. **Continuous passive motion (CPM)** of any injured joint appears to encourage the repair process by improving the circulation of synovial fluid. A physical therapist or a machine often performs the movement during the recovery process.

With age, bone mass decreases and bones become weaker, so the risk of fractures increases. \supset p. 199 If osteoporosis develops, the bones may weaken to the point at which fractures occur in response to stresses that could easily be tolerated by normal bones. Hip fractures are among the most dangerous fractures seen in elderly people, with or without osteoporosis. These fractures, most often involving persons over age 60, may be accompanied by hip dislocation or by pelvic fractures. Although severe hip fractures are most common among those over age 60, in recent years the frequency of hip fractures has increased dramatically among young, healthy professional athletes.

CHECKPOINT

- **21**. Define rheumatism.
- 22. Define arthritis.

See the blue Answers tab at the back of the book.

9-8 ■ The skeletal system supports and stores energy and minerals for other body systems

Learning Outcome Explain the functional relationships between the skeletal system and other body systems.

The bones you study in the lab may seem to be rigid and unchanging structures, but the living skeleton is dynamic and undergoes continuous remodeling. The balance between osteoblast and osteoclast activity is subject to change at a moment's notice. When osteoblast activity predominates, bones thicken and strengthen. When osteoclast activity predominates, bones get thinner and weaker.

The balance between bone formation and bone recycling varies with (1) the age of the individual, (2) the physical stresses applied to the bone, (3) circulating hormone levels, (4) rates of calcium and phosphorus absorption and excretion, and (5) genetic or environmental factors. Most of these variables involve some interaction between the skeletal system and other body systems.

In fact, the skeletal system is intimately associated with other systems. For instance, the bones of the skeleton are attached to the muscular system, extensively connected with the cardiovascular and lymphatic systems, and largely under the physiological control of the endocrine system. The digestive and urinary systems also play important roles in providing the calcium and phosphate minerals needed for bone growth. In return, the skeleton represents a reserve of calcium, phosphate, and other minerals that can compensate for reductions in their supply from the diet. **Figure 9–11** reviews the components and functions of the skeletal system, and diagrams the major functional relationships between that system and other systems studied so far.

- CHECKPOINT

- Explain why there must be a balance between osteoclast activity and osteoblast activity.
- 24. Describe the functional relationship between the skeletal system and the integumentary system.
- See the blue Answers tab at the back of the book.

Body System

Page 174

Skeletal System -

INTEGRATOR SYSTEM ---> Skeletal System Provides structural support

Body System –

Synthesizes vitamin D₃, essential for calcium and phosphorus absorption (bone maintenance and growth)

The SKELETAL System

The skeletal system provides structural support and protection for the body. The skeleton also stores calcium, phosphate, and other minerals necessary for many functions in other organ systems. In addition, the lipids in the yellow bone marrow serve as an energy reserve and blood cell production occurs in the red bone marrow.

Figure 9–11 diagrams the functional relationships between the skeletal system and the other body system we have studied so far.

Related Clinical Terms

- **ankylosing spondylitis:** A chronic, progressive inflammatory disease of the intervertebral spaces that causes abnormal fusion of the vertebrae.
- **arthroplasty:** The surgical reconstruction or creation of an artificial joint.
- **arthroscopy:** Insertion of a narrow tube containing optical fibers and a tiny camera (arthroscope) directly into the joint for visual examination.
- **Bouchard's nodes:** Bony enlargements on the proximal interphalangeal joints due to osteoarthritis.
- **chondromalacia:** Softening of cartilage as a result of strenuous activity or an overuse injury.
- **Heberden's nodes:** Bony overgrowths on the distal interphalangeal joints due to osteoarthritis that cause the patient to have knobby fingers.

- **joint mice:** Small fibrous, cartilaginous, or bony loose bodies in the synovial cavity of a joint.
- **Lyme disease:** An infectious disease transmitted to humans from the bite of a tick infected with *Borrelia burgdorferi*, causing flulike symptoms and joint pain.
- **pannus:** Granulation tissue (combination of fibrous connective tissue and capillaries) forming within a synovial membrane, which releases cartilage-destroying enzymes.
- **prepatellar bursitis:** Inflammation of the bursa over the front of the knee just above the kneecap; also known as housemaid's knee.

prosthesis: An artificial substitute for a body part.

synovitis: Inflammation of the synovial membrane.

tophi: Deposits of uric acid crystals often found around joints and usually associated with gout.

An Introduction to Joints p. 264

- **1.** Joints, or articulations, exist wherever two bones interconnect.
- 9-1 Joints are categorized according to their range of motion or structure p. 264
- 2. *Immovable joints* are **synarthroses**; *slightly movable joints* are **amphiarthroses**; and joints that are *freely movable* are called **diarthroses** or synovial joints. (*Table 9–1*)
- 3. Alternatively, joints are classified structurally as *fibrous*, *cartilaginous*, *bony*, or *synovial*. (*Table* 9–1)
- 4. The four major types of synarthroses are a **suture** (skull bones bound together by dense connective tissue), a **gomphosis** (teeth bound to bony sockets by *periodontal ligaments*), a **syn-chondrosis** (two bones joined by a rigid cartilaginous bridge), and a **synostosis** (two bones completely fused).
- 5. The two major types of amphiarthroses are a **syndesmosis** (bones connected by a ligament) and a **symphysis** (bones connected by fibrocartilage).

9-2 Synovial joints are freely movable joints containing synovial fluid p. 266

6. The bony surfaces at diarthroses are enclosed within a **joint capsule**, also called an **articular capsule**, that is lined by a synovial membrane.

- 7. The bony surfaces within a synovial joint are covered by **articular cartilages**, and lubricated by **synovial fluid**. Functions of synovial fluid include lubrication, nutrient distribution, and shock absorption.
- 8. Accessory synovial structures include **menisci**, or *articular discs;* **fat pads; accessory ligaments; tendons;** and **bursae**. (*Figure 9–1*)
- **9.** A **dislocation** (**luxation**) occurs when articulating surfaces are forced out of position.
- **9-3** The structure and function of synovial joints enable various skeletal movements p. 268
- **10.** The possible types of articular movements are **linear movement (gliding)**, **angular movement**, and **rotation**. (*Spotlight Figure 9–2*)
- 11. Joints are called **monaxial**, **biaxial**, or **triaxial**, depending on the planes of movement they allow. (*Spotlight Figure 9–2*)
- **12.** In **gliding joints**, two opposing surfaces slide past one another.
- **13.** Important terms that describe angular movement are **flexion**, **extension**, **hyperextension**, **abduction**, **adduction**, and **circumduction**. (*Figure 9–3*)
- 14. Rotational movement can be **left** or **right**, **medial** (*internal*) or **lateral** (*external*), or, in the bones of the forearm, **pronation** or **supination**. (*Figure* 9–4)
- **15.** Movements of the foot include **inversion** and **eversion**. The ankle undergoes flexion and extension, also known as **dorsiflexion** and **plantar flexion**, respectively. (*Figure 9–5*)
- **16. Opposition** is the thumb movement that enables us to grasp objects. **Reposition** is the opposite of opposition. (*Figure 9–5*)
- 17. Protraction involves moving something anteriorly; retraction involves moving it posteriorly. Depression and elevation occur when we move a structure inferiorly and superiorly, respectively. Lateral flexion occurs when the vertebral column bends to one side. (*Figure 9–5*)
- **18. Gliding joints** permit limited movement, generally in a single plane. (*Spotlight Figure 9–2*)
- **19. Hinge joints** are monaxial joints that permit only angular movement in one plane. (*Spotlight Figure 9–2*)

- **20. Pivot joints** are monaxial joints that permit only rotation. (*Spotlight Figure 9–2*)
- **21.** Condylar joints (ellipsoid joints) are biaxial joints with an oval articular face that nestles within a depression in the opposing articular surface. (*Spotlight Figure 9–2*)
- **22.** Saddle joints are biaxial joints with articular faces that are concave on one axis and convex on the other. (*Spotlight Figure* 9–2)
- **23.** Ball-and-socket joints are triaxial joints that permit rotation as well as other movements. (*Spotlight Figure 9–2*)
- 9-4 Intervertebral discs and ligaments are structural components of intervertebral joints p. 274
- 24. The articular processes of vertebrae form gliding joints with those of adjacent vertebrae. The bodies form symphyseal joints that are separated and cushioned by **intervertebral discs**, which contain an outer **anulus fibrosus** and an inner **nucleus pulposus. Vertebral end plates** cover the superior and inferior surfaces of the disc. Several ligaments stabilize the vertebral column. (*Figure 9–6; Table 9–2*)
- 9-5 The shoulder is a ball-and-socket joint, and the elbow is a hinge joint p. 276
- **25.** The **shoulder joint**, or *glenohumeral joint*, is formed by the glenoid cavity and the head of the humerus. This articulation permits the greatest range of motion of any joint. It is a ball-and-socket diarthrosis with various stabilizing ligaments. Strength and stability are sacrificed in favor of mobility. (*Figure 9–7; Table 9–3*)
- **26.** The **elbow joint** permits only flexion–extension. It is a hinge diarthrosis whose capsule is reinforced by strong ligaments. (*Figure 9–8; Table 9–3*)

9-6 The hip is a ball-and-socket joint, and the knee is a hinge joint **p**. 279

- 27. The hip joint is a ball-and-socket diarthrosis formed between the acetabulum of the hip bone and the head of the femur. The joint permits flexion–extension, adduction–abduction, circumduction, and rotation. Numerous ligaments stabilize the joint. (*Figure 9–9; Table 9–3*)
- 28. The knee joint is a hinge joint made up of three articulations: two formed between the femur and tibia and one between the patella and femur. The joint permits flexion–extension and limited rotation, and it has various supporting ligaments. (*Figure 9–10; Table 9–3*)

9-7 With advancing age, arthritis and other degenerative changes impair joint mobility p. 283

29. Problems with joint function are relatively common, especially in older individuals. **Rheumatism** is a general term for pain and stiffness affecting the musculoskeletal system; several major forms exist. **Arthritis** encompasses all the rheumatic diseases that affect synovial joints. Arthritis becomes increasingly common with age.

9-8 The skeletal system supports and stores energy and minerals for other body systems p. 284

30. Growth and maintenance of the skeletal system are supported by the integumentary system. The skeletal system also interacts with the muscular, cardiovascular, lymphatic, digestive, urinary, and endocrine systems. (*Figure 9–11*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Label the structures in the following illustration of a synovial joint.

- A synarthrosis located between the bones of the skull is a

 (a) symphysis,
 (b) syndesmosis,
 (c) synchondrosis,
 (d) suture.
- The joint between adjacent vertebral bodies is a (a) syndesmosis,
 (b) symphysis, (c) synchondrosis, (d) synostosis.
- The anterior joint between the two pubic bones is a
 (a) synchondrosis, (b) synostosis, (c) symphysis, (d) synarthrosis.
- Joints typically located between the ends of adjacent long bones are

 (a) synarthroses,
 (b) amphiarthroses,
 (c) diarthroses,
 (d) symphyses.

See the blue Answers tab at the back of the book.

- 6. The function of the articular cartilage is (a) to reduce friction,
 (b) to prevent bony surfaces from contacting one another,
 (c) to provide lubrication, (d) both a and b.
- Which of the following is *not* a function of synovial fluid? (a) shock absorption, (b) nutrient distribution, (c) maintenance of ionic balance, (d) lubrication of the articular surfaces, (e) waste disposal.
- 8. The structures that limit the range of motion of a joint and provide mechanical support across or around the joint are (a) bursae,
 (b) tendons, (c) menisci, (d) a, b, and c.
- 9. A partial dislocation of an articulating surface is a (a) circumduction,(b) hyperextension, (c) subluxation, (d) supination.
- 10. Abduction and adduction always refer to movements of the (a) axial skeleton, (b) appendicular skeleton, (c) skull, (d) vertebral column.
- 11. Rotation of the forearm that makes the palm face posteriorly is (a) supination, (b) pronation, (c) proliferation, (d) projection.
- 12. A saddle joint permits _____ movement but prevents _____ movement. (a) rotational; gliding, (b) angular; gliding, (c) gliding; rotational, (d) angular; rotational.
- 13. Standing on tiptoe is an example of _____ at the ankle.(a) elevation, (b) flexion, (c) extension, (d) retraction.
- 14. Examples of monaxial joints, which permit angular movement in a single plane, are (a) the intercarpal and intertarsal joints,(b) the shoulder and hip joints, (c) the elbow and knee joints,(d) all of these.

- 15. Decreasing the angle between bones is termed (a) flexion,(b) extension, (c) abduction, (d) adduction, (e) hyperextension.
- Movements that occur at the shoulder and the hip represent the actions that occur at a ______ joint. (a) hinge, (b) ball-and-socket, (c) pivot, (d) gliding.
- 17. The anulus fibrosus and nucleus pulposus are structures associated with the (a) intervertebral discs, (b) knee and elbow, (c) shoulder and hip, (d) carpal and tarsal bones.
- **18.** Subacromial, subcoracoid, and subscapular bursae reduce friction in the ______ joint. **(a)** hip, **(b)** knee, **(c)** elbow, **(d)** shoulder.
- Although the knee joint is only one joint, it resembles _____ separate joints. (a) two, (b) three, (c) four, (d) five, (e) six.

LEVEL 2 Reviewing Concepts

- 20. Dislocations involving synovial joints are usually prevented by all of the following *except* (a) structures such as ligaments that stabilize and support the joint, (b) the position of bursae that limits the degree of movement, (c) the presence of other bones that prevent certain movements, (d) the position of muscles and fat pads that limits the degree of movement, (e) the shape of the articular surface.
- 21. The hip is an extremely stable joint because it has (a) a complete bony socket, (b) a strong articular capsule, (c) supporting ligaments, (d) all of these.

- 22. How does a meniscus (articular disc) function in a joint?
- Partial or complete dislocation of the acromioclavicular joint is called a(n) _____.
- 24. How do articular cartilages differ from other cartilages in the body?
- **25.** Differentiate between a bulging disc and a herniated disc.
- **26.** How would you explain to your grandmother the characteristic decrease in height with advancing age?
- 27. List the six different types of diarthroses, and give an example of each.

LEVEL 3 Critical Thinking and Clinical Applications

- 28. While playing tennis, Dave "turns his ankle." He experiences swelling and pain. After being examined, he is told that he has no ruptured ligaments and that the structure of the ankle is not affected. On the basis of the signs and symptoms and the examination results, what happened to Dave's ankle?
- **29.** Joe injures his knee during a football practice such that the synovial fluid in the knee joint no longer circulates normally. The physician who examines him tells him that they have to re-establish circulation of the synovial fluid before the articular cartilages become damaged. Why?
- **30.** When playing a contact sport, which injury would you expect to occur more frequently, a dislocated shoulder or a dislocated hip? Why?

CLINICAL CASE

Wrap-Up

What's Ailing the Birthday Girl?

Jessica's mother takes her to see her pediatrician. After hearing about Jessica's symptoms, the pediatrician refers her to a rheumatologist, a doctor who specializes in rheumatic diseases.

This doctor withdraws some synovial fluid using a small needle (a procedure known as *arthrocentesis*) from a warm, swollen, tender knee that has limited motion. Instead of a small amount of clear, viscous fluid with the consistency of heavy molasses, there is a large amount of thin, cloudy, "sick" looking synovial fluid. This fluid is not capable of doing its important jobs of joint lubrication, nutrient distribution, and shock absorption.

Jessica is suffering from juvenile rheumatoid arthritis, the most common type of childhood arthritis.

Arthritis has many forms. The most common type is osteoarthritis, which is thought of as wear and tear of the articular cartilage. Rheumatoid arthritis, however, is an autoimmune, inflammatory disease of the synovial membrane. For unknown reasons, the immune response mistakenly attacks the synovial

membrane, causing it to grow abnormally and produce large amounts of unhealthy synovial fluid. This synovitis eventually destroys the joint cartilage.

- 1. What category of joints is likely to be affected by juvenile rheumatoid arthritis?
- **2.** If you could look inside Jessica's knee joint, what do you think the synovial membrane would look like?

See the blue Answers tab at the back of the book.

Muscle Tissue

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **10-1** Specify the functions of skeletal muscle tissue.
- **10-2** Describe the organization of muscle at the tissue level.
- **10-3** Describe the characteristics of skeletal muscle fibers, and identify the structural components of a sarcomere.
- **10-4** Identify the components of the neuromuscular junction, and summarize the events involved in the neural control of skeletal muscle contraction and relaxation.
- **10-5** Describe the mechanism responsible for tension production in a muscle fiber, and compare the different types of muscle contraction.
- **10-6** Describe the mechanisms by which muscle fibers obtain the energy to power contractions.
- **10-7** Relate the types of muscle fibers to muscle performance, and distinguish between aerobic and anaerobic endurance.
- **10-8** Identify the structural and functional differences between skeletal muscle fibers and cardiac muscle cells.
- 10-9 Identify the structural and functional differences between skeletal muscle fibers and smooth muscle cells, and discuss the roles of smooth muscle tissue in systems throughout the body.

SPOTLIGHTS

- Events at the Neuromuscular Junction pp. 300–301
- Excitation–Contraction Coupling p. 303

Clinical Notes

- Tetanus p. 306
- Rigor Mortis p. 308
- Delayed-Onset Muscle Soreness p. 323

CLINICAL CASE

A Real Eye Opener

Tamara, a 33-year-old violinist, has waited for this neurology appointment for three weeks. That's

how long she has been unable to play gigs with her band. She can still play her violin in the morning, but by afternoon her arms are so tired and weak, they feel like wood. During her last performance, she noticed she had drooled on her instrument, much to her embarrassment. This morning she feared she might choke on her toast. She has been unable to drive because of double vision. Her eyelids have been increasingly droopy, and when she woke up this morning, she couldn't open her left eyelid at all.

Tamara's neurologist takes a complete medical history and does a thorough physical exam. Tamara hadn't realized how weak her legs have gotten until the doctor asks her to stand up from her chair without using her arms. Walking on her toes is impossible. When the doctor lifts her weak left eyelid, she is not able to track his finger with her gaze and is still seeing double.

"I would like to perform a test," says the neurologist, starting an IV. He injects a small amount of a drug. Suddenly Tamara's strength returns.

She opens both eyes wide and no longer sees double. She can toe walk, heel walk, and get up unassisted many times in a row. She feels like she could play her instrument forever. But after 30 minutes, her weakness returns. What is going on with Tamara? To find out, turn to the Clinical Case Wrap-Up on p. 331.

An Introduction to Muscle Tissue

In this chapter we discuss muscle tissue, one of the four primary tissue types, with particular attention to skeletal muscle tissue. We examine the histological and physiological characteristics of skeletal muscle cells, and relate those features to the functions of the entire tissue. We also give an overview of the differences among skeletal, cardiac, and smooth muscle tissues. Reading this chapter will prepare you for our discussion of the muscular system in Chapter 11.

10–1 Skeletal muscle performs six major functions

Learning Outcome Specify the functions of skeletal muscle tissue.

Muscle tissue consists chiefly of muscle cells that are highly specialized for contraction. Our bodies contain three types of muscle tissue: (1) *skeletal muscle*, (2) *cardiac muscle*, and (3) *smooth muscle*. ⊃ **p**. 140 Without these muscle tissues, nothing in the body would move, and the body itself could not move. Skeletal muscle tissue moves the body by pulling on our bones, making it possible for us to walk, dance, bite an apple, or play the guitar. Cardiac muscle tissue pumps blood through the cardiovascular system. Smooth muscle tissue pushes fluids and solids along the digestive tract and other internal organs and regulates the diameters of small arteries.

Skeletal muscles are organs composed mainly of skeletal muscle tissue, but they also contain connective tissues, nerves, and blood vessels. Each cell in skeletal muscle tissue is a single muscle *fiber*. Skeletal muscles attach directly or indirectly to bones. Our skeletal muscles perform the following six functions:

- 1. *Produce Skeletal Movement.* Skeletal muscle contractions pull on tendons to move our bones. Their effects range from simple motions, such as extending the arm or breathing, to the highly coordinated movements of swimming, skiing, or playing a piano.
- 2. *Maintain Posture and Body Position.* Tension in our skeletal muscles maintains body posture—for example, holding your head still when you read a book or balancing your body weight above your feet when you walk. Without constant muscular activity, we could neither sit upright nor stand.
- **3.** *Support Soft Tissues.* Layers of skeletal muscle make up the abdominal wall and the floor of the pelvic cavity. These muscles support the weight of our visceral organs and shield our internal tissues from injury.
- 4. *Guard Body Entrances and Exits.* Skeletal muscles encircle the openings of the digestive and urinary tracts. These muscles give us voluntary control over swallowing, defecating, and urinating.
- 5. *Maintain Body Temperature.* Muscle contractions use energy, and whenever energy is used in the body, some of it is converted to heat. The heat released by working muscles keeps body temperature in the range needed for normal functioning.
- 6. *Store Nutrients.* When our diet contains too few proteins or calories, the contractile proteins in skeletal muscles are broken down, and their amino acids released into the circulation. The liver can use some of these amino acids to synthesize glucose, and others can be broken down to provide energy.

Let's begin our discussion with the functional anatomy of a typical skeletal muscle, with particular emphasis on the microscopic structural features that make contractions possible.

CHECKPOINT

- 1. Identify the three types of muscle tissue.
- 2. Identify the six major functions of skeletal muscle.

- See the blue Answers tab at the back of the book.

10-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves

Learning Outcome Describe the organization of muscle at the tissue level.

Figure 10–1 illustrates the organization of a representative skeletal muscle. Here we consider how connective tissues are organized in skeletal muscle, and how skeletal muscles are supplied

Figure 10–1 The Organization of Skeletal Muscles. A skeletal muscle consists of fascicles (bundles of muscle fibers) enclosed by the epimysium. The bundles are separated by connective tissue fibers of the perimysium, and within each bundle, each of the muscle fibers is surrounded by an endomysium. Each muscle fiber has many superficial nuclei, as well as mitochondria and other organelles (*see Figure 10–3*).

with blood vessels and nerves. In the next section we examine skeletal muscle tissue in detail.

Organization of Connective Tissues

As you can see in Figure 10–1, each muscle has three layers of connective tissue: (1) an epimysium, (2) a perimysium, and (3) an endomysium.

The **epimysium** (ep-i-MIZ- \bar{e} -um; *epi*-, on + *mys*, muscle) is a dense layer of collagen fibers that surrounds the entire muscle. It separates the muscle from nearby tissues and organs. The epimysium is connected to the deep fascia, a dense connective tissue layer. \bigcirc p. 139

The **perimysium** (per-i-MIZ-ē-um; *peri-*, around) divides the skeletal muscle into a series of compartments. Each compartment contains a bundle of muscle fibers called a **fascicle** (FAS-i-kl; *fasciculus*, a bundle). In addition to collagen and elastic fibers, the perimysium contains blood vessels and nerves that supply the muscle fibers within the fascicles. Each fascicle receives branches of these blood vessels and nerves.

Within a fascicle, the delicate connective tissue of the **endomysium** (en-dō-MIZ-ē-um; *endo-*, inside) surrounds the individual skeletal muscle cells, called *muscle fibers*, and loosely interconnects adjacent muscle fibers. This flexible, elastic connective tissue layer contains (1) capillary networks that supply blood to the muscle fibers; (2) **myosatellite cells**, stem cells that help repair damaged muscle tissue; and (3) nerve fibers that control the muscle. All these structures are in direct contact with the individual muscle fibers. \bigcirc p. 140

The collagen fibers of the perimysium and endomysium are interwoven and blend into one another. At each end of the muscle, the collagen fibers of the epimysium, perimysium, and endomysium come together to form either a bundle known as a **tendon**, or a broad sheet called an **aponeurosis** (ap-ō-nū-RŌ-sis). Tendons and aponeuroses usually attach skeletal muscles to bones. Where they contact the bone, the collagen fibers extend into the bone matrix, providing a firm attachment. As a result, any contraction of the muscle pulls on the attached bone.

Blood Vessels and Nerves

As we have seen, the connective tissues of the endomysium and perimysium contain the blood vessels and nerves that supply the muscle fibers. Muscle contraction requires tremendous quantities of energy. An extensive vascular network delivers the necessary oxygen and nutrients and carries away the metabolic wastes generated by active skeletal muscles. The blood vessels and the nerves generally enter the muscle together and follow the same branching course through the perimysium. Within the endomysium, arterioles (small arteries) supply blood to a capillary network that services the individual muscle fiber.

Skeletal muscles contract only when the central nervous system stimulates them. Axons, *nerve fibers* extending from

neurons, penetrate the epimysium, branch through the perimysium, and enter the endomysium to innervate individual muscle fibers. Skeletal muscles are often called voluntary muscles, because we have voluntary control over their contractions. We may also control many skeletal muscles at a subconscious level. For example, skeletal muscles involved with breathing, such as the *diaphragm*, usually work outside our conscious awareness.

Next, let's examine the microscopic structure of a typical skeletal muscle fiber and relate that microstructure to the physiology of the contraction process.

10–3 Skeletal muscle fibers have distinctive features

Learning Outcome Describe the characteristics of skeletal muscle fibers, and identify the structural components of a sarcomere.

Skeletal muscle fibers are quite different from the "typical" cells we described in Chapter 3. One obvious difference is size: Skeletal muscle fibers are enormous. A muscle fiber from a thigh muscle could have a diameter of 100 μ m and a length up to 30 cm (12 in.). A second major difference is that skeletal muscle fibers are *multinucleate*: Each contains hundreds of nuclei just internal to the plasma membrane. The genes in these nuclei control the production of enzymes and structural proteins required for normal muscle contraction. The more copies of these genes, the faster these proteins can be produced. A third difference is that skeletal muscle fibers are banded, or striated. \bigcirc **p.** 142 As we will see, the striations are due to the precise arrangements of thin (actin) and thick (myosin) filaments.

The distinctive features of size and multiple nuclei are related. During development, groups of embryonic cells called **myoblasts** (*myo*-, muscle + *blastos*, formative cell) fuse, forming individual multinucleate skeletal muscle fibers (Figure 10–2a). Each nucleus in a skeletal muscle fiber reflects the contribution of a single myoblast.

Some myoblasts do not fuse with developing muscle fibers. These unfused cells remain in adult skeletal muscle tissue as the myosatellite cells seen in Figures 10–1 and 10–2a. After an injury, myosatellite cells may enlarge, divide, and fuse with damaged muscle fibers, thereby assisting in the repair of the tissue.

The Sarcolemma and Transverse Tubules

The **sarcolemma** (sar-kō-LEM-uh; *sarkos*, flesh + *lemma*, husk), or plasma membrane of a muscle fiber, surrounds the **sarcoplasm**

Figure 10–2 The Formation of a Multinucleate Skeletal Muscle Fiber.

Mature muscle fiber

(SAR-kō-plazm), or cytoplasm of the muscle fiber (Figure 10–3). Like the plasma membranes of other body cells, the sarcolemma has a characteristic membrane potential, also called the transmembrane potential, due to more negative charges on its cytoplasmic side and more positive charges on its extracellular side. ⊃ p. 100 In a skeletal muscle fiber, a sudden change in the membrane potential is the first step that leads to a contraction.

Even though a skeletal muscle fiber is very large, all regions of the cell must contract at the same time. For this reason, the signal to contract must be distributed quickly throughout the interior of the cell. This signal is conducted through the transverse tubules. **Transverse tubules**, or **T tubules**, are narrow tubes whose surfaces are continuous with the sarcolemma and extend deep into the sarcoplasm (**Figure 10–3**). They are filled with extracellular fluid and form passageways through the muscle fiber, like a network of tunnels through a mountain. As extensions of the sarcolemma, T tubules share the same special property of being able to conduct an electrical impulse. As a result, electrical impulses conducted by the sarcolemma also travel along the T tubules into the cell interior. These impulses, called *action potentials*, trigger muscle fiber contraction.

Myofibrils

Each muscle fiber contains hundreds to thousands of cylindrical structures called **myofibrils** (Figure 10–3). A myofibril is $1-2 \mu m$ in diameter and as long as the entire cell. Branches of the T tubules encircle each myofibril. The active shortening of myofibrils is responsible for skeletal muscle fiber contraction.

Myofibrils consist of bundles of protein filaments called **myofilaments**. Myofibrils contain two types of myofilaments that we introduced in Chapter 3: **thin filaments** composed primarily of actin, and **thick filaments** composed primarily of myosin. \bigcirc pp. 71, 73 In addition, myofibrils contain *titin*, elastic myofilaments associated with the thick filaments. (We will consider the role of titin later in the chapter.)

Myofibrils are anchored to the inner surface of the sarcolemma at each end of a skeletal muscle fiber. In turn, the outer surface of the sarcolemma is attached to collagen fibers of the

tendon or aponeurosis of the skeletal muscle. As a result, when the myofibrils shorten or contract, the entire cell shortens and pulls on the tendon.

Scattered among the myofibrils are mitochondria and granules of glycogen, the storage form of glucose. Mitochondrial activity and glucose breakdown by glycolysis provide energy in the form of ATP for short-duration, maximum-intensity muscular contractions. \bigcirc **p**. 77

The Sarcoplasmic Reticulum

In skeletal muscle fibers, a membrane complex called the **sarcoplasmic reticulum (SR)** forms a tubular network around each individual myofibril, fitting over it like lacy shirtsleeves (**Figure 10–3**). The SR is similar to the smooth endoplasmic reticulum of other cells.

Wherever a T tubule encircles a myofibril, the tubule is tightly bound to the membranes of the SR. On either side of a T tubule, the tubules of the SR enlarge, fuse, and form expanded chambers called **terminal cisternae** (sis-TUR-nē). This combination of a pair of terminal cisternae plus a T tubule is known as a **triad**. Although the membranes of the triad are tightly bound together, their fluid contents are separate and distinct.

In Chapter 3, we noted that special ion pumps keep the intracellular concentration of calcium ions (Ca^{2+}) very low. **> p. 96** Most cells pump calcium ions out across their plasma membranes and into the extracellular fluid. Although skeletal muscle fibers do export Ca^{2+} in this way, they also remove calcium ions from the cytosol by actively transporting them into the terminal cisternae of the SR. The cytosol of a resting skeletal muscle fiber contains very low concentrations of Ca^{2+} , around 10^{-7} mmol/L. The free Ca^{2+} concentration levels inside the terminal cisternae may be as much as 1000 times higher. In addition, terminal cisternae contain the protein *calsequestrin*, which reversibly binds Ca^{2+} . Including both the free calcium and the bound calcium, the total concentration of Ca^{2+} inside terminal cisternae can be 40,000 times that of the surrounding cytosol.

A muscle contraction begins when stored calcium ions are released into the cytosol. These ions then diffuse into individual contractile units called *sarcomeres*.

10

Sarcomeres

As we have seen, myofibrils are bundles of thin and thick myofilaments. These myofilaments are organized into repeating functional units called **sarcomeres** (SAR- $k\bar{o}$ -merz; *sarkos*, flesh + *meros*, part). Sarcomeres are the smallest functional units of the muscle fiber. Interactions between the thick and thin filaments within sarcomeres are responsible for muscle contraction.

A myofibril consists of approximately 10,000 sarcomeres, end to end. Each sarcomere has a resting length of about 2 μ m. A sarcomere contains (1) thick filaments, (2) thin filaments, (3) proteins that stabilize the positions of the thick and thin filaments, and (4) proteins that regulate the interactions between thick and thin filaments.

Differences in the size, density, and distribution of thick filaments and thin filaments account for the banded appearance of each myofibril (Figure 10–4). Each sarcomere has dark bands called **A bands** and light bands called **I bands**. The names of these bands are derived from *anisotropic* and *isotropic*, which refer to their appearance when viewed using polarized light microscopy.

TIPS&TRICKS

You can remember that actin occurs in thin filaments by associating the "tin" in actin with the word thin. Then remember that thin filaments look light and form the l band. Similarly, the **A** bands are d**A**rk.

The A Band

The A bands contain regions of overlapping thick (myosin) and thin (actin) filaments. The thick filaments are at the center of each sarcomere, in the A band. The A band is about as long as a typical thick filament. The A band also includes portions of thin filaments and contains these three subdivisions (Figure 10–4):

- 1. *The M Line*. The **M line** is in the center of the A band. Proteins of the M line connect the central portion of each thick filament to neighboring thick filaments. (The M is for *middle*.) These dark-staining proteins help stabilize the positions of the thick filaments.
- 2. *The H Band*. In a resting sarcomere, the **H band** is a lighter region on either side of the M line. The H band contains thick filaments, but no thin filaments.
- **3.** *The Zone of Overlap.* The **zone of overlap** is a dark region where thin filaments are located between the thick filaments. Here three thick filaments surround each thin filament, and six thin filaments surround each thick filament.

The longitudinal views in **Figure 10–4** and the cross-sectional views in **Figure 10–5b** should help you to visualize a threedimensional image of these regions of a sarcomere. Two T tubules encircle each sarcomere, and the triads containing them are located in the zones of overlap, at the edges of the A band (Figure 10–3). As a result, calcium ions released by the SR enter the regions where thick and thin filaments can interact.

The I Band

The I band is a region of the sarcomere that contains thin filaments but no thick filaments. It extends from the A band of one sarcomere to the A band of the next sarcomere (Figure 10–4). **Z lines** bisect the I bands and mark the boundary between adjacent sarcomeres. The Z lines consist of proteins called *actinins*, which interconnect thin filaments of adjacent sarcomeres. At both ends of the sarcomere, thin filaments extend from the Z lines toward the M line and into the zone of overlap.

Strands of the elastic protein **titin** extend from the tips of the thick filaments to attachment sites at the Z line (**Figures 10–4a** and **10–5**). Titin helps keep the thick and thin filaments in proper alignment and aids in restoring resting sarcomere length after contraction. It also helps the muscle fiber resist extreme stretching that would otherwise disrupt the contraction mechanism.

Each Z line is surrounded by a meshwork of intermediate filaments that interconnect adjacent myofibrils. The myofibrils closest to the sarcolemma, in turn, are bound to attachment sites on the interior surface of the membrane. Because the Z lines of all the myofibrils are aligned in this way, the muscle fiber as a whole has a banded appearance due to the alternating A bands and I bands (Figure 10–2b). These bands, or *striations*, are visible with the light microscope, so skeletal muscle tissue is also known as striated muscle. \supset p. 142

Figure 10–6 reviews the levels of skeletal muscle organization we have discussed so far. Now let's consider the molecular structure of the thin and thick myofilaments responsible for muscle contraction.

Thin Filaments

A typical thin filament is 5–6 nm in diameter and 1 μ m in length (Figure 10–7a). A single thin filament contains four proteins: F-actin, nebulin, tropomyosin, and troponin (Figure 10–7b).

Filamentous actin, or F-actin, is a twisted strand composed of two rows of 300–400 individual globular molecules of **G-actin** (Figure 10–7b). A long strand of **nebulin** extends along the F-actin strand in the cleft between the rows of G-actin molecules. Nebulin holds the F-actin strand together. Each G-actin molecule contains an **active site**, where myosin (in the thick filaments) can bind. This is similar to enzymatic reactions in which a substrate molecule binds to the active site of an enzyme. (Recall that a substrate is a substance that is acted upon by an enzyme.) ⊃ p. 54 Under resting conditions, however, the *troponin–tropomyosin complex* prevents myosin binding.

Strands of **tropomyosin** (trō-pō-MĪ-ō-sin; *trope*, turning) cover the active sites on G-actin and prevent actin–myosin interaction. A tropomyosin molecule is a double-stranded protein that covers seven active sites. It is bound to one molecule of troponin midway along its length. A **troponin** (TRŌ-pō-nin) molecule consists of three globular subunits. One subunit binds to tropomyosin, locking them together as a troponin–tropomyosin complex, and a second subunit binds to one G-actin, holding the troponin–tropomyosin complex in position. The third subunit has a receptor that binds two calcium ions. In a resting muscle, intracellular Ca²⁺ concentrations are very low, and that binding site is empty.

A contraction can occur only when the troponin–tropomyosin complex changes position, exposing the active sites on actin. The necessary change in position takes place when calcium ions bind to receptors on the troponin molecules.

The thin filaments are attached to the Z lines at either end of the sarcomere (Figure 10–7a). Although it is called a "line" because it looks like a dark line on the surface of the myofibril, the Z line in sectional view is more like a disc with an open meshwork (Figure 10–5b). For this reason, the Z line is often called the Z disc.

Figure 10–6 Levels of Functional Organization in a Skeletal Muscle.

Thick Filaments

Thick filaments are 10-12 nm in diameter and $1.6 \ \mu$ m long (Figure 10-7c). A thick filament contains about 300 myosin molecules, each made up of a pair of myosin subunits twisted around one another (Figure 10-7d). The long tail is bound to other myosin molecules in the thick filament. The free head, which projects outward toward the nearest thin filament, has two globular protein subunits.

When the myosin heads interact with thin filaments during a contraction, they are known as **cross-bridges**. The connection between the head and the tail functions as a hinge that lets the head pivot. When it pivots, the head swings toward or away from the M line. As we will see in a later section, this pivoting is the key step in muscle contraction.

All the myosin molecules are arranged with their tails pointing toward the M line (Figure 10–7c). The H band includes a central region where there are no myosin heads. Elsewhere on the thick filaments, the myosin heads are arranged in a spiral, each facing one of the surrounding thin filaments.

Each thick filament has a core of titin. On either side of the M line, a strand of titin extends the length of the thick filament and then continues across the I band to the Z line on that side. The portion of the titin strand exposed within the I band is *elastic*, which means that it will recoil after stretching. In the normal resting sarcomere, the titin strands are completely relaxed. They become tense only when some external force stretches the sarcomere.

Sliding Filaments and Muscle Contraction

What happens to a sarcomere when a skeletal muscle fiber contracts? As you can see in **Figure 10–8**, (1) the H bands and I bands of the sarcomeres narrow, (2) the zones of overlap widen, (3) the Z lines move closer together, and (4) the width of the A band remains constant.

These observations make sense only if the thin filaments are sliding toward the center of each sarcomere, alongside the thick filaments. This explanation is known as the **sliding filament theory**. The contraction weakens with the disappearance of the I bands, at which point the Z lines are in contact with the ends of the thick filaments.

7 line

Figure 10–8 Changes in the Appearance of a Sarcomere during the Contraction of a Skeletal Muscle Fiber.

During a contraction, sliding occurs in every sarcomere along the myofibril. As a result, the myofibril gets shorter. Because myofibrils are attached to the sarcolemma at each Z line and at either end of the muscle fiber, when myofibrils get shorter, so does the muscle fiber.

$\mathsf{TIPS}^{\mathcal{N}}$ TRICKS

To better understand the actions of sliding filaments during a muscle contraction, hold your hands in front of you, palms toward your body and thumbs sticking straight up. Now move your hands together, so that the fingers of one hand move in between the fingers of the other hand. Your fingers represent thin and thick filaments, and your thumbs the Z lines. Notice that finger length stays the same, but your thumbs move closer together.

When muscle cells contract, they pull on the attached tendon fibers the way a line of people might pull on a rope. Let's consider what is happening in light of some basic physical principles that apply to muscle cells. The pull, called tension, is an active force: Energy must be expended to produce it. Tension is applied to some object, whether a rope, a rubber band, or a book on a tabletop. Tension applied to an object tends to pull the object toward the source of the tension. However, before movement can occur, the applied tension must overcome the object's load (or resistance), a passive force that opposes movement. The amount of load can depend on the weight of the object, its shape, friction, and other factors. When the applied tension exceeds the load, the object moves.

In contrast, *compression*, or a push applied to an object, tends to force the object away from the source of the compression. Again, no movement can occur until the applied compression exceeds the load of the object. Muscle cells can use energy to

10-4 The nervous system communicates with skeletal muscles at the neuromuscular junction

Learning Outcome Identify the components of the neuromuscular junction, and summarize the events involved in the neural control of skeletal muscle contraction and relaxation.

You have seen that the myofilaments in a sarcomere change position during a contraction, but not how these changes occur. In this section we first discuss how the plasma membranes of neurons and skeletal muscle fibers propagate electrical impulses. (This topic is explored more fully in Chapter 12.) We then look at how skeletal muscle activity is under neural control (as you will see in Spotlight Figure 10-9), how neural stimulation of a muscle fiber is coupled to the contraction of the fiber (presented in Spotlight Figure 10-10), and how actin and myosin interact to cause sarcomere contraction (shown in **Spotlight Figure 10-11**). Read the text on p. 302 before studying these three Spotlights.

SPOTLIGHT Figure 10–9 Events at the Neuromuscular Junction

A single axon may branch to control more than one skeletal muscle fiber, but each muscle fiber has only one neuromuscular junction (NMJ). At the NMJ, the axon terminal of the neuron lies near the motor end plate of the muscle fiber.

Muscle Fiber

The action potential generated at the motor end plate now sweeps across the entire membrane surface. The effects are almost immediate because an action potential is an electrical event that flashes like a spark across the sarcolemmal surface. The effects are brief because the ACh has been removed, and no further stimulus acts upon the motor end plate until another action potential arrives at the axon terminal.

3

When the action potential reaches the neuron's axon terminal, permeability changes in its membrane trigger the exocytosis of ACh into the synaptic cleft. Exocytosis occurs as vesicles fuse with the neuron's plasma membrane. 4 ACh molect synaptic cle receptors o motor end alters the m ity to sodiu extracellula concentrati and sodium inside the c

ACh molecules diffuse across the synaptic cleft and bind to ACh receptors on the surface of the motor end plate. ACh binding alters the membrane's permeability to sodium ions. Because the extracellular fluid contains a high concentration of sodium ions, and sodium ion concentration inside the cell is very low, sodium ions rush into the cytosol.

The sudden inrush of sodium ions results in the generation of an action potential in the sarcolemma. ACh is removed from the synaptic cleft in two ways. ACh either diffuses away from the synapse, or it is broken down by AChE into acetic acid and choline. This removal inactivates the ACh receptor sites. The muscle fiber pictured above indicates the propagation of the action potential along the sarcolemma.

5

Motor end plate

Electrical Impulses and Excitable Membranes

As we learned in Chapter 3, all the cells of the body maintain a membrane potential due to an unequal distribution of positive and negative charges across their plasma membrane. \bigcirc p. 100 The unequal charge distribution means cells are *polarized*, much like miniature batteries. In cells, the inner surface of the plasma membrane is slightly negative compared to the outer surface. The membrane potential is a measure of cellular polarization (in millivolt units) that compares the cytoplasmic membrane surface charge to the extracellular membrane surface charge. In unstimulated (resting) neurons and skeletal muscle fibers, typical resting membrane potentials are -70 mV and -85 mV, respectively.

Recall that the main contributors of negative charges within a cell are proteins that cannot cross the plasma membrane. There is also an excess of sodium ions outside a cell and an excess of potassium ions inside a cell. These ions can cross a membrane through membrane channels that are specific for each ion.

Various stimuli can lead to a temporary change in the distribution of electrical charges across the plasma membranes of all body cells. Differences in sodium ion and potassium ion membrane permeability underlie such changes. An influx of sodium ions leads to *depolarization* as the membrane potential becomes less negative. The movement of potassium ions out of a cell leads to *hyperpolarization* as the membrane potential becomes more negative. A return to the resting potential is called *repolarization*. In most cells, the depolarization or hyperpolarization of a plasma membrane is a localized change limited by the presence or absence of stimulation. Called a *graded potential*, it does not continue to spread over the plasma membrane.

Neurons and skeletal muscle fibers, however, have electrically excitable membranes. Excitable membranes permit rapid communication between different parts of a cell. In neurons and skeletal muscle fibers, the depolarization and repolarization events produce an electrical impulse, or action potential, that is propagated along their plasma membranes. Unlike the plasma membranes of most cells, excitable membranes contain voltagegated channels that are activated and inactivated by changes in the membrane potential. These electrical channels become activated when the membranes of neurons and skeletal muscle fibers first depolarize from the resting potential to a threshold potential (from -70 to -60 mV for neurons and from -85 to -55 mV for skeletal muscle fibers). Upon reaching the threshold potential, voltage-gated sodium channels open and there is a rapid influx of positively charged sodium ions into the cell. The inside of the membrane reverses from a negative to positive charge, and the depolarization peaks at a membrane potential of +30 mV with the closure of the voltage-gated sodium channels. Repolarization of the membrane then begins as voltage-gated potassium channels open and positively charged potassium ions leave the cell. The loss of more positive charges than entered the cell causes the membrane potential to become negative again. A "resting" refractory period follows and the former concentrations of sodium

and potassium ions across the plasma membrane are restored through the action of sodium–potassium ion pumps. \bigcirc p. 96 A further depolarization cannot occur until the refractory period is over. As a result, the action potential travels in one direction because the refractory period prevents it from propagating back in the direction from where it was initiated.

The Control of Skeletal Muscle Activity

Skeletal muscle fibers begin contraction with the release of their internal stores of calcium ions. That release is under the control of the nervous system. Communication between a neuron and another cell occurs at a *synapse*. When the other cell is a skeletal muscle fiber, the synapse is known as a **neuromuscular junction (NMJ)**, or *myoneural junction*. The NMJ is made up of an *axon terminal* (synaptic terminal) of a neuron, a specialized region of the sarcolemma called the *motor end plate*, and, in between, a narrow space called the *synaptic cleft*.

Motor neurons of the central nervous system (brain and spinal cord) carry instructions in the form of action potentials to skeletal muscle fibers. A motor neuron stimulates a muscle fiber through a series of steps as shown in **Spotlight Figure 10–9** (pp. 300–301).

Excitation-Contraction Coupling

The link between the generation of an action potential in the sarcolemma and the start of a muscle contraction is called excitationcontraction coupling. This coupling occurs at the triads. On reaching a triad, an action potential triggers the release of Ca²⁺ from the cisternae of the sarcoplasmic reticulum. The change in the permeability of the SR to Ca^{2+} is temporary, lasting only about 0.03 second. Yet within a millisecond, the Ca²⁺ concentration in and around the sarcomere reaches 100 times resting levels. Because the terminal cisternae are located at the zones of overlap, where the thick and thin filaments interact, the effect of calcium ion release on the sarcomere is almost instantaneous. Troponin is the lock that keeps the active sites inaccessible. Calcium is the key to that lock. Recall from Figure 10-7b that troponin binds to both actin and tropomyosin, and that the tropomyosin molecules cover the active sites and prevent interactions between thick filaments and thin filaments. Each troponin molecule also has a binding site for calcium, and this site is empty when the muscle fiber is at rest. Calcium binding changes the shape of the troponin molecule and weakens the bond between troponin and actin. The troponin molecule then changes position, rolling the attached tropomyosin strand away from the active sites (Spotlight Figure 10-10). With this change, the contraction cycle begins.

The Contraction Cycle

The contraction cycle is a series of molecular events that enable muscle contraction. **Spotlight Figure 10–11**, pp. 304–305, shows the interlocking steps of the contraction cycle.

SPOTLIGHT Figure 10–10 Excitation-Contraction Coupling

Watch the Mastering A&P" > A&PFlix on Excitation-Contraction Coupling.

Neural Control

A skeletal muscle fiber contracts when stimulated by a motor neuron at a neuromuscular junction. The stimulus arrives in the form of an action potential at the axon terminal.

2

3

4

5

Excitation

The action potential causes the release of ACh into the synaptic cleft, which leads to excitation—the production of an action potential in the sarcolemma.

Release of Calcium Ions

This action potential travels along the sarcolemma and down T tubules to the triads. This triggers the release of calcium ions (Ca2+) from the terminal cisternae of the sarcoplasmic reticulum.

Contraction Cycle Begins

The contraction cycle begins when the calcium ions (Ca²⁺) bind to troponin, resulting in the exposure of the active sites on the thin filaments. This allows cross-bridge formation and will continue as long as ATP is available. (See Spotlight Figure 10-11 for the details of the contraction cycle.)

Sarcomere Shortening

As the thick and thin filaments interact, the sarcomeres shorten, pulling the ends of the muscle fiber closer together.

Generation of Muscle Tension

During the contraction, the entire skeletal muscle shortens and produces a pull, or tension, on the tendons at either end.

Muscle fiber

contraction

leads to

Tension

production

SPOTLIGHT Figure 10–11 The Contraction Cycle and Cross-Bridge Formation

Contraction Cycle Begins

The contraction cycle involves a series of interrelated steps. It begins with the arrival of calcium ions (Ca²⁺) within the zone of overlap in a sarcomere.

ADF

Active-Site Exposure

Calcium ions bind to troponin, weakening the bond between actin and the troponin-tropomyosin complex. The troponin molecule then changes position, rolling the tropomyosin molecule away from the active sites on actin and allowing interaction with the energized myosin heads.

Cytosol

Cross-Bridge Formation

Once the active sites are exposed, the energized myosin heads bind to them, forming cross-bridges.

RESTING SARCOMERE

In the resting sarcomere, each myosin head is already "energized"-charged with the energy that will be used to power a contraction. Each myosin head points away from the M line. In this position, the myosin head is "cocked" like the spring in a mousetrap. Cocking the myosin head requires energy, which is obtained by breaking down ATP; in doing so, the myosin head functions as ATPase, an enzyme that breaks down ATP. At the start of the contraction cycle, the breakdown products, ADP and phosphate (represented as P), remain bound to the myosin head.

Myosin Head Pivoting

After cross-bridge formation, the energy that was stored in the resting state is released as the myosin head pivots toward the M line. This action is called the power stroke; when it occurs, the bound ADP and phosphate group are released.

Cross-Bridge Detachment

When another ATP binds to the myosin head, the link between the myosin head and the active site on the actin molecule is broken. The active site is now exposed and able to form another cross-bridge.

6

Myosin Reactivation

Myosin reactivation occurs when the free myosin head splits ATP into ADP and P. The energy released is used to recock the myosin head.

M

۱۸ſ

W

W

N

N

CONTRACTED SARCOMERE

The entire cycle is repeated several times each second, as long as Ca²⁺ concentrations remain elevated and ATP reserves are sufficient. Calcium ion levels will remain elevated only as long as action potentials continue to pass along the T tubules and stimulate the terminal cisternae. Once that stimulus is removed, the calcium channels in the SR close and calcium ion pumps pull Ca²⁺ from the cytosol and store it within the terminal cisternae. Troponin

molecules then shift position, swinging the tropomyosin strands over the active sites and preventing further cross-bridge formation. As we have noted, the power stroke refers to the molecular interactions of muscle contraction. Each power stroke shortens the sarcomere by about 0.5 percent. The entire muscle shortens at the same rate because all the sarcomeres contract together. The speed of the shortening depends on the cycling rate (the number of power strokes per second). The greater the load, the slower the cycling rate.

To understand how the contraction cycle produces tension in a muscle fiber, imagine that you are on a tug-of-war team. You reach forward, grab the rope with both hands, and pull it in. This grab-and-pull corresponds to cross-bridge attachment and pivoting. You then let go of the rope, reach forward and grab it, and pull once again. Your actions are not synchronized with the rest of your team. At any given time, some people are reaching and grabbing, some are pulling, and others are letting go. (If everyone let go at the same time, your opponents would pull the rope away.) The amount of tension produced depends on how many people are pulling at the same time.

The situation is similar in a muscle fiber. The myosin heads along a thick filament work together in a similar way to pull a thin filament toward the center of the sarcomere. Each myofibril consists of a string of sarcomeres, and in a contraction all of the thin filaments are pulled toward the centers of the sarcomeres.

If neither end of the myofibril is held in position, both ends move toward the middle, as you can see in Figure 10–12a.

Such a contraction seldom occurs in an intact skeletal muscle, because one end of the muscle (the *origin*) is usually fixed in position during a contraction, while the other end (the *insertion*) moves. In that case, the free end moves toward the fixed end (Figure 10–12b).

If neither end of the myofibril can move, thick and thin filament interactions consume energy and generate tension, but sliding cannot occur. We will discuss this kind of contraction, called an *isometric contraction*, in a later section.

Figure 10–13 reviews the contraction process, beginning with ACh release and ending with relaxation.

Figure 10–12 Shortening during a Contraction.

b When only one end of a myofibril is fixed in position, the free end is pulled toward the fixed end.

Tetanus Children are often told to be careful around rusty nails. But it's not the rust or the nail, but instead an infection by the very common bacterium Clostridium tetani that causes the disease called tetanus. This disease and the normal muscle response to rapid neural stimulation share the same name, but the mechanisms involved are very different. Clostridium bacteria occur in soil and virtually everywhere else in the environment, but they can thrive only in tissues with low oxygen levels. For this reason, a deep puncture wound, such as that from a nail, is much more likely to result in tetanus than a shallow, open cut that bleeds freely. When active in body tissues, these bacteria release a powerful toxin called tetanospasmin that affects the central nervous system. Motor neurons, which control skeletal muscles throughout the body, are particularly sensitive to it. The toxin suppresses the mechanism that inhibits motor neuron activity. The result is a sustained, powerful contraction of skeletal muscles throughout the body.

The incubation period (the time between exposure and the development of symptoms) is generally less than two

weeks. The most common early complaints are headache, muscle stiffness, and difficulty in swallowing. The disease is also called *lockjaw* because patients also find it difficult to open the mouth. Widespread muscle spasms typically develop within two or three days of the initial symptoms and continue for a week before subsiding. After two to four weeks, patients who survive recover with no aftereffects.

Severe tetanus has a 40–60 percent mortality rate. In other words, for every 100 people who develop severe tetanus, 40 to 60 die. Approximately 500,000 cases of tetanus occur worldwide each year, but only about 100 of them occur in the United States, thanks to an effective immunization program. (Recommended immunization involves a "tetanus shot" followed by a booster shot every 10 years.) In unimmunized patients, early administration of an antitoxin—in most cases, *human tetanus immunoglobulin*—can prevent severe symptoms. However, this treatment does not reduce signs and symptoms that have already appeared.

10

Figure 10–13 Steps Involved in Skeletal Muscle Contraction and Relaxation.

Relaxation

How long does a contraction last? Its duration depends on (1) the period vof stimulation at the neuromuscular junction, (2) the presence of free calcium ions in the cytosol, and (3) the availability of ATP. A single stimulus has only a brief effect on a muscle fiber, because the ACh released as a result of a single action potential is rapidly broken down by AChE. Inside the muscle fiber, the permeability changes in the SR are also very brief. For these reasons, a contraction will continue only if additional action potentials arrive at the axon terminal in rapid succession. When they do, the continual release of ACh into the synaptic cleft produces a series of action potentials in the sarcolemma that keeps Ca^{2+} levels elevated in the cytosol. Under these conditions, the contraction cycle will be repeated over and over.

If just one action potential arrives at the neuromuscular junction, Ca^{2+} concentrations in the cytosol will quickly return to normal resting levels. Two mechanisms are involved in this process: (1) active Ca^{2+} transport across the sarcolemma into the extracellular fluid, and (2) active Ca^{2+} transport into the SR. Of the two, transport into the SR is far more important. Virtually as soon as the calcium ions have been released, the SR returns to its normal permeability and begins to actively take up Ca^{2+} from the surrounding cytosol. As Ca^{2+} concentrations in the cytosol fall, earlier events reverse themselves: (1) Calcium ions detach from troponin, (2) troponin returns to its original position, and (3) the active sites on actin are once again covered by tropomyosin. The contraction has ended.

The sarcomeres do not automatically return to their original length. Sarcomeres shorten actively, but there is no active mechanism for reversing the process. External forces must act on the contracted muscle fiber to stretch the myofibrils and sarcomeres to their original dimensions. We describe those forces in a later section.

CHECKPOINT

- 8. Describe the neuromuscular junction.
- 9. How would a drug that blocks acetylcholine release affect muscle contraction?
- **10**. What would happen to a resting skeletal muscle if the sarcolemma suddenly became very permeable to calcium ions?
- 11. Predict what would happen to a muscle if the motor end plate failed to produce acetylcholinesterase (AChE).

10-5 Sarcomere shortening and muscle fiber stimulation produce tension

Learning Outcome Describe the mechanism responsible for tension production in a muscle fiber, and compare the different types of muscle contraction.

When sarcomeres shorten in a contraction, they shorten the muscle fiber. This shortening exerts tension on the connective tissue fibers attached to the muscle fiber. The tension produced by an individual muscle fiber can vary, and in the next section we consider the specific factors involved. In a subsequent section, we see that the tension produced by an entire skeletal *muscle* can vary even more widely. Why? Not only can tension production vary among the individual muscle fibers, but the number of stimulated muscle fibers can change from moment to moment.

Tension Production by Muscle Fibers

The amount of tension produced by an individual muscle fiber ultimately depends on the number of pivoting cross-bridges. There is no way to regulate the amount of tension produced in that contraction by changing the number of contracting sarcomeres within a muscle fiber. When calcium ions are released, they are released from all triads in the muscle fiber. For this

Rigor Mortis When death occurs, circulation ceases and the skeletal muscles are deprived of nutrients and oxygen. Within a few hours, the skeletal muscle fibers run out of ATP and the sarcoplasmic reticulum becomes unable to pump Ca²⁺ out of the cytosol. Calcium ions diffusing into the cytosol from the extracellular fluid or leaking out of the SR then trigger a sustained contraction. Without ATP, the cross-bridges cannot detach from the active sites, so skeletal muscles throughout the body become locked in the contracted position. Because all

the skeletal muscles are involved, the body becomes "stiff as a board." This physical state—**rigor mortis**—lasts until the lysosomal enzymes released by autolysis break down the Z lines and titin filaments. Rigor mortis begins two to seven hours after death and ends after one to six days or when decomposition begins. The timing depends on environmental factors, such as temperature. Forensic pathologists can estimate the time of death on the basis of the degree of rigor mortis and environmental conditions. reason, a muscle fiber is either "on" (producing tension) or "off" (relaxed).

The tension produced by an individual muscle fiber *does* vary, however, for other reasons. It depends on (1) the fiber's resting length at the time of stimulation, which determines the degree of overlap between thick and thin filaments; and (2) the frequency of stimulation, which affects the internal concentration of calcium ions and thus the amount bound to troponin.

Length–Tension Relationships

Figure 10–14 shows the effect of sarcomere length on active tension. When many people pull on a rope, the amount of tension produced is proportional to the number of people pulling. Similarly, in a skeletal muscle fiber, the amount of tension generated during a contraction depends on the number of pivoting cross-bridges in each of the myofibrils. The number of cross-bridges that can form, in turn, depends on the degree

of overlap between thick filaments and thin filaments within these sarcomeres. When the muscle fiber is stimulated to contract, only myosin heads in the zones of overlap can bind to active sites and produce tension. For these reasons, we can relate the tension produced by the entire muscle fiber to the structure of individual sarcomeres.

A sarcomere works most efficiently within an optimal range of lengths. When the resting sarcomere length is within this range, the maximum number of cross-bridges can form, and the tension produced is highest. If the resting sarcomere length falls outside the range—if the sarcomere is compressed and shortened, or stretched and lengthened—it cannot produce as much tension when stimulated. The reason is that the number of cross-bridges that form largely determines the amount of tension produced. An increase in sarcomere length reduces the tension produced by reducing the size of the zone of overlap and the number of potential cross-bridges.

Figure 10–14 The Effect of Sarcomere Length on Active Tension.

A decrease in the resting sarcomere length reduces efficiency because the stimulated sarcomere cannot shorten very much before the thin filaments extend across the center of the sarcomere and collide with or overlap the thin filaments of the opposite side. This disrupts the precise three-dimensional relationship between thick and thin filaments and interferes with the binding of myosin heads to active sites and the propagation of the action potential along the T tubules. Because the number of cross-bridges is reduced, tension declines in the stimulated muscle fiber.

Tension production falls to zero when the resting sarcomere is at its shortest length. At this point, the thick filaments are jammed against the Z lines and no further shortening is possible. Although cross-bridge binding can still occur, the myosin heads cannot pivot and generate tension, because the thin filaments cannot move.

In summary, skeletal muscle fibers contract most forcefully when stimulated over a narrow range of lengths (Figure 10–14). The arrangement of skeletal muscles, connective tissues, and bones normally prevents extreme compression or excessive stretching. For example, straightening your elbow stretches your *biceps brachii muscle*, but the bones and ligaments of the elbow stop this movement before the muscle fibers stretch too far. During an activity such as walking, in which muscles contract and relax cyclically, muscle fibers are stretched to a length very close to "ideal" before they are stimulated to contract. When muscles must contract over a larger range of resting lengths, they often "team up" to improve efficiency. (We will discuss the mechanical principles involved in Chapter 11.)

The Frequency of Stimulation

A single stimulation produces a single contraction, or *twitch*, that may last 7–100 milliseconds, depending on the muscle stimulated. Although muscle twitches can be produced by electrical stimulation in a laboratory, they are too brief to be part of any normal activity. The duration of a contraction can be extended by repeated stimulation, and a muscle fiber undergoing such a sustained contraction produces more tension than it does in a single twitch. To understand why, we need to take a closer look at tension production during a twitch and then follow the changes that occur as the rate of stimulation increases. This is an important subject, as all consciously and subconsciously directed muscular activities—standing, walking, running, reaching, and so forth—involve sustained muscular contractions rather than twitches.

Twitches. A **twitch** is a single stimulus–contraction–relaxation sequence in a muscle fiber. Twitches vary in duration, depending on the type of muscle, its location, internal and external environmental conditions, and other factors. Twitches in an eye muscle fiber can be as brief as 7.5 msec, but a twitch in a muscle fiber from the *soleus*, a small calf muscle, lasts about 100 msec.

Figure 10–15a is a myogram, or graphic representation, showing twitch tension development in muscle fibers from various skeletal muscles.

Figure 10–15b details the phases of a 40-msec twitch in a muscle fiber from the *gastrocnemius muscle*, a prominent calf muscle. We can divide a single twitch into a *latent period*, a *contraction phase*, and a *relaxation phase*:

 The **latent period** begins at stimulation and lasts about 2 msec. During this period, the action potential sweeps across the sarcolemma, and the SR releases calcium ions. The muscle fiber does not produce tension during the latent period, because the contraction cycle has yet to begin.

- 2. In the **contraction phase**, tension increases to a peak. As the tension increases, calcium ions are binding to troponin, active sites on thin filaments are being exposed, and cross-bridge interactions are occurring. For this muscle fiber, the contraction phase ends roughly 15 msec after stimulation.
- **3.** The **relaxation phase** lasts about 25 msec. During this period, Ca²⁺ levels are decreasing, active sites are being covered by tropomyosin, and the number of active cross-bridges is declining as they detach. As a result, tension decreases to resting levels.

Treppe. If a skeletal muscle is stimulated a second time immediately after the relaxation phase has ended, the resulting contraction will develop a slightly higher maximum tension than did the first contraction. The increase in peak tension shown in **Figure 10–16a** will continue over the first 30–50 stimulations. After that, the amount of tension produced will remain constant. This pattern is called **treppe** (TREP-eh, German for staircase) because the tension rises in stages, like the steps in a staircase. The rise is thought to result from a gradual increase in the concentration of Ca²⁺ in the cytosol, in part because the calcium ion pumps in the SR have too little time to recapture the ions between stimulations. Most skeletal muscles don't undergo treppe. (However, treppe is a phenomenon in cardiac muscle. It occurs if stimuli of the same intensity are sent to the muscle fiber after a latent period.)

Figure 10–16 Effects of Repeated Stimulations.

further. Tension production rises to a peak, and the periods of relaxation are very brief. **Wave Summation.** If a second stimulus arrives before the relaxation phase has ended, a second, more powerful contraction occurs. The addition of one twitch to another in this way is the summation of twitches, or **wave summation** (Figure 10–16b). The duration of a single twitch determines the maximum time available for wave summation. For example, if a twitch lasts 20 msec (1/50 sec), subsequent stimuli must be separated by less than 20 msec—a stimulation rate of more than 50 stimuli per second. This rate is usually expressed in terms of *stimulus frequency*, which is the number of stimuli per unit time. In this instance, a stimulus frequency of greater than 50 per second produces wave summation, whereas a stimulus frequency of less than 50 per second produces individual twitches and treppe.

Incomplete Tetanus. If the stimulation continues and the muscle is never allowed to relax completely, tension will increase until it reaches a peak value roughly four times the maximum produced by treppe (Figure 10–16c). A muscle producing almost peak tension during rapid cycles of contraction and relaxation is in **incomplete tetanus** (*tetanos*, convulsive tension).

Complete Tetanus. When a higher stimulation frequency eliminates the relaxation phase, **complete tetanus** occurs (Figure 10–16d). Action potentials arrive so rapidly that the SR does not have time to reclaim the Ca^{2+} . The high Ca^{2+} concentration in the cytosol prolongs the contraction, making it continuous.

Tension Production by Skeletal Muscles

Now that you are familiar with the basic mechanisms of muscle contraction at the level of the individual muscle fiber, we can begin to examine the performance of skeletal muscles—the organs of the muscular system. In this section, we will consider the coordinated contractions of an entire population of skeletal muscle fibers. The amount of tension produced in the skeletal muscle *as a whole* is determined by (1) the tension produced by the stimulated muscle fibers and (2) the total number of muscle fibers stimulated.

As muscle fibers actively shorten, they pull on the attached tendons, which become stretched. The tension is transferred in turn to bones, which are moved against an external load. (We will look at the interactions between the muscular and skeletal systems in Chapter 11.)

Muscle studies performed in the laboratory generally measure the tension in a tendon of a muscle. A single twitch is so brief that there isn't enough time to activate a significant percentage of the available cross-bridges. For this reason, twitches are ineffective in performing useful work. However, if a second twitch occurs before the tension returns to zero, tension will peak at a higher level, because additional cross-bridges will form. Think of pushing a child on a swing: You push gently to start the swing moving, but if you push harder the second time, the child swings higher because the energy of the second push is added to the energy remaining from the first. Likewise, each successive contraction begins before the tension has fallen to resting levels, so the tension continues to increase until it peaks. During a tetanic contraction, there is enough time for essentially all of the potential cross-bridges to form, and tension peaks. Muscles are rarely used this way in the body, but, in a laboratory setting, muscles can be stimulated into tetanic contractions.

Motor Units and Tension Production

The amount of tension produced by the muscle as a whole is the sum of the tensions generated by the individual muscle fibers, since they are all pulling together. For this reason, you can control the amount of tension produced by a skeletal muscle by controlling the number of muscle fibers stimulated.

A typical skeletal muscle contains thousands of muscle fibers. Some motor neurons control a few muscle fibers, but most control hundreds of them. All the muscle fibers controlled by a single motor neuron constitute a **motor unit**. The size of a motor unit is an indication of how fine the control of movement can be. In the muscles of the eye, where precise control is extremely important, a motor neuron may control 4–6 muscle fibers. We have much less precise control 1000–2000 muscle fibers. The muscle fibers of each motor unit are intermingled with those of other motor units (Figure 10–17a). Because of this intermingling, the direction of pull exerted on the tendon does not change when the number of activated motor units changes.

We have all probably seen or felt an involuntary "muscle twitch" under the skin. Such a muscle twitch is called a **fasciculation**. Unlike the twitches discussed earlier, a fasciculation involves more than one muscle fiber. It is the synchronous contraction of a motor unit.

When you decide to move your arm, specific groups of motor neurons in the spinal cord are stimulated. The contraction begins with the activation of the smallest motor units in the stimulated muscle. These motor units generally contain muscle fibers that contract relatively slowly. As the movement continues, larger motor units containing faster and more powerful muscle fibers are activated, and tension rises steeply. The smooth, but steady, increase in muscular tension produced by increasing the number of active motor units is called **recruitment**.

Peak tension occurs when all motor units in the muscle contract in a state of complete tetanus. Such powerful contractions do not last long, however, because the individual muscle

fibers soon use up their available energy reserves. During a sustained contraction, motor units are activated on a rotating basis, so some of them are resting and recovering while others are actively contracting. In this "relay team" approach, called *asynchronous motor unit summation*, each motor unit can recover somewhat before it is stimulated again (Figure 10–17b). As a result, when your muscles contract for sustained periods, they produce slightly less than maximum tension.

Muscle Tone

In any skeletal muscle, some motor units are always active, even when the entire muscle is not contracting. Their contractions do not produce enough tension to cause movement, but they do tense and firm the muscle. This resting tension in a skeletal muscle is called **muscle tone**. A muscle with little muscle tone appears limp and flaccid, whereas one with moderate muscle tone is firm and solid. Different motor units are stimulated at different times so some individual muscle fibers can relax while others maintain a constant tension in the attached tendon.

Resting muscle tone stabilizes the positions of bones and joints. For example, in muscles involved with balance and posture, enough motor units are stimulated to produce the tension needed to maintain body position. Muscle tone also helps prevent sudden, uncontrolled changes in the positions of bones and joints. In addition to bracing the skeleton, the elastic nature of muscles and tendons lets skeletal muscles act as shock absorbers that cushion the impact of a sudden bump or shock. Heightened muscle tone accelerates the recruitment process during a voluntary contraction, because some of the motor units are already stimulated. Strong muscle tone also makes skeletal muscles appear firm and well defined, even at rest.

Activated muscle fibers use energy, so the greater the muscle tone, the higher the "resting" rate of metabolism. Increasing this rate is one of the significant effects of exercise in a weight-loss program. You lose weight when your daily energy use exceeds your daily energy intake in food. Although exercise consumes energy very quickly, the period of activity is usually quite brief. In contrast, elevated muscle tone increases resting energy consumption by a small amount, but the effects are cumulative, and they continue 24 hours per day.

Isotonic and Isometric Contractions

We can classify muscle contractions as *isotonic* or *isometric* on the basis of their pattern of tension production.

Isotonic Contractions. In an **isotonic contraction** (*iso-*, equal + *tonos*, tension), tension increases and the skeletal muscle's length changes. Lifting an object off a desk, walking, and running involve isotonic contractions.

There are two types of isotonic contractions: concentric and eccentric. In a **concentric contraction**, the muscle tension *exceeds* the load and the muscle *shortens*. Consider an experiment with a skeletal muscle that is 1 cm² in cross-sectional area and can produce roughly 4 kg (8.8 lb) of tension in complete tetanus. If we hang a load of 2 kg (4.4 lb) from that muscle and stimulate it, the muscle will shorten (Figure 10–18a). Before the muscle can shorten, the cross-bridges must produce enough tension to overcome the load—in this case, the 2-kg weight. At first, tension in the muscle fibers rises until the tension in the tendon exceeds the load. Then, as the muscle shortens, the tension in the skeletal muscle remains constant at a value that just exceeds the load. The term *isotonic* originated from this type of experiment.

In the body, however, the situation is more complicated. Muscles are not always positioned directly above the load, and they are attached to bones rather than to static weights. Changes in the positions of the muscle and the articulating bones, the effects of gravity, and other mechanical and physical factors interact to increase or decrease the load the muscle must overcome as a movement proceeds. Nevertheless, during a concentric contraction, the peak tension produced exceeds that load.

The speed of shortening varies with the difference between the amount of tension produced and the size of the load. If all the motor units are stimulated and the load is fairly small, the muscle will shorten very quickly. In contrast, if the muscle barely produces enough tension to overcome the load, it will shorten very slowly.

In an **eccentric contraction**, the peak tension developed is *less than* the load, and the muscle *elongates* due to the contraction of another muscle or the pull of gravity (**Figure 10–18b**). Think of a tug-of-war team trying to stop a moving car. Although everyone pulls as hard as they can, the rope slips through their fingers. The speed of elongation depends on the difference between the amount of tension developed by the active muscle fibers and the size of the load. In our analogy, the team might slow down a small car, but would have little effect on a large truck.

Eccentric contractions are very common, and they are important in a variety of movements. In these movements, you exert precise control over the amount of tension produced. By varying the tension in an eccentric contraction, you can control the rate of elongation, just as you can vary the tension in a concentric contraction.

During physical training, people commonly perform cycles of concentric and eccentric contractions, as when you do biceps curls by holding a weight in your hand and slowly flex and extend your elbow. The flexion involves concentric contractions that exceed the load posed by the weight. During extension, the same muscles are active, but the contractions are eccentric. The tension produced isn't sufficient to overcome the force of gravity, but it is enough to control the speed of movement.

Isometric Contractions. In an **isometric contraction** (*metric*, measure), the muscle as a whole does not change length, and the tension produced never exceeds the load. Figure 10–18c shows what happens in our experiment if we attach a weight heavier than 4 kg to the muscle and then stimulate the muscle. Although cross-bridges form and tension rises to peak values, the muscle cannot overcome the load of the weight and so cannot shorten. Examples of isometric contractions include carrying a bag of groceries and holding our heads up. Many of the reflexive muscle contractions that keep your body upright when you stand or sit involve isometric contractions of muscles that oppose the force of gravity.

Notice that when you perform an isometric contraction, the contracting muscle bulges, but not as much as it does during an isotonic contraction. In an isometric contraction, the muscle *as a whole* does not shorten, but the individual muscle fibers shorten as connective tissues stretch. The muscle fibers cannot shorten further, because the tension does not exceed the load. Normal daily activities involve a combination of isotonic and isometric muscular contractions. As you sit and read this text, isometric contractions of postural muscles stabilize your vertebrae and maintain your upright position. When you turn a page, a combination of concentric and eccentric isotonic contractions moves your arm, forearm, hand, and fingers.

TIPS&TRICKS

During an *isotonic* contraction such as lifting a baby, muscle tension remains constant while muscle length changes. During an *isometric* contraction such as holding a baby at arm's length, muscle length remains constant but muscle tension changes.

Load and Speed of Contraction

You can lift a light object more rapidly than you can lift a heavy one because load and the speed of contraction are inversely related. If the load is less than the tension produced, a concentric isotonic contraction will occur, and the muscle will shorten. The heavier the load, the longer it takes for the movement to begin, because muscle tension (which increases gradually) must exceed the load before shortening can occur (Figure 10–19). The contraction itself proceeds more slowly. At the molecular level, the speed of cross-bridge pivoting is reduced as the load increases.

For each muscle, an optimal combination of tension and speed exists for any given load. If you have ever ridden a 21-speed bicycle, you are probably already aware of this fact. When you are cruising along comfortably, your thigh and leg muscles are

as a whole cannot shorten. This is an isometric contraction.

10

Figure 10–19 Load and Speed of Contraction. The heavier the load on a muscle, the longer it will take for the muscle to begin to shorten and the less the muscle will shorten.

working at an optimal combination of speed and tension. When you start up a hill, the load increases. Your muscles must now develop more tension, and they move more slowly. They are no longer working at optimal efficiency. If you then shift to a lower gear, the load on your muscles decreases and their speed increases, and the muscles are once again working efficiently.

Muscle Relaxation and the Return to Resting Length

As we noted earlier, there is no active mechanism for muscle fiber elongation. The sarcomeres in a muscle fiber can shorten and develop tension, but the power stroke cannot be reversed to push the Z lines farther apart. After a contraction, a muscle fiber returns to its original length through a combination of elastic forces, opposing muscle contractions, and gravity.

Elastic Forces. When a contraction ends, some of the energy initially "spent" in stretching the tendons and distorting intracellular organelles is recovered as they recoil or rebound to their original dimensions. This elasticity gradually helps return the muscle fiber to its original resting length.

Opposing Muscle Contractions. The contraction of opposing muscles can return a muscle to its resting length more quickly than elastic forces can. Consider the muscles of the arm that flex or extend the elbow. Contraction of the *biceps brachii muscle* on the anterior part of the arm flexes the elbow, and contraction of the *triceps brachii muscle* on the posterior part of the arm extends the elbow. When the biceps brachii muscle contracts, the triceps brachii muscle is stretched. When the biceps brachii muscle extends the elbow and stretches the muscle fibers of the biceps brachii muscle to their original length.

Gravity. Gravity may assist opposing muscle groups in quickly returning a muscle to its resting length after a contraction. For

example, imagine the biceps brachii muscle fully contracted with the elbow pointed at the ground. When the muscle relaxes, gravity will pull the forearm down and stretch the muscle. Although gravity can help in stretching muscles, some active muscle tension is needed to control the rate of movement and to prevent damage to the joint. In our example, eccentric contraction of the biceps brachii muscle can control the movement.

CHECKPOINT

- 12. Why does a muscle that has been overstretched produce less tension?
- 13. Can a skeletal muscle contract without shortening?
- See the blue Answers tab at the back of the book.

10-6 I ATP provides energy for muscle contraction

Learning Outcome Describe the mechanisms by which muscle fibers obtain the energy to power contractions.

A single muscle fiber may contain 15 billion thick filaments. When that muscle fiber is actively contracting, each thick filament breaks down around 2500 ATP molecules per second. Even a small skeletal muscle contains thousands of muscle fibers, so the ATP demands of a contracting skeletal muscle are enormous.

In practical terms, the demand for ATP in a contracting muscle fiber is so high that it would be impossible to have all the necessary energy available as ATP before the contraction begins. Instead, a resting muscle fiber contains only enough ATP and other high-energy compounds to sustain a contraction until additional ATP can be generated. Throughout the rest of the contraction, the muscle fiber will generate ATP at roughly the same rate as it is used.

ATP and CP Reserves

The primary function of ATP is to transfer energy from one location to another rather than to store it long-term. At rest, a skeletal muscle fiber produces more ATP than it needs. Under these conditions, ATP transfers energy to creatine. *Creatine* (KRĒ-uh-tēn) is a small molecule that muscle cells assemble from fragments of amino acids. The energy transfer creates another high-energy compound, **creatine phosphate (CP)**, also known as phosphocreatine:

 $ATP + creatine \longrightarrow ADP + creatine phosphate$

During a contraction, each myosin head breaks down ATP, producing ADP and phosphate. The energy stored in creatine phosphate is then used to "recharge" ADP, converting it back to ATP through the reverse reaction:

 $ADP + creatine phosphate \longrightarrow ATP + creatine$

The enzyme that catalyzes this reaction is **creatine kinase (CK)**. When muscle cells are damaged, CK leaks across the plasma membranes and into the bloodstream. For this reason, a high blood concentration of CK usually indicates serious muscle damage.

Table 10–1 compares the energy sources of a representative muscle fiber. A resting skeletal muscle fiber contains about six times as much creatine phosphate as readily available ATP, but when a muscle fiber is undergoing a sustained contraction, these energy reserves are exhausted in only about 15 seconds. The muscle fiber must then rely on other mechanisms to generate ATP from ADP.

ATP Generation

As we saw in Chapter 3, most cells in the body generate ATP through (1) aerobic metabolism in mitochondria and (2) glycolysis in the cytoplasm. \bigcirc p. 80

Aerobic Metabolism

Aerobic metabolism normally provides 95 percent of the ATP demands of a resting cell. In this process, mitochondria absorb oxygen, ADP, phosphate ions, and organic substrates (such as pyruvate) from the surrounding cytoplasm. The molecules then enter the citric acid cycle (also known as the tricarboxylic acid cycle or the Krebs cycle), an enzymatic pathway that breaks down organic molecules. The carbon atoms are released from the organic substrate as carbon dioxide. The hydrogen atoms are shuttled to respiratory enzymes in the inner mitochondrial membrane, where their electrons are removed. After a series of intermediate steps involving the electron transport chain, the protons and electrons are combined with oxygen to form water. Along the way, large amounts of energy are released and used to make ATP. The entire process is very efficient: For each molecule of pyruvate "fed" into the citric acid cycle, the cell gains 17 ATP molecules.

Resting skeletal muscle fibers rely almost exclusively on the aerobic metabolism of fatty acids to generate ATP. These fatty acids are absorbed from the circulation. When the muscle starts contracting, the mitochondria begin breaking down molecules of pyruvate instead of fatty acids. The pyruvate is provided by the enzymatic pathway of glycolysis, which breaks down glucose in the cytoplasm. The glucose can come either from the surrounding interstitial fluid or through the breakdown of glycogen reserves within the sarcoplasm. Because a typical skeletal muscle fiber contains large amounts of glycogen, the shift from fatty acid metabolism to glucose metabolism makes it possible for the cell to continue contracting for an extended period, even without an external source of nutrients.

Glycolysis

Glycolysis is the anaerobic breakdown of glucose to pyruvate in the cytoplasm of a cell. It is an **anaerobic process** because it does not require oxygen. Glycolysis provides a net gain of 2 ATP molecules and generates 2 pyruvate molecules from each glucose molecule. The ATP produced by glycolysis in the cytoplasm is only a small fraction of that produced by aerobic metabolism, in which the breakdown of the 2 pyruvate molecules within mitochondria generates 34 ATP molecules. Thus, when energy demands are relatively low and oxygen is readily available, glycolysis is important only because it provides the substrates for aerobic metabolism in the mitochondria. Yet, because it can proceed in the absence of oxygen, glycolysis becomes an important source of energy when energy demands are at a maximum and the available supply of oxygen limits how quickly the mitochondria can produce ATP.

The glucose broken down under these conditions comes primarily from the reserves of glycogen in the sarcoplasm. Glycogen is a chain of glucose molecules. \bigcirc **p**. 45 It is stored in granules close to the I bands of sarcomeres. Typical skeletal muscle fibers contain large glycogen reserves, which may account for 1.5 percent of the total muscle weight. When the muscle fiber begins to run short of ATP and CP, enzymes split the glycogen molecules, releasing glucose, which can be used to generate more ATP.

When energy demands are low and oxygen is abundant, glycolysis provides substrates for aerobic metabolism, and then aerobic metabolism provides the ATP needed for contraction. However, during peak periods of muscular activity, energy demands are extremely high and oxygen supplies are very limited. During these periods, glycolysis provides most of the ATP needed to sustain muscular contraction.

Table 10–1	Sources of Energy in a Typical Muscle Fiber				
Energy Source	Utilization Process	Initial Available Quantity	Number of Twitches Supported by Each Energy Source Alone	Duration of Isometric Tetanic Contraction Supported by Each Energy Source Alone	
ATP	$ATP \longrightarrow ADP + P$	3 mmol	10	2 sec	
СР	$ADP + CP \longrightarrow ATP + C$	20 mmol	70	15 sec	
Glycogen	Glycolysis (anaerobic metabolism)	100 mmol	670	130 sec	
Glycogen	Aerobic metabolism	100 mmol	12,000	2400 sec (40 min)	

Energy Use and the Level of Muscular Activity

As physical exertion and muscular activity increases, the pattern of energy production and use changes. Figure 10–20 illustrates muscle metabolism in a muscle fiber at rest, and at moderate and peak levels of activity.

The anaerobic process of glycolysis enables the cell to generate additional ATP when the mitochondria are unable to meet the energy demands at peak exertion (Figure 10–20). Unfortunately, the anaerobic production of energy from glycolysis has two important drawbacks. First, the underutilized pyruvate molecules produced through glycolysis are converted to lactic acid. Lactic acid is an organic acid that dissociates in body fluids. Because it releases hydrogen ions, production of lactic acid can lower the intracellular pH. Buffers in the sarcoplasm resist pH shifts, but these mechanisms are limited. Eventually, changes in pH affect the workings of key enzymes so that the muscle fiber can no longer contract.

Second, glycolysis is a relatively inefficient way to generate ATP. Under anaerobic conditions, each glucose molecule generates 2 pyruvate molecules, which are converted to lactic acid. In return, the cell gains 2 ATP molecules through glycolysis. Had those 2 pyruvate molecules been catabolized aerobically in a mitochondrion, the cell would have produced 34 additional ATP.

Muscle Fatigue

We say an active skeletal muscle is **fatigued** when it can no longer perform at the required level of activity. Many factors are involved in muscle fatigue. For example, muscle fatigue has been correlated with (1) depletion of metabolic reserves within the muscle fibers; (2) damage to the sarcolemma and sarcoplasmic reticulum; (3) a decline in pH within the muscle fibers and the muscle as a whole, which decreases calcium ion binding to troponin and alters enzyme activities; and (4) a sense of weariness and a reduction in the desire to continue the activity, due to the effects of low blood pH and sensations of pain. Muscle fatigue is cumulative—the effects become more pronounced as more neurons and muscle fibers are affected. The result is a gradual reduction in the capabilities and performance of the entire skeletal muscle.

If a muscle fiber is contracting at moderate levels and ATP demands can be met through aerobic metabolism, fatigue will not occur until glycogen, lipid, and amino acid reserves are depleted. This type of fatigue affects the muscles of endurance athletes, such as marathon runners, after hours of exertion. In contrast, sprinters get a different type of muscle fatigue. When a muscle produces a sudden, intense burst of activity at peak levels, glycolysis provides most of the ATP. After just seconds to minutes, tissue pH decreases due to lactic acid buildup and its dissociation, and the muscle can no longer function normally. We will return to the topics of fatigue, athletic training, and metabolic activity later in the chapter.

Normal muscle function requires (1) substantial intracellular energy reserves, (2) a normal circulatory supply, (3) normal blood oxygen levels, and (4) blood pH within normal limits. Anything that interferes with any of these factors will promote premature muscle fatigue. For example, reduced blood flow from tight clothing, heart problems, or blood loss slows the delivery of oxygen and nutrients, accelerates the buildup of lactic acid, and leads to muscle fatigue.

The Recovery Period

When a muscle fiber contracts, conditions in the sarcoplasm change. Energy reserves are consumed, heat is released, and, if the contraction was at peak levels, lactic acid is generated. In the **recovery period**, the conditions in muscle fibers are returned to normal, pre-exertion levels. After a period of moderate activity, muscle fibers may need several hours to recover. After sustained activity at higher levels, complete recovery can take a week.

Lactic Acid Removal and Recycling

Glycolysis enables a skeletal muscle to continue contracting even when mitochondrial activity is limited by the availability of oxygen. As we have seen, however, the anaerobic process of glycolysis and its production of lactic acid is not an ideal way to generate ATP. It wastes the glucose reserves of the muscle fibers, and it is potentially dangerous because lactic acid dissociation can lower the pH of the blood and tissues. During the recovery period, when oxygen is available in abundance, lactate can be converted back to pyruvate. The pyruvate can then be used either by mitochondria to generate ATP or as a substrate for enzyme pathways that synthesize glucose and rebuild glycogen reserves. During exertion, lactate diffuses out of muscle fibers and into the bloodstream. The process continues after the exertion has ended, because intracellular lactate concentrations are still relatively high. The liver absorbs the lactate and converts it to pyruvate. About 20-30 percent of these new pyruvate molecules enter liver mitochondria where they are catabolized, providing the ATP needed to convert the other 70-80 percent of the pyruvate molecules to glucose. (We will cover these processes more fully in Chapter 25.) The glucose molecules are then released into the circulation, where they are absorbed by skeletal muscle fibers and used to rebuild their glycogen reserves. This shuffling of lactate to the liver and glucose back to muscle cells is called the Cori cycle.

The Oxygen Debt

During the recovery period, the body's oxygen demand remains elevated above normal resting levels. The more ATP required, the more oxygen will be needed. The amount of oxygen required to restore normal, pre-exertion conditions is called the **oxygen debt**, or **excess postexercise oxygen consumption (EPOC)**.

Figure 10–20 Muscle Metabolism.

Muscle Metabolism in a Resting Muscle Fiber

- In a resting skeletal muscle, the demand for ATP is low, and there is more than enough oxygen available for mitochondria to meet that demand.
- Resting muscle fibers absorb fatty acids, which are broken down in the mitochondria creating a surplus of ATP.
- Some mitochondrial ATP is used to convert absorbed a glucose to glycogen.
- Mitochondrial ATP is also used to convert creatine to creatine phosphate (CP).
- This results in the buildup of energy reserves (glycogen and CP) in the muscle.

Muscle Metabolism during Moderate Activity

- During moderate levels of activity, the demand for ATP increases.
- There is still enough oxygen for the mitochondria to meet that demand, but no excess ATP is produced.
- The muscle fiber now relies primarily on the aerobic metabolism of glucose from stored glycogen to generate ATP.
- If the glycogen reserves are low, the muscle fiber can also break down other substrates, such as fatty acids.
- All of the ATP now produced is used to power muscle contraction.

Muscle Metabolism during Peak Activity

- During peak levels of activity, the demand for ATP is enormous. Oxygen cannot diffuse into the fiber fast enough for the mitochondria to meet that demand. Only a third of the cell's ATP needs can be met by the mitochondria (not shown).
- The rest of the ATP comes from glycolysis, and when this produces pyruvate faster than the mitochondria can utilize it, the pyruvate builds up in the cytosol. This process is called anaerobic metabolism because no oxygen is used.
- Under these conditions, pyruvate is converted to lactic acid, which dissociates into a lactate ion and a hydrogen ion.
- The buildup of hydrogen ions increases fiber acidity, which inhibits muscle contraction, leading to rapid fatigue.

Most of the additional oxygen consumption occurs in skeletal muscle fibers, which must restore ATP, CP, and glycogen concentrations to their former levels, and in liver cells, which generate the ATP needed to convert excess lactate to glucose. However, several other tissues also increase their rate of oxygen consumption and ATP generation during the recovery period. For example, sweat glands increase their secretory activity until normal body temperature is restored. While the oxygen debt is being repaid, breathing rate and depth are increased. As a result, you continue to breathe heavily long after you stop exercising.

Heat Production and Loss

Muscular activity generates considerable heat. During a catabolic process, such as the breakdown of glycogen or the reactions of glycolysis, a muscle fiber captures only a portion of the released energy. $\supset p. 36$ The rest escapes as heat. A resting muscle fiber relying on aerobic metabolism captures about 42 percent of the energy released in catabolism. The other 58 percent warms the sarcoplasm, interstitial fluid, and circulating blood. Active skeletal muscles release roughly 85 percent of the heat needed to maintain normal body temperature.

When muscles become active, their energy consumption increases dramatically. As anaerobic energy production becomes the primary method of ATP generation, muscle fibers become less efficient at capturing energy. At peak levels of exertion, only about 30 percent of the released energy is captured as ATP, and the remaining 70 percent warms the muscle and surrounding tissues. Body temperature soon climbs, and heat loss at the skin accelerates through mechanisms introduced in Chapters 1 and 5. \bigcirc pp. 10, 168

Hormones and Muscle Metabolism

Hormones of the endocrine system adjust metabolic activities in skeletal muscle fibers. *Growth hormone* from the pituitary gland and *testosterone* (the primary sex hormone in males) stimulate the synthesis of contractile proteins and the enlargement of skeletal muscles. *Thyroid hormones* elevate the rate of energy consumption in resting and active skeletal muscles. During a sudden crisis, hormones of the adrenal gland, notably *epinephrine* (adrenaline), stimulate muscle metabolism and increase both the duration of stimulation and the force of contraction. We will further examine the effects of hormones on muscle and other tissues in Chapter 18.

- CHECKPOINT

- 14. How do muscle cells continuously synthesize ATP?
- **15**. What is muscle fatigue?
- 16. Define oxygen debt.

See the blue Answers tab at the back of the book.

10-7 Muscle performance capabilities depend on muscle fiber type and physical conditioning

Learning Outcome Relate the types of muscle fibers to muscle performance, and distinguish between aerobic and anaerobic endurance.

We can consider muscle performance in terms of **force**, the maximum amount of tension produced by a particular muscle or muscle group, and **endurance**, the amount of time during which the individual can perform a particular activity. Here we consider the factors that determine the performance capabilities of any skeletal muscle: the type, distribution, and size of muscle fibers in the muscle, and physical conditioning or training.

Types of Skeletal Muscle Fibers

The human body has three major types of skeletal muscle fibers: *fast fibers, slow fibers,* and *intermediate fibers* (Table 10–2).

Fast Fibers

Most of the skeletal muscle fibers in the body are called **fast fibers**, because they can reach peak twitch tension in 0.01 sec or less after stimulation. Fast fibers are large in diameter and contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. Muscles dominated by fast fibers produce powerful contractions because the tension produced by a muscle fiber is directly proportional to the number of myofibrils. However, fast fibers fatigue rapidly because their contractions use ATP in massive amounts, and they have relatively few mitochondria to generate ATP. As a result, prolonged activity is supported primarily by anaerobic metabolism.

Slow Fibers

Slow fibers have only about half the diameter of fast fibers and take three times as long to reach peak tension after stimulation. These fibers are specialized in ways that enable them to continue contracting long after a fast fiber would have become fatigued. The most important specializations support aerobic metabolism in the numerous mitochondria.

One of the main characteristics of slow muscle fibers is that they are surrounded by a more extensive network of capillaries than is typical of fast muscle tissue. For this reason, they have a dramatically higher oxygen supply to support mitochondrial activity. Slow fibers also contain the red pigment **myoglobin** ($M\overline{I}$ - \overline{o} -gl \overline{o} -bin). This globular protein is similar to hemoglobin, the red oxygen-carrying pigment in blood. Both myoglobin and hemoglobin reversibly bind oxygen molecules. Other muscle fiber types contain small amounts of myoglobin, but it is most abundant in slow fibers. As a result, resting slow fibers hold substantial oxygen reserves that can be used during a

Table 10-2 **Properties of Skeletal Muscle Fiber Types Slow Fibers** Intermediate Fibers Property **Fast Fibers Cross-sectional diameter** Large Small Intermediate Rapid Prolonaed Medium Time to peak tension Fast **Contraction speed** Fast Slow **Fatigue resistance** Low High Intermediate White Pink Color Red Low High Low **Myoglobin content Capillary supply** Scarce Dense Intermediate Mitochondria Few Many Intermediate High **Glycolytic enzyme concentration** High I ow in sarcoplasm Substrates used for ATP generation Carbohydrates (anaerobic) Lipids, carbohydrates, amino acids Primarily carbohydrates (anaerobic) during contraction (metabolism) (aerobic) **Alternative names** Type II-B, FF (fast fatigue), white, Type I, S (slow), red, SO (slow Type II-A, FR (fast resistant), fast-twitch glycolytic oxidative), slow-twitch oxidative fast-twitch oxidative

contraction. Skeletal muscles dominated by slow fibers are dark red because slow fibers have both an extensive capillary supply and a high concentration of myoglobin.

With oxygen reserves and a more efficient blood supply, the mitochondria of slow fibers can contribute more ATP during contractions. In addition, demand for ATP is reduced because the cross-bridges in slow fibers cycle more slowly than those of fast fibers. Thus, slow fibers are less dependent on anaerobic metabolism than are fast fibers. Glycogen reserves of slow fibers are also smaller than those of fast fibers, because some of the mitochondrial energy production involves the breakdown of stored lipids rather than glycogen. **Figure 10–21** compares the appearance of fast and slow fibers.

Intermediate Fibers

Most properties of **intermediate fibers** are intermediate between those of fast fibers and slow fibers. In appearance, intermediate fibers most closely resemble fast fibers, for they contain little myoglobin and are relatively pale. They have an intermediate capillary network and mitochondrial supply around them and are more resistant to fatigue than are fast fibers.

Muscle Performance and the Distribution of Muscle Fibers

The percentages of fast, intermediate, and slow fibers in a skeletal muscle can be quite variable. In muscles that contain a mixture of fast and intermediate fibers, the proportion can change with physical conditioning. For example, if a muscle is used repeatedly for endurance events, some of the fast fibers will develop the appearance and functional capabilities of intermediate fibers. The muscle as a whole will become more resistant to fatigue.

Muscles dominated by fast fibers appear pale and are often called **white muscles**. Chicken breasts contain "white meat" because chickens use their wings only for brief intervals, as when fleeing a predator, and the power for flight comes from the anaerobic process of glycolysis in the fast fibers of their breast muscles. As we noted earlier, extensive blood vessels and myoglobin give slow fibers a reddish color, so muscles dominated by slow fibers are known as **red muscles**. Chickens walk around all day, and these movements are powered by aerobic metabolism in the slow fibers of the "dark meat" of their legs.

What about human muscles? Most contain a mixture of fiber types and so appear pink. However, there are no slow fibers in muscles of the eye or hand, where swift, but brief, contractions are required. Many back and calf muscles are dominated by slow fibers, and these muscles contract almost continuously to maintain an upright posture. Our genes determine the percentage of fast versus slow fibers in each muscle. As we noted earlier, athletic training can increase the ratio of intermediate fibers to fast fibers.

Muscle Hypertrophy and Atrophy

As a result of repeated, exhaustive stimulation, muscle fibers develop more mitochondria, a higher concentration of glycolytic enzymes, and larger glycogen reserves. Such muscle fibers have more myofibrils than do less-stimulated fibers, and each myofibril contains more thick and thin filaments. The net effect is **hypertrophy**, an enlargement of the stimulated muscle. The number of muscle fibers does not change significantly, but the muscle as a whole enlarges because each muscle fiber increases in diameter.

Figure 10–21 Fast versus Slow Fibers. The LM on the right is a longitudinal section of skeletal muscle, showing more mitochondria (M) and a more extensive capillary supply in a slow fiber (R, for red) than in a fast fiber (W, for white).

Hypertrophy occurs in muscles that have been repeatedly stimulated to produce near-maximal tension. The intracellular changes that occur increase the amount of tension produced when these muscles contract. The muscles of a bodybuilder are excellent examples of muscular hypertrophy.

A skeletal muscle that is not regularly stimulated by a motor neuron loses muscle tone and mass. The muscle becomes flaccid, and the muscle fibers become smaller and weaker. This reduction in muscle size, tone, and power is called atrophy. Individuals paralyzed by spinal cord injuries or other damage to the nervous system gradually lose muscle tone and size in the areas affected. Even a temporary reduction in muscle use can lead to muscular atrophy, as you can easily observe by comparing "before and after" limb muscles in someone who has worn a cast. Muscle atrophy is reversible at first, but dving muscle fibers are not replaced. In extreme atrophy, the functional losses are permanent. That is why physical therapy is crucial for people who are temporarily unable to move normally. Direct electrical stimulation by an external device can substitute for nerve stimulation and prevent or reduce muscle atrophy.

Because skeletal muscles depend on motor neurons for stimulation, disorders that affect the nervous system can indirectly affect the muscular system. In *polio*, a virus attacks motor neurons in the spinal cord and brain, causing muscular paralysis and atrophy.

Physical Conditioning

Physical conditioning and training schedules enable athletes and ordinary people of all ages to improve both power and endurance. In practice, the training schedule varies, depending on whether the activity is supported primarily by anaerobic or aerobic energy production.

Anaerobic endurance is the length of time muscular contraction can continue to be supported by glycolysis and by the existing energy reserves of ATP and CP. Conditioning for anaerobic endurance improves an individual's power. Anaerobic endurance is limited by (1) the amount of ATP and CP available, (2) the amount of glycogen available for breakdown, and (3) the ability of the muscle to tolerate the lactic acid generated during the period of anaerobic metabolism. Typically, the onset of muscle fatigue occurs within 2 minutes of the start of maximal activity.

Activities that require above-average levels of anaerobic endurance include a 50-meter race or swim, pole vaulting, and competitive weight lifting. These activities involve the contractions of fast fibers. The energy for the first 10–20 seconds of activity comes from the ATP and CP reserves of the cytoplasm. As these energy sources decrease, an increase in glycogen breakdown and glycolysis provide additional energy. Athletes training to improve anaerobic endurance perform frequent, brief, intensive workouts that stimulate muscle hypertrophy. **Aerobic endurance** is the length of time a muscle can continue to contract while supported by mitochondrial activities. Aerobic activities do not promote muscle hypertrophy. Conditioning for aerobic endurance improves an individual's ability to continue an activity for longer periods of time. Aerobic endurance is determined primarily by the availability of substrates for aerobic respiration, which muscle fibers can obtain by breaking down carbohydrates, lipids, or amino acids. Initially, many of the nutrients broken down by muscle fibers come from reserves in the sarcoplasm. Prolonged aerobic activity, however, must be supported by nutrients provided by the circulating blood.

During exercise, blood vessels in the skeletal muscles dilate, which increases blood flow and the supply of oxygen and nutrients to the active muscle tissue. Warm-up periods are important because they both stimulate circulation in the muscles before the serious workout begins and activate the enzyme that breaks down glycogen to release glucose. Warm-ups also increase muscle temperature and thus accelerate the contraction process. Because glucose is a preferred energy source, endurance athletes such as marathon runners typically "load" or "bulk up" on carbohydrates for the three days before an event. They may also consume glucose-rich "sports drinks" during a competition. (We will consider the risks and benefits of these practices in Chapter 25.)

Training to improve aerobic endurance generally involves sustained low levels of muscular activity. Examples include jogging, distance swimming, and other exercises that do not require peak tension production. Improvements in aerobic endurance result from two factors:

- 1. Alterations in the Characteristics of Muscle Fibers. The proportion of fast and slow fibers in each muscle is genetically determined, and individual differences are significant. These variations affect aerobic endurance, because a person with more slow fibers in a particular muscle will be better able to perform under aerobic conditions than will a person with fewer. However, skeletal muscle cells respond to changes in the pattern of neural stimulation. Fast fibers trained for aerobic competition develop the characteristics of intermediate fibers, and this change improves aerobic endurance.
- 2. Improvements in Cardiovascular Performance. Cardiovascular activity affects muscular performance by delivering oxygen and nutrients to active muscles. Physical training alters cardiovascular function by accelerating blood flow, thus improving oxygen and nutrient availability. Another important benefit of endurance training is an increase in capillaries that serve exercising muscles, providing better blood flow at the cellular level. (We will examine factors involved in improving cardiovascular performance in Chapter 21.)

Physical activity, using a combination of aerobic and anaerobic exercises, should be a lifelong pursuit. It is recommended to alternate an aerobic activity, such as swimming or brisk walking, with an anaerobic activity such as weight lifting or resistance training. This combination, known as *cross-training*, enhances health by increasing muscle mass and improving aerobic endurance.

Clinical Note

Delayed-Onset Muscle Soreness Have you experienced muscle soreness the next day or several days after a period of physical exertion? Considerable controversy exists over the source and significance of this pain, which is known as *delayed-onset muscle soreness* (DOMS). You may have noticed a few of its characteristics:

- DOMS is distinct from the soreness you experience immediately after you stop exercising. The initial shortterm soreness is probably related to the biochemical events associated with muscle fatigue.
- DOMS generally begins several hours after exercise and may last three or four days.
- The amount of DOMS is highest when the activity involves eccentric contractions (in which a muscle elongates despite producing tension). Activities dominated by concentric or isometric contractions produce less soreness.
- Levels of CK and myoglobin are elevated in the blood, indicating damage to muscle plasma membranes. The nature of the activity (eccentric, concentric, or isometric) has no effect on these levels. Nor can the levels be used to predict the degree of soreness experienced. Three mechanisms have been proposed to explain DOMS:
- Small tears may occur in the muscle tissue, leaving muscle fibers with damaged membranes. The sarcolemma of each damaged muscle fiber permits the loss of enzymes, myoglobin, and other chemicals that may stimulate nearby pain receptors.
- The pain may result from muscle spasms in the affected skeletal muscles. In some studies, stretching the muscle involved after exercise reduces the degree of soreness.
- **3.** The pain may result from tears in the connective tissue framework and tendons of the skeletal muscle.

Some evidence supports each of these mechanisms, but it is unlikely that any one tells the whole story. For example, muscle fiber damage is certainly supported by biochemical findings. But if this damage were the only factor, the type of activity and level of circulating enzymes would be correlated with the level of pain experienced, and such is not the case. DOMS remains a puzzle to be solved.

CHECKPOINT

- 17. Identify the three types of skeletal muscle fibers.
- 18. Why would a sprinter experience muscle fatigue before a marathon runner would?
- 19. Which activity would be more likely to create an oxygen debt: swimming laps or lifting weights?
- **20**. Which type of muscle fibers would you expect to predominate in the leg muscles of someone who excels at endurance activities, such as cycling or long-distance running?

See the blue Answers tab at the back of the book.

10-8 Cardiac muscle tissue differs structurally and functionally from skeletal muscle tissue

Learning Outcome Identify the structural and functional differences between skeletal muscle fibers and cardiac muscle cells.

We introduced **cardiac muscle tissue** in Chapter 4 and briefly compared its properties with those of other types of muscle. **Cardiac muscle cells** are found only in the heart. We begin a more detailed examination of cardiac muscle tissue by considering its structural characteristics.

Structural Characteristics of Cardiac Muscle Tissue

Like neurons and skeletal muscle fibers, cardiac muscle cells have excitable membranes. \bigcirc p. 302 Cardiac muscle cells also contain organized myofibrils, and the presence of many aligned sarcomeres gives the cells a striated appearance. However, there are important structural differences between skeletal muscle fibers and cardiac muscle cells, including the following:

- Cardiac muscle cells are relatively small, averaging $10-20 \ \mu m$ in diameter and $50-100 \ \mu m$ in length.
- A typical cardiac muscle cell has a single, centrally placed nucleus (Figure 10–22a,b), although a few may have two or more nuclei. Unlike skeletal muscle, cardiac muscle cells are typically branched.
- The T tubules in a cardiac muscle cell are short and broad, and there are no triads (Figure 10–22c). The T tubules encircle the sarcomeres at the Z lines rather than at the zones of overlap.
- The SR of a cardiac muscle cell lacks terminal cisternae, and its tubules contact the plasma membrane as well as the T tubules (Figure 10–22c). As in skeletal muscle fibers, an action potential triggers the release of calcium ions from the SR and the contraction of sarcomeres. However, an action potential in a cardiac muscle cell also makes the sarcolemma more permeable to extracellular calcium ions. Because their contractions require both intracellular and

c Cardiac muscle tissue showing short, broad T tubules and SR that lacks terminal cisternae. extracellular calcium ions, cardiac muscle cells are more sensitive to changes in the extracellular calcium ion concentration than are skeletal muscle fibers.

- Cardiac muscle cells are almost totally dependent on aerobic metabolism for the energy they need to continue contracting. They have energy reserves in the form of glycogen and lipid inclusions. The sarcoplasm of a cardiac muscle cell contains large numbers of mitochondria as well as abundant reserves of myoglobin, which store the oxygen needed to break down energy reserves during times of peak activity.
- Each cardiac muscle cell contacts several others at specialized sites known as **intercalated** (in-TER-ka-lā-ted) **discs**.
 p. 142 Intercalated discs play a vital role in the function of cardiac muscle, as we will see next.

Intercalated Discs

At an intercalated disc (Figure 10–22a,b), the sarcolemmas of two adjacent cardiac muscle cells are extensively intertwined and bound together by gap junctions and desmosomes. \bigcirc p. 116 These connections help stabilize the positions of adjacent cells and maintain the three-dimensional structure of the tissue.

The gap junctions allow ions and small molecules to move from one cell to another. These junctions create a direct electrical connection between two muscle cells. An action potential can travel across an intercalated disc, moving quickly from one cardiac muscle cell to another.

Two muscle cells can "pull together" with maximum efficiency because their myofibrils are essentially locked together at the intercalated disc. There the myofibrils of two interlocking muscle cells are firmly anchored to their plasma membranes.

Because cardiac muscle cells are physically, chemically, and electrically connected to one another, the entire tissue resembles a single, enormous muscle cell. For this reason, cardiac muscle has been called a *functional syncytium* (sin-SISH-ē-um; a fused mass of cells).

Functional Characteristics of Cardiac Muscle Tissue

In Chapter 20, we will examine cardiac muscle physiology in detail, but here we briefly summarize the four major functional specialties of cardiac muscle:

- Cardiac muscle tissue contracts without neural stimulation. This property is called **automaticity**. Specialized cardiac muscle cells called **pacemaker cells** normally determine the timing of contractions.
- **2.** The nervous system can alter the pace or rate set by the pacemaker cells and adjust the amount of tension produced during a contraction.

- **3.** Cardiac muscle cell contractions last about 10 times as long as do those of skeletal muscle fibers. They also have longer refractory periods and do not readily fatigue.
- 4. The properties of cardiac muscle sarcolemmas differ from those of skeletal muscle fibers. As a result, individual twitches cannot undergo wave summation, and cardiac muscle tissue cannot produce tetanic contractions. This difference is important, because a heart in a sustained tetanic contraction could not pump blood.

CHECKPOINT

- **21**. Compare and contrast skeletal muscle tissue and cardiac muscle tissue.
- 22. What feature of cardiac muscle tissue allows the heart to act as a functional syncytium?
- See the blue Answers tab at the back of the book.

10-9 Smooth muscle tissue differs structurally and functionally from skeletal and cardiac muscle tissue

Learning Outcome Identify the structural and functional differences between skeletal muscle fibers and smooth muscle cells, and discuss the roles of smooth muscle tissue in systems throughout the body.

Smooth muscle tissue forms sheets, bundles, or sheaths around other tissues in almost every organ. Smooth muscles around blood vessels regulate blood flow through vital organs. In the digestive and urinary systems, rings of smooth muscle, called *sphincters*, regulate the movement of materials along internal passageways. Smooth muscles play a variety of other roles in various body systems.

- Integumentary System: Smooth muscles around blood vessels regulate the flow of blood to the superficial dermis; smooth muscles of the arrector pili elevate hairs.
 p. 163
- *Cardiovascular System:* Smooth muscles encircling blood vessels control the distribution of blood and help regulate blood pressure.
- *Respiratory System:* Smooth muscles contract or relax to alter the diameters of the respiratory passageways and change the resistance to airflow.
- *Digestive System:* Extensive layers of smooth muscle in the walls of the digestive tract play an essential role in moving materials along the tract. Smooth muscle in the walls of the gallbladder contracts to eject bile into the digestive tract.
- *Urinary System:* Smooth muscle tissue in the walls of small blood vessels alters the rate of filtration in the kidneys. Layers of smooth muscle in the walls of the ureters

transport urine to the urinary bladder, and the contraction of the smooth muscle in the wall of the urinary bladder forces urine out of the body.

• *Reproductive System:* Layers of smooth muscle help move sperm along the reproductive tract in males and cause the ejection of glandular secretions from the accessory glands into the reproductive tract. In females, layers of smooth muscle help move oocytes (and perhaps sperm) along the reproductive tract, and contractions of the smooth muscle in the walls of the uterus expel the fetus at delivery.

Figure 10–23a shows typical smooth muscle tissue as seen under a light microscope. Smooth muscle tissue differs from both skeletal and cardiac muscle tissues in structure and function (Table 10–3).

Structural Characteristics of Smooth Muscle Tissue

All three types of muscle tissue contain actin and myosin. In skeletal and cardiac muscle cells, these proteins are organized in sarcomeres, with thin and thick filaments. The internal organization of a smooth muscle cell is very different:

- Smooth muscle cells are relatively long and slender, ranging from 5 to 10 μ m in diameter and from 30 to 200 μ m in length.
- Each cell is spindle shaped and has a single, centrally located nucleus.
- A smooth muscle fiber has no T tubules, and the sarcoplasmic reticulum forms a loose network throughout the sarcoplasm.
- Smooth muscle cells lack myofibrils and sarcomeres. As a result, this tissue also has no striations and is called **nonstriated muscle.**
- Thick filaments are scattered throughout the sarcoplasm of a smooth muscle cell. The myosin proteins are organized differently than in skeletal or cardiac muscle cells, and smooth muscle cells have more myosin heads per thick filament.
- The thin filaments in a smooth muscle cell are attached to dense bodies, structures distributed throughout the sarcoplasm in a network of intermediate filaments composed of the protein *desmin* (Figure 10–23b). Some of the dense bodies are firmly attached to the sarcolemma. The dense bodies and intermediate filaments anchor the thin filaments such that when sliding occurs between thin and thick

Figure 10–23Smooth Muscle Tissue.

a Many visceral organs contain several layers of smooth muscle tissue oriented in different directions. Here, a single sectional view shows smooth muscle cells in both longitudinal (L) and transverse (T) sections.

b A single relaxed smooth muscle cell is spindle shaped and has no striations. Note the changes in cell shape as contraction occurs.

Table 10–3 A	omparison of Skeletal, Cardiac, and Smooth Muscle Tissues			
Property	Skeletal Muscle	Cardiac Muscle	Smooth Muscle	
Fiber dimensions (diameter $ imes$ length)	100 μ m $ imes$ up to 30 cm	10–20 μ m $ imes$ 50–100 μ m	5–10 μ m $ imes$ 30–200 μ m	
Nuclei	Multiple, near sarcolemma	Generally single, centrally located	Single, centrally located	
Filament organization	In sarcomeres along myofibrils	In sarcomeres along myofibrils	Scattered throughout sarcoplasm	
Sarcoplasmic reticulum (SR)	Terminal cisternae in triads at zones of overlap	SR tubules contact T tubules at Z lines	Dispersed throughout sarcoplasm, no T tubules	
Control mechanism	Neural, at single neuromuscular junction on each muscle fiber	Automaticity (pacemaker cells), neural control limited to moderating pace and tension	Automaticity (pacesetter cells), neural or hormonal control (neural control limited to moderating pace and tension)	
Ca ²⁺ source	Release from SR	Extracellular fluid and release from SR	Extracellular fluid and release from SR	
Ca ²⁺ regulation	Troponin on thin filaments	Troponin on thin filaments	Calmodulin on myosin heads	
Contraction	Rapid onset; may be tetanized; rapid fatigue	Slower onset; cannot be tetanized; resistant to fatigue	Slow onset; may be tetanized; resistant to fatigue	
Energy source	Aerobic metabolism at moderate levels of activity; glycolysis (anaerobic during peak activity)	Aerobic metabolism, usually lipid or carbohydrate substrates	Primarily aerobic metabolism	

filaments, the cell shortens. Dense bodies are not arranged in straight lines, so when a contraction occurs, the muscle cell twists like a corkscrew.

- Adjacent smooth muscle cells are bound together at dense bodies, transmitting the contractile forces from cell to cell throughout the tissue.
- Although smooth muscle cells are surrounded by connective tissue, the collagen fibers never unite to form tendons or aponeuroses, as they do in skeletal muscles.

Functional Characteristics of Smooth Muscle Tissue

Smooth muscle tissue differs from other muscle tissue in (1) excitation–contraction coupling, (2) length–tension relationships, (3) control of contractions, and (4) smooth muscle tone.

Excitation–Contraction Coupling

The trigger for smooth muscle contraction is the appearance of free calcium ions in the cytoplasm. On stimulation, a surge of calcium ions enters the cell from the extracellular fluid, and the sarcoplasmic reticulum releases additional calcium ions. The net result is a rise in calcium ion concentrations throughout the cell.

Once in the sarcoplasm, the calcium ions interact with **calmodulin**, a calcium-binding protein. Calmodulin then activates the enzyme **myosin light chain kinase**, which in turn enables myosin heads to attach to actin. This mechanism is quite different from that in skeletal and cardiac muscles, in which the trigger for contraction is the binding of calcium ions to troponin.

Length–Tension Relationships

Because the thick and thin filaments are scattered and are not organized into sarcomeres in smooth muscle, tension development and resting length are not directly related. A stretched smooth muscle soon adapts to its new length and retains the ability to contract on demand. This ability to function over a wide range of lengths is called **plasticity**. Smooth muscle can contract over a range of lengths four times greater than that of skeletal muscle. Plasticity is especially important in digestive organs, such as the stomach, that change greatly in volume.

Despite the lack of sarcomeres, smooth muscle contractions can be just as powerful as those of skeletal muscles. Like skeletal muscle fibers, smooth muscle cells can undergo sustained contractions.

Control of Contractions

Many smooth muscle cells are not innervated by motor neurons, and the neurons that do innervate smooth muscles are not under voluntary control. We categorize smooth muscle cells as either multiunit or visceral. **Multiunit smooth muscle cells** are innervated in motor units comparable to those of skeletal muscles, but each smooth muscle cell may be connected to more than one motor neuron. In contrast, many **visceral smooth muscle cells** lack a direct contact with any motor neuron.

Multiunit smooth muscle cells have excitable plasma membranes. They resemble skeletal muscle fibers and cardiac muscle cells in that neural activity produces an action potential that travels over the sarcolemma. However, these smooth muscle cells contract more slowly than do skeletal or cardiac muscle cells. We find multiunit smooth muscle cells in the iris of the eye, where they regulate the diameter of the pupil; along portions of the male reproductive tract; within the walls of large arteries; and in the arrector pili muscles of the skin. Multiunit smooth muscle cells do not typically occur in the digestive tract.

Visceral smooth muscle cells are arranged in sheets or layers. Within each layer, adjacent muscle cells are connected by gap junctions. As a result, whenever one muscle cell contracts, the electrical impulse that triggered the contraction can travel to adjacent smooth muscle cells. For this reason, the contraction spreads in a wave that soon involves every smooth muscle cell in the layer. The initial stimulus may be the activation of a motor neuron that contacts one of the muscle cells in the region. But smooth muscle cells also contract or relax in response to chemicals, hormones, local concentrations of oxygen or carbon dioxide, or physical factors such as extreme stretching or irritation.

Many visceral smooth muscle layers show rhythmic cycles of activity in the absence of neural stimulation. For example, these cycles are characteristic of the smooth muscle cells in the wall of the digestive tract, where **pacesetter cells** spontaneously trigger the contraction of entire muscular sheets. Visceral smooth muscle cells are located in the walls of the digestive tract, the gallbladder, the urinary bladder, and many other internal organs.

Smooth Muscle Tone

Both multiunit and visceral smooth muscle tissues have a normal background level of activity, or smooth muscle tone. Neural, hormonal, or chemical factors can also stimulate smooth muscle relaxation, producing a decrease in muscle tone. For example, smooth muscle cells at the entrances to capillaries regulate the amount of blood flow into each vessel. If the tissue becomes starved for oxygen, the smooth muscle cells relax, whereupon blood flow increases, delivering additional oxygen. As conditions return to normal, the smooth muscle regains its normal muscle tone.

- CHECKPOINT

- 23. Identify the structural characteristics of smooth muscle tissue.
- 24. Which type of muscle tissue is least affected by changes in extracellular Ca²⁺ concentration during contraction?
- **25**. Why can smooth muscle contract over a wider range of resting lengths than skeletal muscle can?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

botulism: A severe, potentially fatal paralysis of skeletal muscles, resulting from the consumption of a bacterial toxin.
Duchenne muscular dystrophy (DMD): One of the most common and best understood of the muscular dystrophies.
fibromyalgia: A chronic disorder characterized by widespread musculoskeletal pain, fatigue, and localized tenderness.
muscular dystrophies: A varied collection of inherited diseases that produce progressive muscle weakness and deterioration.

myasthenia gravis: A general muscular weakness resulting from a reduction in the number of ACh receptors on the motor end plate.

myopathy: Disease of muscle tissue.

RICE (rest, ice, compression, and elevation): Acronym for the standard treatment for muscle injuries, bruises, strains, and sprains.

10-1 Skeletal muscle performs six major functions p. 290

- 1. The three types of muscle tissue are *skeletal muscle, cardiac muscle,* and *smooth muscle.*
- 2. **Skeletal muscles** attach to bones directly or indirectly. Their functions are to (1) produce skeletal movement, (2) maintain posture and body position, (3) support soft tissues, (4) guard body entrances and exits, (5) maintain body temperature, and (6) store nutrient reserves.

10-2 A skeletal muscle contains muscle tissue, connective tissues, blood vessels, and nerves p. 291

- 3. The entire muscle is covered by an **epimysium**. Bundles of muscle fibers (cells) are sheathed by a **perimysium**, and each muscle fiber is surrounded by an **endomysium**. At the ends of the muscle are tendons or aponeuroses that attach the muscle to bones. (*Figure 10–1*)
- 4. The perimysium and endomysium contain the blood vessels and nerves that supply the muscle fibers.

10-3 Skeletal muscle fibers have distinctive features p. 292

- 5. A skeletal muscle fiber has a sarcolemma (plasma membrane); sarcoplasm (cytoplasm); and sarcoplasmic reticulum (SR), similar to the smooth endoplasmic reticulum of other cells. Transverse (T) tubules and myofibrils aid in contraction. Filaments in a myofibril are organized into repeating functional units called sarcomeres. (*Figures 10–2 to 10–6*)
- 6. Myofibrils contain myofilaments called thin filaments and thick filaments. (*Figures 10–2 to 10–6*)
- Thin filaments consist of F-actin, nebulin, tropomyosin, and troponin. Tropomyosin molecules cover active sites on the G-actin subunits that form the F-actin strand. Troponin binds to G-actin and tropomyosin and holds the tropomyosin in position. (*Figure 10–7*)
- Thick filaments consist of a bundle of myosin molecules around a titin core. Each myosin molecule has a long tail and a globular head, which forms cross-bridges with a thin filament during contraction. In a resting muscle cell, tropomyosin prevents the myosin heads from attaching to active sites on G-actin. (*Figure 10–7*)
- 9. The relationship between thick and thin filaments changes as a muscle fiber contracts. (*Figure 10–8*)
- **10.** When muscle cells contract, they create *tension* and pull on the attached tendons.
- **10-4** The nervous system communicates with skeletal muscles at the neuromuscular junction p. 299
- 11. Neurons and skeletal muscle fibers have **excitable mem-branes**, plasma membranes that can propagate electrical impulses, or action potentials.
- **12.** A neuron controls the activity of a muscle fiber at a **neuromuscular junction (NMJ).** (*Spotlight Figure 10–9*)
- **13.** At the neuromuscular junction, when an **action potential** arrives at the neuron's **axon** (synaptic) **terminal**, **acetylcholine (ACh)** is released into the **synaptic cleft**. The binding of ACh to receptors on the motor end plate (and its junctional folds) of the muscle fiber leads to the generation of an action potential in the sarcolemma. (*Spotlight Figure 10–9*)
- 14. **Excitation–contraction coupling** occurs as the passage of an action potential along a T tubule triggers the release of Ca²⁺ from the cisternae of the SR at triads. (*Spotlight Figure 10–10*)
- 15. Release of Ca²⁺ initiates a **contraction cycle** of myosin head active-site exposure, cross-bridge formation, pivoting of the myosin head, cross-bridge detachment, and myosin reactivation. The calcium ions bind to troponin, which changes position and moves tropomyosin away from the active sites of actin. Cross-bridges of myosin heads then bind to actin. Next, each myosin head pivots, pulling the actin filament toward the center of the sarcomere, and then detaches. (*Spotlight Figure 10–11*)
- **16.** During a contraction, the free end of a myofibril moves toward the end that is attached or fixed. This occurs in an intact

skeletal muscle, when one end of the muscle (the *origin*) is fixed in position during a contraction and the other end (the *insertion*) moves. (*Figure 10–12*)

17. Acetylcholinesterase (AChE) breaks down ACh and limits the duration of muscle stimulation. (*Figure 10–13*)

10-5 Sarcomere shortening and muscle fiber stimulation produce tension p. 308

- **18.** The amount of tension produced by a muscle fiber depends on the number of cross-bridges formed.
- **19.** Skeletal muscle fibers can contract most forcefully when stimulated over a narrow range of resting lengths. (*Figure 10–14*)
- **20.** A **twitch** is a cycle of contraction and relaxation produced by a single stimulus. (*Figure 10–15*)
- **21.** Repeated stimulation at a slow rate produces **treppe**, a progressive increase in twitch tension. (*Figure 10–16*)
- 22. Repeated stimulation before the relaxation phase ends may produce **wave summation**, in which one twitch is added to another; **incomplete tetanus**, in which tension peaks and falls at intermediate stimulus rates; or **complete tetanus**, in which the relaxation phase is eliminated by very rapid stimuli. (*Figure 10–16*)
- **23.** The number and size of a muscle's motor units determine how precisely controlled its movements are. (*Figure 10–17*)
- 24. Resting **muscle tone** stabilizes bones and joints.
- 25. Normal activities generally include both **isotonic contractions** (in which the tension in a muscle rises and the length of the muscle changes) and **isometric contractions** (in which tension rises, but the length of the muscle stays the same). There are two types of isotonic contractions: **concentric** and **eccentric**. (*Figure 10–18*)
- **26.** Load and speed of contraction are inversely related. *(Figure 10–19)*
- **27.** The return to resting length after a contraction may involve elastic forces, the contraction of opposing muscle groups, and gravity.

10-6 ATP provides energy for muscle contraction p. 316

- **28.** Muscle contractions require large amounts of energy. *(Table 10–1)*
- **29. Creatine phosphate (CP)** can release stored energy to convert ADP to ATP. (*Table 10–1*)
- **30.** At rest or at moderate levels of activity, **aerobic metabolism** (the citric acid cycle and the electron transport chain in the mitochondria) can provide most of the ATP needed to support muscle contractions.
- **31.** At peak levels of activity, the muscle cell relies heavily on **anaerobic metabolism (glycolysis)** to generate ATP, because the mitochondria cannot obtain enough oxygen to meet the existing ATP demands.
- **32.** As muscular activity changes, the pattern of energy production and use changes. *(Figure 10–20)*
- **33.** A fatigued muscle can no longer contract, because of a drop in pH due to the buildup and dissociation of **lactic acid**, the exhaustion of energy resources, or other factors.
- 34. The **recovery period** begins immediately after a period of muscle activity and continues until conditions inside the muscle have returned to pre-exertion levels. The **oxygen debt**, or **excess postexercise oxygen consumption (EPOC)**, created during exercise is the amount of oxygen required during the recovery period to restore the muscle to its normal condition.

- **35.** Circulating hormones may alter metabolic activities in skeletal muscle fibers.
- **10-7** Muscle performance capabilities depend on muscle fiber type and physical conditioning p. 320
- **36**. The three types of skeletal muscle fibers are **fast fibers**, **slow fibers**, and **intermediate fibers**. (*Table 10–2; Figure 10–21*)
- **37.** Fast fibers, which are large in diameter, contain densely packed myofibrils, large glycogen reserves, and relatively few mitochondria. They produce rapid and powerful contractions of relatively brief duration. *(Figure 10–21)*
- **38.** Slow fibers are about half the diameter of fast fibers and take three times as long to contract after stimulation. Specializations such as abundant mitochondria, an extensive capillary supply, and high concentrations of **myoglobin** enable slow fibers to continue contracting for extended periods. (*Figure 10–21*)
- **39.** Intermediate fibers are very similar to fast fibers, but have a greater resistance to fatigue.
- **40.** Muscles dominated by fast fibers appear pale and are known as **white muscles**.
- 41. Muscles dominated by slow fibers are rich in myoglobin, appear red, and are known as **red muscles**.
- **42.** Training to develop anaerobic endurance can lead to **hypertrophy** (enlargement) of the stimulated muscles.
- **43. Anaerobic endurance** is the time over which muscular contractions can be sustained by glycolysis and reserves of ATP and CP.
- 44. **Aerobic endurance** is the time over which a muscle can continue to contract while supported by mitochondrial activities.

- **10-8** Cardiac muscle tissue differs structurally and functionally from skeletal muscle tissue p. 324
- 45. **Cardiac muscle tissue** is located only in the heart. **Cardiac muscle cells** are small; have one centrally located nucleus; have short, broad T tubules; and are dependent on aerobic metabolism. **Intercalated discs** connect neighboring cardiac muscle cells where their sarcolemmas connect. (*Figure 10–22; Table 10–3*)
- **46.** Cardiac muscle cells contract without neural stimulation (**automaticity**), and their contractions last longer than those of skeletal muscle.
- **47.** Because cardiac muscle twitches do not exhibit wave summation, cardiac muscle tissue cannot produce tetanic contractions.
- **10-9** Smooth muscle tissue differs structurally and functionally from skeletal and cardiac muscle tissue p. 325
- **48. Smooth muscle tissue** is nonstriated, involuntary muscle tissue.
- 49. Smooth muscle cells lack sarcomeres and the resulting striations. The thin filaments are anchored to **dense bodies**. (*Figure 10–23; Table 10–3*)
- **50.** Smooth muscle contracts when calcium ions interact with **calmodulin**, which activates **myosin light chain kinase**.
- **51.** Smooth muscle functions over a wide range of lengths (**plasticity**).
- **52.** In **multiunit smooth muscle cells**, each smooth muscle cell acts relatively independently of other smooth muscle cells in the organ. **Visceral smooth muscle cells** are not always innervated by motor neurons. Neurons that innervate smooth muscle cells are not under voluntary control.

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures in the following figure.

The connective tissue coverings of a skeletal muscle, listed from superficial to deep, are (a) endomysium, perimysium, and epimysium, (b) endomysium, epimysium, and perimysium, (c) epimysium, endomysium, and perimysium, (d) epimysium, perimysium, and endomysium.

See the blue Answers tab at the back of the book.

- The signal to contract is distributed deep into a muscle fiber by the (a) sarcolemma, (b) sarcomere, (c) transverse tubules, (d) myotubules, (e) myofibrils.
- The detachment of the myosin cross-bridges is directly triggered by

 (a) the repolarization of T tubules,
 (b) the attachment of ATP to
 myosin heads,
 (c) the hydrolysis of ATP,
 (d) calcium ions.
- 5. A muscle producing near-peak tension during rapid cycles of contraction and relaxation is said to be in (a) incomplete tetanus, (b) treppe, (c) complete tetanus, (d) a twitch.
- The type of contraction in which the tension rises, but the load does not move, is (a) a wave summation, (b) a twitch, (c) an isotonic contraction, (d) an isometric contraction.
- Which of the following statements about myofibrils is *not* correct?
 (a) Each skeletal muscle fiber contains hundreds to thousands of myofibrils.
 (b) Myofibrils contain repeating units called sarcomeres.
 (c) Myofibrils extend the length of a skeletal muscle fiber.
 (d) Filaments consist of bundles of myofibrils.
 (e) Myofibrils are attached to the plasma membrane at both ends of a muscle fiber.
- An action potential can travel quickly from one cardiac muscle cell to another because of the presence of (a) gap junctions, (b) tight junctions, (c) intercalated discs, (d) both a and c.
- 9. List the three types of muscle tissue in the body.

- **10.** What three layers of connective tissue are part of each muscle? What functional role does each layer play?
- The _____ contains vesicles filled with acetylcholine. (a) axon terminal, (b) motor end plate, (c) neuromuscular junction, (d) synaptic cleft, (e) transverse tubule.
- **12.** What structural feature of a skeletal muscle fiber propagates action potentials into the interior of the cell?
- 13. What five interlocking steps are involved in the contraction process?
- 14. What two factors affect the amount of tension produced when a skeletal muscle contracts?
- **15.** What forms of energy reserves do resting skeletal muscle fibers contain?
- **16.** What two mechanisms are used to generate ATP from glucose in muscle cells?
- 17. What is the calcium-binding protein in smooth muscle tissue?

LEVEL 2 Reviewing Concepts

- An activity that would require anaerobic endurance is (a) a 50-meter dash, (b) a pole vault, (c) a weight-lifting competition, (d) all of these.
- **19.** Areas of the body where you would *not* expect to find slow fibers include the **(a)** back and calf muscles, **(b)** eye and hand, **(c)** chest and abdomen, **(d)** a, b, and c.
- 20. During relaxation, muscles return to their original length because of all of the following *except* (a) actin and myosin actively pushing away from one another, (b) the contraction of opposing muscles, (c) the pull of gravity, (d) the elastic nature of the sarcolemma, (e) elastic forces.
- 21. According to the length-tension relationship, (a) longer muscles can generate more tension than shorter muscles, (b) the greater the zone of overlap in the sarcomere, the greater the tension the muscle can develop, (c) the greatest tension is achieved in sarcomeres where actin and myosin initially do not overlap, (d) there is an optimum range of

actin and myosin overlap that will produce the greatest amount of tension, (e) both b and d are correct.

- **22.** For each portion of a myogram tracing a twitch in a stimulated calf muscle fiber, describe the events that occur within the muscle.
- **23.** What three processes are involved in repaying the oxygen debt during a muscle's recovery period?
- 24. How does cardiac muscle tissue contract without neural stimulation?
- **25.** Atracurium is a drug that blocks the binding of ACh to ACh receptors. Give an example of a site where such binding normally occurs, and predict the physiological effect of this drug.
- **26.** Explain why a murder victim's time of death can be estimated according to the flexibility or rigidity of the body.
- 27. Which of the following activities would employ isometric contractions? (a) flexing the elbow, (b) chewing food, (c) maintaining an upright posture, (d) running, (e) writing.

LEVEL 3 Critical Thinking and Clinical Applications

- 28. Many potent insecticides contain toxins, called organophosphates, that interfere with the action of the enzyme acetylcholinesterase. Ivan is using an insecticide containing organophosphates and is very careless. Because he does not use gloves or a dust mask, he absorbs some of the chemical through his skin and inhales a large amount as well. What signs would you expect to observe in Ivan as a result of organophosphate poisoning?
- **29.** Linda's father suffers an apparent heart attack and is rushed to the emergency room of the local hospital. The doctor on call tells her that he has ordered some blood work and that he will be able to tell if her father actually had an attack by looking at the blood levels of CK and cardiac troponin. Why would knowing the level of CK and cardiac troponin help to indicate if a person suffered a heart attack?
- **30.** Bill broke his leg in a football game, and after six weeks the cast is finally removed. As he steps down from the examination table, he loses his balance and falls. Why?

CLINICAL CASE Wrap-Up

A Real Eye Opener

Tamara is suffering from myasthenia gravis, an autoimmune disease of the neuromuscular junction (NMJ). In people with this autoimmune disease, the immune system mistakenly makes antibodies that damage the acetylcholine receptor sites on the surface of the motor end plates of skeletal muscle fibers. The acetylcholine (ACh) that is released by the axon terminal of the motor neuron cannot find enough intact ACh receptors on which to bind. For this reason, the muscle fiber membrane permeability to sodium ions does not change enough, and the cascade of events leading to muscular contraction is feeble. The result is weakness and easy fatiguability. This weakness improves with rest as the ACh store is built up again. Often the muscles of the eyes, including the eyelids, and other facial muscles, are affected first. All voluntary, skeletal muscles can be affected.

The neurologist injected Tamara with Tensilon (edrophonium chloride), a short-acting acetylcholinesterase inhibitor. The drug blocks acetylcholinesterase (AChE), the enzyme that breaks down ACh. This prolongs muscle stimulation. Sadly, the dramatic effects, such as suddenly being able to open and move both eyes, are short-lived. There are, however,

many treatments available for myasthenia gravis, including longacting acetylcholinesterase inhibitors. Tamara responded well to treatment and was able to resume playing with her band.

- 1. How would a drug that inhibits AChE make a myasthenia gravis patient stronger?
- 2. Do you think myasthenia gravis would affect Tamara's heart muscle?

See the blue Answers tab at the back of the book.

The Muscular System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **11-1** Describe the arrangement of fascicles in the various types of muscles, and explain the resulting functional differences.
- **11-2** Describe the classes of levers, and explain how they make muscles more efficient.
- 11-3 Predict the actions of a muscle on the basis of its origin and insertion, and explain how muscles interact to produce or oppose movements.
- **11-4** Explain how the name of a muscle can help identify its location, appearance, or function.
- **11-5** Identify the principal axial muscles of the body, plus their origins, insertions, actions, and innervation.
- 11-6 Identify the principal appendicular muscles of the body, plus their origins, insertions, actions, and innervation, and compare the major functional differences between the upper and lower limbs.
- **11-7** Identify age-related changes of the muscular system.
- 11-8 Explain the functional relationship between the muscular system and other body systems, and explain the role of exercise in producing various responses in other body systems.

SPOTLIGHT

• Muscle Action p. 338

CLINICAL CASE

• The Weekend Warrior p. 333

Clinical Notes

- Intramuscular Injections p. 344
- Hernia p. 378

CLINICAL CASE

The Weekend Warrior

David is a 25-year-old insurance salesman and avid "weekend warrior" water-skier. He is skiing

behind a powerful speedboat with both feet strapped into a wake board when the boat driver hits the throttle. David starts to fall awkwardly to his right. He resists the fall and digs into the board with his right foot. Suddenly he feels an extremely painful, incapacitating pop below his right gluteal region and falls into the water.

David is unable to swim; it feels as if his right lower extremity is paralyzed. Fortunately he is wearing a life vest, and within minutes he is pulled into the boat and rescued. Back at the dock, he finds he cannot flex his knee at all, but is able to get around by locking his quads, "hiking" his hip (knee in extension), and doing an "abduction swing" to place his right foot forward while leaning on a friend for support. He cannot sit on his right side. The next evening, massive bruising appears on the entire posterior surface of his thigh and knee. Three weeks later, the bruising and swelling finally begin to resolve, but David can still feel a ball of muscle behind his right knee.

One month post injury, David is still unable to flex his knee. He visits an orthopedist, who immediately schedules him for surgery. What kind of injury has David sustained? To find out, turn to the Clinical Case Wrap-Up on p. 384.

An Introduction to the Muscular System

In this chapter we describe the gross anatomy of the muscular system and consider functional relationships between muscles and bones of the body. Most skeletal muscle fibers contract at similar rates and shorten to the same degree, but variations in microscopic and macroscopic organization can dramatically affect the power, range, and speed of movement produced when muscles contract.

11-1 Fascicle arrangement is correlated with muscle power and range of motion

Learning Outcome Describe the arrangement of fascicles in the various types of muscles, and explain the resulting functional differences.

Muscle fibers in a skeletal muscle form bundles called *fascicles*. \bigcirc **p**. 292 The muscle fibers in a single fascicle are parallel, but the organization of fascicles in skeletal muscles can vary, as can the relationship between the fascicles and the associated tendon. Based on the patterns of fascicle organization, we can classify skeletal muscles as *parallel muscles, convergent muscles, pennate muscles,* and *circular muscles* (Figure 11–1).

Parallel Muscles

In a **parallel muscle**, the fascicles are parallel to the long axis of the muscle. Most of the skeletal muscles in the body are parallel muscles. Some are flat bands with broad attachments *(aponeuroses)* at each end. Others are plump and cylindrical, with tendons at one or both ends. Such a muscle is spindle shaped, with a central **body**, also known as the *belly*. For

example, the *biceps brachii muscle* of the arm is a parallel muscle with a central body (Figure 11–1a). When a parallel muscle contracts, it shortens and gets larger in diameter. You can see the bulge of the contracting biceps brachii muscle on the anterior surface of your arm when you flex your elbow. Other parallel muscles include the rectus abdominis and supinator (Figures 11–1b and 11–1c).

A skeletal muscle fiber can contract until it has shortened about 30 percent. The entire parallel muscle shortens by this amount when its fibers contract together, because these fibers are parallel to the long axis of the muscle. Thus, if the muscle is 10 cm (3.94 in.) long and one end is held in place, the other end will move 3 cm when the muscle contracts. The tension developed during this contraction depends on the total number of myofibrils the muscle contains. \bigcirc **p. 312**

We can use the cross-sectional area of the resting muscle to estimate the tension, because the myofibrils are distributed evenly through the sarcoplasm of each cell. For each 6.45 cm² (1 in.²) in cross-sectional area, a parallel muscle can develop approximately 23 kg (50 lb) of isometric tension.

Convergent Muscles

In a **convergent muscle**, muscle fascicles extending over a broad area come together, or converge, on a common attachment site (Figure 11–1d). The muscle may pull on a tendon, an aponeurosis, or a slender band of collagen fibers known as a **raphe** ($R\bar{A}$ -f \bar{e} ; seam). The muscle fibers typically spread out, like a fan or a broad triangle, with a tendon at the apex. Examples include the prominent *pectoralis muscles* of the chest.

A convergent muscle is versatile, because the stimulation of different portions of the muscle can change the direction of pull. However, when the entire muscle contracts, the muscle Figure 11–1 Muscle Types Based on Pattern of Fascicle Organization.

fibers do not pull as hard on the attachment site as would a parallel muscle of the same size. Why not? The reason is that convergent muscle fibers pull in different directions, rather than all pulling in the same direction as in parallel muscles.

Pennate Muscles

In a **pennate muscle** (*penna*, feather), the fascicles form a common angle with the tendon. Because the muscle fibers pull at an angle, contracting pennate muscles do not move their tendons as far as parallel muscles do. But a pennate muscle contains more muscle fibers—and thus more myofibrils—than does a parallel muscle of the same size. For this reason, the pennate muscle produces more tension.

If all the muscle fibers are on the same side of the tendon, the pennate muscle is *unipennate*. The *extensor digitorum muscle*, a forearm muscle that extends the finger joints, is unipennate (Figure 11–1e).

More commonly, a pennate muscle has fibers on both sides of the tendon. Such a muscle is called *bipennate*. The *rectus femoris muscle*, a prominent muscle that extends the knee, is bipennate (Figure 11–1f).

If the tendon branches within a pennate muscle, the muscle is said to be *multipennate*. The triangular *deltoid muscle* of the shoulder is multipennate (Figure 11–1g).

Circular Muscles

In a **circular muscle**, or **sphincter** (SFINK-ter), the fascicles are concentrically arranged around an opening. When the muscle contracts, the diameter of the opening becomes smaller. Circular muscles guard body entrances and exits of internal passageways, or act as valves along the digestive and urinary tracts. An example is the *orbicularis oris muscle* of the mouth (Figure 11–1h).

CHECKPOINT

- 1. Based on patterns of fascicle organization, name the four classifications of skeletal muscle tissue.
- 2. Why does a pennate muscle generate more tension than does a parallel muscle of the same size?
- 3. Which type of fascicle arrangement would you expect in a muscle guarding the opening between the stomach and the small intestine?

• See the blue Answers tab at the back of the book.

11-2 The three classes of levers increase muscle efficiency

Learning Outcome Describe the classes of levers, and explain how they make muscles more efficient.

Skeletal muscles do not work in isolation. For muscles attached to the skeleton, the nature and site of the connection determine the force, speed, and range of the movement. These characteristics are interdependent, and the relationships can explain a great deal about the general organization of the muscular and skeletal systems.

Attaching the muscle to a lever can modify the force, speed, or direction of movement produced by muscle contraction. A *lever* is a rigid structure—such as a board, a crowbar, or a bone—that moves on a fixed point called the *fulcrum*. A lever moves when pressure called an *applied force* is sufficient to overcome any load that would otherwise oppose or prevent such movement.

In the body, each bone is a lever and each joint is a fulcrum. Muscles provide the applied force. The load can vary from the weight of an object held in the hand to the weight of a limb or the weight of the entire body, depending on the situation. The important thing about levers is that they can change (1) the direction of an applied force, (2) the distance and speed of movement produced by an applied force, and (3) the effective strength of an applied force. There are three classes of levers. We find examples of each in the human body (Figure 11–2). A pry bar or crowbar is an example of a **first-class lever**. In such a lever, the fulcrum (F) lies between the applied force (AF) and the load (L). The body has few first-class levers. One, involved with extension of the neck, is shown in Figure 11–2a.

In a **second-class lever** (Figure 11–2b), the load lies between the applied force and the fulcrum. A familiar example is a loaded wheelbarrow. The weight is the load, and the upward lift on the handle is the applied force. In this arrangement, a small force can move a larger weight because the force is always farther from the fulcrum than the load is. That is, the effective force is increased. Notice, however, that when a force moves the handle, the load moves more slowly and covers a shorter distance. In other words, the effective force is increased at the expense of speed and distance. The body has few second-class levers. Ankle extension (plantar flexion) by the calf muscles involves a second-class lever (Figure 11–2b).

In a **third-class lever**, such as a catapult, the applied force is between the load and the fulcrum (Figure 11–2c). Third-class levers are the most common levers in the body. The effect is the reverse of that for a second-class lever: Speed and distance traveled are increased at the expense of effective force. In the example shown (the biceps brachii muscle, which flexes the elbow), the load is six times farther from the fulcrum than is the applied force. The effective force is reduced to the same degree. The muscle must generate 180 kg (396 lb) of tension at its attachment to the forearm to support 30 kg (66 lb) held in the hand. However, the distance traveled and the speed of movement are increased by that same 6:1 ratio: The load will travel 45 cm (almost 18 in.) when the point of attachment moves 7.5 cm (nearly 3 in.).

Not every muscle is part of a lever system, but the presence of levers provides speed and versatility far in excess of what we would predict for the body on the basis of muscle physiology alone. Skeletal muscle fibers resemble one another closely, and their abilities to contract and generate tension are quite similar. Consider a skeletal muscle that can shorten 1 cm (0.39 in.) while it exerts a 10-kg (22-lb) pull. Without using a lever, this muscle would be performing efficiently only when moving a 10-kg (22-lb) weight a distance of 1 cm (0.39 in.). By using a lever, however, the same muscle operating at the same efficiency could move 20 kg (44 lb) a distance of 0.5 cm (0.2 in.), 5 kg (11 lb) a distance of 2 cm (0.79 in.), or 1 kg (2.2 lb) a distance of 10 cm (3.9 in.).

CHECKPOINT

- 4. Define a lever, and describe the three classes of levers.
- 5. The joint between the occipital bone of the skull and the first cervical vertebra (atlas) is an example of which class of lever?

See the blue Answers tab at the back of the book.

Figure 11–2 The Three Classes of Levers.

11-3 Muscle origins are at the fixed end of muscles, and insertions are at the movable end of muscles

Learning Outcome Predict the actions of a muscle on the basis of its origin and insertion, and explain how muscles interact to produce or oppose movements.

In this chapter we focus on the functional anatomy of skeletal muscles and muscle groups. Once you are familiar with the basic terminology that we introduce in this section, you will find the names and actions of skeletal muscles easy to understand.

Origins and Insertions

In Chapter 10 we noted that when both ends of a myofibril are free to move, the ends move toward the center during a contraction. \bigcirc **p. 306** In the body, the ends of a skeletal muscle are always attached to other structures that limit their movement. In most cases one end is fixed in position, and during a contraction the other end moves toward the fixed end. The place where

the fixed end attaches to a bone, cartilage, or connective tissue is called the **origin** of the muscle. The site where the movable end attaches to another structure is called the **insertion** of the muscle. The origin is typically proximal to the insertion. When a muscle contracts, it produces a specific **action**, or movement. We describe actions using the terms introduced in Chapter 9 (flexion, extension, adduction, and so forth).

As an example, consider the *gastrocnemius muscle*, a calf muscle that extends from the distal portion of the femur to the calcaneus. As **Figure 11–2b** shows, when the gastrocnemius muscle contracts, it pulls the calcaneus toward the knee. As a result, we say that the gastrocnemius muscle has its origin at the femur and its insertion at the calcaneus. We describe its action as "extension at the ankle" or "plantar flexion."

The decision as to which end is the origin and which is the insertion is usually based on movement from the anatomical position. Part of the fun of studying the muscular system is that you can actually do the movements and think about the muscles involved. As a result, laboratory activities focusing on muscle actions are often like disorganized aerobics classes.

When we cannot easily determine the origins and insertions on the basis of movement from the anatomical position, we have other rules to use. If a muscle extends between a broad aponeurosis and a narrow tendon, the aponeurosis is the origin and the tendon is the insertion. If several tendons are at one end and just one is at the other, the muscle has multiple origins and a single insertion. These simple rules cannot cover every situation. Knowing which end is the origin and which is the insertion is ultimately less important than knowing where the two ends attach and what the muscle accomplishes when it contracts.

Most muscles originate at a bone, but some originate at a connective tissue sheath or band. Examples of these sheaths or bands include *intermuscular septa* (components of the deep fascia that may separate adjacent skeletal muscles), *tendinous inscriptions* that join muscle fibers to form long muscles such as the *rectus abdominis*, the interosseous membranes of the forearm or leg, and the fibrous sheet that spans the obturator foramen of the pelvis.

Actions

Almost all skeletal muscles either originate or insert on the skeleton. When a muscle moves a portion of the skeleton, that movement may involve flexion, extension, adduction, abduction, protraction, retraction, elevation, depression, rotation, circumduction, pronation, supination, inversion, eversion, lateral flexion, opposition, or reposition. (Before proceeding, you may want to review the discussions of planes of motion and **Spotlight Figure 9-2** and **Figures 9-3** to **9-5**.) \bigcirc pp. 269–273

We can describe actions in two ways. One way describes actions in terms of the bone or region affected. For example, we say a muscle such as the biceps brachii performs "flexion of the forearm."

Specialists such as kinesiologists and physical therapists increasingly use the second way. It identifies the joint involved. In this approach, we say the action of the biceps brachii muscle is "flexion at (or of) the elbow." Examples of muscle action are presented in **Spotlight Figure 11–3**.

In complex movements, muscles commonly work in groups rather than individually. Their cooperation improves the efficiency of a particular movement. For example, large muscles of the limbs produce flexion or extension over an extended range of motion. These muscles cannot produce powerful movements at full extension due to the positions of the articulating bones, but they are usually paired with one or more smaller muscles that provide assistance until the larger muscle can perform at maximum efficiency. At the start of the movement, the smaller muscle produces maximum tension, while the larger muscle produces minimum tension. The importance of the smaller "assistant" decreases as the movement proceeds and the effectiveness of the primary muscle increases.

We describe muscles as follows, based on their functions:

- An **agonist**, or **prime mover**, is a muscle whose contraction is mostly responsible for producing a particular movement. The biceps brachii muscle is an agonist that produces flexion at the elbow.
- An antagonist is a muscle whose action opposes that of a particular agonist. The *triceps brachii muscle* is an agonist that extends the elbow. For this reason, it is an antagonist of the biceps brachii muscle. Likewise, the biceps brachii is an antagonist of the triceps brachii.

Agonists and antagonists are functional opposites. If one produces flexion, the other produces extension. When an agonist contracts to produce a particular movement, the corresponding antagonist is stretched, but it usually does not relax completely. Instead, it contracts eccentrically, with just enough tension to control the speed of the movement and ensure its smoothness. \supset p. 314

You may find it easiest to learn about muscles in agonist–antagonist pairs (flexors–extensors, abductors– adductors) that act at a specific joint. This method highlights the functions of the muscles involved, and it can help organize the information into a logical framework. The tables in this chapter are arranged to support such an approach.

When a synergist (syn-, together + ergon, work) contracts, it helps a larger agonist work efficiently. Synergists may provide additional pull near the insertion or may stabilize the point of origin. Their importance in assisting a particular movement may change as the movement progresses. In many cases, they are most useful at the start, when the agonist is stretched and unable to develop maximum tension.

SPOTLIGHT Figure 11-3 Muscle Action

The action produced by a muscle at any one joint is largely dependent upon the structure of the joint and the location of the insertion of the muscle relative to the axis of movement at the joint. The direction, or geometric paths, of the action produced by a muscle—called *lines of action*—is often represented by an arrow (or more than one arrow in fan-shaped muscles).

Flexion and Extension

At joints that permit flexion and extension, muscles whose lines of action cross the anterior side of a joint are flexors of that joint, and muscles whose lines of action cross the posterior side of a joint are extensors of that joint.

Abduction and Adduction

At joints that permit adduction and abduction, muscles whose lines of action cross the medial side of a joint are adductors of that joint, and muscles whose lines of action cross the lateral side of a joint are abductors of that joint.

Medial and Lateral Rotation

At joints that permit rotation, movement or turning of the body part occurs around its axis. The shoulder joint is a ball-and-socket joint that permits rotation. The subscapularis muscle has lines of action that cross the anterior aspect of the shoulder joint. When the subscapularis contracts it produces medial rotation at the joint. The teres minor muscle has lines of action that cross the posterior aspect of the shoulder joint. When the teres minor contracts, it produces lateral rotation at the shoulder.

For example, the *latissimus dorsi muscle* is a large trunk muscle that extends, adducts, and medially rotates the arm at the shoulder joint. A much smaller muscle, the *teres* (TER-ēz) *major muscle*, assists in starting such movements when the shoulder joint is at full flexion.

• A **fixator** is a synergist that assists an agonist by preventing movement at another joint, thereby stabilizing the origin of the agonist. Recall that the biceps brachii muscle is an agonist that produces flexion at the elbow. It has two tendons that originate on the scapula and one that inserts on the radius. During flexion, the trapezius and rhomboid muscles act as fixators by stabilizing and preventing the movement of the scapula.

CHECKPOINT

- 6. The gracilis muscle is attached to the anterior surface of the tibia at one end, and to the pubis and ischium of the pelvis at the other. When the muscle contracts, flexion occurs at the hip. Which attachment point is considered the muscle's origin?
- 7. Muscle A abducts the humerus, and muscle B adducts the humerus. What is the relationship between these two muscles?
- 8. Define the term *synergist* as it relates to muscle action.

See the blue Answers tab at the back of the book.

11-4 Descriptive terms are used to name skeletal muscles

Learning Outcome Explain how the name of a muscle can help identify its location, appearance, or function.

Except for the *platysma* and the *diaphragm*, the complete names of all skeletal muscles include the term *muscle*. The full name, such as the biceps brachii muscle, will usually appear in the text, but for simplicity, only the descriptive name (biceps brachii) will appear in figures and tables.

You need not learn every one of the approximately 700 muscles in the human body, but you will have to become familiar with the most important ones. Fortunately, the names anatomists assigned to the muscles include descriptive terms that can help you remember the names and identify the muscles. When faced with a new muscle name, it is helpful to first identify the descriptive portions of the name. The name of a muscle may include descriptive information about its location in the body, origin and insertion, fascicle organization, position, structural characteristics, and action.

Location in the Body

Table 11–1 includes a useful summary of muscle terminology, including terms that designate specific regions of the body.

Regional terms are most common as modifiers that help identify individual muscles. In a few cases, a muscle is such a prominent feature of a body region that a name referring to the region alone will identify it. Examples include the *temporalis muscle* of the head and the *brachialis* (brā-kē-A-lis) *muscle* of the arm.

Origin and Insertion

Many muscle names include terms for body places that tell you the specific origin and insertion of each muscle. In such cases, the first part of the name indicates the origin, the second part the insertion. The *genioglossus muscle*, for example, originates at the chin (*geneion*) and inserts in the tongue (*glossus*). The names may be long and difficult to pronounce, but Table 11–1 and the anatomical terms introduced in Chapter 1 can help you identify and remember them. \bigcirc pp. 14–18

Fascicle Organization

A muscle name may refer to the orientation of the muscle fascicles within a particular skeletal muscle. **Rectus** means "straight," and rectus muscles are parallel muscles whose fibers run along the long axis of the body. Because we have several rectus muscles, the name typically includes a second term that refers to a precise region of the body. For example, the *rectus ab*-*dominis muscle* is located on the abdomen, and the *rectus femo*-*ris muscle* on the thigh. Other common directional indicators include **transversus** and **oblique**, for muscles whose fibers run across (transversus) or at a slanting (oblique) angle to the longitudinal axis of the body.

Position

Muscles visible at the body surface are often called **externus** or **superficialis**. Deeper muscles are termed **internus** or **pro-fundus**. Superficial muscles that position or stabilize an organ are called **extrinsic**. Muscles located entirely within an organ are **intrinsic**.

Structural Characteristics

Some muscles are named after distinctive structural features. The biceps brachii muscle, for example, is named after its origin. It has two tendons of origin (bi-, two + caput, head). Similarly, the triceps brachii muscle has three, and the *quadriceps* group has four.

Shape is sometimes an important clue to the name of a muscle. For example, the *trapezius* (tra-PĒ-zē-us), *deltoid*, *rhomboid* (ROM-boyd), and *orbicularis* (or-bik-ū-LĀ-ris) muscles look like a trapezoid, a triangle, a rhomboid, and a circle, respectively.

Table 11–1	Muscle Tern	ninology		
Terms Indicating S Regions of the Boc	pecific ly	Terms Indicating Position, Direction, or Fascicle Organization	Terms Indicating Structural Characteristics of the Muscle	Terms Indicating Actions
Abdominal (abdom	nen)	Anterior (front)	Nature of Origin	General
Ancon (elbow)		External (on the outside)	Biceps (two heads)	Abductor (movement away)
Auricular (ear)		Extrinsic (outside the structure)	Triceps (three heads)	Adductor (movement toward)
Brachial (arm)		Inferior (below)	Quadriceps (four heads)	Depressor (lowering movement)
Capitis (head)		Internal (away from the surface)		Extensor (straightening movement)
Carpi (wrist)		Intrinsic (within the structure)	Shape	Flexor (bending movement)
Cervicis (neck)		Lateral (on the side)	Deltoid (triangle)	Levator (raising movement)
Coccygeal (coccyx)		Medial (middle)	Orbicularis (circle)	Pronator (turning into prone position)
Costal (rib)		Oblique (slanting)	Pectinate (comblike)	Supinator (turning into supine position)
Cutaneous (skin)		Posterior (back)	Piriformis (pear-shaped)	Tensor (tensing movement)
Femoris (thigh)		Profundus (deep)	Platysma (flat plate)	
Glossal (tongue)		Rectus (straight)	Pyramidal (pyramid)	Specific
Hallux (great toe)		Superficial (toward the surface)	Rhomboid (parallelogram)	Buccinator (trumpeter)
llium (groin)		Superior (toward the head)	Serratus (serrated)	Risorius (laugher)
Inguinal (groin)		Transverse (crosswise)	Splenius (bandage)	Sartorius (like a tailor)
Lumbar (lumbar re	gion)		Teres (round and long)	
Nasalis (nose)			Trapezius (trapezoid)	
Nuchal (back of ne	ck)			
Ocular (eye)			Other Striking Features	
Oris (mouth)			Alba (white)	
Palpebra (eyelid)			Brevis (short)	
Pollex (thumb)			Gracilis (slender)	
Popliteal (posterior	r to knee)		Latae (wide)	
Psoas (loin)			Latissimus (widest)	
Radial (forearm)			Longissimus (longest)	
Scapular (scapula)			Longus (long)	
Temporal (temple)			Magnus (large)	
Thoracic (thorax)			Major (larger)	
Tibial (tibia; shin)			Maximus (largest)	
Ulnar (ulna)			Minimus (smallest)	
			Minor (smaller)	
			Vastus (great)	

Many terms refer to muscle size. Long muscles are called **longus** (long) or **longissimus** (longest). **Teres** muscles are both long and round. Short muscles are called **brevis**. Large ones are called **magnus** (big), **major** (bigger), or **maximus** (biggest). Small ones are called **minor** (smaller) or **minimus** (smallest).

Action

Many muscles are named *flexor, extensor, pronator, abductor,* and so on. These are such common actions that the names almost

always include other clues as to the appearance or location of the muscle. For example, the *extensor carpi radialis longus muscle* is a long muscle along the radial (lateral) border of the forearm. When it contracts, its primary function is extension at the carpus (wrist).

A few muscles are named after the specific movements associated with special occupations or habits. The *sartorius* (sar-TOR-ē-us) *muscle*, the longest in the body, is active when you cross your legs. Before sewing machines were invented, a tailor would sit on the floor cross-legged. The name of this muscle was derived from *sartor*, the Latin word for "tailor." The *buccinator* (BUK-si-nā-tor) *muscle* on the face compresses the cheeks—when, for example, you purse your lips and blow forcefully. *Buccinator* translates as "trumpet player."

Another facial muscle, the *risorius* (ri-SOR-ē-us) *muscle*, was supposedly named after the mood expressed. However, the Latin word *risor* means "one who laughs." A more appropriate description for the effect would be "a grimace."

Axial and Appendicular Muscles

The separation of the skeletal system into axial and appendicular divisions serves as a useful guideline for subdividing the muscular system as well:

- 1. The **axial muscles** arise on the axial skeleton. This category includes approximately 60 percent of the skeletal muscles in the body. They position the head and spinal column and also move the rib cage, assisting in the movements that make breathing possible. They do not play a role in movement or support of either the pectoral or pelvic girdle or the limbs.
- **2.** The **appendicular muscles** stabilize or move components of the appendicular skeleton. These muscles include the remaining 40 percent of all skeletal muscles.

Figure 11–4 provides an overview of the major axial and appendicular muscles of the human body. These are superficial muscles, which tend to be rather large. The superficial muscles cover deeper, smaller muscles that we cannot see unless the overlying muscles are removed or *reflected*—that is, cut and pulled out of the way. Later figures that show deep muscles in specific regions will indicate whether superficial muscles have been removed or reflected.

Next we will study examples of both muscular divisions. Pay attention to patterns of origin, insertion, and action. In the figures in this chapter, you will find that some bony and cartilaginous landmarks are labeled to provide orientation. Should you need further review of skeletal anatomy, figure captions in this chapter indicate the relevant figures in *Martini's Atlas of the Human Body*.

The tables that follow also contain information about the innervation of the individual muscles. **Innervation** is the distribution of nerves to a region or organ. The tables indicate the nerves that control each muscle. Many of the muscles of the head and neck are innervated by *cranial nerves*, which originate at the brain and pass through the foramina of the skull. In addition, *spinal nerves* are connected to the spinal cord and pass through the intervertebral foramina. For example, spinal nerve L_1 passes between vertebrae L_1 and L_2 . Spinal nerves may form a complex network called a *plexus* after exiting the spinal cord. One branch of this network may contain axons from several spinal nerves. Many tables identify the spinal nerves involved as well as the names of their specific branches.

CHECKPOINT

- **9**. Identify the kinds of descriptive information used to name skeletal muscles.
- 10. What does the name *flexor carpi radialis longus* tell you about this muscle?
- See the blue Answers tab at the back of the book.

11-5 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor

Learning Outcome Identify the principal axial muscles of the body, plus their origins, insertions, actions, and innervation.

The axial muscles fall into logical groups on the basis of location, function, or both. The groups do not always have distinct anatomical boundaries. For example, a function such as extension of the vertebral column involves muscles along its entire length and movement at each of the intervertebral joints. We will discuss the axial muscles in four groups:

- 1. *The Muscles of the Head and Neck.* This group includes muscles that move the face, tongue, and larynx. They are responsible for verbal and nonverbal communication—laughing, talking, frowning, smiling, whistling, and so on. You also use these muscles while eating—especially in sucking and chewing—and even while looking for food, as some of them control your eye movements. The group does not include muscles of the neck that are involved with movements of the vertebral column.
- **2.** *The Muscles of the Vertebral Column.* This group includes numerous flexors, extensors, and rotators of the vertebral column.
- **3.** *The Oblique and Rectus Muscles.* This group forms the muscular walls of the trunk between the first thoracic vertebra and the pelvis. In the thoracic area the ribs separate these muscles, but over the abdominal surface the muscles form broad muscular sheets. The neck also has oblique and rectus muscles. They do not form a complete muscular wall, but they share a common developmental origin with the oblique and rectus muscles of the trunk.
- 4. *The Muscles of the Pelvic Floor.* These muscles extend between the sacrum and pelvic girdle. The group forms the *perineum*, a muscular sheet that closes the pelvic outlet.

Muscles of the Head and Neck

We can divide the muscles of the head and neck into several functional groups. The *muscles of facial expression*, the *muscles of mastication* (chewing), the *muscles of the tongue*, and the *muscles of the pharynx* originate on the skull or hyoid bone.

Figure 11–4 An Overview of the Major Skeletal Muscles (continued).

Muscles involved with sight and hearing also are based on the skull. Here, we will consider the *extrinsic eye muscles*—those associated with movements of the eye. In Chapter 17 we will discuss the intrinsic eye muscles, which control the diameter of the pupil and the shape of the lens, and the tiny skeletal muscles associated with the auditory ossicles.

In the neck, the *extrinsic muscles of the larynx* adjust the position of the hyoid bone and larynx. We will examine the intrinsic laryngeal muscles, including those of the vocal cords, in Chapter 23.

Muscles of Facial Expression

The muscles of facial expression originate on the surface of the skull (Figure 11–5 and Table 11–2). At their insertions, the fibers of the epimysium are woven into those of the superficial fascia and the dermis of the skin. For this reason, when these muscles contract, the skin moves.

The largest group of facial muscles is associated with the mouth. The **orbicularis oris** muscle constricts the opening, and other muscles move the lips or the corners of the mouth. The **buccinator** muscle has two functions related to eating (in addition to its importance to musicians). During chewing, it cooperates with the masticatory muscles by moving food back across the teeth from the *vestibule*, the space inside the cheeks. In infants, the buccinator provides suction for suckling at the breast.

Smaller groups of muscles control movements of the eyebrows and eyelids, the scalp, the nose, and the external ear. The **epicranium** (ep-i-KRĀ-nē-um; *epi-*, on + *kranion*, skull), or scalp, contains the **temporoparietalis** muscle and

the **occipitofrontalis** muscle, which has a *frontal belly* and an *occipital belly*. The two bellies are separated by the **epicranial aponeurosis**, a thick, collagenous sheet.

The **platysma** (pla-TIZ-muh; *platys*, flat) covers the anterior surface of the neck. This muscle extends from the base of the neck to the periosteum of the mandible and the fascia at the corner of the mouth. One of the effects of aging is the loss of muscle tone in the platysma, resulting in a looseness of the skin of the anterior throat.

Extrinsic Eye Muscles

Six **extrinsic eye muscles**, also known as the *oculomotor muscles*, originate on the surface of the orbit and control the position of each eye. These muscles, shown in Figure 11–6 and detailed in Table 11–3, are the **inferior rectus**, **medial rectus**, **superior rectus**, **lateral rectus**, **inferior oblique**, and **superior oblique** muscles.

Muscles of Mastication

The muscles of mastication move the mandible at the temporomandibular joint (TMJ) (Figure 11–7 and Table 11–4). The large **masseter** muscle is the strongest jaw muscle. The **temporalis** muscle assists in elevation of the mandible. You can feel these muscles in action by clenching your teeth while resting your hand on the side of your face below and then above the zygomatic arch. The **pterygoid** muscles, used in various combinations, can elevate, depress, or protract the mandible or slide it from side to side, a movement called *lateral excursion*. These movements are important in making efficient use of your teeth while you chew foods of various consistencies.

Clinical Note

Intramuscular Injections Drugs are commonly injected into muscle or adipose tissues rather than directly into the bloodstream. (Accessing blood vessels may be technically more complicated.) An **intramuscular (IM) injection** introduces a fairly large volume of a drug, which then enters the circulation gradually. The drug is introduced into the mass of a large skeletal muscle. Uptake is generally faster and accompanied by less tissue irritation than when drugs are administered *intradermally* (injected into the dermis) or *hypodermally* (injected into the hypodermis). Depending on the size of the muscle, up to 5 mL of fluid may be injected at one time. Multiple injections are possible. A decision on the injection technique and the injection site is based on the type of drug and its concentration.

For IM injections, the most common complications involve accidental injection into a blood vessel or piercing of a nerve. The sudden entry of massive guantities of drug into the bloodstream can have fatal consequences. Damage to a nerve can cause motor paralysis or sensory loss. For these reasons, the site of the injection must be selected with care. Bulky muscles that contain few large vessels or nerves are ideal sites. The gluteus medius muscle or the posterior, lateral, superior part of the gluteus maximus muscle is commonly selected. The deltoid muscle of the arm, about 2.5 cm (1 in.) distal to the acromion, is another effective site. Probably most satisfactory from a technical point of view is the vastus lateralis muscle of the thigh. An injection into this thick muscle will not encounter vessels or nerves, but may cause pain later when the muscle is used in walking. This is the preferred injection site in infants before they start walking, as their gluteal and deltoid muscles are relatively small. The site is also used in elderly patients or others with atrophied gluteal and deltoid muscles.

Table 11–2	Muscles o	f Facial Expression (Figure	11–5)		
Region and Muscl	le	Origin	Insertion	Action	Innervation
MOUTH					
Buccinator		Alveolar processes of maxilla and mandible	Blends into fibers of orbicularis oris	Compresses cheeks	Facial nerve (N VII)*
Depressor labii ir	nferioris	Mandible between the anterior midline and the mental foramen	Skin of lower lip	Depresses lower lip	Facial nerve (N VII)
Levator labii sup	erioris	Inferior margin of orbit, superior to the infra-orbital foramen	Orbicularis oris	Elevates upper lip	Facial nerve (N VII)
Levator anguli or	ris	Maxilla below the infra- orbital foramen	Corner of mouth	Elevates corner of mouth	Facial nerve (N VII)
Mentalis		Incisive fossa of mandible	Skin of chin	Elevates and protrudes lower lip	Facial nerve (N VII)
Orbicularis oris		Maxilla and mandible	Lips	Compresses, purses lips	Facial nerve (N VII)
Risorius		Fascia surrounding parotid salivary gland	Angle of mouth	Draws corner of mouth to the side	Facial nerve (N VII)
Depressor anguli	i oris	Anterolateral surface of mandibular body	Skin at angle of mouth	Depresses corner of mouth	Facial nerve (N VII)
Zygomaticus maj	jor	Zygomatic bone near zygomaticomaxillary suture	Angle of mouth	Retracts and elevates corner of mouth	Facial nerve (N VII)
Zygomaticus min	or	Zygomatic bone posterior to zygomaticotemporal suture	Upper lip	Retracts and elevates upper lip	Facial nerve (N VII)
EYE					
Corrugator super	rcilii	Orbital rim of frontal bone near nasal suture	Eyebrow	Pulls skin inferiorly and anteriorly; wrinkles brow	Facial nerve (N VII)
Levator palpebra (Figure 11–6a,b)	e superioris	Tendinous band around optic foramen	Upper eyelid	Elevates upper eyelid	Oculomotor nerve (N III)**
Orbicularis oculi		Medial margin of orbit	Skin around eyelids	Closes eye	Facial nerve (N VII)
NOSE					
Procerus		Nasal bones and lateral nasal cartilages	Aponeurosis at bridge of nose and skin of forehead	Moves nose, changes position and shape of nostrils	Facial nerve (N VII)
Nasalis		Maxilla and alar cartilage of nose	Bridge of nose	Compresses bridge, depresses tip of nose; elevates corners of nostrils	Facial nerve (N VII)
EAR					
Temporoparietal	is	Fascia around external ear	Epicranial aponeurosis	Tenses scalp, moves auricle of ear	Facial nerve (N VII)
SCALP (EPICRANI	IUM)				
Occipitofrontalis Frontal belly		Epicranial aponeurosis	Skin of eyebrow and bridge of nose	Raises eyebrows, wrinkles forehead	Facial nerve (N VII)
Occipital belly		Occipital bone and mastoid region of temporal bones	Epicranial aponeurosis	Tenses and retracts scalp	Facial nerve (N VII)
NECK					
Platysma		Superior thorax between cartilage of 2nd rib and acromion of scapula	Mandible and skin of cheek	Tenses skin of neck; depresses mandible; pulls lower lip down	Facial nerve (N VII)

*An uppercase N followed by a Roman numeral refers to a cranial nerve.

**This muscle originates in association with the extrinsic eye muscles, so its innervation is unusual.

Figure 11–6 Extrinsic Eye Muscles. ATLAS: Plates 12a; 16a,b

Table 11–3	Extrinsic Eye Muscles (Figure 11–6)			
Muscle	Origin	Insertion	Action	Innervation
Inferior rectus	Sphenoid around optic canal	Inferior, medial surface of eyeball	Eye looks inferiorly	Oculomotor nerve (N III)
Medial rectus	Sphenoid around optic canal	Medial surface of eyeball	Eye looks medially	Oculomotor nerve (N III)
Superior rectus	Sphenoid around optic canal	Superior surface of eyeball	Eye looks superiorly	Oculomotor nerve (N III)
Lateral rectus	Sphenoid around optic canal	Lateral surface of eyeball	Eye looks laterally	Abducens nerve (N VI)
Inferior oblique	Maxilla at anterior portion of orbit	Inferior, lateral surface of eyeball	Eye rolls, looks superiorly and laterally	Oculomotor nerve (N III)
Superior oblique	Sphenoid around optic canal	Superior, lateral surface of eyeball	Eye rolls, looks inferiorly and laterally	Trochlear nerve (N IV)

a Lateral view. The temporalis muscle passes medial to the zygomatic arch to insert on the coronoid process of the mandible. The masseter inserts on the angle and lateral surface of the mandible. b Lateral view, pterygoid muscles exposed. The location and orientation of the pterygoid muscles are seen after the overlying muscles and a portion of the mandible are removed.

Table 11–4	Muscles of Mastication (Figure 11-	scles of Mastication (Figure 11–7)				
Muscle	Origin	Insertion	Action	Innervation		
Masseter	Zygomatic arch	Lateral surface of mandibular ramus	Elevates mandible and closes the jaws	Trigeminal nerve (N V), mandibular branch		
Temporalis	Along temporal lines of skull	Coronoid process of mandible	Elevates mandible	Trigeminal nerve (N V), mandibular branch		
Pterygoids (medial and	Lateral pterygoid plate ateral)	Medial surface of mandibular ramus	<i>Medial</i> : Elevates the mandible and closes the jaws, or slides the mandible from side to side (lateral excursion)	Trigeminal nerve (N V), mandibular branch		
			<i>Lateral:</i> Opens jaws, protrudes mandible, or performs lateral excursion	Trigeminal nerve (N V), mandibular branch		

TIPS&TRICKS

The medial and lateral *ptery*goid muscles are named for their origin on the pterygoid ("winged") portion of the sphenoid bone. The *ptero*dactyl was a prehistoric winged reptile.

Muscles of the Tongue

The four muscles of the tongue have names ending in *glossus*, the Greek word for "tongue." The **palatoglossus** muscle originates at the palate, the **styloglossus** muscle at the styloid process of the temporal bone, the **genioglossus** muscle at the chin, and the **hyoglossus** muscle at the hyoid bone (Figure 11–8). These muscles, used in various combinations, move the tongue in the delicate and complex patterns necessary for speech. They also

maneuver food within the mouth in preparation for swallowing (Table 11–5).

Muscles of the Pharynx

The muscles of the pharynx are responsible for initiating the swallowing process (Figure 11–9 and Table 11–6). The **pharyngeal constrictor** muscles (*superior, middle,* and *inferior*) move food (in the form of a compacted mass called a *bolus*) into the esophagus by constricting the pharyngeal walls. The two **palatal muscles**—the *tensor veli palatini* and the *levator veli palatini*—elevate the soft palate and adjacent portions of the pharyngeal wall and also pull open the entrance to the auditory tube. The **laryngeal elevator** muscles elevate the larynx. As a

Figure 11–8 Muscles of the Tongue.

Figure 11–9 Muscles of the Pharynx.

result, swallowing repeatedly can help you adjust to pressure changes when you fly or dive by opening the entrance to the auditory tube.

Anterior Muscles of the Neck

The anterior muscles of the neck include (1) five muscles that control the position of the larynx, (2) muscles that depress the mandible and tense the floor of the mouth, and (3) muscles that provide a stable foundation for muscles of the tongue and pharynx (Figure 11–10 and Table 11–7).

The **digastric** (dī-GAS-trik) muscle has two bellies, as the name implies (di-, two + gaster, stomach). One belly extends from the chin to the hyoid bone. The other continues from the hyoid bone to the mastoid portion of the temporal bone. Depending on which belly contracts and whether fixator muscles

are stabilizing the position of the hyoid bone, the digastric muscle can open the mouth by depressing the mandible, or it can elevate the larynx by raising the hyoid bone.

The digastric muscle covers the broad, flat **mylohyoid** muscle, which provides a muscular floor to the mouth, aided by the deeper **geniohyoid** muscles that extend between the hyoid bone and the chin. The **stylohyoid** muscle forms a muscular connection between the hyoid bone and the styloid process of the skull.

The **sternocleidomastoid** (ster-nō-klī-dō-MAS-toyd) muscle extends from the clavicle and the sternum to the mastoid

Table 11–5	Muscles of the Tongue (Figure 11–8)					
Muscle	Origin	Insertion	Action	Innervation		
Genioglossus	Medial surface of mandible around chin	Body of tongue, hyoid bone	Depresses and protracts tongue	Hypoglossal nerve (N XII)		
Hyoglossus	Body and greater horn of hyoid bone	Side of tongue	Depresses and retracts tongue	Hypoglossal nerve (N XII)		
Palatoglossus	Anterior surface of soft palate	Side of tongue	Elevates tongue, depresses soft palate	Internal branch of accessory nerve (N XI)		
Styloglossus	Styloid process of temporal bone	Along the side to tip and base of tongue	Retracts tongue, elevates side of tongue	Hypoglossal nerve (N XII)		

Esophagus

Table 11–6	Muscles c	iscles of the Pharynx (Figure 11–9)			
Muscle		Origin	Insertion	Action	Innervation
PHARYNGEAL CO	ONSTRICTORS				
Superior constrictor		Pterygoid process of sphenoid, medial surfaces of mandible	Median raphe attached to occipital bone	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (N X)
Middle constrictor		Horns of hyoid bone	Median raphe	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (N X)
Inferior constrictor		Cricoid and thyroid cartilages of larynx	Median raphe	Constricts pharynx to propel bolus into esophagus	Branches of pharyngeal plexus (N X)
PALATAL MUSCL	ES				
Levator veli palatini		Petrous part of temporal bone; tissues around the auditory tube	Soft palate	Elevates soft palate	Branches of pharyngeal plexus (N X)
Tensor veli palat	ini	Sphenoidal spine; tissues around the auditory tube	Soft palate	Elevates soft palate	Trigeminal nerve (N V)
LARYNGEAL ELE	VATORS*				
		Ranges from soft palate, to cartilage around inferior portion of auditory tube, to styloid process of temporal bone	Thyroid cartilage	Elevate larynx	Branches of pharyngeal plexus (N IX and N X)

*Refers to the palatopharyngeus, salpingopharyngeus, and stylopharyngeus, assisted by the thyrohyoid, geniohyoid, stylohyoid, and hyoglossus muscles, discussed in Tables 11–5 and 11–7.

11

Table 11–7 Anterio	or Muscles of the Neck (Figure	e 11–10)		
Muscle	Origin	Insertion	Action	Innervation
Digastric	Two bellies: <i>anterior</i> from inferior surface of mandible at chin; <i>posterior</i> from mastoid region of temporal bone	Hyoid bone	Depresses mandible or elevates larynx	Anterior belly: Trigeminal nerve (N V), mandibular branch Posterior belly: Facial nerve (N VII)
Geniohyoid	Medial surface of mandible at chin	Hyoid bone	As above and pulls hyoid bone anteriorly	Cervical nerve C ₁ by hypoglossal nerve (N XII)
Mylohyoid	Mylohyoid line of mandible	Median connective tissue band (raphe) that runs to hyoid bone	Elevates floor of mouth and hyoid bone or depresses mandible	Trigeminal nerve (N V), mandibular branch
Omohyoid (superior and inferior bellies united at central tendon anchored to clavicle and first rib)	Superior border of scapula near scapular notch	Hyoid bone	Depresses hyoid bone and larynx	Cervical spinal nerves C ₂ -C ₃
Sternohyoid	Clavicle and manubrium	Hyoid bone	Depresses hyoid bone and larynx	Cervical spinal nerves C ₁ -C ₃
Sternothyroid	Dorsal surface of manubrium and first costal cartilage	Thyroid cartilage of larynx	Depresses hyoid bone and larynx	Cervical spinal nerves $C_1 - C_3$
Stylohyoid	Styloid process of temporal bone	Hyoid bone	Elevates larynx	Facial nerve (N VII)
Thyrohyoid	Thyroid cartilage of larynx	Hyoid bone	Elevates thyroid, depresses hyoid bone	Cervical spinal nerves C ₁ –C ₂ by hypoglossal nerve (N XII)
Sternocleidomastoid	Two bellies: <i>clavicular head</i> attaches to sternal end of clavicle; <i>sternal head</i> attaches to manubrium	Mastoid region of skull and lateral portion of superior nuchal line	Together, they flex the neck; alone, one side flexes head toward shoulder and rotates face to opposite side	Accessory nerve (N XI) and cervical spinal nerves (C_2 – C_3) of cervical plexus

region of the skull (Figures 11–5 and 11–10). The **omohyoid** (ō-mō-HĪ-oyd) muscle attaches to the scapula, the clavicle and first rib, and the hyoid bone. The other members of this group are strap-like muscles that extend between the sternum and larynx (*sternothyroid*) or hyoid bone (*sternohyoid*), and between the larynx and hyoid bone (*thyrohyoid*).

Muscles of the Vertebral Column

The muscles of the vertebral column are covered by more superficial back muscles, such as the trapezius and latissimus dorsi muscles (Figure 11–4b). The **erector spinae** muscles include superficial and deep layers. The superficial layer can be divided into **spinalis**, **longissimus**, and **iliocostalis** groups (Figure 11–11 and Table 11–8). In the inferior lumbar and sacral regions, the boundary between the longissimus and iliocostalis muscles is indistinct. When contracting together, the erector spinae extend the vertebral column. When the muscles on only one side contract, the result is lateral flexion of the vertebral column.

Deep to the spinalis muscles, smaller muscles interconnect and stabilize the vertebrae. These muscles include the **semispinalis** group; the **multifidus** muscle; and the **interspinales**, **intertransversarii**, and **rotatores** muscles (Figure 11–11). In various combinations, they produce slight extension or rotation of the vertebral column. They are also important in making delicate adjustments in the positions of individual vertebrae, and they stabilize adjacent vertebrae. If injured, these muscles can start a cycle of pain \rightarrow muscle stimulation \rightarrow contraction \rightarrow pain. Resultant pressure on adjacent spinal nerves can lead to sensory losses and mobility limitations. Many of the warm-up and stretching exercises recommended before athletic activity are intended to prepare these small but very important muscles for their supporting role.

The muscles of the vertebral column include many posterior extensors, but few anterior flexors. Why doesn't the vertebral column have a massive series of flexor muscles? One reason is that many of the large trunk muscles flex the vertebral column when they contract. A second reason is that most of the body weight lies anterior to the vertebral column, so gravity tends to flex the spine. However, a few spinal flexors are associated with the anterior surface of the vertebral column. In the neck, the **longus capitis** and the **longus colli** muscles rotate or flex the neck, depending on whether the muscles of one or both sides are contracting (Figure 11–11). In the lumbar region, the large **quadratus lumborum** muscles flex the vertebral column and depress the ribs (Figure 11–11).

Oblique and Rectus Muscles

The oblique and rectus muscles lie within the body wall, between the spinous processes of vertebrae and the ventral midline (Figures 11–4, 11–12, and Table 11–9). The oblique muscles compress underlying structures or rotate the vertebral column, depending on whether one or both sides contract. The rectus muscles are important flexors of the vertebral column, acting in opposition to the erector spinae. The oblique and rectus muscle groups share embryological origins. We can divide these groups into cervical, thoracic, and abdominal regions.

The oblique group includes the **scalene** muscles of the neck (Figure 11–12a) and the **intercostal** and **transversus** muscles of the thorax (Figure 11–12b,c). The scalene muscles (*anterior, middle,* and *posterior*) elevate the first two ribs and assist in flexion of the neck. In the thorax, the oblique muscles extend between the ribs, with the **external intercostal** muscles. Both

groups of intercostal muscles aid in respiratory movements of the ribs. A small **transversus thoracis** muscle crosses the inner surface of the rib cage and is separated from the pleural cavity by the parietal pleura, a *serous membrane*. \bigcirc p. 137 The sternum occupies the place where we might otherwise expect thoracic rectus muscles to be.

The same basic pattern of musculature extends unbroken across the abdominopelvic surface (Figure 11–12b,d). Here, the muscles are called the **external oblique**, **internal oblique**, **transversus abdominis**, and **rectus abdominis** muscles (the "abs"). The rectus abdominis muscle inserts at the xiphoid process and originates near the pubic symphysis. This muscle is longitudinally divided by the **linea alba** (white line), a median collagenous partition (Figure 11–4a). The rectus abdominis muscle is separated into segments by transverse bands of collagen fibers called **tendinous inscriptions**. Each segment contains muscle fibers that extend longitudinally, originating and inserting on the tendinous inscriptions. Due to the bulging of enlarged muscle fibers between the tendinous inscriptions, bodybuilders often refer to the rectus abdominis as the "six-pack."

The Diaphragm

The term *diaphragm* refers to any muscular sheet that forms a wall. When used without a modifier, however, **diaphragm**, or *diaphragmatic muscle*, specifies the muscular partition that separates the abdominopelvic and thoracic cavities (Figure 11–12c). We include this muscle here because it develops in association with the other muscles of the chest wall. The diaphragm is a major muscle used in breathing.

Table 11–9 Oblique ai	nd Rectus Muscle Groups (F	igure 11–12)		
Group and Muscles	Origin	Insertion	Action	Innervation*
OBLIQUE GROUP				
Cervical region				
Scalenes (anterior, middle, and posterior)	Transverse and costal processes of cervical vertebrae	Superior surfaces of first two ribs	Elevate ribs or flex neck	Cervical spinal nerves
Thoracic region				
External intercostals	Inferior border of each rib	Superior border of more inferior rib	Elevate ribs	Intercostal nerves (branches of thoracic spinal nerves)
Internal intercostals	Superior border of each rib	Inferior border of the preceding rib	Depress ribs	Intercostal nerves (branches of thoracic spinal nerves)
Transversus thoracis	Posterior surface of sternum	Cartilages of ribs	Depress ribs	Intercostal nerves (branches of thoracic spinal nerves)
Serratus posterior superior (Figure 11–14b)	Spinous processes of C_7-T_3 and ligamentum nuchae	Superior borders of ribs 2–5 near angles	Elevates ribs, enlarges thoracic cavity	Thoracic nerves (T ₁ -T ₄)
Serratus posterior inferior (Figure 11–14b)	Aponeurosis from spinous processes of T ₁₀ -L ₃	Inferior borders of ribs 8–12	Pulls ribs inferiorly; also pulls outward, opposing diaphragm	Thoracic nerves (T ₉ -T ₁₂)
Abdominal region				
External oblique	External and inferior borders of ribs 5–12	Linea alba and iliac crest	Compresses abdomen, depresses ribs, flexes or bends spine	Intercostal, iliohypogastric, and ilioinguinal nerves
Internal oblique	Thoracolumbar fascia and iliac crest	Inferior ribs, xiphoid process, and linea alba	Compresses abdomen, depresses ribs, flexes or bends spine	Intercostal, iliohypogastric, and ilioinguinal nerves
Transversus abdominis	Cartilages of ribs 6–12, iliac crest, and thoracolumbar fascia	Linea alba and pubis	Compresses abdomen	Intercostal, iliohypogastric, and ilioinguinal nerves
RECTUS GROUP				
Cervical region	See muscles in Table 11–6			
Thoracic region				
Diaphragm	Xiphoid process, cartilages of ribs 4–10, and anterior surfaces of lumbar vertebrae	Central tendinous sheet	Contraction expands thoracic cavity and compresses abdominopelvic cavity	Phrenic nerves (C ₃ –C ₅)
Abdominal region				
Rectus abdominis	Superior surface of pubis around symphysis	Inferior surfaces of costal cartilages (ribs 5–7) and xiphoid process	Depresses ribs, flexes vertebral column, compresses abdomen	Intercostal nerves (T ₇ -T ₁₂)

*Where appropriate, spinal nerves involved are given in parentheses.

Muscles of the Pelvic Floor

The muscles of the pelvic floor extend from the sacrum and coccyx to the ischium and pubis (Figure 11–13 and Table 11–10). These muscles (1) support the organs of the pelvic cavity, (2) flex the sacrum and coccyx, and (3) control the movement of materials through the urethra and anus.

The boundaries of the **perineum**, the muscular sheet that forms the pelvic floor, are formed by the inferior margins of the pelvis. A line drawn between the ischial tuberosities divides the perineum into two triangles: an anterior **urogenital triangle** and a posterior **anal triangle (Figure 11–13)**. The superficial muscles of the urogenital triangle are the muscles of the external genitalia. They cover deeper muscles that strengthen the pelvic floor and encircle the urethra. These muscles constitute the **urogenital diaphragm**, a deep muscular layer that extends between the pubic bones.

An even more extensive muscular sheet, the **pelvic dia-phragm**, forms the muscular foundation of the anal triangle. This layer, covered by the urogenital diaphragm, extends as far as the pubic symphysis.

The urogenital and pelvic diaphragms do not completely close the pelvic outlet. The urethra, vagina, and anus pass through them to open on the exterior. Muscular sphincters surround the passageways, and the external sphincters permit voluntary control of urination and defecation. Muscles, nerves, and blood vessels also pass through the pelvic outlet as they travel to or from the lower limbs.

Ta	Table 11–10 Muscles of the Pelvic Floor (Figure 11–13)

CHECKPOINT

- 11. Describe the location of axial muscles.
- 12. If you were contracting and relaxing your masseter muscle, what would you probably be doing?
- **13**. Which facial muscle would you expect to be well developed in a trumpet player?
- 14. Why can swallowing help alleviate the pressure sensations at the eardrum when you are in an airplane that is changing altitude?
- 15. Damage to the external intercostal muscles would interfere with what important process?
- 16. If someone hit you in your rectus abdominis muscle, how would your body position change?
- 17. After spending an afternoon carrying heavy boxes from his basement to his attic, Joe complains that the muscles in his back hurt. Which muscles are most likely sore?

See the blue Answers tab at the back of the book.

11-6 Appendicular muscles are muscles of the shoulders, upper limbs, pelvis, and lower limbs

Learning Outcome Identify the principal appendicular muscles of the body, plus their origins, insertions, actions, and innervation, and compare the major functional differences between the upper and lower limbs.

The appendicular musculature positions and stabilizes the pectoral and pelvic girdles and moves the upper and lower limbs. There are two major groups of appendicular muscles: (1) *the muscles of the shoulders (pectoral girdles) and upper limbs* and (2) *the muscles of the pelvis (pelvic girdle) and lower limbs*. The functions and required ranges of motion are very different between these groups.

The muscular connections between the pectoral girdles and the axial skeleton increase the mobility of the arms and also act as shock absorbers. For example, while you jog, you can still perform delicate hand movements, because the muscular connections between the axial and appendicular components of the skeleton smooth out the bounces in your stride.

In contrast, the pelvic girdle has evolved to transfer weight from the axial to the appendicular skeleton. Rigid, bony articulations are essential, because the emphasis is on strength rather than versatility, and a muscular connection would reduce the efficiency of the transfer.

Figure 11–14 provides an introduction to the organization of the appendicular muscles of the trunk. The larger appendicular muscles are often used as injection sites for medications.

Muscles of the Shoulders and Upper Limbs

We can divide the muscles associated with the shoulders and upper limbs into four groups: (1) *muscles that position the pecto-ral girdle,* (2) *muscles that move the arm,* (3) *muscles that move the forearm and hand,* and (4) *muscles that move the hand and fingers.*

Muscles That Position the Pectoral Girdle

The large, superficial **trapezius** muscles, commonly called the "traps," cover the back and portions of the neck, reaching to the base of the skull. These muscles originate along the midline of the neck and back and insert on the clavicles and the scapular spines (Figures 11–15 and 11–16). The trapezius muscles are innervated by more than one nerve (Table 11–11). For this reason,

Table 11-11	Muscles That Position the	Muscles That Position the Pectoral Girdle (Figures 11–14, 11–15)					
Muscle	Origin	Insertion	Action	Innervation*			
Levator scapulae	Transverse processes of first four cervical vertebrae	Vertebral border of scapula near superior angle	Elevates scapula	Cervical nerves C_3 - C_4 and dorsal scapular nerve (C_5)			
Pectoralis minor	Anterior-superior surfaces of ribs 2–4, 2–5, or 3–5 depending on anatomical variation	Coracoid process of scapula	Depresses and protracts shoulder; rotates scapula so glenoid cavity moves inferiorly (downward rotation); elevates ribs if scapula is stationary	Medial pectoral nerve (C ₈ , T ₁)			
Rhomboid major	Spinous processes of superior thoracic vertebrae	Vertebral border of scapula from spine to inferior angle	Adducts scapula and performs downward rotation	Dorsal scapular nerve (C ₅)			
Rhomboid minor	Spinous processes of vertebrae C ₇ –T ₁	Vertebral border of scapula near spine	Adducts scapula and performs downward rotation	Dorsal scapular nerve (C ₅)			
Serratus anterior	Anterior and superior margins of ribs 1–8 or 1–9	Anterior surface of vertebral border of scapula	Protracts shoulder; rotates scapula so glenoid cavity moves superiorly (upward rotation)	Long thoracic nerve $(C_5 - C_7)$			
Subclavius	First rib	Clavicle (inferior border)	Depresses and protracts shoulder	Nerve to subclavius $(C_5 - C_6)$			
Trapezius	Occipital bone, ligamentum nuchae, and spinous processes of thoracic vertebrae	Clavicle and scapula (acromion and scapular spine)	Depends on active region and state of other muscles; may (1) elevate, retract, depress, or rotate scapula upward, (2) elevate clavicle, or (3) extend neck	Accessory nerve (N XI) and cervical spinal nerves (C_3 – C_4)			

*Where appropriate, spinal nerves involved are given in parentheses.

Figure 11–14 An Overview of the Appendicular Muscles of the Trunk.

ATLAS: Plates 25; 39b

specific regions can be made to contract independently, and their actions are quite varied.

On the chest, the **serratus anterior** muscle originates along the anterior surfaces of several ribs (Figures 11–4 and 11–15a,b). This fan-shaped muscle inserts along the anterior margin of the vertebral border of the scapula. When the serratus anterior muscle contracts, it abducts (protracts) the scapula and swings the shoulder anteriorly.

Two other deep chest muscles arise along the anterior surfaces of the ribs on either side. The **subclavius** (sub-KLĀ-vē-us; *sub-*, below + *clavius*, clavicle) muscle inserts on the inferior border of the clavicle (Figure 11–15a). When it contracts, it depresses and protracts the scapular end of the clavicle. Because

ligaments connect this end to the shoulder joint and scapula, those structures move as well. The **pectoralis** (pek-tō-RA-lis) **minor** muscle attaches to the coracoid process of the scapula. The contraction of this muscle generally complements that of the subclavius muscle.

Removing the trapezius muscle reveals the **rhomboid major**, **rhomboid minor**, and **levator scapulae** muscles (Figure 11–15b). These muscles are attached to the posterior surfaces of the cervical and thoracic vertebrae. They insert along the vertebral border of each scapula, between the superior and inferior angles. Contraction of a rhomboid muscle adducts (retracts) the scapula on that side. The levator scapulae muscle, as its name implies, elevates the scapula.

Figure 11–14 An Overview of the Appendicular Muscles of the Trunk (Continued).

Muscles That Move the Arm

The muscles that move the arm (Figures 11–14, 11–15, and 11–16) are easiest to remember when they are grouped by their actions at the shoulder joint (Table 11–12). The **deltoid** muscle is the major abductor, but the **supraspinatus** (sū-pra-spī-NĀ-tus) muscle assists at the start of this movement. The **subscapularis** and **teres major** muscles produce medial rotation at the shoulder, whereas the **infraspinatus** and the **teres minor** muscles produce lateral rotation. All these muscles originate on the scapula. The small **coracobrachialis** (KOR-uh-kō-brā-kē-A-lis) muscle is the only muscle attached to the scapula that produces flexion and adduction at the shoulder (Figure 11–16a).

TIPS & TRICKS

The supraspinatus and infraspinatus muscles are named for their origins above and below the spine of the scapula, respectively, not because they are located on the spinal column.

The **pectoralis major** muscle extends between the anterior portion of the chest and the crest of the greater tubercle of the humerus (**Figure 11–16a**). The **latissimus dorsi** (la-TIS-i-mus DOR-sē) muscle extends between the thoracic vertebrae at the posterior midline and the intertubercular groove of the humerus (**Figure 11–16b**). The pectoralis major muscle produces flexion at the shoulder joint, and the latissimus dorsi muscle

Latissimus dorsi	Spinous processes of inferior thoracic and all lumbar vertebrae, ribs 8–12, and thoracolumbar fascia	Floor of intertubercular groove of the humerus	Extension, adduction, and medial rotation at shoulder	Thoracodorsal nerve (C ₆ -C ₈)		
Triceps brachii (long head)	See Table 11–13					

*Where appropriate, spinal nerves involved are given in parentheses.

produces extension. These muscles, commonly known as the "pecs" and the "lats," can also work together to produce adduction and medial rotation of the humerus at the shoulder.

Collectively, the supraspinatus, infraspinatus, teres minor, and subscapularis muscles and their associated tendons form the **rotator cuff**. Sports that involve throwing a ball, such as baseball or football, place considerable strain on the rotator cuff, and rotator cuff injuries are common.

TIPS&TRICKS

The acronym SITS is useful in remembering the four muscles of the rotator cuff.

Muscles That Move the Forearm and Hand

Most of the muscles that insert on the forearm and hand originate on the humerus, but the biceps brachii and triceps brachii muscles are noteworthy exceptions. The **biceps brachii** muscle and the *long head* of the **triceps brachii** muscle originate on the scapula and insert on the bones of the forearm (Figure 11–17). The triceps brachii muscle inserts on the olecranon of the ulna. Contraction of the triceps brachii muscle extends the elbow, as when you do push-ups. The biceps brachii muscle inserts on the radial tuberosity, a roughened bump on the anterior surface of the radius. \bigcirc **p**. 247 Contraction of the biceps brachii muscle flexes the elbow and supinates the forearm. With the forearm pronated (palm facing back), the biceps brachii muscle cannot function effectively. As a result, you are strongest when you flex your elbow with a supinated forearm. The biceps brachii muscle then makes a prominent bulge.

The biceps brachii muscle is important in stabilizing the shoulder joint. The short head originates on the coracoid process and supports the posterior surface of the capsule. The long head originates at the supraglenoid tubercle, inside the shoulder joint. \bigcirc p. 245 After crossing the head of the humerus, it passes along the intertubercular groove. In this position, the tendon helps to hold the head of the humerus within the glenoid cavity while arm movements are underway.

More muscles are shown in Figure 11–17 and listed in Table 11–13. As you study these muscles, notice that, in general, the extensor muscles lie along the posterior and lateral surfaces of the arm, whereas the flexors are on the anterior and medial surfaces. Connective tissue partitions separate major muscle groups, dividing the muscles into *compartments* formed by dense collagenous sheets.

The **brachialis** and **brachioradialis** (BRĀ-kē-ō-rā-dē-Alis) muscles flex the elbow and are opposed by the **anconeus** muscle and the triceps brachii muscle, respectively.

Figure 11–17 Muscles That Move the Forearm and Hand. ATLAS: Plates 27a–c; 29a; 30; 33a–d; 37a,b

Table 11–13 Muscles That Move the Forearm and Hand (Figure 11–17)								
Muscle		Origin	Insertion	Action	Innervation			
ACTION AT THE ELBOW								
Flexors	Biceps brachii	<i>Short head</i> from the coracoid process; <i>long head</i> from the supraglenoid tubercle (both on the scapula)	Tuberosity of radius	Flexion at elbow and shoulder; supination	Musculocutaneous nerve (C ₅ –C ₆)			
	Brachialis	Anterior, distal surface of humerus	Tuberosity of ulna	Flexion at elbow	Musculocutaneous nerve (C_5-C_6) and radial nerve (C_7-C_8)			
	Brachioradialis	Ridge superior to the lateral epicondyle of humerus	Lateral aspect of styloid process of radius	Flexion at elbow	Radial nerve ($C_5 - C_6$)			
Extensors	Anconeus	Posterior, inferior surface of lateral epicondyle of humerus	Lateral margin of olecranon on ulna	Extension at elbow	Radial nerve ($C_7 - C_8$)			
	Triceps brachii							
	lateral head	Superior, lateral margin of humerus	Olecranon of ulna	Extension at elbow	Radial nerve (C ₆ –C ₈)			
	long head	Infraglenoid tubercle of scapula	Olecranon of ulna	As above, plus extension and adduction at the shoulder	Radial nerve (C ₆ –C ₈)			
	medial head	Posterior surface of humerus inferior to radial groove	Olecranon of ulna	Extension at elbow	Radial nerve ($C_6 - C_8$)			
PRONATORS/SUPINATORS								
Pronator quadratus		Anterior and medial surfaces of distal portion of ulna	Anterolateral surface of distal portion of radius	Pronation	Median nerve (C_8 – T_1)			
Pronator teres		Medial epicondyle of humerus and coronoid process of ulna	Midlateral surface of radius	Pronation	Median nerve ($C_6 - C_7$)			
Supinator		Lateral epicondyle of humerus, annular ligament, and ridge near radial notch of ulna	Anterolateral surface of radius distal to the radial tuberosity	Supination	Deep radial nerve (C ₆ -C ₈)			
ACTION AT THE HAND								
Flexors	Flexor carpi radialis	Medial epicondyle of humerus	Bases of second and third metacarpal bones	Flexion and abduction at wrist	Median nerve ($C_6 - C_7$)			
	Flexor carpi ulnaris	Medial epicondyle of humerus; adjacent medial surface of olecranon and anteromedial portion of ulna	Pisiform, hamate, and base of fifth metacarpal bone	Flexion and adduction at wrist	Ulnar nerve (C ₈ -T ₁)			
	Palmaris longus	Medial epicondyle of humerus	Palmar aponeurosis and flexor retinaculum	Flexion at wrist	Median nerve ($C_6 - C_7$)			
Extensors	Extensor carpi radialis longus	Lateral supracondylar ridge of humerus	Base of second metacarpal bone	Extension and abduction at wrist	Radial nerve ($C_6 - C_7$)			
	Extensor carpi radialis brevis	Lateral epicondyle of humerus	Base of third metacarpal bone	Extension and abduction at wrist	Radial nerve ($C_6 - C_7$)			
	Extensor carpi ulnaris	Lateral epicondyle of humerus; adjacent dorsal surface of ulna	Base of fifth metacarpal bone	Extension and adduction at wrist	Deep radial nerve (C_6-C_8)			

The **flexor carpi ulnaris**, **flexor carpi radialis**, and **palmaris longus** muscles are superficial muscles that work together to produce flexion of the wrist. The flexor carpi radialis muscle flexes and *ab*ducts, and the flexor carpi ulnaris muscle flexes and *ad*ducts. *Pitcher's arm* is an inflammation at the origins of the flexor carpi muscles at the medial epicondyle of the humerus. This condition results from forcibly flexing the wrist just before releasing a baseball.

The **extensor carpi radialis** muscles and the **extensor carpi ulnaris** muscle have a similar relationship to that between the flexor carpi muscles. That is, the extensor carpi radialis muscles produce extension and *ab*duction, whereas the extensor carpi ulnaris muscle produces extension and *ad*duction.

The muscles involved in pronation and supination are shown in Figure 11–18. The **pronator teres** and **supinator** muscles originate on both the humerus and ulna. These muscles rotate the radius without either flexing or extending the elbow. The **pronator quadratus** muscle originates on the ulna and assists the pronator teres muscle in opposing the actions of

Table 11–14 M	11–14 Muscles That Move the Hand and Fingers (Figure 11–18)					
Muscle	Origin	Insertion	Action	Innervation		
Abductor pollicis longus	Proximal dorsal surfaces of ulna and radius	Lateral margin of first metacarpal bone	Abduction at joints of thumb and wrist	Deep radial nerve ($C_6 - C_7$)		
Extensor digitorum	Lateral epicondyle of humerus	Posterior surfaces of the phalanges, fingers 2–5	Extension at finger joints and wrist	Deep radial nerve (C_6-C_8)		
Extensor pollicis brevis	Shaft of radius distal to origin of abductor pollicis longus	Base of proximal phalanx of thumb	Extension at joints of thumb; abduction at wrist	Deep radial nerve ($C_6 - C_7$)		
Extensor pollicis longus	Posterior and lateral surfaces of ulna and interosseous membrane	Base of distal phalanx of thumb	Extension at joints of thumb; abduction at wrist	Deep radial nerve ($C_6 - C_8$)		
Extensor indicis	Posterior surface of ulna and interosseous membrane	Posterior surface of phalanges of index finger (2), with tendon of extensor digitorum	Extension and adduction at joints of index finger	Deep radial nerve (C_6 – C_8)		
Extensor digiti minimi	By extensor tendon to lateral epicondyle of humerus and from intermuscular septa	Posterior surface of proximal phalanx of little finger (5)	Extension at joints of little finger	Deep radial nerve (C_6 – C_8)		
Flexor digitorum superficialis	Medial epicondyle of humerus; adjacent anterior surfaces of ulna and radius	Midlateral surfaces of middle phalanges of fingers 2–5	Flexion at proximal interphalangeal, metacarpophalangeal, and wrist joints	Median nerve (C ₇ –T ₁)		
Flexor digitorum profundus	Medial and posterior surfaces of ulna, medial surface of coronoid process, and interosseus membrane	Bases of distal phalanges of fingers 2–5	Flexion at distal interphalangeal joints and, to a lesser degree, proximal interphalangeal joints and wrist	Palmar interosseous nerve, from median nerve, and ulnar nerve (C_8-T_1)		
Flexor pollicis longus	Anterior shaft of radius, interosseous membrane	Base of distal phalanx of thumb	Flexion at joints of thumb	Median nerve (C_8-T_1)		

the supinator or biceps brachii muscles. During pronation, the tendon of the biceps brachii muscle rotates with the radius. As a result, this muscle cannot assist in flexion of the elbow when the forearm is pronated.

Muscles That Move the Hand and Fingers

Several superficial and deep muscles of the forearm flex and extend the finger joints (Figure 11–18 and Table 11–14). These large muscles end before reaching the wrist, and only their tendons cross the articulation. This arrangement ensures maximum mobility at both the wrist and hand. The tendons that cross the posterior and anterior surfaces of the wrist pass through **synovial tendon sheaths**, elongated bursae that reduce friction. \Box p. 267

The muscles of the forearm provide strength and crude control of the hand and fingers. These muscles are known as the *extrinsic muscles of the hand*. Fine control of the hand involves small *intrinsic muscles*, which originate on the carpal and metacarpal bones. No muscles originate on the phalanges, and only tendons extend across the distal joints of the fingers. The intrinsic muscles of the hand are detailed in Figure 11–19 and Table 11–15.

The fascia of the forearm thickens on the posterior surface of the wrist, forming the **extensor retinaculum** (ret-i-NAK-ūlum; plural, *retinacula*), a wide band of connective tissue. The extensor retinaculum holds the tendons of the extensor muscles in place. On the anterior surface, the fascia also thickens to form another wide band of connective tissue, the **flexor retinaculum**, which stabilizes the tendons of the flexor muscles.

Inflammation of the retinacula and synovial tendon sheaths can restrict movement and put pressure on the distal portions of the *median nerve*, a mixed (sensory and motor) nerve that innervates the hand. This condition, known as *carpal tunnel syndrome*, causes tingling, numbness, weakness, and chronic pain. A common cause is repetitive hand or wrist movements. \supset p. 249

Figure 11–18 Muscles That Move the Hand and Fingers.

Table 11–15	Intrinsic N	ntrinsic Muscles of the Hand (Figure 11–19)				
Muscle		Origin	Insertion	Action	Innervation	
Palmaris brevis		Palmar aponeurosis	Skin of medial border of hand	Moves skin on medial border toward midline of palm	Ulnar nerve, superficial branch (C ₈)	
ADDUCTION/ABDU	JCTION					
Adductor pollicis		Metacarpal and carpal bones	Proximal phalanx of thumb	Adduction of thumb	Ulnar nerve, deep branch (C ₈ –T ₁)	
Palmar interosseus* (3–4)		Sides of metacarpal bones II, IV, and V	Bases of proximal phalanges of fingers 2, 4, and 5	Adduction at metacarpophalangeal joints of fingers 2, 4, and 5; flexion at metacarpophalangeal joints; extension at interphalangeal joints	Ulnar nerve, deep branch (C ₈ –T ₁)	
Abductor pollicis brevis		Transverse carpal ligament, scaphoid, and trapezium	Radial side of base of proximal phalanx of thumb	Abduction of thumb	Median nerve (C ₆ –C ₇)	
Dorsal interosseus (4)		Each originates from opposing faces of two metacarpal bones (I and II, II and III, III and IV, IV and V)	Bases of proximal phalanges of fingers 2–4	Abduction at metacarpophalangeal joints of fingers 2 and 4; flexion at metacarpophalangeal joints; extension at interphalangeal joints	Ulnar nerve, deep branch (C ₈ –T ₁)	
Abductor digiti mi	inimi	Pisiform	Proximal phalanx of little finger	Abduction of little finger and flexion at its metacarpophalangeal joint	Ulnar nerve, deep branch (C ₈ –T ₁)	
FLEXION	FLEXION					
Flexor pollicis brev	vis	Flexor retinaculum, trapezium, capitate, and ulnar side of first metacarpal bone	Radial and ulnar sides of proximal phalanx of thumb	Flexion and adduction of thumb	Branches of median and ulnar nerves	
Lumbrical (4)		Tendons of flexor digitorum profundus	Tendons of extensor digitorum to digits 2–5	Flexion at metacarpophalangeal joints 2–5; extension at proximal and distal interphalangeal joints, digits 2–5	No. 1 and no. 2 by median nerve; no. 3 and no. 4 by ulnar nerve, deep branch	
Flexor digiti minin	ni brevis	Hamate	Proximal phalanx of little finger	Flexion at joints of little finger	Ulnar nerve, deep branch (C ₈ –T ₁)	
OPPOSITION						
Opponens pollicis		Trapezium and flexor retinaculum	First metacarpal bone	Opposition of thumb	Median nerve $(C_6 - C_7)$	
Opponens digiti m	ninimi	Trapezium and flexor retinaculum	Fifth metacarpal bone	Opposition of fifth metacarpal bone	Ulnar nerve, deep branch (C ₈ –T ₁)	

*The deep, medial portion of the flexor pollicis brevis originating on the first metacarpal bone is sometimes called the *first palmar interosseus muscle;* it inserts on the ulnar side of the phalanx and is innervated by the ulnar nerve.

Muscles of the Pelvis and Lower Limbs

The pelvic girdle is tightly bound to the axial skeleton, permitting little movement. Few muscles of the axial musculature can influence the position of the pelvis. The muscles that position the lower limbs can be divided into three functional groups: (1) *muscles that move the thigh*, (2) *muscles that move the leg*, and (3) *muscles that move the foot and toes*.

Muscles That Move the Thigh

Table 11–16 lists the muscles that move the thigh. **Gluteal muscles** cover the lateral surfaces of the ilia (Figure 11–20a,b,c). The **gluteus maximus** muscle is the largest and most posterior of the gluteal muscles. Its origin includes parts of the ilium; the sacrum, coccyx, and associated ligaments; and the

thoracolumbar fascia. Acting alone, this massive muscle produces extension and lateral rotation at the hip joint.

The gluteus maximus shares an insertion with the **tensor fasciae latae** (FASH-ē-ē LAH-tā) muscle, which originates on the iliac crest and the anterior superior iliac spine. Together, these muscles pull on the **iliotibial** (il-ē-ō-TIB-ē-ul) **tract**, a band of collagen fibers that extends along the lateral surface of the thigh and inserts on the tibia. This tract provides a lateral brace for the knee that becomes particularly important when you balance on one foot.

The **gluteus medius** and **gluteus minimus** muscles (Figure 11–20a,b,c) originate anterior to the origin of the gluteus maximus muscle and insert on the greater trochanter of the femur. The anterior gluteal line on the lateral surface of the ilium marks the boundary between these muscles.

Table 11–16	Muscles That Move the Thigh (Figure 11–20)					
Group and Muscle	Origin	Insertion	Action	Innervation*		
GLUTEAL GROUP						
Gluteus maximus	lliac crest, posterior gluteal line, and lateral surface of ilium; sacrum, coccyx, and thoracolumbar fascia	lliotibial tract and gluteal tuberosity of femur	Extension and lateral rotation at hip	Inferior gluteal nerve (L_5-S_2)		
Gluteus medius	Anterior iliac crest of ilium, lateral surface between posterior and anterior gluteal lines	Greater trochanter of femur	Abduction and medial rotation at hip	Superior gluteal nerve $(L_4 - S_1)$		
Gluteus minimus	Lateral surface of ilium between inferior and anterior gluteal lines	Greater trochanter of femur	Abduction and medial rotation at hip	Superior gluteal nerve $(L_4 - S_1)$		
Tensor fasciae latae	lliac crest and lateral surface of anterior superior iliac spine	lliotibial tract	Flexion and medial rotation at hip; tenses fasciae latae, which laterally supports the knee	Superior gluteal nerve (L_4-S_1)		
LATERAL ROTATOR G	ROUP					
Obturators (externus and internus)	Lateral and medial margins of obturator foramen	Trochanteric fossa of femur (externus); medial surface of greater trochanter (internus)	Lateral rotation at hip	Obturator nerve (externus: L_3-L_4) and special nerve from sacral plexus (internus: L_5-S_2)		
Piriformis	Anterolateral surface of sacrum	Greater trochanter of femur	Lateral rotation and abduction at hip	Branches of sacral nerves (S_1-S_2)		
Gemelli (superior and inferior)	lschial spine and tuberosity	Medial surface of greater trochanter with tendon of obturator internus	Lateral rotation at hip	Nerves to obturator internus and quadratus femoris		
Quadratus femoris	Lateral border of ischial tuberosity	Intertrochanteric crest of femur	Lateral rotation at hip	Special nerve from sacral plexus (L_4-S_1)		
ADDUCTOR GROUP						
Adductor brevis	Inferior ramus of pubis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip	Obturator nerve $(L_3 - L_4)$		
Adductor longus	Inferior ramus of pubis anterior to adductor brevis	Linea aspera of femur	Adduction, flexion, and medial rotation at hip	Obturator nerve $(L_3 - L_4)$		
Adductor magnus	Inferior ramus of pubis posterior to adductor brevis and ischial tuberosity	Linea aspera and adductor tubercle of femur	Adduction at hip; superior part produces flexion and medial rotation; inferior part produces extension and lateral rotation	Obturator and sciatic nerves		
Pectineus	Superior ramus of pubis	Pectineal line inferior to lesser trochanter of femur	Flexion, medial rotation, and adduction at hip	Femoral nerve (L_2-L_4)		
Gracilis	Inferior ramus of pubis	Medial surface of tibia inferior to medial condyle	Flexion at knee; adduction and medial rotation at hip	Obturator nerve $(L_3 - L_4)$		
ILIOPSOAS GROUP**	÷					
lliacus	lliac fossa of ilium	Femur distal to lesser trochanter; tendon fused with that of psoas major	Flexion at hip	Femoral nerve (L ₂ –L ₃)		
Psoas major	Anterior surfaces and transverse processes of vertebrae $(T_{12}-L_5)$	Lesser trochanter in company with iliacus	Flexion at hip or lumbar intervertebral joints	Branches of the lumbar plexus (L_2-L_3)		

*Where appropriate, spinal nerves involved are given in parentheses.

**The psoas major and iliacus are often considered collectively as the iliopsoas.

The **lateral rotators** originate at or inferior to the horizontal axis of the acetabulum. There are six lateral rotator muscles in all. The **piriformis** (pir-i-FOR-mis) muscle and the **obturator** muscles are dominant (Figure 11–20c,d).

The **adductors** (Figure 11–20c,d) originate inferior to the horizontal axis of the acetabulum. This muscle group includes the **adductor magnus**, **adductor brevis**, **adductor longus**,

pectineus (pek-ti-NĒ-us), and **gracilis** (GRAS-i-lis) muscles. All but the adductor magnus originate both anterior and inferior to the joint, so they perform hip flexion as well as adduction. The adductor magnus muscle can produce either adduction and flexion or adduction and extension, depending on the region stimulated. The adductor magnus muscle can also produce medial or lateral rotation at the hip. The other

Figure 11–20 Muscles That Move the Thigh. ATLAS: Plates 68a–c; 72a,b; 73a,b

muscles, which insert on low ridges along the posterior surface of the femur, produce medial rotation. When an athlete suffers a *pulled groin*, the problem is a *strain*—a muscle tear—in one of these adductor muscles.

A pair of muscles controls the internal surface of the pelvis. The large **psoas** (SO-us) **major** muscle originates alongside the inferior thoracic and lumbar vertebrae. Its insertion lies on the lesser trochanter of the femur. Before reaching this insertion, its tendon merges with that of the **iliacus** (il- \bar{I} -ah-kus) muscle, which nestles within the iliac fossa. These two powerful hip flexors are often grouped together and collectively referred to as the **iliopsoas** (il- \bar{e} - \bar{o} -SO-us) muscle (**Figure 11–20d**).

11

Muscles That Move the Leg

As in the upper limb, muscle distribution in the lower limb has a pattern: Extensor muscles are located along the anterior and lateral surfaces of the leg, and flexors lie along the posterior and medial surfaces (Figure 11–21 and Table 11–17). As in the upper limb, sturdy connective tissue partitions divide the lower limb into separate muscular compartments. The flexors and adductors originate on the pelvic girdle, but most extensors originate on the femoral surface.

The *flexors of the knee* include the **biceps femoris**, **semi-membranosus** (sem-ē-mem-bra-NŌ-sus), **semitendinosus**

(sem-ē-ten-di-NŌ-sus), and **sartorius** muscles (Figure 11–21). These muscles originate along the edges of the pelvis and insert on the tibia and fibula. The sartorius muscle is the only knee flexor that originates superior to the acetabulum. Its insertion lies along the medial surface of the tibia. When the sartorius muscle contracts, it produces flexion at the knee and lateral rotation at the hip. This happens when you cross your legs.

Three of these muscles—the biceps femoris, semimembranosus, and semitendinosus muscles—are often called the **hamstrings.** Because they originate on the pelvic surface inferior and posterior to the acetabulum, their contractions produce not only flexion at the knee, but also extension at the hip. A *pulled hamstring* is a common sports injury caused by a strain affecting one of the hamstring muscles.

TIPS&TRICKS

To remember that three muscles make up the **ham**strings, think "the three little pigs." These three muscles are portions of the cut of meat sold as ham.

The knee joint can be locked at full extension by a slight lateral rotation of the tibia. \bigcirc p. 280 The small **popliteus** (pop-LI-tē-us) muscle originates on the femur near the lateral condyle

Table 11-17	Muscles That Move the Leg (Figure 11-	es That Move the Leg (Figure 11–21)				
Muscle	Origin	Insertion	Action	Innervation*		
FLEXORS OF THE KI	FLEXORS OF THE KNEE					
Biceps femoris	lschial tuberosity and linea aspera of femur	Head of fibula, lateral condyle of tibia	Flexion at knee; extension and lateral rotation at hip	Sciatic nerve; tibial portion $(S_1-S_3; to long head)$ and common fibular branch $(L_5-S_2; to short head)$		
Semimembranosu	s Ischial tuberosity	Posterior surface of medial condyle of tibia	Flexion at knee; extension and medial rotation at hip	Sciatic nerve (tibial portion; L ₅ –S ₂)		
Semitendinosus	Ischial tuberosity	Proximal, medial surface of tibia near insertion of gracilis	Flexion at knee; extension and medial rotation at hip	Sciatic nerve (tibial portion; L_5-S_2)		
Sartorius	Anterior superior iliac spine	Medial surface of tibia near tibial tuberosity	Flexion at knee; flexion and lateral rotation at hip	Femoral nerve (L ₂ -L ₃)		
Popliteus	Lateral condyle of femur	Posterior surface of proximal tibial shaft	Medial rotation of tibia (or lateral rotation of femur); flexion at knee	Tibial nerve $(L_4 - S_1)$		
EXTENSORS OF THE	KNEE					
Rectus femoris	Anterior inferior iliac spine and superior acetabular rim of ilium	Tibial tuberosity by patellar ligament	Extension at knee; flexion at hip	Femoral nerve (L_2-L_4)		
Vastus intermedius	Anterolateral surface of femur and linea aspera (distal half)	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ -L ₄)		
Vastus lateralis	Anterior and inferior to greater trochanter of femur and along linea aspera (proximal half)	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ –L ₄)		
Vastus medialis	Entire length of linea aspera of femur	Tibial tuberosity by patellar ligament	Extension at knee	Femoral nerve (L ₂ -L ₄)		

*Where appropriate, spinal nerves involved are given in parentheses.

Figure 11–21 Muscles That Move the Leg. ATLAS: Plates 69a,b; 70b; 72a,b; 74; 76a,b; 78a–g

a Hip and thigh, posterior view

b Quadriceps and thigh muscles, anterior view

and inserts on the posterior tibial shaft (Figure 11–22a). When flexion is started, this muscle contracts to produce a slight medial rotation of the tibia that unlocks the knee joint.

Collectively, four *knee extensors*—the three **vastus muscles**, which originate along the shaft of the femur, and the **rec-tus femoris muscle**—make up the **quadriceps femoris** (the "quads"). Together, the vastus muscles cradle the rectus femoris muscle the way a bun surrounds a hot dog (Figure 11–21c). All four muscles insert on the patella by way of the quadriceps tendon. The force of their contraction is relayed to the tibial tuberosity by way of the patellar ligament. The rectus femoris muscle originates on the anterior inferior iliac spine and the superior acetabular rim—so in addition to extending the knee, it assists in flexion of the hip.

TIPS&TRICKS

Think of the quadriceps muscles as "the four at the fore."

Muscles That Move the Foot and Toes

The extrinsic muscles that move the foot and toes are shown in Figure 11–22 and listed in Table 11–18. Most of the muscles that move the ankle produce the plantar flexion involved with walking and running movements. The **gastrocnemius** (gas-trok-NĒ-mē-us; *gaster*, stomach + *kneme*, knee) muscle of the calf is an important plantar flexor, but the slow muscle fibers of the underlying **soleus** (SŌ-lē-us) muscle are better suited for making continuous postural adjustments against the pull of gravity.

Table 11–18	Extrinsic	nsic Muscles That Move the Foot and Toes (Figure 11–22)				
Muscle		Origin	Insertion	Action	Innervation	
ACTION AT THE AND	KLE					
Flexors (Dorsiflexors)	;)					
Tibialis anterior		Lateral condyle and proximal shaft of tibia	Base of first metatarsal bone and medial cuneiform bone	Flexion (dorsiflexion) at ankle; inversion of foot	Deep fibular nerve (L ₄ –S ₁)	
Fibularis tertius		Distal anterior surface of fibula and interosseous membrane	Dorsal surface of fifth metatarsal bone	Flexion (dorsiflexion) at ankle; eversion of foot	Deep fibular nerve (L_5-S_1)	
Extensors (Plantar fle	exors)					
Gastrocnemius		Femoral condyles	Calcaneus by calcaneal tendon	Extension (plantar flexion) at ankle; inversion of foot; flexion at knee	Tibial nerve $(S_1 - S_2)$	
Fibularis brevis		Midlateral margin of fibula	Base of fifth metatarsal bone	Eversion of foot and extension (plantar flexion) at ankle	Superficial fibular nerve (L_4-S_1)	
Fibularis longus		Lateral condyle of tibia, head and proximal shaft of fibula	Base of first metatarsal bone and medial cuneiform bone	Eversion of foot and extension (plantar flexion) at ankle; supports longitudinal arch	Superficial fibular nerve (L_4-S_1)	
Plantaris		Lateral supracondylar ridge	Posterior portion of calcaneus	Extension (plantar flexion) at ankle; flexion at knee	Tibial nerve (L ₄ –S ₁)	
Soleus		Head and proximal shaft of fibula and adjacent posteromedial shaft of tibia	Calcaneus by calcaneal tendon (with gastrocnemius)	Extension (plantar flexion) at ankle	Sciatic nerve, tibial branch (S_1-S_2)	
Tibialis posterior		Interosseous membrane and adjacent shafts of tibia and fibula	Tarsal and metatarsal bones	Adduction and inversion of foot; extension (plantar flexion) at ankle	Sciatic nerve, tibial branch (S_1-S_2)	
ACTION AT THE TOE	S					
Digital flexors						
Flexor digitorum lo	ongus	Posteromedial surface of tibia	Inferior surfaces of distal phalanges, toes 2–5	Flexion at joints of toes 2–5	Sciatic nerve, tibial branch (L_5-S_1)	
Flexor hallucis long	gus	Posterior surface of fibula	Inferior surface, distal phalanx of great toe	Flexion at joints of great toe	Sciatic nerve, tibial branch (L_5-S_1)	
Digital extensors						
Extensor digitorum	n longus	Lateral condyle of tibia, anterior surface of fibula	Superior surfaces of phalanges, toes 2–5	Extension at joints of toes 2–5	Deep fibular nerve $(L_4 - S_1)$	
Extensor hallucis lo	ongus	Anterior surface of fibula	Superior surface, distal	Extension at joints of great	Deep fibular nerve $(L_4 - S_1)$	

Figure 11–22 Extrinsic Muscles That Move the Foot and Toes. ATLAS: Plates 81a,b; 82a,b; 84a,b

These muscles are best seen in posterior and lateral views (Figure 11–22a,b). The gastrocnemius muscle arises from two heads located on the medial and lateral epicondyles of the femur just proximal to the knee. The *fabella*, a sesamoid bone, is occasionally present within the lateral head of the gastrocnemius muscle. The gastrocnemius and soleus muscles share a common tendon, the **calcaneal tendon**, commonly known as the *Achilles tendon*.

TIPS&TRICKS

The soleus is so named because it resembles the flat-bodied fish we call sole.

The term "Achilles tendon" comes from Greek mythology. Achilles was a warrior who was invincible but for one vulnerable spot: the calcaneal tendon. Outside mythology, damage to the calcaneal tendon isn't a fatal problem. Although it is among the largest, strongest tendons in the body, its rupture is common. The applied forces increase markedly during rapid acceleration or deceleration. Sprinters can rupture the calcaneal tendon pushing off from the starting blocks, and the elderly often snap this tendon during a stumble or fall. Surgery may be necessary to reposition and reconnect the torn ends of the tendon to promote healing.

Deep to the gastrocnemius and soleus muscles are a pair of **fibularis** muscles, or *peroneus* muscles (Figure 11–22a,b,d). The fibularis muscles produce eversion and extension (plantar flexion) at the ankle. Inversion is caused by the contraction of the **tibialis** (tib-ē-A-lis) muscles. The large **tibialis anterior** muscle flexes the ankle and opposes the gastrocnemius muscle (Figure 11–22b,c,d).

Important digital muscles originate on the surface of the tibia, the fibula, or both (Figure 11–22a,b,c,d). Large synovial tendon sheaths surround the tendons of the tibialis anterior, **extensor digitorum longus**, and **extensor hallucis longus** muscles, where they cross the ankle joint. The positions of these sheaths are stabilized by superior and inferior **extensor retinacula** (Figure 11–22b,c,d).

Intrinsic muscles of the foot originate on the tarsal and metatarsal bones (Figure 11–23 and Table 11–19). Their contractions move the toes and maintain the longitudinal arch of the foot. \bigcirc p. 258

Table 11–19 Intrinsi	trinsic Muscles of the Foot (Figure 11–23)				
Muscle	Origin	Insertion	Action	Innervation	
FLEXION/EXTENSION					
Flexor hallucis brevis	Cuboid and lateral cuneiform bones	Proximal phalanx of great toe	Flexion at metatarsophalangeal joint of great toe	Medial plantar nerve (L_4-L_5)	
Flexor digitorum brevis	Calcaneus (tuberosity on inferior surface)	Sides of middle phalanges, toes 2–5	Flexion at proximal interphalangeal joints of toes 2–5	Medial plantar nerve (L ₄ –L ₅)	
Quadratus plantae	Calcaneus (medial, inferior surfaces)	Tendon of flexor digitorum longus	Flexion at joints of toes 2–5	Lateral plantar nerve (L ₄ –L ₅)	
Lumbrical (4)	Tendons of flexor digitorum longus	Insertions of extensor digitorum longus	Flexion at metatarsophalangeal joints; extension at proximal interphalangeal joints of toes 2–5	Medial plantar nerve (1), lateral plantar nerve (2–4)	
Flexor digiti minimi brevis	Base of metatarsal bone V	Lateral side of proximal phalanx of toe 5	Flexion at metatarsophalangeal joint of toe 5	Lateral plantar nerve (S ₁ –S ₂)	
Extensor digitorum brevis	Calcaneus (superior and lateral surfaces)	Dorsal surfaces of toes 1–4	Extension at metatarsophalangeal joints of toes 1–4	Deep fibular nerve (L ₅ –S ₁)	
Extensor hallucis brevis	Superior surface of anterior calcaneus	Dorsal surface of the base of proximal phalanx of great toe	Extension of great toe	Deep fibular nerve $(L_5 - S_1)$	
ADDUCTION/ABDUCTION					
Adductor hallucis	Bases of metatarsal bones II–IV and plantar ligaments	Proximal phalanx of great toe	Adduction at metatarsophalangeal joint of great toe	Lateral plantar nerve (S ₁ –S ₂)	
Abductor hallucis	Calcaneus (tuberosity on inferior surface)	Medial side of proximal phalanx of great toe	Abduction at metatarsophalangeal joint of great toe	Medial plantar nerve (L ₄ –L ₅)	
Plantar interosseus (3)	Bases and medial sides of metatarsal bones	Medial sides of toes 3–5	Adduction at metatarsophalangeal joints of toes 3–5	Lateral plantar nerve (S ₁ –S ₂)	
Dorsal interosseus (4)	Sides of metatarsal bones	Medial and lateral sides of toe 2; lateral sides of toes 3 and 4	Abduction at metatarsophalangeal joints of toes 3 and 4	Lateral plantar nerve (S ₁ –S ₂)	
Abductor digiti minimi	As above	Lateral side of proximal phalanx, toe 5	Abduction at metatarsophalangeal joint of toe 5	Lateral plantar nerve ($L_4 - L_5$)	

Figure 11–23 Intrinsic Muscles

Clinical Note

Hernia When the abdominal muscles contract forcefully, pressure in the abdominopelvic cavity can increase dramatically. That pressure is applied to internal organs. If the individual exhales at the same time, the pressure is relieved because the diaphragm can move upward as the lungs collapse. But during vigorous isometric exercises or when lifting a weight while holding one's breath, pressure in the abdominopelvic cavity can rise to 106 kg/cm², roughly 100 times the normal pressure. A pressure that high can cause a variety of problems, including hernias. A **hernia** develops when a visceral organ or part of an organ protrudes abnormally through an opening in a surrounding muscular wall or partition. There are many types of hernia. Here we will consider only *inguinal* (groin) *hernias* and *diaphragmatic hernias*.

Late in the development of male fetuses, the testes descend into the scrotum. They pass through the abdominal wall at the **inguinal canals.** In adult males, the sperm ducts and associated blood vessels penetrate the abdominal musculature at the inguinal canals as the *spermatic cords*, on their way to the abdominal reproductive organs. In an inguinal hernia, the inguinal canal enlarges. The abdominal contents, such as a portion of the greater omentum, small intestine, or (more rarely) urinary bladder, enter the inguinal canal. If these structures become trapped or twisted, surgery may be required to prevent serious complications. Inguinal hernias are not always caused by unusually high abdominal pressures. Injuries to the abdomen or inherited weakness or distensibility of the canal can have the same effect.

The esophagus and major blood vessels pass through openings in the diaphragm, the muscle that separates the thoracic and abdominopelvic cavities. In a **diaphragmatic hernia** abdominal organs slide into the thoracic cavity. If entry is through the *esophageal hiatus*, the passageway used by the esophagus, a *hiatal hernia* (hī-Ā-tal; *hiatus*, a gap or opening) exists. The severity of the condition depends on the location and size of the herniated organ or organs. Hiatal hernias are very common. Most go unnoticed, although they may increase the severity of gastric acid entry into the esophagus. (This condition is gastroesophageal reflux disease, or GERD, commonly known as heartburn.) Radiologists see hiatal hernias in about 30 percent of individuals whose upper gastrointestinal tracts are examined with barium-contrast techniques.

Sometimes clinical complications other than GERD develop. They generally do so because abdominal organs that have pushed into the thoracic cavity are exerting pressure on structures or organs there. Like inguinal hernias, a diaphragmatic hernia can result from congenital factors or from an injury that weakens or tears the diaphragm. If abdominal organs occupy the thoracic cavity during fetal development, the lungs may be poorly developed at birth.

CHECKPOINT

- 18. Shrugging your shoulders uses which muscles?
- **19**. Baseball pitchers sometimes suffer from rotator cuff injuries. Which muscles are involved in this type of injury?
- **20**. An injury to the flexor carpi ulnaris muscle would impair which two movements?
- 21. Which leg movement would be impaired by injury to the obturator muscle?
- 22. To what does a "pulled hamstring" refer?
- 23. How would a torn calcaneal tendon affect movement of the foot?
- See the blue Answers tab at the back of the book.

11-7 With advancing age, the size and power of muscle tissue decrease

Learning Outcome Identify age-related changes of the muscular system.

We can summarize the effects of aging on the muscular system as follows:

- Skeletal Muscle Fibers Become Smaller in Diameter. This reduction in size reflects a decrease in the number of myofibrils. In addition, the muscle fibers contain smaller ATP, CP, and glycogen reserves and less myoglobin. The overall effect is a reduction in skeletal muscle size, strength, and endurance, combined with a tendency to fatigue quickly. Because cardiovascular performance also decreases with age, blood flow to active muscles does not increase with exercise as rapidly as it does in younger people. These factors interact to produce decreases of 30–50 percent in anaerobic and aerobic performance by age 65.
- Skeletal Muscles Become Less Elastic. Aging skeletal muscles develop increasing amounts of fibrous connective tissue, a process called **fibrosis**. Fibrosis makes the muscle less flexible, and the collagen fibers can restrict movement and circulation.
- Tolerance for Exercise Decreases. A lower tolerance for exercise comes in part from tiring quickly and in part from reduced thermoregulation, described in Chapter 5. ⊃ p. 168 Individuals over age 65 cannot eliminate the heat their muscles generate during contraction as effectively as younger people can. For this reason, they are subject to overheating.

• *The Ability to Recover from Muscular Injuries Decreases.* The number of satellite cells steadily decreases with age, and the amount of fibrous tissue increases. As a result, when an injury occurs, repair capabilities are limited. Scar tissue formation is the usual result.

Regular exercise helps control body weight, strengthens bones, and generally improves the quality of life at all ages. Extremely demanding exercise is not as important as regular exercise. In fact, extreme exercise in the elderly can damage tendons, bones, and joints.

CHECKPOINT

- 24. Describe general age-related effects on skeletal muscle tissue.
- **25**. Define fibrosis.
- See the blue Answers tab at the back of the book.

11-8 Exercise produces responses in multiple body systems

Learning Outcome Explain the functional relationship between the muscular system and other body systems, and explain the role of exercise in producing various responses in other body systems.

To operate at maximum efficiency, the muscular system must be supported by many other systems. The changes that take place during exercise provide a good example of such interaction. As noted earlier, active muscles consume oxygen and generate carbon dioxide and heat. The immediate effects of exercise on various body systems include the following:

- Cardiovascular System: Blood vessels in active muscles and the skin dilate, and heart rate increases. These adjustments speed up oxygen and nutrient delivery to and carbon dioxide removal from the muscle. They also bring heat to the skin for radiation into the environment.
- Respiratory System: Respiratory rate and depth of respiration increase. Air moves into and out of the lungs more quickly, keeping pace with the increased rate of blood flow through the lungs.
- Integumentary System: Blood vessels dilate, and sweat gland secretion increases. This combination increases evaporation at the skin surface and removes the excess heat generated by muscular activity.

SYSTEM INTEGRATOR

Body System ------> Muscular System

egumentary

Removes excess body heat; synthesizes vitamin D₃ for calcium and phosphate absorption; protects underlying muscles

Provides mineral reserve for maintaining normal calcium and phosphate levels in body fluids; supports skeletal muscles; provides sites of muscle attachment

Skeletal muscles pulling on skin of face produce facial expressions

Provides movement and support; stresses exerted by tendons maintain bone mass; stabilizes bones and joints

The MUSCULAR System

The muscular system performs six critical functions for the human body. It produces skeletal movement, helps maintain posture and body position, supports soft tissues, guards body entrances and exits, helps maintain body temperature, and stores nutrients.

Figure 11–24 diagrams the functional relationships between the muscular system and the other body systems we have studied so far.

 Nervous and Endocrine Systems: The responses of other systems are directed and coordinated through neural and endocrine (hormonal) adjustments in heart rate, respiratory rate, sweat gland activity, and mobilization of stored nutrient reserves.

Even when the body is at rest, the muscular system has extensive interactions with other systems. Figure 11–24 summarizes the range of interactions between the muscular system and other body systems studied so far.

CHECKPOINT

- **26**. What major function does the muscular system perform for the body as a whole?
- 27. Identify the physiological effects of exercise on the cardiovascular, respiratory, and integumentary systems, and indicate the relationship between those physiological effects and the nervous and endocrine systems.

• See the blue Answers tab at the back of the book.

Related Clinical Terms

- **charley horse:** Common name for a muscle spasm, especially in the leg.
- **compartment syndrome:** A condition in which increased pressure within the muscle compartment of a limb produces ischemia or "blood starvation."
- **fibromyositis:** Chronic illness characterized by widespread musculoskeletal aches, pains, and stiffness, and soft tissue tenderness.
- **groin pull:** An injury that is due to a strain of the muscles of the inner thigh.
- **impingement syndrome:** Pain on elevation of the shoulder due to an injured or inflamed tendon or bursa coming into contact with the overlying acromial process.
- **physical therapist:** Healthcare professional who uses specially designed exercises and equipment to help patients regain or improve their physical abilities.
- **plantar fasciitis:** Inflammation of the plantar fascia causing foot or heel pain.
- **shin-splints:** Pain along the shinbone (tibia) caused by an overload on the tibia and connective tissues that connect muscle to the bone.
- **tenosynovitis:** Inflammation of a tendon and the sheath that covers it.
- **torticollis:** A shortening or contraction of the muscles of the neck resulting in the head being tipped to one side with the chin turned to the other side.

11-1 Fascicle arrangement is correlated with muscle power and range of motion p. 333

- 1. Structural variations among skeletal muscles affect their power, range, and speed of movement.
- 2. A muscle can be classified as a **parallel muscle**, **convergent muscle**, **pennate muscle**, or **circular muscle (sphincter)** according to the arrangement of fibers and fascicles in it. A pennate muscle may be *unipennate*, *bipennate*, or *multipennate*. (*Figure 11–1*)

- **11-2** The three classes of levers increase muscle efficiency p. 335
- **3.** A **lever** is a rigid structure that moves around a fixed point called the **fulcrum**. Levers can change the direction and effective strength of an applied force, and the distance and speed of the movement such a force produces.
- 4. Levers are classified as **first-class**, **second-class**, or **third-class levers**. Third-class levers are the most common levers in the body. (*Figure 11–2*)

11-3 Muscle origins are at the fixed end of muscles, and insertions are at the movable end of muscles p. 336

- **5.** Each muscle can be identified by its *origin, insertion,* and *action.*
- 6. The site of attachment of the fixed end of a muscle is called the **origin**; the site where the movable end of the muscle attaches to another structure is called the **insertion**.
- 7. The movement produced when a muscle contracts is its action. (*Spotlight Figure 11–3*)
- 8. According to the function of its action, a muscle can be classified as an agonist, or prime mover; an antagonist; a synergist; or a fixator.

11-4 Descriptive terms are used to name skeletal muscles p. 339

- 9. The names of muscles commonly provide clues to their body region, origin and insertion, fascicle organization, position, structural characteristics, and action. (*Table 11–1*)
- **10.** The **axial musculature** arises on the axial skeleton; it positions the head and spinal column and moves the rib cage. The **appendicular musculature** stabilizes or moves components of the appendicular skeleton. (*Figure 11–4*)
- **11. Innervation** refers to the distribution of nerves that control a region or organ, including a muscle.

11-5 Axial muscles are muscles of the head and neck, vertebral column, trunk, and pelvic floor p. 341

- **12.** The axial muscles fall into logical groups on the basis of location, function, or both.
- Important muscles of facial expression include the orbicularis oris, buccinator, occipitofrontalis muscles and the platysma. (*Figure 11-5; Table 11-2*)
- 14. Six extrinsic eye muscles (*oculomotor muscles*) control eye movements: the **inferior** and **superior rectus** muscles, the **lateral** and **medial rectus** muscles, and the **inferior** and **superior oblique** muscles. (*Figure 11–6; Table 11–3*)
- **15.** The muscles of mastication (chewing) are the **masseter**, **temporalis**, and **pterygoid** muscles. (*Figure* 11–7; *Table* 11–4)
- 16. The four muscles of the tongue are necessary for speech and swallowing and assist in mastication. They are the palatoglossus, styloglossus, genioglossus, and hyoglossus muscles. (*Figure 11–8; Table 11–5*)
- 17. The muscles of the pharynx constrict the pharyngeal walls (pharyngeal constrictors), elevate the larynx (laryngeal elevators), or raise the soft palate (palatal muscles). (*Figure 11–9; Table 11–6*)
- The anterior muscles of the neck control the position of the larynx, depress the mandible, and provide a foundation for the muscles of the tongue and pharynx. The neck muscles include the digastric and sternocleidomastoid muscles and seven muscles that originate or insert on the hyoid bone. (*Figure 11–10; Table 11–7*)
- 19. The superficial muscles of the spine can be classified into the spinalis, longissimus, and iliocostalis groups. (*Figure 11–11; Table 11–8*)
- **20.** Other muscles of the spine include the **longus capitis** and **longus colli** muscles of the neck, the small intervertebral muscles of the deep layer, and the **quadratus lumborum** muscle of the lumbar region. (*Figure 11–11; Table 11–8*)
- 21. The oblique muscles include the scalene muscles and the intercostal and transversus muscles. The external and internal intercostal muscles are important in respiratory (breathing) movements of the ribs. Also important to respiration is the diaphragm. (*Figures* 11–11, 11–12; *Table* 11–9)
- 22. The **perineum** can be divided into an anterior **urogenital triangle** and a posterior **anal triangle**. The pelvic floor consists of the **urogenital diaphragm** and the **pelvic diaphragm**. (*Figure 11–13; Table 11–10*)

11-6 Appendicular muscles are muscles of the shoulders, upper limbs, pelvis, and lower limbs p. 358

23. The **trapezius** muscle affects the positions of the shoulder girdle, head, and neck. Other muscles inserting on the scapula include the **rhomboid**, **levator scapulae**, **serratus anterior**, **subclavius**, and **pectoralis minor** muscles. (*Figures* 11–14, 11–16; *Table* 11–11)

- 24. Among muscles that move the arm, the **deltoid** and the **supraspinatus** muscles are important abductors. The **subscapularis** and **teres major** muscles produce medial rotation at the shoulder; the **infraspinatus** and **teres minor** muscles produce lateral rotation; and the **coracobrachialis** muscle produces flexion and adduction at the shoulder. (*Figures* 11–14, 11–15, 11–16; *Table* 11–12)
- **25.** The **pectoralis major** muscle flexes the shoulder joint, and the **latissimus dorsi** muscle extends it. (*Figures* 11–14, 11–15, 11–16; *Table* 11–12)
- 26. Among muscles that move the forearm and hand, the actions of the **biceps brachii** muscle and the **triceps brachii** muscle (long head) affect the elbow joint. The **brachialis** and **brachioradialis** muscles flex the elbow, opposed by the **anconeus** muscle. The **flexor carpi ulnaris, flexor carpi radialis**, and **palmaris longus** muscles cooperate to flex the wrist. The **extensor carpi radialis** muscles and the **extensor carpi ulnaris** muscle oppose them. The **pronator teres** and **pronator quadratus** muscles pronate the forearm and are opposed by the **supinator** muscle. (*Figures* 11–16 to 11–19; *Tables* 11–13 to 11–15)
- 27. Among muscles that move the thigh, **gluteal muscles** cover the lateral surfaces of the ilia. The largest is the **gluteus maximus** muscle, which shares an insertion with the **tensor fasciae latae**. Together, these muscles pull on the **iliotibial tract**. (*Figure 11–20; Table 11–16*)
- **28.** The **piriformis** muscle and the **obturator** muscles are the most important **lateral rotators**. The **adductors** can produce a variety of movements. (*Figure 11–20; Table 11–17*)
- **29.** The **psoas major** and **iliacus** muscles merge to form the **iliopsoas** muscle, a powerful flexor of the hip. (*Figures* 11–20, 11–21; *Table* 11–16)
- 30. Among muscles that move the leg, the flexors of the knee include the biceps femoris, semimembranosus, and semitendinosus muscles (the three hamstrings) and the sartorius muscle. The popliteus muscle unlocks the knee joint. (*Figures 11–21, 11–22; Table 11–17*)
- **31.** Collectively, the knee extensors are known as the **quadriceps femoris.** This group consists of the three **vastus** muscles (intermedius, lateralis, medialis) and the **rectus femoris** muscle. (*Figure 11–21; Table 11–17*)
- **32.** Among muscles that move the foot and toes, the **gastroc-nemius** and **soleus** muscles produce plantar flexion (ankle extension). The **fibularis** brevis and longus muscles produce eversion as well as extension (plantar flexion) at the ankle. The fibularis tertius produces eversion and flexion (dorsiflexion) at the ankle. (*Figure 11–22; Table 11–18*)
- 33. Smaller muscles of the calf and shin position the foot and move the toes. Muscles originating at the tarsal and metatarsal bones provide precise control of the phalanges. (*Figure 11–23*; *Table 11–19*)

11-7 With advancing age, the size and power of muscle tissue decrease p. 379

34. With advanced age, skeletal muscles undergo **fibrosis**, the tolerance for exercise decreases, and repair of injuries slows.

11-8 Exercise produces responses in multiple body systems p. 379

35. Exercise illustrates the integration of the muscular system with the cardiovascular, respiratory, integumentary, nervous, and endocrine systems. (*Figure 11–24*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Name the three pennate muscles in the following figure, and for each muscle indicate the type of pennate muscle based on the relationship of muscle fibers to the tendon.

2. Label the three visible muscles of the rotator cuff in the following posterior view of the deep muscles that move the arm.

- The bundles of muscle fibers within a skeletal muscle are called
 (a) muscles, (b) fascicles, (c) fibers, (d) myofilaments, (e) groups.
- 4. Levers make muscle action more versatile by all of the following, *except* (a) changing the location of the muscle's insertion, (b) changing the speed of movement produced by an applied force, (c) changing the distance of movement produced by an applied force, (d) changing the strength of an applied force, (e) changing the direction of an applied force.
- The more movable end of a muscle is the (a) insertion, (b) belly,
 (c) origin, (d) proximal end, (e) distal end.
- The muscles of facial expression are innervated by cranial nerve (a) VII, (b) V, (c) IV, (d) VI.
- 7. The strongest masticatory muscle is the _____ muscle.
 (a) pterygoid, (b) masseter, (c) temporalis, (d) mandible.
- 8. The muscle that rotates the eye medially is the _____ muscle.
 (a) superior oblique, (b) inferior rectus, (c) medial rectus,
 (d) lateral rectus.
- Important flexors of the vertebral column that act in opposition to the erector spinae are the ______ muscles.
 (a) rectus abdominis, (b) longus capitis, (c) longus colli, (d) scalene.

See the blue Answers tab at the back of the book.

- The major extensor of the elbow is the _____ muscle.
 (a) triceps brachii, (b) biceps brachii, (c) deltoid, (d) subscapularis.
- The muscles that rotate the radius without producing either flexion or extension of the elbow are the _____ muscles.
 (a) brachialis and brachioradialis, (b) pronator teres and supinator, (c) biceps brachii and triceps brachii, (d) a, b, and c.
- 12. The powerful flexors of the hip are the _____ muscles.(a) piriformis, (b) obturator, (c) pectineus, (d) iliopsoas.
- 13. Knee extensors known as the quadriceps consist of the (a) three vastus muscles and the rectus femoris muscle, (b) biceps femoris, gracilis, and sartorius muscles, (c) popliteus, iliopsoas, and gracilis muscles, (d) gastrocnemius, tibialis, and peroneus muscles.
- 14. List the four fascicle organizations that produce the different patterns of skeletal muscles.
- 15. What is an aponeurosis? Give two examples.
- 16. Which four muscle groups make up the axial musculature?
- **17.** What three functions are accomplished by the muscles of the pelvic floor?
- 18. On which bones do the four rotator cuff muscles originate and insert?
- 19. What three functional groups make up the muscles of the lower limbs?

LEVEL 2 Reviewing Concepts

- 20. Of the following actions, the one that illustrates that of a second-class lever is (a) knee extension, (b) ankle extension (plantar flexion), (c) flexion at the elbow, (d) a, b, and c.
- Compartment syndrome can result from all of the following *except*
 (a) compressing a nerve in the wrist, (b) compartments swelling with blood due to an injury involving blood vessels, (c) torn ligaments in a given compartment, (d) pulled tendons in the muscles of a given compartment, (e) torn muscles in a particular compartment.
- 22. A(n) ______ develops when an organ protrudes through an abnormal opening.
- Elongated bursae that reduce friction and surround the tendons that cross the dorsal and ventral surfaces of the wrist form ______.
- 24. The muscles of the vertebral column include many dorsal extensors but few ventral flexors. Why?
- **25.** Why does a convergent muscle exhibit more versatility when contracting than does a parallel muscle?
- **26.** Why can a pennate muscle generate more tension than can a parallel muscle of the same size?
- **27.** Why is it difficult to lift a heavy object when the elbow is at full extension?
- **28.** Which types of movements are affected when the hamstrings are injured?

LEVEL 3 Critical Thinking and Clinical Applications

- **29.** Mary sees Jill coming toward her and immediately contracts her frontalis and procerus muscles. She also contracts her right levator labii muscles. Is Mary glad to see Jill? How can you tell?
- 30. Mary's newborn is having trouble suckling. The doctor suggests that it may be a problem with a particular muscle. What muscle is the doctor probably referring to? (a) orbicularis oris, (b) buccinator, (c) masseter, (d) risorius, (e) zygomaticus.
- **31.** While unloading her car trunk, Amy strains a muscle and as a result has difficulty moving her arm. The doctor in the emergency room tells her that she strained her pectoralis major. Amy tells you that she thought the pectoralis major was a chest muscle and doesn't understand what that has to do with her arm. What would you tell her?

CLINICAL CASE

The Weekend Warrior

David sustained a complete avulsion, or tearing away, of his hamstrings tendons from their origin on the ischial tuberosity. The long head of the biceps femoris (together with the short head) forms the lateral hamstrings. The semitendinosus and semimembranosus together form the medial hamstrings. When the tendons were forcibly detached from the pelvis, the muscle bellies contracted to about 70 percent of their resting length. With no proximal attachment, they remained contracted.

Under anesthesia, David is placed in a prone position on the operating table. On his right side, the surgeon makes a "7"-shaped incision, traversing the gluteal fold and extending down the posterior thigh. It is very difficult to get tendons to grow back to bone after they have been torn away from their natural attachment. The ischial tuberosity is prepared by scraping away the relatively avascular cortical bone, down to the bleeding, cancellous bone beneath. This roughening allows for better tendon healing to bone. The tendon mass of the biceps femoris, semitendinosus, and semimembranosus is

Wrap-Up

pulled proximally to the ischial tuberosity, helped by flexing the knee. The tendons are attached with "bone anchoring" sutures until healing can take place. Postoperatively, David is placed in a knee flexion sling (waist band, ankle band, connecting strap that keeps the knee flexed behind him) for 10 weeks.

- 1. What other muscle, in addition to the hamstrings, assists in flexing the knee?
- **2.** Why does flexing the knee help to bring the avulsed hamstring tendons back up to the ischial tuberosity?

See the blue Answers tab at the back of the book.

12

Neural Tissue

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **12-1** Describe the anatomical and functional divisions of the nervous system.
- 12-2 Sketch and label the structure of a typical neuron, describe the functions of each component, and classify neurons on the basis of their structure and function.
- **12-3** Describe the locations and functions of the various types of neuroglia.
- **12-4** Explain how the resting membrane potential is established and maintained.
- **12-5** Describe the events involved in the generation and propagation of an action potential.
- 12-6 Discuss the factors that affect the speed with which action potentials are propagated.
- **12-7** Describe the structure of a synapse, and explain the mechanism involved in synaptic activity.
- **12-8** Describe the major types of neurotransmitters and neuromodulators, and discuss their effects on postsynaptic membranes.
- **12-9** Discuss the interactions that enable information processing to occur in neural tissue.

CLINICAL CASE

• Did President Franklin D. Roosevelt Really Have Polio? p. 386

Clinical Notes

- Rabies p. 390
- Tumors p. 392
- Demyelination p. 395

SPOTLIGHTS

- Resting Membrane Potential p. 400
- Generation of an Action Potential pp. 408–409
- Propagation of an Action Potential pp. 410–411

CLINICAL CASE

Did Franklin D. Roosevelt Really Have Polio?

On August 10, 1921, at age 39, Franklin D. Roosevelt (FDR) went to bed early feeling tired and complaining of back pain, fever, and chills. The next day, he experienced progressive weakness: first in one leg, then the other, in an ascending pattern. By August 12, both legs were paralyzed and numb, though he still felt pain when lightly touched. Over the following month, the symptoms progressed to involve weakness and abnormal sensations of his upper extremities and his face, and he developed an inability to voluntarily urinate or defecate. His diagnosis of poliomyelitis, or polio, included him in one of the most feared epidemics of the early 20th century.

In the following months, Mr. Roosevelt gradually recovered from the severe weakness and pain. He also regained control

of his bodily functions. His legs and buttocks, however, were permanently weakened.

Franklin Roosevelt went on to become the 32nd and longest serving president of the United States. He assisted in the founding of the March of Dimes, an organization that contributed to the elimination of polio from most of the world. **But looking back on his**

clinical course, did President Franklin D. Roosevelt *really* suffer from poliomyelitis, a viral disease of the motor neurons of the spinal cord? To find out, turn to the Clinical Case Wrap-Up on p. 428.

An Introduction to Neural Tissue

The nervous system includes all the neural tissue in the body. \bigcirc **p**. 142 The basic functional units of the nervous system are individual cells called **neurons**. Neurons perform all the communication, information processing, and control functions of the nervous system. Supporting cells, called **neuroglia** (nū-ROG-lē-uh; *glia*, glue) or *glial cells*, have functions essential to the survival and functionality of neurons and to preserving the physical and biochemical structure of neural tissue. They separate and protect the neurons, provide a supportive framework for neural tissue, act as phagocytes, and help regulate the composition of the interstitial fluid. Neuroglia far outnumber neurons.

Neural tissue, with supporting blood vessels and connective tissues, forms the organs of the nervous system. These include the brain; the spinal cord; the receptors in complex sense organs, such as the eye and ear; and the *nerves* that link the nervous system with other systems.

12-1 The nervous system has anatomical and functional divisions

Learning Outcome Describe the anatomical and functional divisions of the nervous system.

We can look at the nervous system from anatomical and functional perspectives (Figure 12–1).

The Anatomical Divisions of the Nervous System

Viewed anatomically, the nervous system has two divisions: the central nervous system and the peripheral nervous system. The **central nervous system (CNS)** consists of the brain and spinal cord. These complex organs include not only neural tissue, but also blood vessels and the various connective tissues that physically protect and support.

What are the general functions of the CNS? It is responsible for integrating, processing, and coordinating sensory data and motor commands. Sensory data convey information about conditions inside or outside the body. Motor commands control or adjust peripheral organs, such as skeletal muscles. When you stumble, for example, the CNS integrates information about your balance and the position of your limbs and then coordinates your recovery by sending motor commands to appropriate skeletal muscles—all in a split second and without your conscious effort. The CNS—specifically, the brain—is also the seat of higher functions, such as intelligence, memory, learning, and emotion.

The **peripheral nervous system (PNS)** includes all the neural tissue outside the CNS. The PNS delivers sensory information to the CNS and carries motor commands to peripheral tissues and systems. Bundles of axons, or *nerve fibers*, carry sensory information and motor commands in the PNS. Such bundles, with associated blood vessels and connective tissues, are called *peripheral nerves*, or simply **nerves**. Nerves connected to the brain are called **cranial nerves**, and those attached to the spinal cord are called **spinal nerves**.

The Functional Divisions of the Nervous System

We can divide the PNS into afferent and efferent divisions, each with different functions. The **afferent division** (*afferens*, to bring to) of the PNS brings sensory information *to* the CNS from receptors in peripheral tissues and organs. **Receptors** are sensory structures that either detect changes in the environment (internal or external) or respond to specific stimuli (**Figure 12–1**). Our receptors range from the slender cytoplasmic extensions of single cells to complex receptor organs, such as the eye and ear. Receptors may be neurons or specialized cells of other tissues. \supset p. 161

The **efferent division** (*effero*, to bring out) of the PNS carries motor commands *from* the CNS to muscles, glands, and adipose tissue. These target organs, which respond by *doing* something, are called **effectors**. The efferent division has both somatic and autonomic components:

Figure 12–1 A Functional Overview of the Nervous System.

• The **somatic nervous system (SNS)** controls skeletal muscle contractions. *Voluntary* contractions are under conscious control. For example, you exert conscious control over your arm as you raise a full glass of water to your lips. *Involuntary* contractions may be simple, automatic responses or complex movements, but they are controlled at the subconscious level, outside your awareness. For instance, if you accidentally place your hand on a hot stove, you will withdraw it immediately, usually before you even notice any pain. This type of automatic response is called a **reflex**.

• The **autonomic nervous system (ANS)**, or *visceral motor system*, automatically regulates smooth muscle, cardiac muscle, glandular secretions, and adipose tissue at the subconscious level. The ANS includes a *sympathetic division* and a *parasympathetic division*, which commonly have antagonistic (opposite) effects. For example, activity of the sympathetic division accelerates the heart rate, whereas parasympathetic activity slows the heart rate.

Now that you have an overview of the nervous system, let's look at the structure of neural tissue and the functional principles that govern neural activities. We begin with neurons, the basic functional units of the nervous system.

CHECKPOINT

- 1. Identify the two anatomical divisions of the nervous system.
- 2. Identify the two functional divisions of the peripheral nervous system, and cite their primary functions.
- 3. Identify the two components of the efferent division of the PNS.
- 4. What would be the effect of damage to the afferent division of the PNS?

See the blue Answers tab at the back of the book.

12-2 Neurons are nerve cells specialized for intercellular communication

Learning Outcome Sketch and label the structure of a typical neuron, describe the functions of each component, and classify neurons on the basis of their structure and function.

Let's examine the structure of a representative neuron and see how it is specialized for intercellular communication before

Figure 12–2 The Anatomy of a Multipolar Neuron.

we consider the structural and functional classifications of neurons.

The Structure of Neurons

Neurons have a variety of shapes. Figure 12–2 shows a *multipolar neuron*, the most common type of neuron in the central nervous system. Each multipolar neuron has a large *cell body*, several short, branched *dendrites*, and a single, long *axon*, ending in terminal branches called *telodendria*.

The Cell Body

The **cell body**, or *soma*, contains a large, round nucleus with a prominent nucleolus (Figure 12–2). The cytoplasm surrounding the nucleus is the **perikaryon** (per-i-KAR- \bar{e} -on; *peri*, around + *karyon*, nucleus). The cytoskeleton of the perikaryon contains **neurofilaments** and **neurotubules**, which are similar to the intermediate filaments and microtubules of other types of cells. Bundles of neurofilaments, called **neurofibrils**, extend into the dendrites and axon, providing internal support for them.

The perikaryon contains organelles that provide energy and synthesize organic materials, especially the chemical neurotransmitters that are important in cell-to-cell communication. ⊃ p. 300 The numerous mitochondria, free and fixed ribosomes, and membranes of rough endoplasmic reticulum (RER) give the perikaryon a coarse, grainy appearance. Mitochondria generate ATP to meet the high energy

demands of an active neuron. The ribosomes and RER synthesize proteins.

Some areas of the perikaryon contain clusters of RER and free ribosomes. These regions, which stain darkly, are called *Nissl bodies*, after the German microscopist Franz Nissl, who first described them. Nissl bodies give a gray color to areas containing neuron cell bodies—the *gray matter* seen in gross dissection of the brain and spinal cord.

Most neurons lack centrioles, important organelles that help to organize the cytoskeleton and the microtubules that move chromosomes during mitosis. \bigcirc **p**. 105 As a result, typical CNS neurons cannot divide. For this reason, they cannot be replaced if lost to injury or disease. Neural stem cells persist in the adult nervous system, but they are typically inactive except in the nose, where the regeneration of olfactory (smell) receptors maintains our sense of smell, and in the *hippocampus*, a part of the brain involved in storing memories. Researchers are investigating the control mechanisms that trigger neural stem cell activity, with the goal of preventing or reversing neuron loss due to trauma, disease, or aging.

Dendrites and Axons

A variable number of slender, sensitive processes (extensions) known as **dendrites** extend out from the cell body (Figure 12–2). Dendrites play key roles in intercellular communication. Typical dendrites are highly branched, and each branch has fine 0.5-to 1- μ m-long studded processes called *dendriticspines*. In the CNS, a neuron receives information from other neurons primarily at the dendritic spines, which represent 80–90 percent of the neuron's total surface area.

An **axon** is a long cytoplasmic process capable of propagating an electrical impulse known as an *action potential*. \bigcirc **p**. **300** The **axoplasm** (AK-sō-plazm), or cytoplasm of the axon, contains neurofibrils, neurotubules, small vesicles, lysosomes, mitochondria, and various enzymes. The **axolemma** (*lemma*, husk), a specialized portion of the plasma membrane, surrounds the axoplasm. In the CNS, the axolemma may be exposed to the interstitial fluid or, as we'll see, it may be covered by the cellular processes of neuroglia. The base, or **initial segment**, of the axon in a multipolar neuron joins the cell body at a thickened region known as the **axon hillock** (Figure 12–2).

An axon may branch along its length, producing side branches known as **collaterals**. Collaterals enable a single neuron to communicate with several other cells. The main axon trunk and any collaterals end in a series of fine extensions called **telodendria** (tel-ō-DEN-drē-uh; *telo-*, end + *dendron*, tree) or *terminal branches*. The telodendria, in turn, end at **axon terminals** (also called synaptic terminals, synaptic knobs, and synaptic boutons), which play a role in communication with another cell (Figure 12–2).

The Synapse

Each axon terminal is part of a **synapse**, a specialized site where the neuron communicates with another cell (Figure 12–3). Every synapse involves two cells: (1) the *presynaptic cell*, which sends a message and includes the axon terminal; and (2) the *postsynaptic cell*, which receives the message. Typically, a narrow space called the *synaptic cleft* separates the two cells. \supset p. 300

In communication between two cells, the axon terminal of the presynaptic cell most commonly releases chemicals called **neurotransmitters** into the synaptic cleft. Inside the axon terminal, neurotransmitters are contained in *synaptic vesicles*. As we saw in Chapter 10, neurotransmitter release is triggered by electrical events, such as the arrival of an action potential. The neurotransmitters then flood the synaptic cleft and affect the activity of the postsynaptic cell.

The presynaptic cell is usually a neuron. (Specialized receptor cells may form synaptic connections with the dendrites of neurons, a topic we describe in Chapter 15.) The postsynaptic cell can be either a neuron or another type of cell. One neuron may communicate with another at a synapse on a dendrite, on the cell body, or along the length of the axon of the receiving cell. A synapse between a neuron and a muscle cell is called a **neuromuscular junction**. \bigcirc p. 299 At a **neuroglandular junction**, a neuron controls or regulates the activity of a secretory (gland) cell. Neurons also *innervate* (are distributed to) a variety of other cell types, such as adipocytes (fat cells). We consider the nature of that innervation in later chapters.

The structure of the axon terminal varies with the type of postsynaptic cell. A relatively simple, round axon terminal occurs where the postsynaptic cell is another neuron. At a synapse, the narrow synaptic cleft separates the **presynaptic membrane**,

Figure 12–3 The Structure of a Typical Synapse.

where neurotransmitters are released, from the **postsynap-tic membrane**, which bears receptors for neurotransmitters (Figure 12–3). The axon terminal at a neuromuscular junction is much more structurally complex.

Each axon terminal contains mitochondria and thousands of vesicles filled with neurotransmitter molecules. The axon terminal reabsorbs breakdown products of neurotransmitters formed at the synapse and reassembles them. It also receives a continuous supply of neurotransmitters synthesized in the cell body, along with enzymes and lysosomes.

These materials travel the length of the axon on neurotubules, pulled along by protein "molecular motors," called *kinesin* and *dynein*, that run on ATP. The movement of materials between the cell body and axon terminals is called **axoplasmic transport**. Some materials travel slowly, at rates of a few millimeters per day. This transport mechanism is known as the "slow stream." Vesicles containing neurotransmitters move much more rapidly, traveling in the "fast stream" at 5–10 mm per hour.

Axoplasmic transport occurs in both directions. The flow of materials from the cell body to the axon terminal is *anterograde* (AN-ter-ō-grād; *antero-*, forward) *flow*, carried by kinesin. At the same time, other substances are transported from the axon terminal toward the cell body in *retrograde* (RET-rō-grād) *flow* (*retro*, backward), carried by dynein. If debris or unusual chemicals appear in the axon terminal, retrograde flow soon delivers them to the cell body. There they may then alter the activity of the cell by turning certain genes on or off.

Rabies *Rabies* is a dramatic example of a clinical condition involving retrograde flow. A bite from a rabid animal injects the rabies virus into peripheral tissues. There the virus particles quickly enter axon terminals and peripheral axons. Retrograde flow then carries the virus into the CNS, with fatal results. Many toxins (including heavy metals), some pathogenic bacteria, and other viruses also bypass CNS defenses through axoplasmic transport.

The Classification of Neurons

We can group neurons by structure or by function.

Structural Classification of Neurons

Neurons are classified as anaxonic, bipolar, unipolar, or multipolar on the basis of the relationship of the dendrites to the cell body and the axon (Figure 12–4):

- Anaxonic (an-aks-ON-ik) neurons are small and have numerous dendrites, but no axon. Anaxonic neurons are located in the brain and in special sense organs. Their functions are poorly understood.
- Bipolar neurons have two distinct processes—one dendrite that branches extensively into dendritic branches at its distal tip, and one axon—with the cell body between the two. Bipolar neurons are rare. They occur in special sense organs, where they relay information about sight, smell, or hearing from receptor cells to other neurons. Bipolar neurons are small. The largest measure less than 30 μm from end to end.
- In a unipolar neuron, or *pseudounipolar neuron*, the dendrites and axon are continuous—basically, fused—and the cell body lies off to one side. In such a neuron, the initial segment lies where the dendrites converge. The rest of the process, which carries action potentials, is usually considered an axon. Most sensory neurons of the peripheral nervous system are unipolar. Their axons may extend a meter or more, ending at synapses in the central nervous system. The longest carry sensations from the tips of the toes to the spinal cord.
- **Multipolar neurons** have two or more dendrites and a single axon. They are the most common neurons in the CNS. All the motor neurons that control skeletal muscles, for example, are multipolar neurons. The axons of multipolar neurons can be as long as those of unipolar neurons, and the longest carry motor commands from the spinal cord to small muscles that move the toes.

Functional Classification of Neurons

Alternatively, we can categorize neurons by function as (1) sensory neurons, (2) motor neurons, or (3) interneurons.

Sensory Neurons. Sensory neurons, or *afferent neurons*, form the afferent division of the PNS. They deliver information from sensory receptors to the CNS. The cell bodies of sensory neurons are located in peripheral *sensory ganglia*. (A **ganglion** is a collection of neuron cell bodies in the PNS.) Sensory neurons are unipolar neurons whose processes, known as **afferent fibers**, extend between a sensory receptor and the central nervous system (spinal cord or brain). The human body's 10 million or so sensory neurons collect information about the external or internal environment. **Somatic sensory neurons** monitor the outside world and our position within it. **Visceral sensory neurons** monitor internal conditions and the status of other organ systems.

Sensory receptors are either the processes of specialized sensory neurons or cells monitored by sensory neurons. We can broadly categorize receptors in three groups:

Figure 12–4 Structural Classifications of Neurons.

- Interoceptors (*intero-*, inside) monitor the digestive, respiratory, cardiovascular, urinary, and reproductive systems and provide sensations of distension (stretch), deep pressure, and pain.
- **Exteroceptors** (*extero-*, outside) provide information about the external environment in the form of touch, temperature, or pressure sensations and the more complex senses of taste, smell, sight, equilibrium (balance), and hearing.
- Proprioceptors (prō-prē-ō-SEP-torz) monitor the position and movement of skeletal muscles and joints.

Motor Neurons. Motor neurons, or *efferent neurons*, form the efferent division of the PNS. These neurons carry instructions from the CNS to peripheral effectors in a peripheral tissue, organ, or organ system. The human body has about half a million motor neurons. Axons traveling away from the CNS are called **efferent fibers**. As noted earlier, the two major efferent systems are the somatic nervous system (SNS) and the autonomic (visceral) nervous system (ANS).

The somatic nervous system includes all the **somatic motor neurons** that innervate skeletal muscles. You have conscious control over the activity of the SNS. The cell body of a

somatic motor neuron lies in the CNS, and its axon extends into the periphery within a peripheral nerve to innervate skeletal muscle fibers at neuromuscular junctions.

You do not have conscious control over the activities of the ANS. **Visceral motor neurons** innervate all peripheral effectors other than skeletal muscles—that is, smooth muscle, cardiac muscle, glands, and adipose tissue throughout the body. The axons of visceral motor neurons in the CNS innervate a second set of visceral motor neurons in peripheral *autonomic ganglia*. The neurons whose cell bodies are located in those ganglia innervate and control peripheral effectors.

TIPS&TRICKS

To distinguish between *afferent* and *efferent*, think of the **SAME** principle: **S** is for **s**ensory, **A** is for **a**fferent, **M** is for **m**otor, and **E** is for **e**fferent. This way, you associate the **S** and **A** together and the **M** and **E** together.

To get from the CNS to a visceral effector such as a smooth muscle cell, a signal must travel along one axon, be relayed across a synapse, and then travel along a second axon to its final destination. The axons extending from the CNS to an autonomic ganglion are called *preganglionic fibers*, and axons connecting the ganglion cells with the peripheral effectors are known as *postganglionic fibers*.

Interneurons. Interneurons are located between sensory and motor neurons. The 20 billion or so interneurons (*association neurons*) outnumber all other types of neurons combined. Most are located within the brain and spinal cord, but some are in autonomic ganglia. Interneurons distribute sensory information and coordinate motor activity. The more complex the response to a given stimulus, the more interneurons are involved. Interneurons also play a part in all higher functions, such as memory, planning, and learning.

We now turn our attention to the neuroglia, cells that support and protect the neurons.

CHECKPOINT

- 5. Name the structural components of a typical neuron.
- 6. Classify neurons according to their structure.
- 7. Classify neurons according to their function.
- 8. Are unipolar neurons in a tissue sample more likely to function as sensory neurons or motor neurons?

See the blue Answers tab at the back of the book.

12-3 CNS and PNS neuroglia support and protect neurons

Learning Outcome Describe the locations and functions of the various types of neuroglia.

Neuroglia are abundant and diverse, and they make up about half the volume of the nervous system. The organization of neural tissue in the CNS differs from that in the PNS, primarily because the CNS has a greater variety of neuroglial cell types. Histological descriptions have been available for the past century, but the technical problems involved in isolating and manipulating individual glial cells have limited our understanding of their functions. **Figure 12–5** summarizes what we know about the major neuroglial populations in the CNS and PNS.

Neuroglia of the Central Nervous System

The central nervous system has four types of neuroglia: (1) *ependymal cells*, (2) *astrocytes*, (3) *oligodendrocytes*, and (4) *microglia* (Figure 12–5).

Ependymal Cells

A fluid-filled central passageway extends along the longitudinal axis of the spinal cord and brain. **Cerebrospinal fluid (CSF)** fills this passageway and also surrounds the brain and spinal cord. This fluid, which circulates continuously, provides a protective cushion and transports dissolved gases, nutrients, wastes, and other materials. The diameter of the internal passageway

varies from one region to another. In the spinal cord, this narrow passageway is called the *central canal* (Figure 12–6a,b). In several regions of the brain, the passageway forms enlarged chambers called *ventricles*. **Ependymal cells** line the central canal and ventricles, where they form a simple cuboidal to columnar epithelium known as the **ependyma** (e-PEN-dimuh). Unlike other epithelia, it lacks a basement membrane. Ependymal cells assist in producing, monitoring, and circulating CSF. There are three types of ependymal cells: ependymocytes, tanycytes, and specialized CSF-producing ependymal cells.

Ependymocytes have motile cilia that aid in the circulation of CSF and also microvilli. In adults, the cilia do not persist in all areas of the ventricles and central canal. Ependymocytes have long, slender basal processes that branch and make contact with neuroglia. **Tanycytes** are specialized, non-ciliated ependymal cells with microvilli on their apical surfaces. They are found in only one brain ventricle. It is thought that they transport substances between the CSF and the brain. The role of ependymal cells in CSF production is discussed in Chapter 14.

Other regions of the ependyma may have sensory functions, such as monitoring the composition of the CSF. During early embryonic development, stem cells lining the central canal and ventricles divide to give rise to neurons and all CNS neuroglia other than microglia. In adults, the ependyma appears to contain stem cells that can divide to produce additional neurons. The specific regulatory mechanisms involved are now being investigated.

Clinical Note

Tumors Tumors of the brain, spinal cord, and associated membranes result in approximately 90,000 deaths in the United States each year. Primary CNS tumors are tumors that originate in the central nervous system. Secondary CNS tumors arise from the metastasis (spread) of cancer cells that originate elsewhere. Roughly 75 percent of CNS tumors are primary tumors. In adults, primary CNS tumors result from the divisions of abnormal neuroglia rather than from the divisions of abnormal neurons, because typical neurons in adults cannot divide. However, through the divisions of stem cells, neurons increase in number until children reach age 4. For this reason, primary CNS tumors involving abnormal neurons can occur in young children. Symptoms of CNS tumors vary with the location affected. Treatment may involve surgery, radiation, chemotherapy, or a combination of these procedures.

Astrocytes

Astrocytes (AS-trō-sīts; *astro-*, star + *-cyte*, cell) are the largest and most numerous neuroglia in the CNS (Figure 12–6b).

Figure 12–5 An Introduction to Neuroglia.

These cells have a variety of functions, many of them poorly understood:

 Maintaining the Blood–Brain Barrier. Compounds dissolved in circulating blood do not have free access to the interstitial fluid of the CNS. Neural tissue must be physically and biochemically isolated from the general circulation, because hormones, amino acids, or other chemicals in the blood can alter neuron function. The endothelial cells lining CNS capillaries control the chemical exchange between the blood and interstitial fluid. These cells create a **blood–brain barrier** (BBB) that isolates the CNS from the general circulation.

The slender cytoplasmic extensions of astrocytes end in expanded "feet," processes that wrap around capillaries. These processes form a complete blanket around the capillaries, interrupted only where other neuroglia come in contact with the capillary walls. Astrocytes secrete chemicals that are somehow responsible for maintaining the special permeability characteristics of the capillary endothelial cells. (We discuss the blood–brain barrier further in Chapter 14.)

• *Creating a Three-Dimensional Framework for the CNS.* Astrocytes are packed with microfilaments that extend across the breadth of the cell and its processes. This extensive cytoskeleton helps astrocytes to provide a structural framework for the neurons of the brain and spinal cord.

- Repairing Damaged Neural Tissue. In the CNS, damaged neural tissue seldom regains normal function. However, astrocytes that move into an injury site can make structural repairs that stabilize the tissue and prevent further injury. We discuss neural damage and repair in a later section.
- *Guiding Neuron Development.* Astrocytes in the embryonic brain appear to be involved in directing both the growth and interconnection of developing neurons.
- Controlling the Interstitial Environment. Astrocytes appear to adjust the composition of interstitial fluid by several means: (1) regulating the concentration of sodium ions, potassium ions, and carbon dioxide; (2) providing a "rapid-transit system" for transporting nutrients, ions, and dissolved gases between capillaries and neurons; (3) controlling the volume of blood flow through the capillaries; (4) absorbing and recycling some neurotransmitters; and (5) releasing chemicals that enhance or suppress communication across axon terminals.

Figure 12–6 Neuroglia in the CNS.

b A diagrammatic view of neural tissue in the CNS, showing relationships between neuroglia and neurons

Oligodendrocytes

Like astrocytes, **oligodendrocytes** (ol-i-gō-DEN-drō-sīts; *oligo*-, few) have slender cytoplasmic extensions, but the cell bodies of oligodendrocytes are smaller, with fewer processes, than astrocytes (Figure 12–6b). The processes of oligodendrocytes generally are in contact with the exposed surfaces of neurons. The functions of processes ending at the neuron cell body have yet to be determined. Much more is known about the processes that end on the surfaces of axons. Many axons in the CNS are completely sheathed in these processes, which insulate them from contact with the extracellular fluid.

During its maturation, the plasma membrane near the tip of each process of an oligodendrocyte expands to form an enormous pad, and the cytoplasm there becomes very thin. This flattened "pancake" somehow gets wrapped around the axolemma, forming concentric layers of plasma membrane (Figure 12–6b). This membranous wrapping, called **myelin** (M Ī-e-lin), serves as electrical insulation and increases the speed at which an action potential travels along the axon. (We describe this mechanism in a later section.)

Many oligodendrocytes cooperate in forming a **myelin sheath** along the length of an axon. Such an axon is said to be **myelinated**. Each oligodendrocyte myelinates segments of several axons. The fairly large areas of the axon that are wrapped in myelin are called **internodes** (*inter*, between). Internodes

are typically 1-2 mm in length. The small gaps of a few micrometers that separate adjacent internodes are called **nodes**, or *nodes of Ranvier* (rahn-vē-Ā). An axon's collateral branches originate at nodes.

In dissection, myelinated axons appear glossy white, primarily because of the lipids in the myelin. As a result, regions dominated by myelinated axons are known as the **white matter** of the CNS. Not all axons in the CNS are myelinated, however. **Unmyelinated** axons are not completely covered by oligodendrocytes. Such axons are common where short axons and collaterals form synapses with densely packed neuron cell bodies. Areas containing neuron cell bodies, dendrites, and unmyelinated axons have a dusky gray color, and make up the **gray matter** of the CNS.

In summary, oligodendrocytes play an important role in structural organization by tying clusters of axons together. They also improve the functioning of neurons by wrapping axons within a myelin sheath.

TIPS & TRICKS

The overall color of CNS tissue is related to its structure and function. **Gr**ay matter has a **gr**eat concentration of neuron cell bodies and is a region of inte**gr**ation. **Wh**ite matter has a **wh**ole lot of myelinated axons and **wh**isks nerve impulses.

Clinical Note

Demyelination Demyelination is the progressive destruction of myelin sheaths, both in the CNS and in the PNS. The result is a loss of sensation and motor control that leaves affected regions numb and paralyzed. Many unrelated conditions that result in the destruction of myelin can cause symptoms of demyelination.

Chronic exposure to heavy-metal ions, such as arsenic, lead, or mercury, can cause heavy-metal poisoning, leading to damage of neuroglia and to demyelination. As demyelination occurs, the affected axons deteriorate, and the condition becomes irreversible.

Diphtheria (dif-THER-ē-uh; *diphthera*, leather + -*ia*, disease) is a disease that results from a bacterial infection. In the nervous system, diphtheria toxin damages Schwann cells and destroys myelin sheaths in the PNS. The resulting demyelination leads to sensory and motor problems that can ultimately produce a fatal paralysis. Due to an effective vaccine, cases are relatively rare in countries with adequate health care.

Multiple sclerosis (skler-Ō-sis; *sklerosis*, hardness), or **MS**, is a disease characterized by recurrent incidents of demyelination that affects axons in the optic nerve, brain, and spinal cord. Common signs and symptoms include partial loss of vision and problems with speech, balance, and general motor coordination, including bowel and urinary bladder control. The time between incidents and degree of recovery vary from case to case. In about one-third of all cases, the disorder is progressive, and each incident leaves a greater degree of functional impairment. The first attack typically occurs in individuals 30–40 years old. The incidence among women is 1.5 times that among men. In some patients, corticosteroid or interferon injections have slowed the progression of the disease.

Guillain-Barré (ghee-yan bah-ray) **syndrome** is an autoimmune disorder characterized by demyelination of peripheral nerves. The signs and symptoms include weakness or tingling of the legs that spreads to the arms. They typically increase in severity, leading to paralysis. When breathing is affected, the patient is placed on a ventilator. The disorder affects both sexes equally. Each year it afflicts 1 of every 100,000 Americans. A virus appears to trigger the syndrome, because the onset is usually within a few days or weeks of a respiratory or gastrointestinal infection, or occasionally after surgery or immunization. Most patients fully recover, but some continue to have residual weakness.

12

Figure 12–7 Schwann Cells, Peripheral Axons, and Formation of the Myelin Sheath.

c Stages in the formation of a myelin sheath by a single Schwann cell along a portion of a single axon.

Microglia

The least numerous and smallest neuroglia in the CNS are phagocytic cells called **microglia** (mī-KRŌG-lē-uh). **D pp. 99–100** Their slender processes have many fine branches (Figure 12–6b). These cells can migrate through neural tissue. Microglia appear early in embryonic development, originating from mesodermal stem cells related to stem cells that produce monocytes and macrophages. **D pp. 127, 133** Microglia migrate into the CNS as the nervous system forms. There they remain, acting as a wandering janitorial service and police force by engulfing cellular debris, waste products, and pathogens.

Neuroglia of the Peripheral Nervous System

Recall that the cell bodies of neurons in the PNS are clustered in masses called **ganglia** (singular, *ganglion*). The processes of neuroglia completely insulate neuronal cell bodies and most axons in the PNS from their surroundings. The two types of neuroglia in the PNS are satellite cells and Schwann cells.

Satellite cells surround neuron cell bodies in ganglia. They regulate the environment around the neurons, much as astrocytes do in the CNS.

Schwann cells, or *neurilemma cells*, either form a thick, myelin sheath or indented folds of plasma membrane around peripheral axons (**Figures 12–7, 12–8**). Wherever a Schwann cell covers an axon, the outer surface of the Schwann cell is called the **neurilemma** (nū-ri-LEM-uh). Most axons in the PNS, whether myelinated or unmyelinated, are shielded from contact with interstitial fluids by Schwann cells.

A myelinating Schwann cell can myelinate only one segment of a single axon (Figure 12–7a), whereas an oligodendrocyte in the CNS may myelinate portions of several adjacent axons (Figure 12–6b). Nonmyelinating Schwann cells can *enclose* segments of several unmyelinated axons. A series of Schwann cells is required to enclose an axon along its entire length (Figure 12–7b). Stages in the formation of a myelin sheath are shown in Figure 12–7c. Figure 12–8 Peripheral Nerve Regeneration after Injury.

Neural Responses to Injuries

What happens when a neuron is injured? It responds to injury in a very limited way. In the cell body, the Nissl bodies disperse and the nucleus moves away from its centralized location as the cell increases its rate of protein synthesis. If the neuron recovers and regains function, it will regain its normal appearance.

The key to recovery appears to be events in the axon. If, for example, the pressure applied during a crushing injury produces a local decrease in blood flow and oxygen, the affected axonal membrane becomes unexcitable. If the pressure is alleviated after an hour or two, the neuron will recover within a few weeks. More severe or prolonged pressure produces effects similar to those caused by cutting the axon.

In the PNS, Schwann cells play a part in repairing damaged nerves. In the process known as **Wallerian degeneration**, the axon distal to the injury site degenerates, and macrophages migrate into the area to clean up the debris (Figure 12–8). The Schwann cells do not degenerate. Instead, they proliferate and form a solid cellular cord that follows the path of the original axon. As the neuron recovers, its axon grows into the site of injury, and the Schwann cells wrap around the axon.

If the axon grows alongside the appropriate cord of Schwann cells, it may eventually reestablish its normal synaptic contacts. However, if it stops growing or wanders off in some new direction, normal function will not return. The growing axon is most likely to arrive at its appropriate destination if the cut edges of the original nerve bundle remain in contact.

Limited regeneration can occur in the CNS, but the situation is more complicated because (1) many more axons are likely to be involved, (2) astrocytes produce scar tissue that can prevent axon growth across the damaged area, and (3) astrocytes release chemicals that block the regrowth of axons.

CHECKPOINT

- 9. Identify the neuroglia of the central nervous system.
- **10**. Identify the neuroglia of the peripheral nervous system.
- 11. Which type of neuroglia would increase in number in the brain tissue of a person with a CNS infection?

12-4 The membrane potential is the electrical potential of the cell's interior relative to its surroundings

Learning Outcome Explain how the resting membrane potential is established and maintained.

In Chapter 3, we introduced the concepts of the *membrane potential*, or *transmembrane potential*, and the *resting membrane potential*, two characteristic physiological features of all cells. \bigcirc p. 100 In this discussion, we focus on the membranes of neurons, but many of the principles discussed apply to other types of cells as well.

The important membrane processes we will be examining are the resting membrane potential, graded potential, action potential, synaptic activity, and information processing.

- *Resting membrane potential* All living cells have a membrane potential that varies from moment to moment depending on the activities of the cell. The *resting membrane potential* is the membrane potential of an unstimulated, resting cell. All neural activities begin with a change in the resting membrane potential of a neuron.
- *Graded potential* A typical stimulus produces a temporary, localized change in the resting membrane potential. The effect, which decreases with distance from the stimulus, is called a *graded potential*.
- Action potential If the graded potential is large enough, it triggers an *action potential* in the membrane of the axon. An action potential is an electrical impulse that is propagated (spread) along the surface of an axon and does not diminish as it moves away from its source. This impulse travels along the axon to one or more synapses.
- Synaptic activity then produces graded potentials in the plasma membrane of the postsynaptic cell. The presynaptic cell typically releases neurotransmitters, such as ACh. These chemicals bind to receptors on the postsynaptic plasma membrane, changing its permeability and producing graded potentials. The mechanism is comparable to that of the neuromuscular junction, described in Chapter 10.
 p. 300
- Information processing The response of the postsynaptic cell ultimately depends on what the stimulated receptors do and what other stimuli are influencing the cell at the same time. The integration of stimuli at the level of the individual cell is the simplest form of *information processing* in the nervous system.

When you understand each of these processes, you will know how neurons deal with information and communicate with one another and with peripheral effectors.

The Membrane Potential

Chapter 3 introduced three important concepts regarding the membrane potential:

1. The extracellular fluid (ECF) and intracellular fluid (cytosol) differ greatly in ionic composition. The extracellular fluid

contains high concentrations of sodium ions (Na^+) and chloride ions (Cl^-) , whereas the cytosol contains high concentrations of potassium ions (K^+) and negatively charged proteins.

- 2. Cells have selectively permeable membranes. If the plasma membrane were freely permeable, diffusion would continue until all the ions were evenly distributed across the membrane and a state of equilibrium existed. But an even distribution does not occur, because cells have selectively permeable membranes. ⊃ p. 87 Ions cannot freely cross the lipid portions of the plasma membrane. They can enter or leave the cell only through membrane channels. Many kinds of membrane channels exist, each with its own properties. At the resting membrane potential, or membrane potential of an undisturbed cell, ions move through *leak channels*—membrane channels that are always open. ⊃ p. 92 Active transport mechanisms, such as the sodiumpotassium exchange pump, also move specific ions into or out of the cell. ⊃ p. 96
- **3.** *Membrane permeability varies by ion.* The cell's passive and active transport mechanisms do not ensure an equal distribution of charges across its plasma membrane, because membrane permeability varies by ion. For example, it is easier for K⁺ to diffuse out of the cell through a potassium leak channel than it is for Na⁺ to enter the cell through a sodium leak channel. Additionally, negatively charged proteins inside the cell are too large to cross the membrane. As a result, the membrane's inner surface has an excess of negative charges with respect to the outer surface.

Both passive and active forces act across the plasma membrane to determine the membrane potential at any moment. **Spotlight Figure 12–9** shows the membrane at the normal resting membrane potential.

Passive Forces Acting across the Plasma Membrane

The passive forces acting across the plasma membrane involve both chemical and electrical gradients (Spotlight Figure 12–9). Positive and negative charges attract one another. If nothing separates them, oppositely charged ions will move together and eliminate the potential difference between them. A movement of charges to eliminate a potential difference is called a **current**. If a barrier (such as a plasma membrane) separates the oppositely charged ions, the amount of current depends on how easily the ions can cross the membrane. The **resistance** of the membrane is a measure of how much the membrane restricts ion movement. If the resistance is high, the current is very small, because few ions can cross the membrane. If the resistance is low, the current is very large, because ions flood across the membrane. The resistance of a plasma membrane can change as ion channels open or close. The changes result in currents carrying ions into or out of the cytoplasm.

The Electrochemical Gradient. Electrical gradients can either reinforce or oppose the chemical gradient for each ion. The **electrochemical gradient** for a specific ion is the sum of the chemical and electrical forces acting on that ion across the plasma membrane. The electrochemical gradients for K^+ and Na^+ are the primary factors affecting the resting membrane potential of most cells, including neurons. Let's consider the forces acting on each ion independently.

The intracellular concentration of potassium ions is relatively high, whereas the extracellular concentration is very low. Therefore, the chemical gradient for potassium ions tends to drive them out of the cell, as indicated by the orangecolored arrow in **Figure 12–10a**. However, the electrical gradient opposes this movement, because K⁺ inside and outside the cell are attracted to the negative charges on the inside of the plasma membrane, and repelled by the positive charges on the outside of the plasma membrane. The white arrow in **Figure 12–10a** indicates the size and direction of this electrical gradient. The chemical gradient is strong enough to overpower the electrical gradient, but the electrical gradient weakens the force driving K⁺ out of the cell. The lighter orange-colored arrow represents the net driving force of the potassium electrochemical gradient.

If the plasma membrane were freely permeable to K⁺ but impermeable to other positively charged ions, potassium ions would continue to leave the cell until the electrical gradient (opposing the exit of K⁺ from the cell) was as strong as the chemical gradient (driving K⁺ out of the cell). The membrane potential at which there is no net movement of a particular ion across the plasma membrane is called the **equilibrium potential** for that ion. For potassium ions, this equilibrium occurs at a membrane potential of about –90 mV, as illustrated in **Figure 12–10b**. The resting membrane potential is typically –70 mV, a value close to the equilibrium potential for K⁺. The difference is due primarily to Na⁺ leaking continuously into the cell. The equilibrium potential indicates an ion's contribution to the resting membrane potential.

TIPS&TRICKS

To remember the relative distribution of ions across the resting cell membrane, associate **N**egative with i**N**side and p**O**sitive with the **O**utside.

The sodium ion concentration is relatively high in the extracellular fluid, but extremely low inside the cell. As a result, there is a strong chemical gradient driving Na⁺ into the cell (the purple arrow in **Figure 12–10c**). In addition, the extracellular sodium ions are attracted by the excess of negative charges on

SPOTLIGHT

Watch the Mastering A&P° > A&PFlix on Resting Membrane Potential.

All living cells have a membrane potential that varies from moment to moment depending on the activities of the cell. In an unstimulated, resting cell, the *potential difference* between positive and negative ions on either side of the membrane is called the **resting membrane potential**. Passive and active forces determine the resting membrane potential.

Passive Chemical Gradients

The intracellular concentration of potassium ions (K⁺) is relatively high, so these ions tend to move out of the cell through potassium leak channels. Similarly, the extracellular concentration of sodium ions (Na⁺) is relatively high, so sodium ions move into the cell through sodium leak channels. Both of these movements are driven by a concentration gradient, or **chemical gradient**.

Active Na⁺/K⁺ Pumps

Sodium-potassium (Na⁺/K⁺) exchange pumps maintain the concentration of sodium and potassium ions across the plasma membrane.

Passive Electrical Gradients

Potassium ions leave the cytosol more rapidly than sodium ions enter because the plasma membrane is much more permeable to potassium than to sodium. As a result, there are more positive charges outside the plasma membrane. Negatively charged protein molecules within the cytosol cannot cross the plasma membrane, so there are more negative charges on the cytosol side of the plasma membrane. This results in an electrical gradient across the plasma membrane.

Resting Membrane Potential

Whenever positive and negative ions are held apart, a potential difference arises. We measure the size of that potential difference in millivolts (mV). The resting membrane potential for most neurons is about –70 mV. The minus sign shows that the inner surface of the plasma membrane is negatively charged with respect to the exterior.

Potassium Ion Gradients

- **a** At normal resting membrane potential, an electrical gradient opposes the chemical gradient for potassium ions (K⁺). The net electrochemical gradient tends to force potassium ions out of the cell.
- If the plasma membrane were freely permeable to potassium ions, the outflow of K⁺ would continue until the equilibrium potential (-90 mV) was reached. Note how similar it is to the resting membrane potential.

Sodium Ion Gradients

c At the normal resting membrane potential, chemical and electrical gradients combine to drive sodium ions (Na⁺) into the cell.

d If the plasma membrane were freely permeable to sodium ions, the influx of Na⁺ would continue until the equilibrium potential (+66 mV) was reached. Note how different it is from the resting membrane potential.

the inner surface of the plasma membrane. The white arrow in **Figure 12–10c** shows the relative size and direction of this electrical gradient. Both electrical forces and chemical forces drive Na^+ into the cell, and the lavender arrow represents the net driving force.

If the plasma membrane were freely permeable to Na⁺, these ions would continue to cross it until the interior of

the cell contained enough excess positive charges to reverse the electrical gradient. In other words, ion movement would continue until the interior developed such a strongly positive charge that repulsion between the positive charges would prevent any further net movement of Na⁺ into the cell. The equilibrium potential for Na⁺ is approximately +66 mV, as shown in **Figure 12–10d.** The resting membrane potential is nowhere near that value, because the resting membrane permeability to Na⁺ is very low, and because ion pumps in the plasma membrane eject sodium ions as fast as they cross the membrane.

An electrochemical gradient is a form of *potential energy*. **D** p. 36 Potential energy is stored energy—the energy of position, as exists in a stretched spring, a charged battery, or water behind a dam. Without a plasma membrane, diffusion would eliminate all electrochemical gradients. In effect, the plasma membrane acts like a dam across a river. Without the dam, water would simply respond to gravity and flow downstream, gradually losing energy. With the dam in place, even a small opening releases water under tremendous pressure. Similarly, any stimulus that increases the permeability of the plasma membrane to sodium or potassium ions produces sudden and dramatic ion movement. For example, a stimulus that opens sodium ion channels triggers a rush of Na⁺ into the cell. Note that the nature of the stimulus does not determine the amount of ion movement: If the stimulus opens the door, the electrochemical gradient does the rest.

Active Forces across the Membrane: The Sodium–Potassium Exchange Pump

We can compare a cell to a leaky fishing boat loaded with tiny fish floating in the sea. The hull represents the plasma membrane; the fish, K^+ ; and the ocean water, Na⁺. As the boat rumbles and rolls, water comes in through the cracks, and fish swim out. If the boat is to stay afloat and the catch kept, we must pump the water out and recapture the lost fish.

Similarly, at the normal resting membrane potential, the cell must bail out sodium ions that leak in and recapture potassium ions that leak out. The "bailing" takes place through the activity of an exchange pump powered by ATP (Spotlight Figure 12–9). The ion pump involved is the carrier protein *sodium–potassium ATPase.* \bigcirc p. 96 This pump exchanges three intracellular sodium ions for two extracellular potassium ions. At the normal resting membrane potential, this pump ejects sodium ions as quickly as they enter the cell. In this way, the activity of the exchange pump exactly balances the passive forces of diffusion, and the resting membrane potential remains stable because the ionic concentration gradients are maintained.

Table 12–1 summarizes the important features of the resting membrane potential.

Changes in the Membrane Potential

As noted previously, the resting membrane potential is the membrane potential of an "undisturbed" cell. Recall that it exists because (1) the cytosol differs from extracellular fluid in chemical and ionic composition, and (2) the plasma membrane is selectively permeable. Yet cells are dynamic structures that continually modify their activities, either in response to external stimuli or to perform specific functions. The membrane

Table 12–1 The Resting Membrane Potential

- Because the plasma membrane is highly permeable to potassium ions, the resting membrane potential of approximately –70 mV is fairly close to –90 mV, the equilibrium potential for K⁺.
- The electrochemical gradient for sodium ions is very large, but the membrane's permeability to these ions is very low. Consequently, Na⁺ has only a small effect on the normal resting membrane potential, making it just slightly less negative than the equilibrium potential for K⁺.
- The sodium–potassium exchange pump ejects 3 Na⁺ ions for every 2 K⁺ ions that it brings into the cell. It serves to stabilize the resting membrane potential when the ratio of Na⁺ entry to K⁺ loss through passive channels is 3:2.
- At the normal resting membrane potential, these passive and active mechanisms are in balance. The resting membrane potential varies widely with the type of cell. A typical neuron has a resting membrane potential of approximately –70 mV.

potential is equally dynamic, rising or falling in response to temporary changes in membrane permeability. Those changes result from the opening or closing of specific membrane channels.

Membrane channels control the movement of ions across the plasma membrane. We will focus on the permeability of the membrane to sodium and potassium ions. These ions are the primary determinants of the membrane potential of many cell types, including neurons. Sodium and potassium ion channels are either passive or active.

Passive channels, or **leak channels**, are always open. However, their permeability can vary from moment to moment as the proteins that make up the channel change shape in response to local conditions. As noted earlier, leak channels are important in establishing the normal resting membrane potential of the cell (**Spotlight Figure 12–9**).

Plasma membranes also contain **active channels**, often called **gated channels**, which open or close in response to specific stimuli. Each gated channel can be in one of three states: (1) closed but capable of opening, (2) open (**activated**), or (3) closed and incapable of opening (**inactivated**).

Three classes of gated channels exist: chemically gated or ligand-gated channels, voltage-gated channels, and mechanically gated channels.

- Chemically gated channels, or ligand-gated channels, open or close when they bind specific chemicals (Figure 12–11a). The receptors that bind acetylcholine (ACh) at the neuromuscular junction are chemically gated channels. ⊃ p. 301 Chemically gated channels are most abundant on the dendrites and cell body of a neuron, the areas where most synaptic communication occurs.
- 2. Voltage-gated channels open or close in response to changes in the membrane potential. They are characteristic of areas of excitable membrane, a membrane capable of generating and propagating an action potential. Examples of excitable membranes are the axons of unipolar and multipolar neurons, and the sarcolemma (including

T tubules) of skeletal muscle fibers and cardiac muscle

3. Mechanically gated channels open or close in response to physical distortion of the membrane surface (Figure 12–11c). Such channels are important in sensory receptors that respond to touch, pressure, or vibration. We discuss these receptors in more detail in Chapter 15.

At the resting membrane potential, most gated channels are closed. When gated channels open, the rate of ion movement

closed; at -60 mV, the channel opens; at +30 mV. the channel is inactivated.

Figure 12–11 Gated Channels.
across the plasma membrane increases, changing the membrane potential.

The distribution of membrane channels varies from one region of the plasma membrane to another, affecting how and where a cell responds to specific stimuli. For example, chemically gated sodium channels are widespread on the surfaces of a neuron, but voltage-gated sodium channels are abundant on the axon, its branches, and the axon terminals. Mechanically gated channels are typically located only on the dendrites of sensory neurons. In later sections you will see how these differences in distribution affect the way the neurons function.

Graded Potentials

Graded potentials, or *local potentials*, are changes in the membrane potential that cannot spread far from the site of stimulation. Any stimulus that opens a gated channel produces a graded potential. Figure 12–12 shows what happens when a resting plasma membrane is exposed to a chemical that opens chemically gated sodium ion channels.

- Sodium ions enter the cell and are attracted to the negative charges along the inner surface of the membrane. As these additional positive charges spread out, the membrane potential shifts toward 0 mV. Any shift from the resting membrane potential toward a more positive potential is called a **depolarization**. Note that this term applies to changes in potential from -70 mV to smaller negative values (-65 mV, -45 mV, -10 mV), as well as to membrane potentials above 0 mV (+10 mV, +30 mV). In all these changes, the membrane potential becomes more positive.
- 2 As the plasma membrane depolarizes, sodium ions are released from its outer surface. These ions, along with other extracellular sodium ions, then move toward the open channels, replacing ions that have already entered the cell. This movement of positive charges parallel to the inner and outer surfaces of a membrane is called a **local current**.

In a graded potential, the degree of depolarization decreases with distance away from the stimulation site. Why? Depolarization lessens with distance because the cytosol offers considerable resistance to ion movement, and because some of the sodium ions entering the cell then move back out across the membrane through sodium leak channels. At some distance from the entry point, the effects on the membrane potential are undetectable.

The maximum change in the membrane potential is proportional to the size of the stimulus, which determines the number of open sodium channels. The more open channels, the more sodium ions enter the cell, the greater the membrane area affected, and the greater the degree of depolarization.

When a chemical stimulus is removed and normal membrane permeability is restored, the membrane potential soon returns to resting levels. The process of restoring the normal resting membrane potential after depolarization is called **repolarization** (Figure 12–13). Repolarization typically involves a combination of ion movement through membrane channels and the activities of ion pumps, especially the sodium–potassium exchange pump.

What happens to the membrane potential when a gated potassium ion channel opens? Opening a gated potassium channel has the opposite effect from opening a gated sodium channel. The rate of potassium ion outflow increases, and the interior of the cell loses positive ions. In other words, the inside of the cell becomes more negative. The loss of positive ions produces **hyperpolarization**, an increase in the negativity of the resting membrane potential, for example, from –70 mV to perhaps –80 mV or more. Again, a local current distributes the effect to adjacent portions of the plasma membrane, and the effect decreases with distance from the open channel or channels.

Graded potentials occur in the membranes of many types of cells—not just nerve and muscle cells, but epithelial cells, gland cells, adipocytes, and a variety of sensory receptors. Graded potentials often trigger specific cell functions. For example, a graded potential at the surface of a gland cell may trigger the exocytosis of secretory vesicles. Similarly, at a neuromuscular junction, the graded depolarization of the motor end plate by ACh triggers an action potential in adjacent portions of the sarcolemma. The motor end plate supports graded potentials, but the rest of the sarcolemma consists of excitable membrane. These areas of membrane are different because they have voltage-gated channels. **Table 12–2** summarizes the basic characteristics of graded potentials.

Table 12–2 Graded Potentials

Graded potentials, whether depolarizing or hyperpolarizing, share four basic characteristics:

- 1. The membrane potential is most changed at the site of stimulation, and the effect decreases with distance.
- 2. The effect spreads passively, due to local currents.
- 3. The graded change in membrane potential may involve either depolarization or hyperpolarization. The properties and distribution of the membrane channels involved determine the nature of the change. For example, in a resting membrane, the opening of sodium channels causes depolarization, whereas the opening of potassium channels causes hyperpolarization. That is, the change in membrane potential reflects whether positive charges enter or leave the cell.
- 4. The stronger the stimulus, the greater is the change in the membrane potential and the larger is the area affected.

Figure 12–12 Graded Potentials. The depolarization radiates in all directions away from the source of stimulation. For clarity, only gated channels are shown. Leak channels are present, but are not responsible for the production of graded potentials. Color changes in the plasma membrane indicate that the resting membrane potential has been disturbed and that the membrane potential is no longer –70 mV.

- 14. What effect would decreasing the concentration of extracellular potassium ions have on the membrane potential of a neuron?

See the blue Answers tab at the back of the book.

12-5 An action potential is an electrical event

Learning Outcome Describe the events involved in the generation and propagation of an action potential.

Action potentials are propagated changes in the membrane potential that, once initiated, affect an entire excitable membrane. These electrical events are also known as **nerve impulses**. Recall that voltage-gated sodium channels are abundant on the axon, its branches, and its axon terminals. The first step in generating an action potential is the opening of voltage-gated sodium ion channels at one site, usually the initial segment of the axon. The movement of sodium ions into the axon depolarizes adjacent sites, triggering the opening of additional voltage-gated sodium channels. The result is a chain reaction that spreads across the surface of the membrane like a line of falling dominoes. In this way, the action potential is propagated along the length of the axon, ultimately reaching the axon terminals.

The All-or-None Principle

The membrane potential at which an action potential begins is called the **threshold**. Threshold for an axon is typically between -60 mV and -55 mV, corresponding to a depolarization of 10 to 15 mV. A stimulus that shifts the resting membrane potential from -70 mV to -62 mV will not produce an action potential, only a graded depolarization. When such a stimulus is removed, the membrane potential returns to the resting level. The depolarization of the initial segment of the axon is caused by local currents resulting from the graded depolarization of the axon hillock.

The initial depolarization acts like pressure on the trigger of a gun. If you apply a slight pressure, the gun does not fire. It fires only when you apply a certain minimum pressure to the trigger. Once the pressure on the trigger reaches this threshold, the firing pin drops and the gun discharges. At that point, it no longer matters whether you applied the pressure gradually or suddenly or whether you moved just one finger or clenched your entire hand. The speed and range of the bullet that leaves the gun do not change, regardless of the forces that you applied to the trigger.

In the case of an axon or another area of excitable membrane, a graded depolarization is similar to the pressure on the trigger, and the action potential is like the firing of the gun. All stimuli that bring the membrane to threshold generate identical action potentials. In other words, the properties of the action potential are independent of the relative strength of the depolarizing stimulus, as long as that stimulus exceeds the threshold. This concept is the **all-or-none principle**, because a given stimulus either triggers a typical action potential, or none at all. The all-or-none principle applies to all excitable membranes.

Now let's take a closer look at how action potentials are generated and propagated. Generation and propagation are closely related concepts, in terms of both time and space: An action potential must be generated at one site before it can be propagated away from that site.

Generation of Action Potentials

Spotlight Figure 12–14 diagrams the steps involved in generating an action potential from the resting state. At the normal resting membrane potential, the activation gates of the voltage-gated sodium channels are closed. The steps are as follows: (1) depolarization to threshold, (2) activation of voltagegated sodium channels and rapid depolarization, (3) inactivation of voltage-gated sodium channels and activation of voltage-gated potassium channels, and (4) closing of voltagegated potassium channels.

The Refractory Period

The plasma membrane does not respond normally to additional depolarizing stimuli from the time an action potential begins until the normal resting membrane potential has stabilized. This period is known as the **refractory period** of the membrane. The membrane cannot respond to further stimulation from the moment the voltage-gated sodium channels open at threshold until sodium channel inactivation ends, because all the voltage-gated sodium channels either are already open or are inactivated. This first part of the refractory period, called the **absolute refractory** period, lasts 0.4–1.0 msec. (The smaller the axon diameter, the longer the duration.) The relative refractory period begins when the sodium channels regain their normal resting condition, and continues until the membrane potential stabilizes at resting levels. Another action potential can occur in this period if the membrane is sufficiently depolarized. That depolarization, however, requires a larger-than-normal stimulus, because (1) the local current must deliver enough Na⁺ to counteract the exit of positively charged K⁺ through open voltage-gated K^+ channels, and (2) the membrane is hyperpolarized to some degree through most of the relative refractory period.

TIPS&TRICKS

Flushing a toilet provides a useful analogy for an action potential. Nothing happens while you press the handle, until the water starts to flow (threshold is reached). After that, the amount of water that is released is independent of how hard or quickly you pressed the handle (all-or-none principle). Finally, you cannot flush the toilet again until the tank refills (refractory period).

The Role of the Sodium–Potassium Exchange Pump

In an action potential, depolarization results from the influx of Na^+ , and repolarization involves the loss of K^+ . Over time, the sodium–potassium exchange pump returns intracellular and extracellular ion concentrations to prestimulation levels. Compared with the total number of ions inside and outside the cell, however, the number involved in a single action potential is insignificant. Tens of thousands of action potentials can occur before intracellular ion concentrations change enough to disrupt the entire mechanism. For this reason, the exchange pump is not essential to any single action potential.

However, a maximally stimulated neuron can generate action potentials at a rate of 1000 per second. Under these circumstances, the exchange pump is needed to keep ion concentrations within acceptable limits over a prolonged period. The sodium–potassium exchange pump requires energy in the form of ATP. Each time the pump exchanges two extracellular potassium ions for three intracellular sodium ions, one molecule of ATP is broken down to ADP. Recall that the membrane protein of the exchange pump is *sodium–potassium ATPase*, which gets the energy to pump ions by splitting a phosphate group from a molecule of ATP, forming ADP. If the cell runs out of ATP, or if a metabolic poison inactivates sodium–potassium ATPase, the neuron will soon stop functioning.

Propagation of Action Potentials

The events that generate an action potential take place in a small portion of the total plasma membrane surface. But unlike graded potentials, which diminish rapidly with distance, action potentials spread along the entire excitable membrane. To understand how this happens, imagine that you are standing by the doors of a movie theater at the start of a long line. Everyone is waiting for the doors to open. The manager steps outside and says to you, "Let everyone know that we're opening in 15 minutes." How would you spread the news?

If you treated the line as an inexcitable membrane, you would shout, "The doors open in 15 minutes!" as loudly as you could. The closest people in the line would hear the news very clearly, but those farther away might not hear the entire message, and those at the end of the line might not hear you at all.

If, on the other hand, you treated the crowd as an excitable membrane, you would tell the message to the next person in line, with instructions to pass it on. In that way, the message would travel along the line undiminished, until everyone had heard the news. Such a message "moves" as each person repeats it to someone else. Distance is not a factor, and the line can contain 50 people or 5000.

Having each person repeat the message is comparable to the way an action potential spreads along an excitable membrane. An action potential (message) is relayed from one location to another in a series of steps. At each step, the message is repeated. Because the same events take place over and over, the term **propagation** is preferable to the term *conduction*, which suggests a flow of charge similar to that in a conductor such as a copper wire. (In fact, compared to wires, axons are poor conductors of electricity.) Action potentials may travel along an axon by continuous propagation (unmyelinated axons) or by saltatory propagation (myelinated axons).

Continuous Propagation

In an unmyelinated axon, an action potential moves along by **continuous propagation** (Spotlight Figure 12–15).

SPOTLIGHT

Figure 12–14 Generation of an Action Potential

Each neuron receives information in the form of graded potentials on its dendrites and cell body, and graded potentials at the synaptic terminals trigger the release of neurotransmitters. However, the two ends of the neuron may be a meter apart, and even the largest graded potentials affect only a tiny area. Such relatively long-range communication requires a different mechanism—the action potential. Action potentials are propagated changes in the membrane potential that, once initiated, affect an entire excitable membrane. Whereas the resting potential depends on leak channels and the graded potential we considered depends on chemically gated channels, action potentials depend on voltage-gated channels.

Steps in the formation of an action potential at the initial segment of an axon. The first step is a graded depolarizaton caused by the opening of chemically gated sodium ion channels, usually at the axon hillock. Note that when illustrating action potentials, we can ignore both the leak channels and the chemically gated channels, because their properties do not change. The membrane colors in steps 1-4 match the colors of the line graph showing membrane potential changes.

RESTING POTENTIAL

The axolemma contains both voltage-gated sodium channels and voltage-gated potassium channels that are closed when the membrane is at the resting potential.

KEY ⊕ = Sodium ion ⊕ = Potassium ion

The stimulus that initiates an action potential is a graded depolarization large enough to open voltage-gated sodium channels. The opening of the channels occurs at a membrane potential known as the threshold. Axon hillock

Initial segment

Activation of Sodium Channels and Rapid Depolarization

When the sodium channel activation gates open, the plasma membrane becomes much more permeable to Na⁺. Driven by the large electrochemical gradient, sodium ions rush into the cytoplasm, and rapid depolarization occurs. The inner membrane surface now contains more positive ions than negative ones, and the membrane potential has changed from –60 mV to a positive value.

Changes in the membrane potential at one location during the generation of an action potential. The circled numbers in the graph correspond to the steps illustrated below.

3 Inactivation of Sodium

Channels and Activation of Potassium Channels

As the membrane potential approaches +30 mV, the inactivation gates of the voltagegated sodium channels close. This step is known as **sodium channel inactivation**, and it coincides with the opening of voltagegated potassium channels. Positively charged potassium ions move out of the cytosol, shifting the membrane potential back toward resting levels. Repolarization now begins.

Closing of Potassium Channels

The voltage-gated sodium channels remain inactivated until the membrane has repolarized to near threshold levels. At this time, they regain their normal status: closed but capable of opening. The voltage-gated potassium channels begin closing as the membrane reaches the normal resting potential (about -70 mV). Until all of these potassium channels have closed, potassium ions continue to leave the cell. This produces a brief hyperpolarization.

RESTING POTENTIAL

As the voltage-gated potassium channels close, the membrane potential returns to normal resting levels. The action potential is now over, and the membrane is once again at the resting potential.

3

As the sodium ions entering at segment (2) spread laterally, a graded depolarization quickly brings the membrane in segment (3) to threshold, and the cycle is repeated.

Saltatory Propagation along a Myelinated Axon

Because myelin limits the movement of ions across the axon membrane, the action potential must "jump" from node to node during propagation. This results in much faster propagation along the axon.

For convenience, think of the plasma membrane as a series of adjacent segments.

The action potential begins at the axon's initial segment. For a brief moment at the peak of the action potential, the membrane potential becomes positive rather than negative (1). A local current then develops as sodium ions begin moving in the cytosol and the extracellular fluid (2). The local current spreads in all directions, depolarizing adjacent portions of the membrane. (The axon hillock cannot respond with an action potential because, like the rest of the cell body, it lacks voltagegated sodium channels.) The process then continues in a chain reaction (3 and 4).

Each time a local current develops, the action potential moves forward, but not backward, because the previous segment of the axon is still in the absolute refractory period. As a result, an action potential always proceeds away from the site of generation and cannot reverse direction. Eventually, the most distant portions of the plasma membrane are affected.

As in our "movie line" model, the message is relayed from one location to another. At each step along the way, the message is retold, so distance has no effect on the process. The action potential reaching the axon terminal is identical to the one generated at the initial segment. The net effect is the same as if a single action potential had traveled across the surface of the membrane.

In continuous propagation, an action potential appears to move across the surface of the membrane in a series of tiny steps. Even though the events at any one location take only about a millisecond, they must be repeated at each step along the way. Continuous propagation along unmyelinated axons occurs at a speed of about 1 meter per second (approximately 2 mph). For a second action potential to occur at the same site, a second stimulus must be applied.

TIPS&TRICKS

The "wave" performed by fans in a football stadium illustrates the continuous propagation of an action potential. The "wave" moves, but the people remain in place.

Saltatory Propagation

Saltatory propagation (*saltare*, leaping) in the CNS and PNS carries action potentials along an axon much more rapidly than does continuous propagation. To get the general idea, let's return to the line in front of the movie theater, and assume that it takes 1 second to relay the message to another person. In a model of continuous propagation, the people are jammed together. In 4 seconds, four people would hear the news, and the message would move perhaps 2 meters along the line. In a model of saltatory propagation, in contrast, the people in the line are spaced 5 meters apart. So after 4 seconds the same message would move 20 meters.

Table 12–3	A Comparison of Graded Potentials and Action Potentials				
Graded Potentials		Action Potentials			
Depolarizing or hyperpolarizing		Always depolarizing			
No threshold value		Depolarization to threshold must occur before action potential begins			
Amount of depola hyperpolarization on intensity of stin	rization or depends nulus	All-or-none; all stimuli that exceed threshold produce identical action potentials			
Passive spread from stimulation	n site of	Action potential at one site depolarizes adjacent sites to threshold			
Effect on membrane potential decreases with distance from stimulation site		Propagated along entire membrane surface without decrease in strength			
No refractory period		Refractory period occurs			
Occur in most plasma membranes		Occur only in excitable membranes of specialized cells such as neurons and muscle cells			

In a myelinated axon, the "people" are the nodes, and the spaces between them are the internodes wrapped in myelin (Figures 12–6b, 12–7a). Continuous propagation cannot occur along a myelinated axon, because myelin increases resistance to the flow of ions across the membrane. Ions can readily cross the plasma membrane only at the nodes. As a result, only the nodes with their voltage-gated channels can respond to a depolarizing stimulus.

When an action potential appears at the initial segment of a myelinated axon, the local current skips the internodes and depolarizes the closest node to threshold (Spotlight Figure 12–15). Because the nodes may be 1–2 mm apart in a large myelinated axon, the action potential "jumps" from node to node rather than moving along the axon in a series of tiny steps. In addition to being faster, saltatory propagation uses proportionately less energy, because less surface area is involved and fewer sodium ions must be pumped out of the cytoplasm.

Table 12–3 reviews the key differences between graded potentials and action potentials.

CHECKPOINT

- **15**. Define action potential.
- **16**. List the steps involved in the generation and propagation of an action potential.
- See the blue Answers tab at the back of the book.

12-6 Axon diameter, in addition to myelin, affects propagation speed

Learning Outcome Discuss the factors that affect the speed with which action potentials are propagated.

As we have seen, myelin greatly increases the propagation speed of action potentials. The diameter of the axon also affects the propagation speed, although less dramatically. Axon diameter is important because ions must move through the cytosol in order to depolarize adjacent portions of the plasma membrane. Cytosol offers much less resistance to ion movement than does the plasma membrane. In this instance, an axon behaves like an electrical cable: The larger the diameter, the lower the resistance. (That is why motors with large current demands, such as the starter on a car, an electric stove, or a big air conditioner, use such thick wires.)

We can classify axons into three groups according to the relationships among the diameter, myelination, and propagation speed:

- 1. **Type A fibers** are the largest myelinated axons, with diameters ranging from 4 to 20 μ m. These fibers carry action potentials at speeds of up to 120 meters per second, or 268 mph.
- 2. Type B fibers are smaller myelinated axons, with diameters of $2-4 \mu m$. Their propagation speeds average around 18 meters per second, or roughly 40 mph.
- **3. Type C fibers** are unmyelinated and less than 2 μm in diameter. These axons propagate action potentials at the leisurely pace of 1 meter per second, or a mere 2 mph.

The advantage of myelin becomes clear when you compare Type C to Type A fibers and note that the diameter increases tenfold but the propagation speed increases 120 times.

Type A fibers carry sensory information about position, balance, and delicate touch and pressure sensations from the skin surface to the CNS. The motor neurons that control skeletal muscles also send their commands over large, myelinated Type A axons.

Type B fibers and Type C fibers carry information to and from the CNS. They deliver temperature, pain, and general touch and pressure sensations. They also carry instructions to smooth muscle, cardiac muscle, glands, and other peripheral effectors.

Why isn't every axon in the nervous system large and myelinated? The most likely reason is that it would be physically impossible. If all sensory information were carried by large Type A fibers, your peripheral nerves would be the size of garden hoses, and your spinal cord would be the diameter of a garbage can. Instead, only about one-third of all axons carrying sensory information are myelinated, and most sensory information arrives over slender Type C fibers.

In essence, information transfer in the nervous system represents a compromise between propagation time and available space. Messages are routed according to priority: Urgent news sensory information about things that threaten survival and motor commands that prevent injury—travels over Type A fibers (the equivalent of instant messaging, or texting). Less urgent sensory information and motor commands are relayed by Type B fibers (e-mail) or Type C fibers (regular "snail mail").

- CHECKPOINT

- 17. What is the relationship between myelin and the propagation speed of action potentials?
- 18. Which of the following axons is myelinated: one that propagates action potentials at 50 meters per second, or one that carries them at 1 meter per second?

See the blue Answers tab at the back of the book.

12-7 At synapses, communication occurs among neurons or between neurons and other cells

Learning Outcome Describe the structure of a synapse, and explain the mechanism involved in synaptic activity.

In the nervous system, messages move from one location to another in the form of action potentials (nerve impulses) along axons. To be effective, a message must be not only propagated along an axon but also transferred in some way to another cell. This transfer takes place at synapses.

Synaptic Activity

At a synapse between two neurons, the nerve impulse passes from the **presynaptic neuron** to the **postsynaptic neuron**. Synapses may also involve other types of postsynaptic cells. For example, the neuromuscular junction is a synapse where the postsynaptic cell is a skeletal muscle fiber. Now let's take a closer look at the ways that synapses work.

General Properties of Synapses

A synapse may be *electrical*, with direct physical contact between the cells, or *chemical*, involving a neurotransmitter.

Electrical Synapses

At **electrical synapses**, the presynaptic and postsynaptic membranes are locked together at gap junctions (Figure 4–2, p. 117). The lipid portions of opposing membranes, separated by only 2 nm, are held in position by binding between integral membrane proteins called *connexons*. These proteins form pores that permit ions to pass between the cells. Because the two cells are linked in this way, changes in the membrane potential of one cell produce local currents that affect the other cell as if the two shared a common membrane. As a result, an electrical synapse propagates action potentials quickly and efficiently from one cell to the next. Electrical synapses are extremely rare in both the CNS and PNS. They occur in some areas of the brain, including the vestibular nuclei, the eye, and in at least one pair of PNS ganglia (the ciliary ganglia).

Chemical Synapses

The situation at a **chemical synapse** is far more variable than that at an electrical synapse, because the cells are not directly coupled. For example, an action potential that reaches an electrical synapse is *always* propagated to the next cell. But at a chemical synapse, an arriving action potential *may or may not* release enough neurotransmitter to bring the postsynaptic neuron to threshold. In addition, other factors may intervene and make the postsynaptic cell more or less sensitive to arriving stimuli. In essence, the postsynaptic cell at a chemical synapse is not a slave to the presynaptic neuron, and its activity can be adjusted, or "tuned," by a variety of factors.

Chemical synapses are by far the most abundant type of synapse. Most synapses between neurons, and all communications between neurons and other types of cells, involve chemical synapses. Normally, communication across a chemical synapse takes place in only one direction: from the presynaptic membrane to the postsynaptic membrane.

Acetylcholine (ACh) is the neurotransmitter that has received most of our attention so far, but there are other important chemical transmitters. Based on their effects on postsynaptic membranes, neurotransmitters are often classified as excitatory or inhibitory. **Excitatory neurotransmitters** cause depolarization and promote the generation of action potentials. **Inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.

This classification is useful, but not always precise. For example, acetylcholine typically produces a depolarization in the postsynaptic membrane, but acetylcholine released at neuromuscular junctions in the heart has an inhibitory effect, producing a transient hyperpolarization of the postsynaptic membrane. This situation highlights an important aspect of neurotransmitter function: *The effect of a neurotransmitter on the postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter.*

Let's continue our discussion of chemical synapses with a look at a synapse that releases the neurotransmitter **acetylcholine (ACh)**. Then we will introduce other important neurotransmitters that you will encounter in later chapters.

Cholinergic Synapses

Synapses that release ACh are known as **cholinergic synapses**. The neuromuscular junction is an example of a cholinergic synapse. **D p**. **300** ACh is the most widespread (and best-studied) neurotransmitter. It is released (1) at all neuromuscular

junctions involving skeletal muscle fibers, (2) at many synapses in the CNS, (3) at all neuron-to-neuron synapses in the PNS, and (4) at all neuromuscular and neuroglandular junctions in the parasympathetic division of the ANS.

At a cholinergic synapse between two neurons, the presynaptic and postsynaptic membranes are separated by a synaptic cleft that averages 20 nm (0.02 μ m) in width. Most of the ACh in the axon terminal is packaged in synaptic vesicles, each containing several thousand molecules of the neurotransmitter. A single axon terminal may contain a million such vesicles.

TIPS&TRICKS

Cholinergic synapses are so named because the neurotransmitter involved is acetyl**cholin**e.

Events at a Cholinergic Synapse

Figure 12–16 diagrams the events that take place at a cholinergic synapse between neurons after an action potential arrives at an axon terminal. For convenience, we will assume that this synapse is adjacent to the initial segment of the axon, an arrangement that is easy to illustrate.

- An Action Potential Arrives and Depolarizes the Axon Terminal. The normal stimulus for neurotransmitter release is the depolarization of the axon terminal by the arrival of an action potential.
- 2 *Extracellular Calcium Ions Enter the Axon Terminal, Triggering the Exocytosis of ACh.* The depolarization of the axon terminal briefly opens its voltage-gated calcium channels, allowing calcium ions to rush in. Their arrival triggers exocytosis of ACh into the synaptic cleft. The ACh is released in packets of roughly 3000 molecules, the average number of ACh molecules in a single vesicle. ACh release stops very soon, because active transport mechanisms rapidly remove the calcium ions from the terminal cytosol. These ions are either pumped out of the cell or transferred into mitochondria.

ACh Binds to Receptors and Depolarizes the Postsynaptic Membrane. ACh diffuses across the synaptic cleft toward receptors on the postsynaptic membrane. These ACh receptors are chemically gated ion channels. The primary response is an increased permeability to Na⁺, producing a depolarization in the postsynaptic membrane that lasts about 20 msec. (These cation channels also let potassium ions out of the cell, but because sodium ions are driven by a much stronger electrochemical gradient, the net effect is a slight depolarization of the postsynaptic membrane.)

This depolarization is a graded potential. The greater the amount of ACh released at the presynaptic membrane,

Figure 12–16 Events in the Functioning of a Cholinergic Synapse.

the greater the number of open cation channels in the postsynaptic membrane, and so the larger the depolarization. If the depolarization brings an adjacent area of excitable membrane (such as the initial segment of an axon) to threshold, an action potential appears in the postsynaptic neuron.

4 ACh Is Removed by AChE. The neurotransmitter's effects on the postsynaptic membrane are temporary, because the synaptic cleft and the postsynaptic membrane contain the enzyme *acetylcholinesterase* (*AChE*, or *cholinesterase*). Roughly half of the ACh released at the presynaptic membrane is broken down before it reaches receptors on the postsynaptic membrane. ACh molecules that bind to receptor sites are generally broken down within 20 msec of their arrival.

AChE breaks down molecules of ACh (by hydrolysis) into **acetate** and **choline**. The choline is actively absorbed by the axon terminal and is used to synthesize more ACh, using acetate provided by *coenzyme A* (*CoA*). (Recall from Chapter 2 that coenzymes derived from vitamins are required in many enzymatic reactions. \bigcirc **p**. 55) Acetate diffusing away from the synapse can be absorbed and metabolized by the postsynaptic cell or by other cells and tissues.

Synaptic Delay

A **synaptic delay** of 0.2–0.5 msec occurs between the arrival of the action potential at the axon terminal and the effect on the postsynaptic membrane. Most of that delay reflects the time involved in calcium influx and neurotransmitter release, not in the neurotransmitter's diffusion—the synaptic cleft is narrow, and neurotransmitters can diffuse across it in very little time.

Although a delay of 0.5 msec is not very long, in that time an action potential may travel more than 7 cm (about 3 in.) along a myelinated axon. When information is being passed along a chain of interneurons in the CNS, the cumulative synaptic delay may exceed the propagation time along the axons. This is why reflexes are important for survival—they involve only a few synapses and thus provide rapid and automatic responses to stimuli. The fewer synapses involved, the shorter the total synaptic delay and the faster the response. The fastest reflexes have just one synapse, with a sensory neuron directly controlling a motor neuron. The muscle spindle reflexes, discussed in Chapter 13, are arranged in this way.

Synaptic Fatigue

Because ACh molecules are recycled, the axon terminal is not totally dependent on the ACh synthesized in the cell body and delivered by axoplasmic transport. But under intensive stimulation, resynthesis and transport mechanisms may not keep up with the demand for neurotransmitter. **Synaptic fatigue** then occurs, and the synapse weakens until ACh has been replenished.

- CHECKPOINT

- 19. Describe the general structure of a synapse.
- If a synapse involves direct physical contact between cells, it is termed _____; if the synapse involves a neurotransmitter, it is termed _____.
- 21. What effect would blocking voltage-gated calcium ion channels at a cholinergic synapse have on synaptic communication?
- 22. One pathway in the central nervous system consists of three neurons, another of five neurons. If the neurons in the two pathways are identical, what process will determine which pathway will transmit impulses more rapidly?

See the blue Answers tab at the back of the book.

12-8 Neurotransmitters and neuromodulators have various functions

Learning Outcome Describe the major types of neurotransmitters and neuromodulators, and discuss their effects on postsynaptic membranes.

Now that we have examined the actions of acetylcholine at cholinergic synapses, let's consider the actions of other neurotransmitters, and of neuromodulators, which change the cell's response to neurotransmitters.

The Activities of Other Neurotransmitters

The nervous system relies on a complex form of chemical communication. Each neuron is continuously exposed to a variety of neurotransmitters. Some usually have excitatory effects, while others usually have inhibitory effects. Yet in all cases, the effects depend on the nature of the receptor rather than the structure of the neurotransmitter. (Many drugs affect the nervous system by stimulating receptors that otherwise respond only to neurotransmitters. These drugs can have complex effects on perception, motor control, and emotional states.)

Major categories of neurotransmitters include *biogenic amines, amino acids, neuropeptides, dissolved gases,* and a variety of other compounds. Here we introduce only a few of the most important neurotransmitters. You will encounter additional examples in later chapters.

• **Norepinephrine** (nor-ep-i-NEF-rin), or **NE**, is a neurotransmitter that is widely distributed in the brain and

in portions of the ANS. Norepinephrine is also called *noradrenaline*, and synapses that release NE are known as **adrenergic synapses**. Norepinephrine typically has an excitatory, depolarizing effect on the postsynaptic membrane, but the mechanism is quite distinct from that of ACh, as we will see in Chapter 16.

- **Dopamine** (DŌ-puh-mēn) is a CNS neurotransmitter released in many areas of the brain. It may have either inhibitory or excitatory effects. Inhibitory effects play an important role in our precise control of movements. For example, dopamine release in one portion of the brain prevents the overstimulation of neurons that control skeletal muscle tone. If the neurons that produce dopamine are damaged or destroyed, the result can be the characteristic rigidity and stiffness of *Parkinson's disease*, a condition we describe in Chapter 14. At other sites, dopamine release has excitatory effects. Cocaine inhibits the removal of dopamine from synapses in specific areas of the brain. The resulting rise in dopamine concentrations at these synapses is responsible for the "high" experienced by cocaine users.
- **Serotonin** (ser-ō-TŌ-nin) is another important CNS neurotransmitter. Inadequate serotonin production can have widespread effects on a person's attention and emotional states and may be responsible for many cases of severe chronic depression. *Fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft),* and related antidepressant drugs inhibit the reabsorption of serotonin by axon terminals (hence their classification as selective serotonin *reuptake inhibitors, or SSRIs*). This inhibition leads to increased serotonin concentrations at synapses, and over time, the increase may relieve the symptoms of depression. Interactions among serotonin, norepinephrine, and other neurotransmitters are thought to be involved in the regulation of sleep and wake cycles.
- Gamma-aminobutyric (a-MĒ-nō-bū-TĒR-ik) acid, or GABA, generally has an inhibitory effect. Roughly 20 percent of the synapses in the brain release GABA, but its functions remain incompletely understood. In the CNS, GABA release appears to reduce anxiety, and some antianxiety drugs work by enhancing this effect.

The functions of many neurotransmitters are not well understood. In a clear demonstration of the principle "the more you look, the more you see," over 100 neurotransmitters have been identified, including certain amino acids, peptides, polypeptides, prostaglandins, and ATP.

In addition, two gases, nitric oxide and carbon monoxide, are known to be important neurotransmitters. **Nitric oxide** (**NO**) is generated by axon terminals that innervate smooth muscle in the walls of blood vessels in the PNS, and at synapses

in several regions of the brain. **Carbon monoxide (CO)**, best known as a component of automobile exhaust, is also generated by specialized axon terminals in the brain, where it functions as a neurotransmitter.

Neuromodulators

It is convenient to discuss each synapse as if it were releasing only one chemical, but axon terminals may release a mixture of active compounds, either through diffusion across the membrane or by exocytosis, along with neurotransmitter molecules. These compounds may have a variety of functions. Those that alter the rate of neurotransmitter release by the presynaptic neuron or change the postsynaptic cell's response to neurotransmitters are called **neuromodulators** (noo-rō-MOD-ū-lā-torz). These substances are typically **neuropeptides**, small peptide chains synthesized and released by the axon terminal. Most neuromodulators act by binding to receptors in the presynaptic or postsynaptic membranes and activating cytoplasmic enzymes.

Neuromodulators called **opioids** (\overline{O} -p \overline{e} -oydz) have effects similar to those of the drugs *opium* and *morphine*, because they bind to the same group of postsynaptic receptors. Four classes of opioids in the CNS are (1) **endorphins** (en-DOR-finz), (2) **enkephalins** (en-KEF-a-linz), (3) **endomorphins**, and (4) **dynorphins** ($D\overline{I}$ -nor-finz). The primary function of opioids is probably to relieve pain. They inhibit the release of the neurotransmitter *substance P* at synapses that relay pain sensations. Dynorphins have far more powerful pain-relieving effects than morphine or the other opioids.

TIPS&TRICKS

*Endorphin*s are so named because they act like *endo*genous (coming from within the body) m*orphin*e.

In general, neuromodulators (1) have long-term effects that are relatively slow to appear; (2) trigger responses that involve a number of steps and intermediary compounds; (3) may affect the presynaptic membrane, the postsynaptic membrane, or both; and (4) can be released alone or along with a neurotransmitter. Table 12–4 lists major neurotransmitters and neuromodulators of the brain and spinal cord, and their primary effects (if known). In practice, it can be very difficult to distinguish neurotransmitters from neuromodulators on either biochemical or functional grounds: A neuropeptide may function in one site as a neuromodulator and in another as a neurotransmitter. For this reason, Table 12–4 does not distinguish between neurotransmitters and neuromodulators.

12

Table 12–4	Representative Neurotransmitters and Neuromodulators						
Class and Neurotransmitter	Chemical Structure	Mechanism of Action	Location(s)	Comments			
Acetylcholine	$\begin{array}{c} CH_3 & O\\ I & I\\ CH_3 - N^+ - CH_2 - CH_2 - O - C - CH_3\\ I\\ CH_3 \end{array}$	Primarily direct, through binding to chemically gated channels	CNS: Synapses throughout brain and spinal cord PNS: Neuromuscular junctions; preganglionic synapses of ANS; neuroglandular junctions of parasympathetic division and (rarely) sympathetic division of ANS; amacrine cells of retina	Widespread in CNS and PNS; best known and most studied of the neurotransmitters			
BIOGENIC AMINES							
Norepinephrine	$\overset{OH}{\overset{I}{}}_{VH_2-CH_2-CH} \xrightarrow{OH}_{OH} OH$	Indirect: G proteins and second messengers	CNS: Cerebral cortex, hypothalamus, brain stem, cerebellum, spinal cord PNS: Most neuromuscular and neuroglandular junctions of sympathetic division of ANS	Involved in attention and consciousness, control of body temperature, and regulation of pituitary gland secretion			
Epinephrine	$CH_2 - NH - CH_2 - CH - OH OH OH OH$	Indirect: G proteins and second messengers	CNS: Thalamus, hypothalamus, midbrain, spinal cord	Uncertain functions			
Dopamine	NH2-CH2-CH2-OH	Indirect: G proteins and second messengers	CNS: Hypothalamus, midbrain, limbic system, cerebral cortex, retina	Regulation of subconscious motor function; receptor abnormalities have been linked to development of schizophrenia			
Serotonin	$NH_2-CH_2-CH_2-CH_2$ OH	Primarily indirect: G proteins and second messengers	CNS: Hypothalamus, limbic system, cerebellum, spinal cord, retina	Important in emotional states, moods, and body temperature; several illegal hallucinogenic drugs, such as Ecstasy, target serotonin receptors			
Histamine	$NH_2 - CH_2 - CH_2 - CH_2$	Indirect: G proteins and second messengers	CNS: Neurons in hypothalamus, with axons projecting throughout the brain	Receptors are primarily on presynaptic membranes; functions in sexual arousal, pain threshold, pituitary hormone secretion, thirst, and blood pressure control			
AMINO ACIDS							
<i>Excitatory:</i> Glutamate	ос-сн-сн ₂ -сн ₂ -ссоон но Ин ₂	Indirect: G proteins and second messengers Direct: opens calcium/ sodium channels on pre- and postsynaptic membranes	CNS: Cerebral cortex and brain stem	Important in memory and learning; most important excitatory neurotransmitter in the brain			
Aspartate	ос-сн-сн ₂ -ссонности и странати	Direct or indirect (G proteins), depending on type of receptor	CNS: Cerebral cortex, retina, and spinal cord	Used by pyramidal cells in the brain that provide voluntary motor control over skeletal muscles			
Inhibitory: Gamma- aminobutyric acid (GABA)	NH2-CH2-CH2-CH2-CC	Direct or indirect (G proteins), depending on type of receptor	CNS: Cerebral cortex, cerebellum, interneurons throughout brain and spinal cord	Direct effects: open Cl ⁻ channels; indirect effects: open K ⁺ channels and block entry of Ca ²⁺			
Glycine	NH2-CH2-COH	Direct: Opens Cl ⁻ channels	CNS: Interneurons in brain stem, spinal cord, and retina	Produces postsynaptic inhibition; the poison <i>strychnine</i> produces fatal convulsions by blocking glycine receptors			

(Continued)

Table 12–4	(continued)			
Class and Neurotransmitter	Chemical Structure	Mechanism of Action	Location(s)	Comments
NEUROPEPTIDES				
Substance P	Arg Pro Lys Pro Glu Glu Phe Met Leu	Indirect: G proteins and second messengers	CNS: Synapses of pain receptors within spinal cord, hypothalamus, and other areas of the brain PNS: Enteric nervous system (network of neurons along the digestive tract)	Important in pain pathway, regulation of pituitary gland function, control of digestive tract reflexes
Neuropeptide Y	36-amino-acid peptide	Indirect: G proteins and second messengers	CNS: hypothalamus PNS: sympathetic neurons	Stimulates appetite and food intake
Opioids Endorphins	31-amino-acid peptide	Indirect: G proteins and second messengers	CNS: Thalamus, hypothalamus, brain stem, retina	Pain control; emotional and behavioral effects poorly understood
Enkephalins	Tyr Gly Gy Phe Met	Indirect: G proteins and second messengers	CNS: Basal nuclei, hypothalamus, midbrain, pons, medulla oblongata, spinal cord	Pain control; emotional and behavioral effects poorly understood
Endomorphin	9- or 10-amino-acid peptide	Indirect: G proteins and second messengers	CNS: Thalamus, hypothalamus, basal nuclei	Pain control; emotional and behavioral effects poorly understood
Dynorphin	(In Asp Asp Trp Lys Leu Lys Pro	Indirect: G proteins and second messengers	CNS: Hypothalamus, midbrain, medulla oblongata	Pain control; emotional and behavioral effects poorly understood
PURINES				
PURINES ATP, GTP	(see Figure 2–25)	Direct or indirect (G proteins), depending on type of receptor	CNS: Spinal cord PNS: Autonomic ganglia	
PURINES ATP, GTP Adenosine	(see Figure 2–25) (see Figure 2–25)	Direct or indirect (G proteins), depending on type of receptor Indirect: G proteins and second messengers	CNS: Spinal cord PNS: Autonomic ganglia CNS: Cerebral cortex, hippocampus, cerebellum	Produces drowsiness; stimulatory effect of caffeine is due to inhibition of adenosine activity
PURINES ATP, GTP Adenosine HORMONES	(see Figure 2–25) (see Figure 2–25)	Direct or indirect (G proteins), depending on type of receptor Indirect: G proteins and second messengers	CNS: Spinal cord PNS: Autonomic ganglia CNS: Cerebral cortex, hippocampus, cerebellum	Produces drowsiness; stimulatory effect of caffeine is due to inhibition of adenosine activity
PURINES ATP, GTP Adenosine HORMONES ADH, oxytocin, insulin, glucagon, secretin, CCK, GIP, VIP, inhibins, ANP, BNP, and many others	(see Figure 2–25) (see Figure 2–25) Peptide containing fewer than 200 amino acids	Direct or indirect (G proteins), depending on type of receptor Indirect: G proteins and second messengers Typically indirect: G proteins and second messengers	CNS: Spinal cord PNS: Autonomic ganglia CNS: Cerebral cortex, hippocampus, cerebellum CNS: Brain (widespread)	Produces drowsiness; stimulatory effect of caffeine is due to inhibition of adenosine activity Numerous, complex, and incompletely understood
PURINES ATP, GTP Adenosine Adenosine HORMONES ADH, oxytocin, insulin, glucagon, secretin, CCK, GIP, VIP, inhibins, ANP, BNP, and many others GASES	(see Figure 2–25) (see Figure 2–25) Peptide containing fewer than 200 amino acids	Direct or indirect (G proteins), depending on type of receptor Indirect: G proteins and second messengers Typically indirect: G proteins and second messengers	CNS: Spinal cord PNS: Autonomic ganglia CNS: Cerebral cortex, hippocampus, cerebellum CNS: Brain (widespread)	Produces drowsiness; stimulatory effect of caffeine is due to inhibition of adenosine activity Numerous, complex, and incompletely understood

How Neurotransmitters and Neuromodulators Work

Functionally, neurotransmitters and neuromodulators fall into one of three groups: (1) *compounds that have a direct effect on membrane potential*, (2) *compounds that have an indirect effect on membrane potential*, or (3) *lipid-soluble gases that exert their effects inside the cell*.

Compounds that have direct effects on membrane potential open or close gated ion channels (Figure 12–17a). Examples include ACh and the amino acids *glycine* and *aspartate*. Because these neurotransmitters alter ion movement across the membrane, they are said to have *ionotropic effects*. A few neurotransmitters, notably glutamate, GABA, NE, and serotonin, have both direct and indirect effects, because these compounds target two different classes of receptors. The direct effects are ionotropic. The indirect effects, which involve changes in the metabolic activity of the postsynaptic cell, are called *metabotropic*.

Compounds that have an indirect effect on membrane potential work through intermediaries known as *second messengers*. The neurotransmitter represents a *first messenger*, because it delivers the message to receptors on the plasma membrane or within the cell. Second messengers are ions or molecules that are produced or released inside the cell when a first messenger binds to one of these receptors.

Many neurotransmitters—including epinephrine, norepinephrine, dopamine, serotonin, histamine, and GABA—and many neuromodulators bind to receptors in the plasma membrane. In these instances, the link between the first messenger and the second messenger involves a **G protein**, an enzyme complex coupled to a membrane receptor. The name *G protein* refers to the fact that these proteins bind GTP, a high-energy compound introduced in Chapter 2. \bigcirc p. 59 Several types of G protein exist, but each type includes an enzyme that is "turned on" when an extracellular compound binds to its associated receptor at the cell surface.

Figure 12–17b shows one possible result of this binding: the activation of the enzyme **adenylate cyclase**. This enzyme converts ATP, the energy currency of the cell, to *cyclic-AMP*, a ring-shaped form of the compound AMP that was introduced in Chapter 2. ⊃ p. 58 The conversion takes place at the inner surface of the plasma membrane. Cyclic-AMP (cAMP) is a second messenger that may open membrane channels, activate intracellular enzymes, or both, depending on the nature of the postsynaptic cell. This is only an overview of the function of one type of G protein. We examine several types of G proteins more closely in later chapters.

Two lipid-soluble gases, nitric oxide (NO) and carbon monoxide (CO), are known to be important neurotransmitters in specific regions of the brain. Because they can diffuse

Figure 12–17 Mechanisms of Neurotransmitter Function.

through lipid membranes, these gases can enter the cell and bind to enzymes on the inner surface of the plasma membrane or elsewhere in the cytoplasm (Figure 12–17c). These enzymes then promote the appearance of second messengers that can affect cellular activity.

CHECKPOINT

- 23. Differentiate between a neurotransmitter and a neuromodulator.
- 24. Identify the three functional groups of neurotransmitters and neuromodulators.

See the blue Answers tab at the back of the book.

12-9 Individual neurons process information by integrating excitatory and inhibitory stimuli

Learning Outcome Discuss the interactions that enable information processing to occur in neural tissue.

A single neuron may receive information across thousands of synapses. As we have seen, some of the neurotransmitters arriving at the postsynaptic cell at any moment may be excitatory, and others may be inhibitory. So how does the neuron respond? The net effect on the membrane potential of the cell body—specifically, in the area of the axon hillock—determines how the neuron responds from moment to moment. If the net effect is a depolarization at the axon hillock, that depolarization affects the membrane potential at the initial segment. If threshold is reached at the initial segment, an action potential is generated and propagated along the axon.

Thus it is really the axon hillock that integrates the excitatory and inhibitory stimuli affecting the cell body and dendrites at any given moment. This integration process, which determines the rate of action potential generation at the initial segment, is the simplest level of **information processing** in the nervous system. The excitatory and inhibitory stimuli are integrated through interactions between *postsynaptic potentials*, which we discuss next. Higher levels of information processing involve interactions among neurons and among groups of neurons. We address these topics in later chapters.

Postsynaptic Potentials

Postsynaptic potentials are graded potentials that develop in the postsynaptic membrane in response to a neurotransmitter. (Figure 12–13 illustrated graded depolarizations and hyperpolarizations.) Two major types of postsynaptic potentials develop at neuron-to-neuron synapses: excitatory postsynaptic potentials and inhibitory postsynaptic potentials.

An **excitatory postsynaptic potential**, or **EPSP**, is a graded depolarization caused by the arrival of a neurotransmitter at the postsynaptic membrane. An EPSP results from the opening of chemically gated membrane channels that lead to depolarization of the plasma membrane. For example, the graded depolarization produced by the binding of ACh is an EPSP. Because

it is a graded potential, an EPSP affects only the area immediately surrounding the synapse, as shown in Figure 12–12.

We have already noted that not all neurotransmitters have an excitatory (depolarizing) effect. An **inhibitory postsynaptic potential**, or **IPSP**, is a graded hyperpolarization of the postsynaptic membrane. For example, an IPSP may result from the opening of chemically gated potassium channels. While the hyperpolarization continues, the neuron is said to be **inhibited**, because a larger-than-usual depolarizing stimulus is needed to bring the membrane potential to threshold. A stimulus that shifts the membrane potential by 10 mV (from –70 mV to –60 mV) would normally produce an action potential, but if the membrane potential were reset at –85 mV by an IPSP, the same stimulus would depolarize it to only –75 mV, which is below threshold.

Summation

An individual EPSP has a small effect on the membrane potential, typically producing a depolarization of about 0.5 mV at the postsynaptic membrane. Before an action potential will arise in the initial segment, local currents must depolarize that region by at least 10 mV. Therefore, a single EPSP will not result in an action potential, even if the synapse is on the axon hillock. But individual EPSPs combine through the process of **summation**, which integrates the effects of all the graded potentials that affect one portion of the plasma membrane. The graded potentials may be EPSPs, IPSPs, or both. We will consider EPSPs in our discussion. Two forms of summation exist: temporal summation and spatial summation (Figure 12–18).

Temporal summation (tempus, time) is the addition of stimuli occurring in rapid succession at a single synapse that is active repeatedly. This form of summation can be likened to using a bucket to fill up a bathtub: You can't fill the tub with a single bucket of water, but you will fill it eventually if you keep repeating the process. In the case of temporal summation, the water in a bucket corresponds to the sodium ions that enter the cytosol during an EPSP. A typical EPSP lasts about 20 msec, but under maximum stimulation an action potential can reach the axon terminal each millisecond. Figure 12–18a shows what happens when a second EPSP arrives before the effects of the first EPSP have disappeared: The effects of the two are combined. Every time an action potential arrives, a group of vesicles discharges ACh into the synaptic cleft, and every time more ACh molecules arrive at the postsynaptic membrane, more chemically gated channels open, and the degree of depolarization increases. In this way, a series of small steps can eventually bring the initial segment to threshold.

Spatial summation occurs when simultaneous stimuli applied at different locations have a cumulative effect on the membrane potential. In other words, spatial summation involves *multiple synapses* that are active *simultaneously*. In terms of our bucket analogy, you could fill the bathtub immediately if 50 friends emptied their buckets into it all at the same time.

a **Temporal Summation**. Temporal summation occurs on a membrane that receives two depolarizing stimuli from the same source in rapid succession. The effects of the second stimulus are added to those of the first.

b Spatial Summation. Spatial summation occurs when sources of stimulation arrive simultaneously, but at different locations. Local currents spread the depolarizing effects, and areas of overlap experience the combined effects.

In spatial summation, more than one synapse is active at the same time (Figure 12–18b), and each "pours" sodium ions across the postsynaptic membrane, producing a graded potential with localized effects. At each active synapse, the sodium ions that produce the EPSP spread out along the inner surface of the membrane and mingle with those entering at other synapses. As a result, the effects on the initial segment are cumulative. The degree of depolarization depends on how many synapses are active at any moment, and on their distance from the initial segment. As in temporal summation, an action potential results when the membrane potential at the initial segment reaches threshold.

Facilitation

Now consider a situation in which summation of EPSPs is under way, but the initial segment has not been depolarized to threshold. The closer the initial segment gets to threshold, the easier it will be for the *next* depolarizing stimulus to trigger an action potential. A neuron whose membrane potential shifts closer to threshold is said to be **facilitated**. The larger the degree of facilitation, the smaller is the additional stimulus needed to trigger an action potential. In a highly facilitated neuron, even a small depolarizing stimulus produces an action potential.

Facilitation can result from the summation of EPSPs or from the exposure of a neuron to certain drugs in the extracellular fluid. For example, the nicotine in cigarettes stimulates postsynaptic ACh receptors, producing prolonged EPSPs that facilitate CNS neurons. Nicotine also increases the release of another neurotransmitter, dopamine, producing feelings of pleasure and reward, thereby leading to addiction.

Summation of EPSPs and IPSPs

Like EPSPs, IPSPs combine spatially and temporally. EPSPs and IPSPs reflect the activation of different types of chemically gated channels, producing opposing effects on the membrane potential. The antagonism between IPSPs and EPSPs is important in cellular information processing. In terms of our bucket **Figure 12–19** Interactions between EPSPs and IPSPs. At time 1, a small depolarizing stimulus produces an EPSP. At time 2, a small hyperpolarizing stimulus produces an IPSP of comparable magnitude. If the two stimuli are applied simultaneously, as they are at time 3, summation occurs. Because the two are equal in size but have opposite effects, the membrane potential remains at the resting level. If the EPSP were larger, a net depolarization would result; if the IPSP were larger, a net hyperpolarization would result; if the IPSP were larger, a net hyperpolarization would result; if the IPSP were larger, a net hyperpolarization would result; if the IPSP were larger, a net hyperpolarization would result instead.

analogy, EPSPs put water into the bathtub, and IPSPs take water out. If more buckets add water than remove water, the water level in the tub rises. If more buckets remove water, the level falls. If a bucket of water is removed every time another bucket is dumped in, the level remains stable. Comparable interactions between EPSPs and IPSPs determine the membrane potential at the boundary between the axon hillock and the initial segment (Figure 12–19).

Neuromodulators, hormones, or both can change the postsynaptic membrane's sensitivity to excitatory or inhibitory neurotransmitters. By shifting the balance between EPSPs and IPSPs, these compounds promote facilitation or inhibition of CNS and PNS neurons.

Presynaptic Inhibition and Presynaptic Facilitation

Inhibitory or excitatory responses may occur not only at synapses involving the cell body and dendrites, but also at synapses found along an axon or its collaterals. At an *axoaxonic* (axon to axon) *synapse*, a synapse occurs between the axons of two neurons. An axoaxonic synapse at the axon terminal can either decrease (inhibit) or increase (facilitate) the rate of neurotransmitter release at the presynaptic membrane. In one form of **presynaptic inhibition**, the release of GABA inhibits the opening of voltage-gated calcium channels in the axon terminal (**Figure 12–20a**). This inhibition reduces the amount of neurotransmitter released when an action potential arrives there, and thus reduces the effects of synaptic activity on the postsynaptic membrane.

In **presynaptic facilitation**, activity at an axoaxonic synapse increases the amount of neurotransmitter released when an action potential arrives at the axon terminal (Figure 12–20b). This increase enhances and prolongs the neurotransmitter's effects on the postsynaptic membrane. The neurotransmitter *serotonin* is involved in presynaptic facilitation. In the presence of serotonin released at an axoaxonic synapse, voltage-gated calcium channels remain open longer.

The Rate of Generation of Action Potentials

In the nervous system, complex information is translated into action potentials that are propagated along axons. On arrival, the message is often interpreted solely on the basis of the frequency of action potentials. For example, action potentials arriving at a neuromuscular junction at the rate of 1 per second may produce a series of isolated twitches in the associated skeletal muscle fiber, but at the rate of 100 per second they cause a sustained tetanic contraction. Similarly, you may perceive a few action potentials per second along a sensory fiber as a featherlight touch, but you would perceive hundreds of action potentials per second along that same axon as unbearable pressure. In general, the degree of sensory stimulation or the strength of the motor response is proportional to the frequency of action potentials. In this section, we examine factors that vary the rate of generation of action potentials.

If a graded potential briefly depolarizes the axon hillock such that the initial segment reaches its threshold, an action potential is propagated along the axon. But what happens when the axon hillock *remains* depolarized past threshold for an extended period? The longer the initial segment remains above threshold, the more action potentials it produces. The *frequency* of action potentials depends on the degree of depolarization

b Presynaptic facilitation

above threshold: The greater the degree of depolarization, the higher the frequency of action potentials. The membrane can respond to a second stimulus as soon as the absolute refractory period ends. Holding the membrane above threshold has the same effect as applying a second, larger-than-normal stimulus.

Action potentials can be generated at a maximum rate when the relative refractory period has been completely eliminated. For this reason, the maximum theoretical frequency of action potentials is established by the duration of the absolute refractory period. The absolute refractory period is shortest in large-diameter axons, in which the *theoretical* maximum frequency of action potentials is 2500 per second. However, the highest frequencies recorded from axons in the body range between 500 and 1000 per second.

Table 12–5 summarizes the basic principles of information processing.

Table 12–5 Information Processing

- Information is relayed in the form of action potentials. In general, the degree of sensory stimulation or the strength of the motor response is proportional to the frequency of action potentials.
- The neurotransmitters released at a synapse may have either excitatory or inhibitory effects. The effect on the axon's initial segment reflects a summation of the stimuli that arrive at any moment. The frequency of generation of action potentials is an indication of the degree of sustained depolarization at the axon hillock.
- Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters.
- Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators.
- The response of a postsynaptic neuron to the activation of a presynaptic neuron can be altered by (1) the presence of neuromodulators or other chemicals that cause facilitation or inhibition at the synapse, (2) activity under way at other synapses affecting the postsynaptic cell, and (3) modification of the rate of neurotransmitter release through presynaptic facilitation or presynaptic inhibition.

You are now familiar with the basic components of neural tissue, and the origin and significance of action potentials. In later chapters we consider higher levels of anatomical and functional organization within the nervous system, examine information processing at these levels, and see how a single process—the generation of action potentials—can be responsible for the incredible diversity of sensations and movements that we experience each day.

CHECKPOINT

- **25.** One EPSP depolarizes the initial segment from a resting membrane potential of –70 mV to –65 mV, and threshold is at –60 mV. Will an action potential be generated?
- **26**. Given the situation in Checkpoint 25, if a second, identical EPSP occurs immediately after the first, will an action potential be generated?
- 27. If the two EPSPs in Checkpoint 26 occurred simultaneously, what form of summation would occur?

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **anesthetic:** An agent that produces a local or general loss of sensation including feelings of pain.
- **anticholinesterase drug:** A drug that blocks the breakdown of ACh by AChE.
- **atropine:** A drug that prevents ACh from binding to the postsynaptic membrane of cardiac muscle cells and smooth muscle cells.
- **d-tubocurarine:** A drug, derived from curare, a South American rainforest vine. It produces paralysis by preventing ACh from binding to the postsynaptic membrane (motor end plate) of skeletal muscle fibers.
- **dysthymia:** A form of clinical depression with a depressed mood for most of the time for at least two years along with at least two of the following signs and symptoms: poor appetite or overeating; insomnia or excessive sleep; low energy or fatigue; low selfesteem; poor concentration or indecisiveness; and hopelessness.
- **excitotoxicity:** Continuous and exaggerated stimulation by a neurotransmitter, especially for the excitatory neurotransmitter

glutamate. The nerve cells can become damaged and killed by the overactivation of receptors.

- **neuroblastoma:** A malignant tumor composed of neuroblasts, most commonly in the adrenal gland; it is the most common cancer in infancy.
- **neuropathy:** Condition that causes tingling, numbness, and/or pain in parts of the body, notably the hands and feet.

neurotoxin: A compound that disrupts normal nervous system function by interfering with the generation or propagation of action potentials. Examples include *tetrodotoxin (TTX), saxitoxin (STX),* and *ciguatoxin (CTX).*

Tay–Sachs disease: A genetic abnormality involving the metabolism of gangliosides, important lipid components of neuron plasma membranes. The result is a gradual deterioration of neurons due to the buildup of metabolic by-products and the release of lysosomal enzymes.

An Introduction to Neural Tissue p. 386

1. The nervous system includes all the neural tissue in the body. The basic functional unit is the **neuron**.

- **12-1** The nervous system has anatomical and functional divisions p. 386
- 2. The anatomical divisions of the nervous system are the **central nervous system (CNS)** (the brain and spinal cord) and the **peripheral nervous system (PNS)** (all the neural tissue outside the CNS). Bundles of **axons** (*nerve fibers*) in the PNS are called **nerves**. (*Figure 12–1*)
- Functionally, the PNS can be divided into an afferent division, which brings sensory information from receptors to the CNS, and an efferent division, which carries motor commands to muscles and glands called effectors. (*Figure 12–1*)
- 4. The efferent division of the PNS includes the **somatic nerv-ous system (SNS)**, which controls skeletal muscle contractions, and the **autonomic nervous system (ANS)**, which controls smooth muscle, cardiac muscle, glandular activity, and adipose tissue. (*Figure 12–1*)

- 12-2 Neurons are nerve cells specialized for intercellular communication p. 388
- 5. The perikaryon of a multipolar neuron surrounds the nucleus and contains organelles, including neurofilaments, neurotubules, and neurofibrils. The axon hillock connects the initial segment of the axon to the cell body, or *soma*. The axoplasm contains numerous organelles. (*Figure 12–2*)
- 6. **Collaterals** may branch from an axon, with **telodendria** branching from the axon's tip.
- 7. A **synapse** is a site of intercellular communication. Telodendria end in **axon terminals** (also known as synaptic terminals, synaptic knobs, and synaptic boutons). **Neurotransmitters** released from the axon terminals of the presynaptic cell affect the postsynaptic cell, which may be a neuron or another type of cell. (*Figures 12–2, 12–3*)
- **8.** Neurons are structurally classified as **anaxonic**, **bipolar**, **unipolar**, or **multipolar**. (*Figure 12–4*)
- 9. The three functional categories of neurons are sensory neurons, motor neurons, and interneurons.
- **10. Sensory neurons**, which form the afferent division of the PNS, deliver information received from **interoceptors**, **exteroceptors**, and **proprioceptors** to the CNS.
- **11. Motor neurons**, which form the efferent division of the PNS, stimulate or modify the activity of a peripheral tissue, organ, or organ system.
- **12. Interneurons** (*association neurons*) are always located in the CNS and may be situated between sensory and motor neurons. They distribute sensory inputs and coordinate motor outputs.

12-3 CNS and PNS neuroglia support and protect neurons p. 392

- 13. The four types of neuroglia, or glial cells, in the CNS are (1) ependymal cells, with functions related to the cerebrospinal fluid (CSF); (2) astrocytes, the largest and most numerous neuroglia; (3) oligodendrocytes, which are responsible for the myelination of CNS axons; and (4) microglia, or phagocytic cells. (*Figures 12–5, 12–6b*)
- 14. Neuron cell bodies in the PNS are clustered into **ganglia**.
- Satellite cells surround neuron cell bodies within ganglia.
 Schwann cells ensheath axons in the PNS. A single Schwann cell may myelinate one segment of an axon or enclose segments of several unmyelinated axons. (*Figure 12–7*)
- 16. In the PNS, functional repair of axons may follow Wallerian degeneration. In the CNS, many factors complicate the repair process and reduce the chances of functional recovery. (*Figure 12–8*)

12-4 The membrane potential is the electrical potential of the cell's interior relative to its surroundings p. 398

- 17. All normal neural signaling depends on events that occur at the plasma membrane. (*Spotlight Figure 12–9*)
- The electrochemical gradient is the sum of all chemical and electrical forces acting across the plasma membrane. (*Figures* 12–10, 12–11)
- **19.** The sodium–potassium exchange pump stabilizes the resting membrane potential at approximately –70 mV. *(Table 12–1)*
- **20.** The plasma membrane contains **passive (leak) channels**, which are always open, and **active (gated) channels**, which open or close in response to specific stimuli. (*Figure 12–10*)

- **21.** The three types of gated channels are **chemically gated channels** (ligand-gated channels), voltage-gated channels, and mechanically gated channels. (*Figure 12–11*)
- **22.** A localized **depolarization** or **hyperpolarization** is a **graded potential** (a change in potential that decreases with distance). (*Figures 12–12, 12–13; Table 12–2*)
- 12-5 An action potential is an electrical event p. 406
- 23. An **action potential** arises when a region of excitable membrane depolarizes to its **threshold**. The steps involved, in order, are membrane depolarization to threshold, activation of voltage-gated sodium channels and rapid depolarization, inactivation of voltage-gated sodium channels, and the return to normal permeability. (*Spotlight Figure 12–14; Table 12–3*)
- 24. The generation of an action potential follows the **all-or-none principle**. The **refractory period** lasts from the time an action potential begins until the normal resting membrane potential has returned. (*Spotlight Figure 12–14; Table 12–3*)
- **25.** In **continuous propagation**, an action potential spreads across the entire excitable membrane surface in a series of small steps. (*Spotlight Figure 12–15*)
- **26.** In **saltatory propagation**, an action potential appears to leap from node to node, skipping the intervening myelinated membrane surface. Saltatory propagation carries nerve impulses many times more rapidly than does continuous propagation. *(Spotlight Figure 12–15)*

12-6 Axon diameter, in addition to myelin, affects propagation speed p. 412

- 27. Axons are classified as **Type A fibers**, **Type B fibers**, or **Type C fibers** on the basis of their diameter, myelination, and propagation speed.
- 12-7 At synapses, communication occurs among neurons or between neurons and other cells p. 413
- 28. An action potential traveling along an axon is a **nerve impulse**. At a synapse between two neurons, information passes from the **presynaptic neuron** to the **postsynaptic neuron**.
- **29.** A synapse is either *electrical* (with direct physical contact between cells) or *chemical* (involving a neurotransmitter).
- **30. Electrical synapses** occur in the CNS and PNS, but they are rare. At an electrical synapse, the presynaptic and postsynaptic plasma membranes are bound by interlocking membrane proteins at a gap junction. Pores formed by these proteins permit the passage of local currents, and the two neurons act as if they share a common plasma membrane.
- **31. Chemical synapses** are far more common than electrical synapses. **Excitatory neurotransmitters** cause depolarization and promote the generation of action potentials, whereas **inhibitory neurotransmitters** cause hyperpolarization and suppress the generation of action potentials.
- **32.** The effect of a neurotransmitter on the postsynaptic membrane depends on the properties of the receptor, not on the nature of the neurotransmitter.
- **33. Cholinergic synapses** release the neurotransmitter **acetyl-choline (ACh)**. Communication moves from the presynaptic neuron to the postsynaptic neuron across a synaptic cleft. A **synaptic delay** occurs because calcium influx and the release of the neurotransmitter takes an appreciable length of time. (*Figure 12–16*)

- **34. Choline** released during the breakdown of ACh in the synaptic cleft is reabsorbed and recycled by the axon terminal. If stores of ACh are exhausted, **synaptic fatigue** can occur.
- **12-8** Neurotransmitters and neuromodulators have various functions p. 416
- **35.** Adrenergic synapses release norepinephrine (NE), also called *noradrenaline*. Other important neurotransmitters include dopamine, serotonin, and gamma aminobutyric acid (GABA).
- **36. Neuromodulators** influence the postsynaptic cell's response to neurotransmitters. (*Table 12–4*)
- **37.** Neurotransmitters can have a direct or indirect effect on membrane potential, and others are lipid-soluble gases that diffuse across the plasma membrane to exert their effects inside the cell. (*Figure 12–17*)
- 12-9 Individual neurons process information by integrating excitatory and inhibitory stimuli p. 421
- **38.** Excitatory and inhibitory stimuli are integrated through interactions between **postsynaptic potentials**. This interaction is the simplest level of **information processing** in the nervous system.
- **39.** A depolarization caused by a neurotransmitter is an **excitatory postsynaptic potential (EPSP)**. Individual EPSPs can combine through **summation**, which can be either **temporal** (occurring at a single synapse when a second EPSP arrives before the effects of the first have disappeared) or **spatial** (resulting from the cumulative effects of multiple synapses at various locations). (*Figure 12–18*)
- **40.** Hyperpolarization of the postsynaptic membrane is an **inhibi-tory postsynaptic potential (IPSP)**.

- **41.** The most important determinants of neural activity are EPSP–IPSP interactions. *(Figure 12–19)*
- **42.** In **presynaptic inhibition**, GABA release at an *axoaxonic synapse* inhibits the opening of voltage-gated calcium channels in the axon terminal. This inhibition reduces the amount of neurotransmitter released when an action potential arrives at the axon terminal. (*Figure 12–20a*)
- 43. In **presynaptic facilitation**, activity at an axoaxonic synapse increases the amount of neurotransmitter released when an action potential arrives at the axon terminal. This increase enhances and prolongs the effects of the neurotransmitter on the postsynaptic membrane. (*Figure 12–20b*)
- 44. The neurotransmitters released at a synapse have excitatory or inhibitory effects. The effect on the initial segment reflects an integration of the stimuli arriving at any moment. The frequency of generation of action potentials depends on the degree of depolarization above threshold at the axon hillock. (*Table 12–5*)
- **45.** Neuromodulators can alter either the rate of neurotransmitter release or the response of a postsynaptic neuron to specific neurotransmitters. Neurons may be facilitated or inhibited by extracellular chemicals other than neurotransmitters or neuromodulators. (*Table 12–5*)
- **46.** The effect of a presynaptic neuron's activation on a postsynaptic neuron may be altered by other neurons. (*Table 12–5*)
- 47. The greater the degree of sustained depolarization at the axon hillock, the higher the frequency of generation of action potentials. At a frequency of about 1000 per second, the relative refractory period has been eliminated, and further depolarization will have no effect. (*Table 12–5*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Label the structures in the following diagram of a neuron.

 Regulation by the nervous system provides (a) relatively slow, but long-lasting, responses to stimuli, (b) swift, long-lasting responses to stimuli, (c) swift, but brief, responses to stimuli, (d) relatively slow, short-lived responses to stimuli.

See the blue Answers tab at the back of the book.

- 3. In the CNS, a neuron typically receives information from other neurons at its (a) axon, (b) Nissl bodies, (c) dendrites, (d) nucleus.
- 4. Phagocytic cells in neural tissue of the CNS are (a) astrocytes,
 (b) ependymal cells, (c) oligodendrocytes, (d) microglia.
- 5. The neural cells responsible for the analysis of sensory inputs and coordination of motor outputs are (a) neuroglia,
 (b) interneurons, (c) sensory neurons, (d) motor neurons.
- Depolarization of a neuron plasma membrane will shift the membrane potential toward (a) 0 mV, (b) -70 mV, (c) -90 mV, (d) all of these.
- 7. What factor determines the direction that ions will move through an open membrane channel? (a) the membrane permeability to sodium ions, (b) the electrochemical gradient, (c) intracellular negatively charged proteins, (d) negatively charged chloride ions in the ECF.
- Receptors that bind acetylcholine at the postsynaptic membrane are

 (a) chemically gated channels,
 (b) voltage-gated channels,
 (c) passive channels,
 (d) mechanically gated channels.
- 9. What are the major components of (a) the central nervous system?(b) the peripheral nervous system?
- **10.** Which two types of neuroglia insulate neuron cell bodies and axons in the PNS from their surroundings?
- 11. What three *functional* groups of neurons are found in the nervous system? What is the function of each type of neuron?

LEVEL 2 Reviewing Concepts

- 12. If the resting membrane potential is -70 mV and the threshold is -55 mV, a membrane potential of -60 mV will (a) produce an action potential, (b) make it easier to produce an action potential, (c) make it harder to produce an action potential, (d) hyperpolarize the membrane.
- **13.** Why can't most neurons in the CNS be replaced when they are lost to injury or disease?
- 14. What is the difference between anterograde flow and retrograde flow?
- **15.** What is the *functional* difference among chemically gated (ligand-gated), voltage-gated, and mechanically gated channels?
- **16.** State the all-or-none principle of action potentials.
- 17. Describe the steps involved in the generation of an action potential.
- **18.** What is meant by saltatory propagation? How does it differ from continuous propagation?
- **19.** What are the structural and functional differences among type A, B, and C fibers?
- **20.** Describe the events that occur during nerve impulse transmission at a typical cholinergic synapse.
- **21.** What is the difference between temporal summation and spatial summation?

LEVEL 3 Critical Thinking and Clinical Applications

- **22.** Harry has a kidney condition that causes changes in his body's electrolyte levels (concentration of ions in the extracellular fluid). As a result, he is exhibiting tachycardia, an abnormally fast heart rate. Which ion is involved, and how does a change in its concentration cause Harry's symptoms?
- **23.** Twenty neurons synapse with a single receptor neuron. Fifteen of the 20 neurons release neurotransmitters that produce EPSPs at the post-synaptic membrane, and the other five release neurotransmitters that produce IPSPs. Each time one of the neurons is stimulated, it releases enough neurotransmitter to produce a 2-mV change in potential at the postsynaptic membrane. If the threshold of the postsynaptic neuron is 10 mV, how many of the excitatory neurons must be stimulated to produce an action potential in the receptor neuron if all five inhibitory neurons are stimulated? (Assume that spatial summation occurs.)
- 24. In multiple sclerosis, there is intermittent and progressive damage to the myelin sheath of peripheral nerves. This results in poor motor control of the affected area. Why does destruction of the myelin sheath affect motor control?
- **25.** What factor determines the maximum frequency of action potentials that could be conducted by an axon?

CLINICAL CASE

Did Franklin D. Roosevelt Really Have Polio?

Poliomyelitis, also known as infantile paralysis, is caused by a virus that spreads easily in human populations. Most people with polio infections show no symptoms of disease. However, in a small percentage of victims, the virus enters the central nervous system, attacks the motor neurons of the spinal cord, and produces a flaccid paralysis (characterized by weakness and loss of muscle tone).

Certain details about Mr. Roosevelt's case call into question whether he really suffered from polio. Polio is a disease primarily of children. By age 30, most adults have natural immunity, a resistance to infection developed after a previous exposure. In addition, paralysis caused by polio is usually asymmetric, does not appear in an ascending pattern, and progresses for only three to five days—not for nearly a month, as in Mr. Roosevelt's case. Polio almost never involves facial muscles or disturbs urinary bladder and bowel functions. Polio also does not cause pain upon light touch, other pain, or numbness—only motor weakness. Mr. Roosevelt recovered from his paralysis in a descending pattern, opposite to its onset. The pathological features Mr. Roosevelt experienced are much more characteristic of Guillain-Barré syndrome, an autoimmune disease that involves the demyelination (destruction of the axonal myelin

Wrap-Up

sheath) of peripheral nerves. It causes symmetrical weakness, numbness, and abnormal sensations. In the first half of the 20th century, doctors had extensive experience with polio, but knew little about Guillain-Barré syndrome.

While it remains inconclusive which condition led to the lifetime impairment of our 32nd president, Franklin D. Roosevelt's polio diagnosis ultimately contributed to the virtual elimination of this dreaded disease.

- 1. Do you think the polio virus attacks sensory neurons, motor neurons, or neuroglia of the spinal cord (CNS)?
- **2.** If Mr. Roosevelt suffered from Guillain-Barré syndrome, where in his nervous system was the pathology taking place?

See the blue Answers tab at the back of the book.

The Spinal Cord, Spinal Nerves, and Spinal Reflexes

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **13-1** Describe the basic structural and organizational characteristics of the nervous system.
- 13-2 Discuss the structure and functions of the spinal cord, and describe the three meningeal layers that surround the central nervous system.
- **13-3** Explain the roles of white matter and gray matter in processing and relaying sensory information and motor commands.
- **13-4** Describe the major components of a spinal nerve, and relate the distribution pattern of spinal nerves to the regions they innervate.
- **13-5** Discuss the significance of neuronal pools, and describe the major patterns of interaction among neurons within and among these pools.
- **13-6** Describe the steps in a neural reflex, and classify the types of reflexes.
- **13-7** Distinguish among the types of motor responses produced by various reflexes, and explain how reflexes interact to produce complex behaviors.
- **13-8** Explain how higher centers control and modify reflex responses.

SPOTLIGHTS

• Peripheral Distribution of Spinal Nerves pp. 440–441

• Spinal Reflexes pp. 450–451

CLINICAL CASE

• Prom Night p. 430

Clinical Notes

- Anesthesia p. 435
- Shingles p. 439
- Sensory Innervation in the Hand p. 444
- Sensory Innervation in the Ankle and Foot p. 447

CLINICAL CASE

Prom Night

Joe is still buzzing from champagne as he kisses his girlfriend goodnight and gets into his car to head

home. It's been a fun prom. The food was great, the band was awesome, and the afterparty at his friend's house had gone until 3 a.m. Joe turns the car stereo to full blast, leans back, and notices the moon through the trees. That is the last thing he remembers.

The emergency medical technicians (EMTs) at the motor vehicle accident scene note that Joe's car had left the road at a high rate of speed and rolled over at least three times. Joe is still unconscious when he is extricated from the car. He is breathing on his own but has obvious abrasions and bruising on his back. The EMTs splint his entire axial skeleton, using a cervical collar and sandbags on a rigid backboard. They start an IV in the field and transport Joe to the closest Level I trauma center.

In the emergency department Joe can hear shouting in his ear as he is moved onto a cart. "Wiggle your toes," someone commands, but Joe can move nothing below his waist. "Can you feel this?" a voice asks. Joe can feel someone

poking him with a pin from his chest down to his abdomen, just inferior to his navel, but nothing below that. "Can you feel me put this catheter in?" a nurse asks as she inserts a small tube into Joe's bladder. Joe cannot feel the catheter. **What has happened to Joe? To find out, turn to the Clinical Case Wrap-Up on p. 460.**

An Introduction to the Spinal Cord, Spinal Nerves, and Spinal Reflexes

In this chapter we discuss the functional anatomy and organization of the spinal cord and spinal nerves. We also describe simple spinal reflexes.

Organization is usually the key to success in any complex environment. A large corporation, for example, has both a system to distribute messages on specific topics and executive assistants who decide whether an issue can be ignored or easily responded to. Only the most complex and important problems reach the desk of the president.

The nervous system works in much the same way. It has input pathways that route sensations, and processing centers that prioritize and distribute information. There are also several levels that issue motor responses. Your conscious mind (the president) gets involved only in a fraction of the day-today activities. The other decisions are handled at lower levels that operate outside your awareness. This very efficient system works only because it is so highly organized.

13-1 The brain and spinal cord make up the central nervous system (CNS), and the cranial nerves and spinal nerves make up the peripheral nervous system (PNS)

Learning Outcome Describe the basic structural and organizational characteristics of the nervous system.

The nervous system has so many components and does so much that we will cover it in four chapters. If our primary interest were the anatomy of this system, we would probably start with an examination of the central nervous system (brain and spinal cord) and then move on to the peripheral nervous system (cranial nerves and spinal nerves). However, our primary interest is how the nervous system *functions,* so we will consider the system from a functional perspective. Our basic approach is diagrammed in Figure 13–1.

Note that Chapter 12 provided the foundation by considering the function of individual neurons. In Chapter 13, we consider the spinal cord and spinal nerves, and the basic wiring of simple *spinal reflexes*. Reflexes are quick, automatic responses triggered by specific stimuli. Spinal reflexes are controlled in the spinal cord. They can function without any input from the brain. For example, a reflex controlled in the spinal cord makes you drop a frying pan you didn't realize was sizzling hot. Before the information reaches your brain and you become aware of the pain, you've already released the pan. There are much more complex spinal reflexes, but this functional pattern still applies.

Your spinal cord is structurally and functionally integrated with your brain. In Chapter 14 we give an overview of the major components and functions of the brain and cranial nerves. We also discuss the *cranial reflexes*—localized reflex responses comparable in organization and complexity to those of the spinal cord.

In Chapters 15 and 16 we consider the nervous system as an integrated functional unit. In Chapter 15 we deal with the interplay between centers in the brain and spinal cord that takes place in the processing of sensory information. We then examine the conscious and subconscious control of skeletal muscles by the *somatic nervous system* (SNS).

In Chapter 16 we continue with a discussion of the control of visceral functions by the *autonomic nervous system* (ANS). The ANS has processing centers in the brain, spinal cord, and peripheral nervous system. It is responsible for the control of visceral effectors, such as smooth muscles, cardiac muscle, glands, and adipose tissue. We then conclude this section of the book by examining what are often called *higher-order functions*: memory, learning, consciousness, and personality. These fascinating topics are difficult to investigate,

Figure 13–1 An Overview of Chapters 13 and 14.

but they can affect activity along the sensory and motor pathways and alter our perception of those activities.

With these basic principles, definitions, and strategies in mind, let's begin our examination of the levels of functional organization in the nervous system.

CHECKPOINT

- 1. Name the components of the central nervous system (CNS) and of the peripheral nervous system (PNS).
- 2. Define spinal reflex.

See the blue Answers tab at the back of the book.

13-2 The spinal cord is surrounded by three meninges and carries sensory and motor information

Learning Outcome Discuss the structure and functions of the spinal cord, and describe the three meningeal layers that surround the central nervous system.

We begin this section with the gross anatomy of the spinal cord. Then we examine the three membranous layers that surround the spinal cord: the spinal meninges.

Gross Anatomy of the Spinal Cord

The adult spinal cord (Figure 13–2a) is approximately 45 cm (18 in.) long, with a maximum width of roughly 14 mm (0.55 in.). Note that the cord itself is not as long as the vertebral column. Instead, the adult spinal cord ends between vertebrae L_1 and L_2 . The posterior (dorsal) surface of the spinal cord has a shallow longitudinal groove, the **posterior median sulcus** (Figure 13–2b). The **anterior median fissure** is a deeper groove along the anterior (ventral) surface.

The amount of gray matter is greatest in segments of the spinal cord dedicated to the sensory and motor control of the limbs. These segments are expanded, forming the **enlargements** of the spinal cord. The **cervical enlargement** supplies nerves to the shoulder and upper limbs. The **lumbar enlargement** provides innervation to structures of the pelvis and lower limbs.

Inferior to the lumbar enlargement, the spinal cord becomes tapered and conical. This region is the **conus medullaris**. The **filum terminale** ("terminal thread"), a slender strand of fibrous tissue, extends from the inferior tip of the conus medullaris. It continues along the length of the vertebral canal as far as the second sacral vertebra, where it provides longitudinal support to the spinal cord as a component of the *coccygeal ligament*.

numbers to the left identify the spinal nerves and indicate where the ner roots leave the vertebral canal. The adult spinal cord extends from the brain only to the level of vertebrae L_1-L_2 ; the spinal segments found at representative locations are indicated in the cross sections.

The series of sectional views in Figure 13–2b illustrate the variations in the proportions of gray matter and white matter in the cervical, thoracic, lumbar, and sacral segments of the spinal cord. The entire spinal cord can be divided into 31 segments on the basis of the origins of the spinal nerves. A letter and number designation, the same method used to identify vertebrae, identify each segment. For example, C_3 , the segment in the uppermost section of Figure 13–2b, is the third cervical segment.

Every spinal segment is associated with a pair of **dorsal root ganglia**, located near the spinal cord (Figure 13–2b). These ganglia contain the cell bodies of sensory neurons. The axons of the neurons form the **dorsal roots**, which bring sensory information into the spinal cord. A pair of **ventral roots** contains the axons of motor neurons that extend into the periphery to control somatic and visceral effectors.

On both sides, the dorsal and ventral roots of each segment pass between the vertebral canal and the periphery at the *intervertebral foramen* between successive vertebrae. The dorsal root ganglion lies between the pedicles of the adjacent vertebrae. (You can review vertebral anatomy in Chapter 7. pp. 227-228)

Distal to each dorsal root ganglion, the sensory and motor roots are bound together into a single **spinal nerve**. Spinal nerves are classified as **mixed nerves**—that is, they contain both afferent (sensory) and efferent (motor) fibers. There are 31 pairs of spinal nerves, each identified by its association with adjacent vertebrae. For example, we may speak of "cervical spinal nerves" or even "cervical nerves" when we make a general reference to spinal nerves of the neck. However, when we indicate specific spinal nerves, it is customary to give them a regional number, as indicated in **Figure 13–2**. Each spinal nerve inferior to the first thoracic vertebra takes its name from the vertebra immediately superior to it. For example, spinal nerve T_1 emerges immediately inferior to vertebra T_1 , spinal nerve T_2 follows vertebra T_2 , and so forth.

The arrangement differs in the cervical region. There the first pair of spinal nerves, C_1 , passes between the skull and the first cervical vertebra. For this reason, each cervical nerve takes its name from the vertebra immediately inferior to it. In other words, cervical nerve C_2 precedes vertebra C_2 , and the same system is used for the rest of the cervical series. The transition from one numbering system to another occurs between the last cervical vertebra and first thoracic vertebra. The spinal nerve found at this location has been designated C_8 . Therefore, although there are only seven cervical vertebrae, there are *eight* cervical nerves.

The spinal cord continues to enlarge and elongate until a person is approximately 4 years old. Up to that time, enlargement of the spinal cord keeps pace with the growth of the vertebral column. Throughout this period, the ventral and dorsal roots are very short, and they enter the intervertebral foramina immediately adjacent to their spinal segment. After age 4, the vertebral column continues to elongate, but the spinal cord does not. This vertebral growth moves the intervertebral foramina, and thus the spinal nerves, farther and farther from their original positions relative to the spinal cord. As a result, the dorsal and ventral roots gradually elongate, and the correspondence between the spinal segment and the vertebral segment is lost. For example, in adults, the sacral segments of the spinal cord are at the level of vertebrae L_1-L_2 (Figure 13–2).

The adult spinal cord extends only to the level of the first or second lumbar vertebra, but the dorsal and ventral roots of spinal segments L_2 to S_5 extend inferiorly, past the inferior tip of the conus medullaris. When seen in gross dissection, the filum terminale and the long ventral and dorsal roots resemble a horse's tail. For this reason, early anatomists called this complex the **cauda equina** (KAW-duh ek-WĪ-nuh; *cauda*, tail + *equus*, horse).

Spinal Meninges

The vertebral column and its surrounding ligaments, tendons, and muscles isolate the spinal cord from the rest of the body. These structures also protect against bumps and shocks to the skin of the back. The delicate neural tissues must also be protected from damaging contacts with the surrounding bony walls of the vertebral canal. The **spinal meninges** (me-NIN-jēz; singular, *meninx*, membrane), a series of specialized membranes surrounding the spinal cord, provide the necessary physical stability and shock absorption. Blood vessels branching within these layers deliver oxygen and nutrients to the spinal cord.

The relationships among the spinal meninges are shown in **Figure 13–3a**. The spinal meninges consist of three layers: (1) the *dura mater*, (2) the *arachnoid mater*, and (3) the *pia mater*. At the foramen magnum of the skull, the spinal meninges are continuous with the **cranial meninges**, which surround the brain. (The cranial meninges have the same three layers. We discuss them in Chapter 14.)

Bacterial or viral infection can cause **meningitis**, or inflammation of the meningeal membranes. Meningitis is dangerous because it can disrupt the normal circulation of cerebrospinal fluid (CSF), damaging or killing neurons and neuroglia in the affected areas. An initial diagnosis may specify the meninges of the spinal cord (*spinal meningitis*) or brain (*cerebral meningitis*), but in later stages the entire meningeal system is usually affected.

The Dura Mater

The tough, fibrous **dura mater** ($D\overline{U}$ -ruh $M\overline{A}$ -ter; *durus*, hard + *mater*, mother) is the layer that forms the outermost covering of the spinal cord (Figure 13–3a). This layer contains dense collagen fibers that are oriented along the longitudinal axis of the cord. Between the dura mater and the walls of the

Figure 13–3 The Spinal Cord and Spinal Meninges.

meninges, spinal cord, and spinal nerves

vertebral canal lies the **epidural space**, a region that contains areolar tissue, blood vessels, and a protective padding of adipose tissue (Figure 13–3b).

The spinal dura mater does not have extensive, firm connections to the surrounding vertebrae. Attachment sites at either end of the vertebral canal provide longitudinal stability. Cranially, the outer layer of the spinal dura mater fuses with the periosteum of the occipital bone around the margins of the foramen magnum. There, the spinal dura mater becomes continuous with the cranial dura mater. Within the sacral canal, the spinal dura mater tapers from a sheath to a dense cord of collagen fibers that blends with components of the filum terminale to form the coccygeal ligament (Figure 13–2a). The coccygeal ligament continues along the sacral canal, ultimately blending into the periosteum of the coccyx. Areolar connective tissue and adipose tissue within the epidural space support the spinal dura mater. In addition, this dura mater extends between adjacent vertebrae at each intervertebral foramen, fusing with the connective tissues that surround the spinal nerves.

The Arachnoid Mater

In most anatomical and tissue specimens, a narrow subdural space separates the dura mater from deeper meningeal layers. In a healthy living person no such space exists. Instead, the inner surface of the dura mater is in contact with the outer surface of the arachnoid (a-RAK-novd; arachne, spider) mater, the middle meningeal layer (Figure 13-3b). The inner surface of the dura mater and the outer surface of the arachnoid mater are covered by simple squamous epithelia. The arachnoid mater includes this epithelium, called the arachnoid membrane, and the arachnoid trabeculae, a delicate network of collagen and elastic fibers that extends between the arachnoid membrane and the outer surface of the pia mater. The region between is called the **sub**arachnoid space. It is filled with cerebrospinal fluid (CSF), which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and wastes.

The spinal arachnoid mater extends inferiorly as far as the filum terminale, and the dorsal and ventral roots of the cauda equina lie within the fluid-filled subarachnoid space. In adults, the withdrawal of cerebrospinal fluid involves the insertion of a needle into the subarachnoid space in the inferior lumbar region. This procedure is known as a **lumbar puncture** or **spinal tap**.

The Pia Mater

The subarachnoid space extends between the arachnoid epithelium and the innermost meningeal layer, the **pia mater** (*pia*, delicate + *mater*, mother). The pia mater consists of a meshwork of elastic and collagen fibers that is firmly bound to the underlying neural tissue (Figure 13–3). These connectivetissue fibers are extensively interwoven with those that span the subarachnoid space, firmly binding the arachnoid to the pia mater. The blood vessels servicing the spinal cord run along the surface of the spinal pia mater, within the subarachnoid space (Figure 13–4).

Figure 13–4 The Spinal Cord and Associated Structures. An anterior view of the cervical spinal cord and spinal nerve roots in the vertebral canal. The dura mater and arachnoid mater have been cut and reflected. Notice the blood vessels that run in the subarachnoid space, bound to the outer surface of the delicate pia mater.

Spinal cord

Along the length of the spinal cord, paired **denticulate ligaments** extend from the pia mater through the arachnoid mater to the dura mater (Figures 13–3b and 13–4). Denticulate ligaments, which originate along either side of the spinal cord, prevent lateral (side-to-side) movement. The dural connections at the foramen magnum and the coccygeal ligament prevent longitudinal (superior–inferior) movement.

The spinal meninges accompany the dorsal and ventral roots as these roots pass through the intervertebral foramina. As the sectional view in Figure 13–3b shows, the meningeal membranes are continuous with the connective tissues that surround the spinal nerves and their peripheral branches.

CHECKPOINT

- 3. Identify the three spinal meninges.
- 4. Damage to which root of a spinal nerve would interfere with motor function?
- 5. Where is the cerebrospinal fluid that surrounds the spinal cord located?

See the blue Answers tab at the back of the book.

13–3 Gray matter integrates information and initiates commands, and white matter carries information from place to place

Learning Outcome Explain the roles of white matter and gray matter in processing and relaying sensory information and motor commands.

We can relate the functional organization of the spinal cord to its sectional organization (Figure 13–5). Together, the anterior median fissure and the posterior median sulcus divide the

Chinical Note

Anesthesia Anesthetics are often injected into the epidural space. Introduced in this way, a drug should affect only the spinal nerves in the immediate area of the injection. The result is a regional pain reliever (analgesic) called an *epidural anes-thesia*, which blocks pain sensations. Some sources refer to this as an *epidural block*.

This procedure can be done either peripherally, as when skin lacerations are sewn up, or at sites around the spinal cord for more widespread anesthetic effects, as during labor and delivery. An epidural anesthetic has at least two advantages: (1) It affects only the spinal nerves in the immediate area of the injection; and (2) it provides mainly sensory anesthesia. If a catheter is left in place, continued injection brings about sustained anesthesia. Local anesthetics can also be introduced as a single dose into the subarachnoid space of the spinal cord. This procedure is commonly called **spinal anesthesia**. The effects include both temporary muscle paralysis and sensory loss. These effects tend to spread as the movement of cerebrospinal fluid distributes the anesthetic along the spinal cord. Problems with overdosing are seldom serious, because controlling the patient's position during administration can limit the distribution of the drug to some degree. Respiration continues even if all thoracic and abdominal segments have been paralyzed. This is possible because the upper cervical spinal nerves control the diaphragm.

showing major landmarks in and surrounding the cord.

13

spinal cord into left and right sides. The gray matter forms an H or butterfly shape and surrounds the narrow **central canal**. **Horns** are the areas of gray matter on each side of the spinal cord. The gray matter is dominated by the cell bodies of neurons, neuroglia, and unmyelinated axons. The superficial white matter contains large numbers of myelinated and unmyelinated axons.

Organization of Gray Matter

How is the gray matter functionally organized within the nervous system as a whole? **Nuclei** are masses of gray matter within the central nervous system. **Sensory nuclei** receive and relay sensory information from peripheral receptors. **Motor nuclei** issue motor commands to peripheral effectors. Sensory and motor nuclei appear small in transverse section, but they may extend for a considerable distance along the length of the spinal cord.

A frontal section along the length of the central canal of the spinal cord separates the sensory (posterior, or dorsal) nuclei from the motor (anterior, or ventral) nuclei. The **posterior gray horns** contain somatic and visceral sensory nuclei, and the **anterior gray horns** contain somatic motor nuclei. The **lateral gray horns**, located only in the thoracic and lumbar segments, contain visceral motor nuclei. The **gray commissures** (*commissura*, a joining together) posterior to and anterior to the central canal contain axons that cross from one side of the cord to the other before they reach an area in the gray matter.

Figure 13–5a shows the relationship between the function of a particular nucleus (sensory or motor) and its position in the gray matter of the spinal cord. The nuclei within each gray horn are also spatially organized. In the cervical enlargement, for example, the anterior gray horns contain nuclei whose motor neurons control the muscles of the upper limbs. On each side of the spinal cord, in medial to lateral sequence, are somatic motor nuclei that control (1) muscles that position the pectoral girdle, (2) muscles that move the arm, (3) muscles that move the forearm and hand, and (4) muscles that move the hand and fingers. Within each of these regions, the motor neurons that control flexor muscles are grouped separately from those that control extensor muscles. Because the spinal cord is so highly organized, we can predict which muscles will be affected by damage to a specific area of gray matter.

Organization of White Matter

How is the white matter functionally organized? The white matter on each side of the spinal cord can be divided into three regions called **columns**, or *funiculi* (Figure 13–5a). The **posterior white columns** lie between the posterior gray horns and the posterior median sulcus. The **anterior white columns**

lie between the anterior gray horns and the anterior median fissure. The anterior white columns are interconnected by the **anterior white commissure**, a region where axons cross from one side of the spinal cord to the other. The white matter between the anterior and posterior columns on each side makes up the **lateral white column**.

Each column contains *tracts* whose axons share functional and structural characteristics. A **tract**, or *fasciculus* (fa-SIK-ū-lus; bundle), is a bundle of axons in the CNS that is somewhat uniform in diameter, myelination, and propagation speed. All the axons within a tract relay the same type of information (sensory or motor) in the same direction. Short tracts carry sensory or motor signals between segments of the spinal cord, and longer tracts connect the spinal cord with the brain. **Ascending tracts** carry *sensory* information toward the brain, and **descending tracts** convey *motor* commands to the spinal cord. We describe the major tracts and their functions in Chapters 15 and 16. Because spinal tracts have very specific functions, damage to one produces a characteristic loss of sensation or motor control.

CHECKPOINT

- 6. Differentiate between sensory nuclei and motor nuclei.
- 7. A person with polio has lost the use of his leg muscles. In which area of his spinal cord would you expect the virus-infected motor neurons to be?
- 8. A disease that damages myelin sheaths would affect which portion of the spinal cord?
- See the blue Answers tab at the back of the book.

13-4 Spinal nerves form plexuses that are named according to their level of emergence from the vertebral canal

Learning Outcome Describe the major components of a spinal nerve, and relate the distribution pattern of spinal nerves to the regions they innervate.

In this section we consider the structure and function of spinal nerves and the interwoven networks of spinal nerves called nerve plexuses.

Anatomy of Spinal Nerves

Every segment of the spinal cord is connected to a pair of spinal nerves. Surrounding each spinal nerve is a series of connective tissue layers continuous with those of the associated peripheral nerves (Figure 13–6). These layers, best seen in sectional view, are comparable to those associated with skeletal muscles. \bigcirc p. 291 The **epineurium**, or outermost layer, consists of a dense network of collagen fibers. The fibers of the **perineurium**, the middle layer, extend inward from the epineurium. These connective tissue partitions divide the nerve into a series

Figure 13–6 A Peripheral Nerve. A diagrammatic view and an electron micrograph of a typical spinal nerve. Note the connective tissue layers that are continuous with the associated spinal nerve.

of compartments that contain bundles of axons, or *fascicles*. Delicate connective tissue fibers of the **endoneurium**, the innermost layer, extend from the perineurium and surround individual axons.

Arteries and veins penetrate the epineurium and branch within the perineurium. Capillaries leaving the perineurium branch in the endoneurium. They supply the axons and Schwann cells of the nerve and the fibroblasts of the connective tissues.

As the spinal nerves extend into the periphery, they branch and interconnect, forming the peripheral nerves that innervate body tissues and organs. The connective tissue sheaths of peripheral nerves are the same as, and continuous with, those of spinal nerves.

If a peripheral *axon* is severed but not displaced, normal function may eventually return as the cut stump grows across the site of injury, away from the cell body and along its former path. **D p**. **398** Repairs made after an entire peripheral *nerve* has been damaged are generally incomplete, primarily due to problems with axon alignment and regrowth. Various technologically sophisticated procedures designed to improve nerve regeneration and repair are currently under evaluation.

Peripheral Distribution of Spinal Nerves

A **dermatome** is the specific bilateral region of the skin surface monitored by a single pair of spinal nerves. Each pair of spinal nerves supplies its own dermatome (Figure 13–7). Note

that the boundaries of adjacent dermatomes overlap to some degree. Dermatomes are clinically important because damage or infection of a spinal nerve or dorsal root ganglion produces a loss of sensation in the corresponding region of the skin. Additionally, characteristic signs may appear on the skin supplied by that specific nerve.

Peripheral *nerve palsies*, or **peripheral neuropathies**, are regional losses of sensory and motor function most often resulting from nerve trauma or compression. (If your arm or leg has ever "fallen asleep" after you leaned or sat in an uncomfortable position, you have experienced a mild, temporary palsy.) The location of the affected dermatomes provides clues to the location of injuries along the spinal cord, but the information is not precise. More exact conclusions can be drawn if there is loss of motor control, based on the origin and distribution of the peripheral nerves originating at nerve plexuses.

Spotlight Figure 13–8 shows the distribution, or pathway, of a typical spinal nerve that originates from the thoracic or superior lumbar segments (T_1-L_2) of the spinal cord. The spinal nerve forms just lateral to the intervertebral foramen, where the dorsal and ventral roots unite. We consider the pathways of both the sensory information and the motor commands.

Nerve Plexuses

The simple distribution pattern of dorsal and ventral *rami*, or branches, in **Spotlight Figure 13–8** applies to spinal nerves T_1-L_2 . But in segments controlling the skeletal musculature of

Chapter 13 The Spinal Cord, Spinal Nerves, and Spinal Reflexes 439

Figure 13–7 Dermatomes. Anterior and posterior distributions of dermatomes on the surface of the skin. NV = cranial nerve five (trigeminal nerve).

the neck, upper limbs, or lower limbs, the situation is more complicated. During development, small skeletal muscles innervated by different ventral rami typically fuse to form larger muscles with compound origins. The anatomical distinctions between the component muscles may disappear, but separate ventral rami continue to provide sensory innervation and motor control to each part of the compound muscle. As they converge, the ventral rami of adjacent spinal nerves blend their fibers, producing a series of compound nerve trunks. Such a complex interwoven network of nerves is called a **nerve plexus** (PLEK-sus; *plexus*, braid).

Clinical Note

Shingles The same virus that causes chickenpox, the varicella-zoster virus (VZV), also causes **shingles** (derived from the Latin *cingulum*, girdle). This herpes virus attacks neurons within the dorsal roots of spinal nerves and sensory ganglia of cranial nerves. Shingles produces a painful rash and blisters whose distribution corresponds to that of the affected sensory nerves and follows its dermatome. Anyone who has had chickenpox is at risk of developing shingles. After the initial encounter, the virus remains dormant within neurons of the anterior gray horns of the spinal cord. It is not known what triggers the reactivation of this pathogen. Fortunately for those affected, attacks of shingles usually heal and leave behind only unpleasant memories.

Many people who contract shingles suffer just a single episode in their adult lives. Some experience a painful condition known as *postherpetic neuralgia* after a bout of shingles. Moreover, the problem can recur in people with weakened immune systems, including the elderly and individuals with AIDS or some forms of cancer. Treatment for shingles typically involves large doses of antiviral drugs. In 2006, the U.S. Food and Drug Administration approved a VZV vaccine (Zostavax) for use in people ages 60 and above who have had chickenpox.

Only the ventral rami form plexuses. These four major plexuses are the (1) *cervical plexus*, (2) *brachial plexus*, (3) *lumbar plexus*, and (4) *sacral plexus* (Figure 13–9). The nerves arising at these plexuses contain sensory as well as motor fibers because these nerves form from the fusion of ventral rami (Spotlight Figure 13–8).
SPOTLIGHT Figure 13–8 Peripheral Distribution of Spinal Nerves

Together, the white and gray rami are known as the **rami communicantes** (RĀ-mī ko-mū-ni-KAN-tēz), or communicating branches (singular, *ramus communicans*).

Recall that Chapter 11 includes tables that list the nerves that control the major axial and appendicular muscles. As we proceed, you may find it helpful to refer to Tables 11-2 through 11-19 in that chapter. \bigcirc pp. 346-379

The Cervical Plexus

The **cervical plexus** consists of the ventral rami of spinal nerves C_1-C_5 (Figures 13–9, 13–10). The branches of the cervical plexus innervate the muscles of the neck and extend into the

Figure 13–10 The Cervical Plexus. ATLAS: Plates 3c,d; 18a-c

thoracic cavity, where they control the diaphragmatic muscles. The **phrenic nerve** is the major nerve of the cervical plexus. The left and right phrenic nerves supply the diaphragm, a key respiratory muscle. Other branches of this nerve plexus are distributed to the skin of the neck and the superior part of the chest.

TIPS&TRICKS

A useful mnemonic for remembering a function of three important cervical nerves is " C_3 , C_4 , C_5 keep the diaphragm alive."

The Brachial Plexus

The **brachial plexus** innervates the pectoral girdle and upper limb, with contributions from the ventral rami of spinal nerves C_5-T_1 (Figures 13–9 and 13–11). The brachial plexus can also have fibers from C_4 , T_2 , or both.

The nerves that form this plexus originate from trunks and cords. **Trunks** are large bundles of axons from several spinal nerves. **Cords** are smaller branches that originate at trunks. We name both trunks and cords according to their location relative to the *axillary artery*, a large artery supplying the upper limb. Hence we have *superior*, *middle*, and *inferior trunks*, and *lateral*, *medial*, and *posterior cords*. The lateral cord forms the **musculocutaneous nerve** exclusively and, together with the medial cord, contributes to the **median nerve**. The **ulnar nerve** is the other major nerve of the medial cord. The posterior cord gives rise to the **axillary nerve** and the **radial nerve**.

The Lumbar and Sacral Plexuses

The **lumbar plexus** and the **sacral plexus** arise from the lumbar and sacral segments of the spinal cord, respectively. The

nerves arising at these plexuses innervate the pelvic girdle and lower limbs (Figures 13–9 and 13–12).

The lumbar plexus contains axons from the ventral rami of spinal nerves T_{12} - L_4 . The major nerves of this plexus are the **genitofemoral nerve**, the **lateral femoral cutaneous nerve**, and the **femoral nerve**.

The sacral plexus contains axons from the ventral rami of spinal nerves L_4 - S_4 . Two major nerves arise at this plexus: the **sciatic nerve** and the **pudendal nerve**. The sciatic nerve passes posterior to the femur, deep to the long head of the biceps femoris muscle. As it approaches the knee, the sciatic nerve divides into

two branches: the **fibular nerve** (or *peroneal nerve*) and the **tibial nerve**. The *sural nerve*, formed by branches of the fibular nerve, is a sensory nerve innervating the lateral portion of the foot. A section of this nerve is often removed for use in nerve grafts.

Discussions of motor performance usually make a distinction between the conscious ability to control motor function—something that requires communication and feedback between the brain and spinal cord—and automatic motor responses coordinated entirely within the spinal cord. These automatic responses, called *reflexes*, are motor responses to specific stimuli. In the rest of this chapter, we look at how sensory neurons, interneurons, and motor neurons interconnect, and

how these interconnections produce both simple and complex reflexes. ATLAS: Embryology Summary 11: The Development of the Spinal Cord and Spinal Nerves

CHECKPOINT

- Identify the major networks of nerves known as plexuses.
- 10. An anesthetic blocks the function of the dorsal rami of the cervical spinal nerves. Which areas of the body will be affected?
- 11. Injury to which of the nerve plexuses would interfere with the ability to breathe?
- **12**. Compression of which nerve produces the sensation that your leg has "fallen asleep"?

See the blue Answers tab at the back of the book.

13-5 Interneurons are organized into functional groups called neuronal pools

Learning Outcome Discuss the significance of neuronal pools, and describe the major patterns of interaction among neurons within and among these pools.

Your body has about 10 million sensory neurons, one-half million motor neurons, and 20 *billion* interneurons. The sensory neurons deliver information to the CNS. The motor neurons distribute commands to peripheral effectors, such as skeletal muscles. Interactions among interneurons provide the interpretation, planning, and coordination of incoming and outgoing signals.

The billions of interneurons of the CNS are organized into a much smaller number of **neuronal pools**—functional groups of interconnected neurons. A neuronal pool may be scattered, involving neurons in several regions of the brain, or localized, with neurons restricted to one specific location in the brain or spinal cord. Estimates of the actual number of neuronal pools range between a few hundred and a few thousand.

Each pool has a limited number of input sources and output destinations. Each pool may contain both excitatory and inhibitory neurons. The output of the entire neuronal pool may stimulate or depress activity in other parts of the brain or spinal cord, affecting the interpretation of sensory information or the coordination of motor commands.

The pattern of interaction among neurons provides clues to the functional characteristics of a neuronal pool. We refer to the "wiring diagrams" in Figure 13–13 as *neural circuits*, just as we refer to electrical circuits in the wiring of a house. We can distinguish five circuit patterns:

- 1. **Divergence** is the spread of information from one neuron to several neurons (Figure 13–13a), or from one pool to multiple pools. Divergence permits the broad distribution of a specific input. Considerable divergence occurs when sensory neurons bring information into the CNS, because the information is distributed to neuronal pools throughout the spinal cord and brain. Visual information arriving from the eyes, for example, reaches your consciousness at the same time it is distributed to areas of the brain that control posture and balance at the subconscious level.
- 2. In **convergence**, several neurons synapse on a single postsynaptic neuron (Figure 13–13b). Several patterns of activity in the presynaptic neurons can therefore have the same

effect on the postsynaptic neuron. Through convergence, the same motor neurons can be subject to both conscious and subconscious control. For example, the movements of your diaphragm and ribs are now being controlled by your brain at the subconscious level. But you can also consciously control the same motor neurons, as when you take a deep breath and hold it. Two neuronal pools are involved, both synapsing on the same motor neurons.

- 3. In **serial processing**, information is relayed in a stepwise fashion, from one neuron to another or from one neuronal pool to the next (Figure 13–13c). This pattern occurs as sensory information is relayed from one part of the brain to another. For example, pain sensations on their way to your consciousness make stops at two neuronal pools along the pain pathway.
- 4. Parallel processing occurs when several neurons or neuronal pools process the same information simultaneously (Figure 13–13d). Divergence must take place before parallel processing can occur. As a result, many responses can occur simultaneously. For example, stepping on a sharp object stimulates sensory neurons that distribute the information to several neuronal pools. As a result of parallel processing, you might withdraw your foot, shift your weight, move your arms, feel the pain, and shout "Ouch!" at about the same time.
- In reverberation, collateral branches of axons somewhere along the circuit extend back toward the source of an impulse and further stimulate the presynaptic neurons (Figure 13–13e). Reverberation is like a positive feedback

loop involving neurons: Once a reverberating circuit has been activated, it will continue to function until synaptic fatigue or inhibitory stimuli break the cycle. Reverberation can take place within a single neuronal pool, or it may involve a series of interconnected pools. Highly complicated examples of reverberation among neuronal pools in the brain may help maintain consciousness, muscular coordination, and normal breathing.

The functions of the nervous system depend on the interactions among neurons organized in neuronal pools. The most complex neural processing steps take place in the spinal cord and brain. The simplest steps occur within the PNS and the spinal cord. These steps control reflexes that are a bit like Legos: Individually, the reflexes are quite simple, but they can be combined in a great variety of ways to create very complex responses. For this reason, reflexes are the basic building blocks of neural function, as you will see in the next section.

CHECKPOINT

13. Define neuronal pool.

14. List the five circuit patterns found in neuronal pools.

13-6 Reflexes are rapid, automatic responses to stimuli

Learning Outcome Describe the steps in a neural reflex, and classify the types of reflexes.

Conditions inside or outside the body can change rapidly and unexpectedly. **Reflexes** are rapid, automatic responses to specific stimuli. Reflexes preserve homeostasis by making rapid adjustments in the function of organs or organ systems. The response shows little variability: Each time a particular reflex is activated, it normally produces the same motor response.

In Chapter 1, we introduced the basic functional components involved in all types of homeostatic regulation: a *receptor*, a *control center* (or *integration center*), and an *effector*. \supset **p**. 7 Here we consider *neural reflexes*, in which sensory fibers deliver information from peripheral receptors to an integration center in the CNS, and motor fibers carry motor commands to peripheral effectors. In Chapter 18, we examine *endocrine reflexes*, in which hormones in the bloodstream carry the commands to peripheral tissues and organs.

The Reflex Arc

The route followed by nerve impulses to produce a reflex is called a reflex arc. **Spotlight Figure 13–14** diagrams the five steps in a simple neural reflex.

1 The Arrival of a Stimulus and Activation of a Receptor.

Reflex arcs begin with activation of a *receptor*, which may be a specialized cell or the dendrites of a sensory neuron. Receptors are sensitive to physical or chemical changes in the body or to changes in the external environment. We introduced the general categories of sensory receptors in Chapter 12. ⊃ p. 390 If you lean on a tack, for example, pain receptors in the palm of your hand are activated. These receptors, the dendrites of sensory neurons, respond to stimuli that cause or accompany tissue damage. (We discuss the link between receptor stimulation and sensory neuron activation further in Chapter 15.)

2 The Activation of a Sensory Neuron. When the dendrites are stretched, there is a graded depolarization that leads to the formation and propagation of action potentials along the axons of the sensory neurons. This information reaches the spinal cord by way of a dorsal root. In our example, 1 and
2 involve the same cell. However, the two steps may involve different cells. For example, reflexes triggered by loud sounds begin when receptor cells in the internal ear release neurotransmitters that stimulate sensory neurons.

3 Information Processing in the CNS. In our example, information processing begins when excitatory neurotransmitter molecules, released by the axon terminal of a sensory neuron, arrive at the postsynaptic membrane of an interneuron. The neurotransmitter produces an excitatory postsynaptic potential (EPSP), which is integrated with other stimuli arriving at the postsynaptic cell at that moment. ⊃ p. 421 The information processing is thus performed by the interneuron. In the simplest reflexes, such as the *stretch reflex*, the sensory neuron innervates a motor neuron directly. In that case, the motor neuron performs the information processing. By contrast, complex reflexes involve several interneurons), and others release inhibitory neurotransmitters (*inhibitory interneurons*).

4 *The Activation of a Motor Neuron.* The axons of the stimulated motor neurons carry action potentials into the periphery—in this example, through the ventral root of a spinal nerve.

5 *The Response of a Peripheral Effector.* The release of neurotransmitters by the motor neurons at axon terminals then leads to a response by a peripheral effector—in this case, a skeletal muscle whose contraction pulls your hand away from the tack.

A reflex response generally removes or opposes the original stimulus, and this is an example of *negative feedback*. \supset p. 10 However, reflexes may be integrated to produce complex movements that support or enhance the primary response. Two examples are given in **Spotlight Figure 13-14**.

By opposing potentially harmful changes in the internal or external environment, reflexes play an important role in homeostasis. The immediate reflex response is typically not the only response to a stimulus. The other responses, which

SPOTLIGHT Figure 13–14 Spinal Reflexes

Reflexes are rapid, automatic responses to specific stimuli. They preserve homeostasis by making rapid adjustments in the function of organs or organ systems.

MONOSYNAPTIC REFLEXES

In the simplest reflex arc, a sensory neuron synapses directly on a motor neuron. Beause there is only one synspase, it is called a monosynaptic reflex. Transmission across a chemical synapse always involves a synaptic delay, but with only one synapse, the delay between the stimulus and the response is minimized.

Stretch Reflex

POLYSYNAPTIC REFLEXES

Polysynaptic reflexes can produce far more complicated responses than monosynaptic reflexes, because the interneurons can control motor neurons that activate several muscle groups simultaneously.

Withdrawal Reflex

Crossed Extensor Reflex

A crossed extensor reflex involves a contralateral reflex arc (contra, opposite). In other words, a motor response to the stimulus also occurs on a side opposite the stimulus. The crossed extensor reflex complements the flexor reflex, and the two occur simultaneously. When you step on a tack, the flexor reflex pulls the affected foot away from the ground, while the crossed extensor reflex straightens the other leg to support your body weight. In the crossed extensor reflex, interneurons responding to the pain have axons that cross to the other side of the spinal cord. There they stimulate motor neurons that control the extensor muscles of the uninjured leg. As a result, your opposite leg straightens to support the shifting weight. Reverberating circuits use positive feedback to ensure that the movement lasts long enough to be effective. All of this happens without motor commands from higher centers of the brain.

KEY

Excitatory	Inhibitory
interneuron	interneuron
Motor neuron (stimulated)	

are directed by your brain, involve multiple synapses and take longer to organize and coordinate.

Classification of Reflexes

Reflexes are classified on the basis of (1) their development, (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, or (4) the site of information processing. These categories are not mutually exclusive. They represent different ways of describing a single reflex (Figure 13–15).

Development of Reflexes

Innate reflexes result from the connections that form between neurons during development. Such reflexes generally appear in a predictable sequence, from the simplest reflex responses (withdrawal from pain) to more complex motor patterns (chewing, suckling, or tracking objects with the eyes). The neural connections responsible for the basic motor patterns of an innate reflex are genetically programmed. Examples include the reflexive removal of your hand from a hot stovetop and blinking when your eyelashes are touched.

More complex, learned motor patterns are called **acquired reflexes**. For example, an experienced driver steps on the brake when trouble appears ahead, or a professional skier makes equally quick adjustments in body position while racing. These motor responses are rapid and automatic, but they were learned rather than preestablished. Repetition enhances such reflexes.

The distinction between innate and acquired reflexes is not absolute. Some people can learn motor patterns more quickly than others. The differences probably have a genetic basis.

Most reflexes, whether innate or acquired, can be modified over time or suppressed through conscious effort. For example, while walking a tightrope over the Grand Canyon, you might ignore a bee sting on your hand. Under other circumstances you would probably withdraw your hand immediately, while shouting and thrashing about as well.

Nature of the Response

Somatic reflexes provide a mechanism for the involuntary control of the muscular system. *Superficial reflexes* are triggered by stimuli at the skin or mucous membranes. *Stretch reflexes* are triggered by the sudden elongation of a tendon, and thus of the muscle to which it attaches. A familiar example is the *patellar*, or *"knee-jerk," reflex* that is usually tested during physical exams. These reflexes are also known as *deep tendon reflexes*, or *myotatic reflexes*.

Visceral reflexes, or *autonomic reflexes*, control the activities of other systems. We consider somatic reflexes in detail in this chapter and visceral reflexes in Chapter 16.

The movements directed by somatic reflexes are neither delicate nor precise. You might wonder why they exist at all, because we have voluntary control over the same muscles. In fact, somatic reflexes are absolutely vital, primarily because they are *immediate*. Making decisions and coordinating voluntary responses take time. In an emergency—when you slip while walking down a flight of stairs, or accidentally press your hand against a knife edge—any delay increases the likelihood of severe injury. Thus, somatic reflexes provide a rapid response that can be modified later, if necessary, by voluntary motor commands.

Complexity of the Circuit

Monosynaptic reflexes involve the simplest reflex arc. Most reflexes are more complicated and have at least one interneuron

between the sensory neuron and the motor neuron. These types are called *polysynaptic reflexes*. Polysynaptic reflexes have a longer delay between stimulus and response. The length of the delay is proportional to the number of synapses involved. **Spotlight Figure 13–14** highlights these reflexes.

Processing Sites

In **spinal reflexes**, the important interconnections and processing events occur in the spinal cord. We discuss these reflexes further in the next section. We consider reflexes processed in the brain, called **cranial reflexes**, in Chapters 14, 16, and 17.

CHECKPOINT

- 15. Define reflex.
- 16. What is the minimum number of neurons in a reflex arc?
- 17. One of the first somatic reflexes to develop is the suckling reflex. Which type of reflex is this?

See the blue Answers tab at the back of the book.

13-7 Spinal reflexes vary in complexity

Learning Outcome Distinguish among the types of motor responses produced by various reflexes, and explain how reflexes interact to produce complex behaviors.

Spinal reflexes range in complexity from simple monosynaptic reflexes involving a single segment of the spinal cord to polysynaptic reflexes that involve many segments. In the most complicated spinal reflexes, called **intersegmental reflex arcs**, many segments interact to produce a coordinated, highly variable motor response.

Monosynaptic Reflexes

In monosynaptic reflexes, there is little delay between sensory input and motor output. These reflexes control the most rapid, *stereotyped* (preexisting, mechanically repetitive) *motor responses* of the nervous system to specific stimuli.

The Stretch Reflex

The best-known monosynaptic reflex is the **stretch reflex**, which automatically regulates skeletal muscle length. The kneejerk or **patellar reflex** is an example. When a physician taps your patellar tendon with a reflex hammer, receptors in the quadriceps muscle are stretched (**Spotlight Figure 13–14**). The distortion of the receptors in turn stimulates sensory neurons that extend into the spinal cord, where they synapse on motor neurons that control the motor units in the stretched muscle. This leads to a reflexive contraction of the stretched muscle that extends the knee in a brief kick. To summarize: The stimulus (increasing muscle length) activates a sensory neuron, which triggers an immediate motor response (contraction of the stretched muscle) that counteracts the stimulus. The entire reflex is completed within 20–40 msec because the action potentials traveling toward and away from the spinal cord are conducted along large, myelinated Type A fibers.

The receptors in stretch reflexes are called *muscle spindles*. (We describe the sensory mechanism in the next section.) The stretching of muscle spindles produces a sudden burst of activity in the sensory neurons that monitor them. This in turn leads to stimulation of motor neurons that control the motor units in the stretched muscle. The result is rapid muscle shortening, which returns the muscle spindles to their resting length. The rate of action potential generation in the sensory neurons then decreases, causing a drop in muscle tone to resting levels.

Muscle Spindles

The sensory receptors involved in the stretch reflex are **muscle spindles**. Each consists of a bundle of small, specialized skeletal muscle fibers called **intrafusal muscle fibers (Figure 13–16)**. The muscle spindle is surrounded by larger skeletal muscle fibers, called **extrafusal muscle fibers**. These fibers are responsible for the resting muscle tone and, at greater levels of stimulation, for the contraction of the entire muscle.

Both sensory and motor neurons innervate each intrafusal fiber. The dendrites of the sensory neuron spiral around the intrafusal fiber in a central sensory region. Axons from spinal motor neurons form neuromuscular junctions on either end of this fiber. Motor neurons innervating intrafusal fibers are called **gamma motor neurons**. Their axons are called **gamma efferents**.

An intrafusal fiber has one set of myofibrils at each end. These myofibrils run from the end of the intrafusal fiber only to the sarcolemma in the central region that is closely monitored by the sensory neuron. The gamma efferents enable the CNS to adjust the sensitivity of the muscle spindle. Before seeing how this is accomplished, let's see how the muscle spindle normally functions as a sensory receptor and look at its effects on the surrounding extrafusal fibers.

The sensory neuron is always active, conducting impulses to the CNS. The axon enters the CNS in a dorsal root and synapses on motor neurons in the anterior gray horn of the spinal cord. Axon collaterals distribute the information to the brain, providing information about the muscle spindle. Stretching the central portion of the intrafusal fiber distorts the dendrites and stimulates the sensory neuron, increasing the frequency of action potential generation. Compressing the central portion inhibits the sensory neuron, decreasing the frequency of action potential generation.

The axon of the sensory neuron synapses on CNS motor neurons that control the extrafusal muscle fibers of the same muscle. An increase in sensory neuron stimulation, caused by stretching of the intrafusal fiber, increases stimulation to the motor neuron controlling the surrounding extrafusal fibers, so muscle tone increases. This increase provides automatic resistance that reduces the chance of muscle damage due to overstretching. The patellar reflex and similar reflexes serve this function.

A decrease in the stimulation of the sensory neuron, due to compression of the intrafusal fiber, leads to a decrease in the stimulation of the motor neuron controlling the surrounding extrafusal fibers, so muscle tone decreases. This decrease reduces resistance to the movement under way. For example, if your elbow is flexed and you let gravity extend it, the triceps brachii muscle, which is compressed by this movement, relaxes.

Many stretch reflexes are **postural reflexes**—reflexes that help us maintain a normal upright posture. Standing, for example, involves a cooperative effort by many muscle groups. Some of these muscles work in opposition to one another, exerting forces that keep the body's weight balanced over the feet. If your body leans forward, stretch receptors in your calf muscles are stimulated. Those muscles then respond by contracting, returning your body to an upright position. If the muscles overcompensate and your body begins to lean back, your calf muscles relax. But then stretch receptors in muscles of your shins and thighs are stimulated, and the problem is corrected immediately.

Postural muscles generally maintain a firm muscle tone and have extremely sensitive stretch receptors. As a result, very fine adjustments are continually being made, and you are not aware of the cycles of contraction and relaxation that occur. Stretch reflexes are only one type of postural reflex. There are many complex polysynaptic postural reflexes.

Now let's return to the role of the gamma efferents. They let the CNS adjust the sensitivity of muscle spindles. Gamma efferents play a vital role whenever voluntary contractions change the length of a muscle. Impulses arriving over gamma efferents cause the contraction of myofibrils in the intrafusal fibers as the biceps brachii muscle shortens. The myofibrils pull on the sarcolemma in the central portion of the intrafusal fiber—the region monitored by the sensory neuron—until that membrane is stretched to its normal resting length. As a result, the muscle spindles remain sensitive to any externally imposed changes in muscle length. For this reason, if someone drops a ball into your palm when your elbow is partially flexed, the muscle spindles automatically adjust the muscle tone to compensate for the increased load.

Polysynaptic Reflexes

Polysynaptic reflexes can produce far more complicated responses than can monosynaptic reflexes. One reason is that the interneurons involved can control several muscle groups. Moreover, these interneurons may produce either excitatory or inhibitory postsynaptic potentials (EPSPs or IPSPs) at CNS motor nuclei. As a result, the response can involve the stimulation of some muscles and the inhibition of others.

The Tendon Reflex

The stretch reflex regulates the length of a skeletal muscle. The **tendon reflex** monitors the external tension produced during a muscular contraction and prevents tearing or breaking of the tendons. The sensory receptors for this reflex have not been identified, but they are distinct from both muscle spindles and proprioceptors in tendons. The receptors are stimulated when the collagen fibers are stretched to a dangerous degree. These receptors activate sensory neurons that stimulate inhibitory interneurons in the spinal cord. These interneurons in turn innervate the motor neurons controlling the skeletal muscle. The greater the tension in the tendon, the greater is the inhibitory effect on the motor neurons. As a result, a skeletal muscle generally cannot develop enough tension to break its tendons.

Withdrawal Reflexes

Withdrawal reflexes move affected parts of the body away from a stimulus. Painful stimuli trigger the strongest withdrawal reflexes, but these reflexes are sometimes initiated by the stimulation of touch receptors or pressure receptors.

The **flexor reflex**, a representative withdrawal reflex, affects the muscles of a limb (**Spotlight Figure 13–14**). Recall from Chapters 9 and 11 that flexion reduces the angle between two articulating bones, and that the contractions of flexor muscles perform this movement. \bigcirc pp. 269, 337 If you grab an

unexpectedly hot pan on the stove, a dramatic flexor reflex will occur. When the pain receptors in your hand are stimulated, the sensory neurons activate interneurons in the spinal cord that stimulate motor neurons in the anterior gray horns. The result is a contraction of flexor muscles that yanks your hand away from the stove.

When a specific muscle contracts, opposing muscles must relax to permit the movement. For example, flexor muscles that bend the elbow (such as the biceps brachii muscle) are opposed by extensor muscles (such as the triceps brachii muscle) that straighten it out. A potential conflict exists: In theory, the contraction of a flexor muscle should trigger a stretch reflex in the extensors that would cause them to contract, opposing the movement. Interneurons in the spinal cord prevent such competition through **reciprocal inhibition**. When one set of motor neurons is stimulated, those neurons that control antagonistic muscles are inhibited. The term *reciprocal* refers to the fact that the system works both ways. When the flexors contract, the extensors relax, and when the extensors contract, the flexors relax.

Withdrawal reflexes are much more complex than any monosynaptic reflex. They also show tremendous versatility, because the sensory neurons activate many pools of interneurons. If the stimuli are strong, interneurons will carry excitatory and inhibitory impulses up and down the spinal cord, affecting motor neurons in many segments. The end result is always the same: a coordinated movement away from the stimulus. But the distribution of the effects and the strength and character of the motor responses depend on the intensity and location of the stimulus.

Mild discomfort might provoke a brief contraction in muscles of your hand and wrist. More powerful stimuli would produce coordinated muscular contractions affecting the positions of your hand, wrist, forearm, and arm. Severe pain would also stimulate contractions of your shoulder, trunk, and arm muscles. These contractions could last for several seconds, due to the activation of reverberating circuits. In contrast, monosynaptic reflexes are invariable and brief. For example, the patellar reflex is completed in about 20–40 msec.

Crossed Extensor Reflexes

The stretch, tendon, and withdrawal reflexes involve *ipsilateral* (*ipsi*, same + *lateral*, side) *reflex arcs*: The sensory stimulus and the motor response occur on the same side of the body. The crossed extensor reflex involves a *contralateral reflex arc* (*contra*, opposite), because the motor response occurs on the side opposite the stimulus (Spotlight Figure 13–14).

General Characteristics of Polysynaptic Reflexes

Polysynaptic reflexes range in complexity from a simple tendon reflex to the complex and variable reflexes associated with standing, walking, and running. Yet all polysynaptic reflexes share the following basic characteristics:

- *They Involve Pools of Interneurons.* Processing takes place in pools of interneurons before motor neurons are activated. The result may be excitation or inhibition. The tendon reflex inhibits motor neurons, and the flexor and crossed extensor reflexes direct specific muscle contractions.
- They Are Intersegmental in Distribution. The interneuron pools extend across spinal segments and may activate muscle groups in many parts of the body.
- They Involve Reciprocal Inhibition. Reciprocal inhibition coordinates muscular contractions and reduces resistance to movement. In the flexor and crossed extensor reflexes, the contraction of one muscle group is associated with the inhibition of opposing muscles.
- They Have Reverberating Circuits, Which Prolong the Reflexive Motor Response. Positive feedback between interneurons that innervate motor neurons and the processing pool maintains the stimulation even after the initial stimulus has faded.
- Several Reflexes May Cooperate to Produce a Coordinated, Controlled Response. As a reflex movement gets under way, antagonistic reflexes are inhibited. For example, during the stretch reflex, antagonistic muscles are inhibited. In contrast, in the tendon reflex, antagonistic muscles are stimulated. In complex polysynaptic reflexes, commands may be distributed along the length of the spinal cord, producing a well-coordinated response.

CHECKPOINT

- **18**. Identify the basic characteristics of polysynaptic reflexes.
- 19. For the patellar (knee-jerk) reflex, how would the stimulation of the muscle spindle by gamma motor neurons affect the speed of the reflex?
- 20. A weight lifter is straining to lift a 200-kg barbell above his head. Shortly after he lifts it to chest height, his muscles appear to relax and he drops the barbell. Which reflex has occurred?
- **21**. During a withdrawal reflex of the foot, what happens to the limb on the side opposite the stimulus? What is this response called?
- See the blue Answers tab at the back of the book.

13-8 The brain can affect spinal cord–based reflexes

Learning Outcome Explain how higher centers control and modify reflex responses.

Reflex motor behaviors happen automatically, without instructions from higher centers. However, higher centers can have a profound effect on the performance of a reflex. Processing centers in the brain can facilitate or inhibit reflex motor patterns based in the spinal cord. Descending tracts originating in the brain synapse on interneurons and motor neurons throughout the spinal cord. These synapses are continuously active, producing EPSPs or IPSPs at the postsynaptic membrane.

Voluntary Movements and Reflex Motor Patterns

Spinal reflexes produce consistent, stereotyped motor patterns that are triggered by specific external stimuli. However, the same motor patterns can also be activated as needed by centers in the brain. By making use of these preexisting patterns, relatively few descending fibers can control complex motor functions.

For example, neuronal pools in the spinal cord direct the motor patterns for walking, running, and jumping. The descending pathways from the brain provide appropriate facilitation, inhibition, or "fine-tuning" of the established patterns. This is a very efficient system that is similar to an order given in a military drill: A single command triggers a complex, predetermined sequence of events.

Motor control involves a series of interacting levels. At the lowest level are monosynaptic reflexes that are rapid, but stereotyped and relatively inflexible. At the highest level, centers in the brain can modulate or build on reflexive motor patterns.

Reinforcement and Inhibition

A single EPSP may not depolarize the postsynaptic neuron sufficiently to generate an action potential, but it does make that neuron more sensitive to other excitatory stimuli. We introduced this process of *facilitation* in Chapter 12. Alternatively, an IPSP makes the neuron less responsive to excitatory stimulation, through the process of *inhibition*. \bigcirc **p**. 421 By stimulating excitatory or inhibitory interneurons within the brain stem or spinal cord, higher centers can adjust the sensitivity of reflexes by creating EPSPs or IPSPs at the motor neurons involved in reflex responses.

When many of the excitatory synapses are chronically active, the postsynaptic neuron can enter a state of generalized facilitation. This facilitation of reflexes can result in **reinforcement**, an enhancement of spinal reflexes. For example, a method used to overemphasize the patellar reflex is called the Jendrassik maneuver. To do this, the subject hooks the hands together by interlocking the fingers and then tries to pull the hands apart while a light tap is applied to the patella. This reinforcement produces a big kick rather than a twitch. This distractive technique still produces a larger reflex response even if the individual realizes it is just a distraction.

If a stimulus fails to elicit a particular reflex response during a clinical exam, there can be many reasons for the failure.

Figure 13–17 The Babinski Reflexes.

The person may be consciously suppressing the response, the nerves involved may be damaged, or there may be underlying problems inside the CNS. The clinician may then ask the patient to perform an action designed to provide reinforcement, such as the Jendrassik maneuver. Reinforced reflexes are usually too strong to suppress consciously. If the reflex still fails to appear, the likelihood of nerve or CNS damage is increased. The clinician may then order more sophisticated tests, such as nerve conduction studies or scans.

TIPS & TRICKS

Facilitation and inhibition are similar to what happens when a symphony conductor raises or lowers one hand to control the music's volume while keeping the rhythm going with the baton hand: The basic pattern of beats doesn't change, but the loudness does.

Other descending fibers have an inhibitory effect on spinal reflexes. In adults, stroking the lateral sole of the foot produces a curling of the toes, called a **plantar reflex**, or *negative Babinski reflex*, after about a 1-second delay (Figure 13–17a). In contrast, stroking an infant's foot on the lateral sole produces a fanning of the toes known as the **Babinski sign**, or *positive Babinski reflex* (Figure 13–17b). This response disappears as descending motor pathways develop. If either the higher centers or the descending tracts are damaged, the Babinski sign reappears in an adult. As a result, clinicians often test this reflex when CNS injury is suspected.

CHECKPOINT

- 22. Define reinforcement as it pertains to spinal reflexes.
- **23.** After injuring her back, Tina exhibits a positive Babinski reflex. What does this imply about Tina's injury?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

areflexia: Absence of reflexes.

- **Brown-Sequard syndrome:** Loss of sensation and motor function that results from unilateral spinal cord lesions. Proprioception loss and weakness occur ipsilateral to the lesion while pain and temperature loss occur contralateral.
- equinovarus: The foot is plantar flexed, inverted, and adducted; also called talipes equinovalgus.
- **Erb's palsy (Erb-Duchenne palsy):** Obstetric condition characterized by paralysis or weakness of a newborn's upper arm muscles caused by a stretch injury to the brachial plexus.
- **hemiparesis:** Slight paralysis or weakness affecting one side of the body.
- **Kernig's sign:** Symptom of meningitis where patient cannot extend the leg at the knee due to stiffness in the hamstring muscles.
- **myelography:** A diagnostic procedure in which a radiopaque dye is introduced into the cerebrospinal fluid to obtain an x-ray image of the spinal cord and cauda equina.
- **nerve conduction study:** Test often performed along with electromyography (EMG); the test stimulates certain nerves and records

their ability to send an impulse to the muscle; it can indicate where any blockage of the nerve pathway exists.

- **nerve growth factor:** A peptide that promotes the growth and maintenance of neurons. Other factors that are important to neuron growth and repair include BDNF, NT-3, NT-4, and GAP-43.
- **paraplegia:** Paralysis involving a loss of motor control of the lower, but not the upper, limbs.
- **quadriplegia:** Paralysis involving the loss of sensation and motor control of the upper and lower limbs.
- **spinal shock:** Term applied to all phenomena surrounding physiological or anatomical transection of the spinal cord that results in temporary loss or depression of all or most spinal reflex activity inferior to the level of the injury.
- **tabes dorsalis:** Slow progressive degeneration of the myelin layer of the sensory neurons of the spinal cord that occurs in the tertiary (third) phase of syphilis. Common signs and symptoms are pain, weakness, diminished reflexes, unsteady gait, and loss of coordination.

- 13-1 The brain and spinal cord make up the central nervous system, and the cranial nerves and spinal nerves make up the peripheral nervous system p. 430
- 1. The CNS consists of the brain and spinal cord; the remainder of the nervous tissue forms the PNS. (*Figure 13–1*)
- **13-2** The spinal cord is surrounded by three meninges and carries sensory and motor information p. 431
- 2. The adult spinal cord includes two localized **enlargements**, which provide innervation to the limbs. The spinal cord has 31 segments, each associated with a pair of **dorsal roots** and a pair of **ventral roots**. (*Figure 13–2*)
- **3.** The **filum terminale** (a strand of fibrous tissue) originates at the **conus medullaris** and ultimately becomes part of the **coccygeal ligament**. (*Figure 13–2*)
- Spinal nerves are mixed nerves: They contain both afferent (sensory) and efferent (motor) fibers.

- 5. The three **spinal meninges** provide physical stability and shock absorption for neural tissues of the spinal cord; the **cranial meninges** surround the brain. (*Figure 13–3*)
- 6. The **dura mater**, the outer meningeal layer, covers the spinal cord; inferiorly, it tapers into the **coccygeal ligament**. The **epidural space** separates the dura mater from the walls of the vertebral canal. (*Figures 13–3, 13–4*)
- 7. Interior to the inner surface of the dura mater are the subdural space, the arachnoid mater (the second meningeal layer), and the subarachnoid space. The subarachnoid space contains cerebrospinal fluid (CSF), which acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemical messengers, and waste products. (*Figures* 13–3, 13–4)
- 8. The **pia mater**, a meshwork of elastic and collagen fibers, is the innermost meningeal layer. **Denticulate ligaments** extend from the pia mater to the dura mater. (*Figures* 13–3, 13–4)

13-3 Gray matter integrates information and initiates commands, and white matter carries information from place to place p. 435

- 9. The white matter of the spinal cord contains myelinated and unmyelinated axons, and the gray matter contains cell bodies of neurons and neuroglia and unmyelinated axons. The projections of gray matter toward the outer surface of the spinal cord are called **horns**. (*Figure 13–5*)
- The posterior gray horns contain somatic and visceral sensory nuclei; nuclei in the anterior gray horns function in somatic motor control. The lateral gray horns contain visceral motor neurons. The gray commissures contain axons that cross from one side of the spinal cord to the other. (*Figure 13–5*)

- 11. The white matter can be divided into six **columns** (*funiculi*), each of which contains **tracts** (*fasciculi*). **Ascending tracts** relay information from the spinal cord to the brain, and **descending tracts** carry information from the brain to the spinal cord. (*Figure 13–5*)
- 13-4 Spinal nerves form plexuses that are named according to their level of emergence from the vertebral canal p. 437
- **12.** There are 31 pairs of spinal nerves. Each has an **epineurium** (outermost layer), a **perineurium**, and an **endoneurium** (innermost layer). (*Figure 13–6*)
- **13.** Each pair of spinal nerves monitors a region of the body surface called a **dermatome**. (*Figure 13–7*)
- 14. A typical spinal nerve has a **white ramus** (containing myelinated axons), a **gray ramus** (containing unmyelinated fibers that innervate glands and smooth muscles in the body wall or limbs), a **dorsal ramus** (providing sensory and motor innervation to the skin and muscles of the back), and a **ventral ramus** (supplying the ventrolateral body surface, structures in the body wall, and the limbs). (*Spotlight Figure 13-8*)
- 15. A complex, interwoven network of nerves is a **nerve plexus**. The four large plexuses are the **cervical plexus**, the **brachial plexus**, the **lumbar plexus**, and the **sacral plexus**. (*Figures* 13–9 to 13–12)
- 13-5 Interneurons are organized into functional groups called neuronal pools p. 447
- **16.** The body has sensory neurons, which deliver information to the CNS; motor neurons, which distribute commands to peripheral effectors; and interneurons, which interpret information and coordinate responses.
- **17.** An organized, functional group of interconnected interneurons is a **neuronal pool**.
- The neural circuit patterns are divergence, convergence, serial processing, parallel processing, and reverberation. (*Figure 13–13*)
- 13-6 Reflexes are rapid, automatic responses to stimuli p. 449
- **19.** A *neural reflex* involves sensory fibers delivering information to the CNS, and motor fibers carrying commands to the effectors by the PNS.
- **20.** A **reflex arc** is the neural "wiring" of a single reflex. (*Spotlight Figure* 13–14)
- 21. The five steps involved in a neural reflex are (1) the arrival of a stimulus and activation of a receptor, (2) the activation of a sensory neuron, (3) information processing in the CNS, (4) the activation of a motor neuron, and (5) a response by an effector. (*Spotlight Figure 13–14*)
- 22. Reflexes are classified according to (1) their development,
 (2) the nature of the resulting motor response, (3) the complexity of the neural circuit involved, and (4) the site of information processing. (*Figure 13–15*)

- Innate reflexes result from the genetically determined connections that form between neurons during development.
 Acquired reflexes are learned and typically are more complex.
- 24. **Somatic reflexes** control skeletal muscles; **visceral reflexes** (*autonomic reflexes*) control the activities of other systems.
- **25.** In a **monosynaptic reflex**—the simplest reflex arc—a sensory neuron synapses directly on a motor neuron, which acts as the processing center. A **polysynaptic reflex** has at least one interneuron between the sensory afferent and the motor efferent, and there is a longer delay between stimulus and response. (*Spotlight Figure 13–14*)
- **26.** Reflexes processed in the brain are **cranial reflexes**. In a **spinal reflex**, the important interconnections and processing events occur in the spinal cord.

13-7 Spinal reflexes vary in complexity p. 453

- 27. Spinal reflexes range from simple monosynaptic reflexes to more complex polysynaptic and **intersegmental reflexes**, in which many spinal segments interact to produce a coordinated motor response.
- 28. The **stretch reflex** (such as the **patellar**, or **knee-jerk**, **reflex**) is a monosynaptic reflex that automatically regulates skeletal muscle length and muscle tone. The sensory receptors involved are **muscle spindles**. (*Spotlight Figure 13–14; Figure 13–16*)
- 29. A **postural reflex** maintains a person's normal upright posture.
- 30. Polysynaptic reflexes can produce more complicated responses than can monosynaptic reflexes. Examples include the tendon reflex (which monitors the tension produced during muscular contractions and prevents damage to tendons) and with-drawal reflexes (which move affected portions of the body away from a source of stimulation). The flexor reflex is a withdrawal reflex affecting the muscles of a limb. The crossed extensor reflex complements withdrawal reflexes. (Spotlight Figure 13–14)
- 31. All polysynaptic reflexes (1) involve pools of interneurons,(2) are intersegmental in distribution, (3) involve reciprocal inhibition, (4) have reverberating circuits, which prolong the reflexive motor response, and (5) can cooperate to produce a coordinated response.

13-8 The brain can affect spinal cord–based reflexes p. 455

- **32.** The brain can facilitate or inhibit reflex motor patterns based in the spinal cord.
- **33.** Motor control involves a series of interacting levels. Monosynaptic reflexes form the lowest level; at the highest level are the centers in the brain that can modulate or build on reflexive motor patterns.
- 34. Facilitation can produce an enhancement of spinal reflexes known as **reinforcement**. Spinal reflexes may also be inhibited, as when the **plantar reflex** in adults replaces the **Babinski sign** in infants. (*Figure 13–17*)

13

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Label the anatomical structures of the spinal cord in the following figure.

- The ventral roots of each spinal segment (a) bring sensory information into the spinal cord, (b) control peripheral effectors, (c) contain the axons of somatic motor and visceral motor neurons, (d) do both b and c.
- 3. Spinal nerves are called mixed nerves because they (a) contain sensory and motor fibers, (b) exit at intervertebral foramina, (c) are associated with a pair of dorsal root ganglia, (d) are associated with dorsal and ventral roots.
- 4. The adult spinal cord extends only to (a) the coccyx, (b) the sacrum, (c) the third or fourth lumbar vertebra, (d) the first or second lumbar vertebra, (e) the last thoracic vertebra.
- 5. Which of the following statements is *false* concerning the gray matter of the spinal cord? (a) It is located in the interior of the spinal cord around the central canal, (b) It functions in processing neural information, (c) It is primarily involved in relaying information to the brain, (d) It contains motor neurons, (e) It is divided into regions called horns.
- 6. The following are the steps involved in a neural reflex.
 - (1) activation of a sensory neuron
 - (2) activation of a motor neuron
 - (3) response by an effector
 - (4) arrival of a stimulus and activation of a receptor
 - (5) information processing

The proper sequence of these steps is

(a)	1, 3, 4, 5, 2.	(b) 4, 5, 3, 1, 2.
(c)	4, 1, 5, 2, 3.	(d) 4, 3, 1, 5, 2.
()	0 1 1 5 0	

- (e) 3, 1, 4, 5, 2.
- 7. A sensory region monitored by the dorsal rami of a single spinal segment is (a) a ganglion, (b) a fascicle, (c) a dermatome, (d) a ramus.
- The major nerve of the cervical plexus that innervates the diaphragm is the (a) median nerve, (b) axillary nerve, (c) phrenic nerve, (d) fibular nerve.

See the blue Answers tab at the back of the book.

- The genitofemoral, femoral, and lateral femoral cutaneous nerves are major nerves of the (a) lumbar plexus, (b) sacral plexus, (c) brachial plexus, (d) cervical plexus.
- 10. The synapsing of several neurons on the same postsynaptic neuron is called (a) serial processing, (b) reverberation, (c) divergence, (d) convergence.
- The reflexes that control the most rapid, stereotyped motor responses to stimuli are (a) monosynaptic reflexes, (b) polysynaptic reflexes, (c) tendon reflexes, (d) extensor reflexes.
- 12. An example of a stretch reflex triggered by passive muscle movement is the (a) tendon reflex, (b) patellar reflex, (c) flexor reflex, (d) ipsilateral reflex.
- The contraction of flexor muscles and the relaxation of extensor muscles illustrate the principle of (a) reverberating circuitry, (b) generalized facilitation, (c) reciprocal inhibition, (d) reinforcement.
- 14. Reflex arcs in which the sensory stimulus and the motor response occur on the same side of the body are (a) contralateral, (b) paraesthetic, (c) ipsilateral, (d) monosynaptic.
- **15.** Proceeding deep from the most superficial structure, number the following in the correct sequence:
 - (a) _____ walls of vertebral canal
 (b) _____ pia mater
 (c) _____ dura mater
 (d) _____ arachnoid membrane
 - (e) _____ subdural space (f) _____ subarachnoid space

13

(g) _____ epidural space (h) _____ spinal cord

LEVEL 2 Reviewing Concepts

- **16.** Explain the anatomical significance of the fact that spinal cord growth ceases at age 4.
- 17. List, in sequence, the five steps involved in a neural reflex.
- 18. Polysynaptic reflexes can produce far more complicated responses than can monosynaptic reflexes because (a) the response time is quicker, (b) the response is initiated by highly sensitive receptors, (c) motor neurons carry impulses at a faster rate than do sensory neurons, (d) the interneurons involved can control several muscle groups.
- 19. Why do cervical nerves outnumber cervical vertebrae?
- **20.** If the anterior gray horns of the spinal cord were damaged, what type of control would be affected?
- **21.** List all of the CNS sites where cerebrospinal fluid (CSF) is located. What are the functions of CSF?
- 22. What five characteristics are common to all polysynaptic reflexes?
- **23.** Predict the effects on the body of a spinal cord transection at segment C_7 . How would these effects differ from those of a spinal cord transection at segment T_{10} ?
- 24. The subarachnoid space contains (a) cerebrospinal fluid, (b) lymph, (c) air, (d) connective tissue and blood vessels, (e) denticulate ligaments.
- 25. Side-to-side movements of the spinal cord are prevented by the(a) filum terminale, (b) denticulate ligaments, (c) dura mater,(d) pia mater, (e) arachnoid mater.
- 26. Ascending tracts (a) carry sensory information to the brain, (b) carry motor information to the brain, (c) carry sensory information from the brain, (d) carry motor information from the brain, (e) connect perceptive areas with the brain.
- **27.** What effect does the stimulation of a sensory neuron that innervates an intrafusal muscle fiber have on muscle tone?

LEVEL 3 Critical Thinking and Clinical Applications

- 28. Mary complains that when she wakes up in the morning, her thumb and forefinger are always "asleep." She mentions this condition to her physician, who asks Mary whether she sleeps with her wrists flexed. She replies that she does. The physician tells Mary that sleeping in that position may compress a portion of one of her peripheral nerves, producing her symptoms. Which nerve is involved?
- **29.** The improper use of crutches can produce a condition known as "crutch paralysis," characterized by a lack of response by the extensor muscles of the arm, and a condition known as "wrist drop," consisting of an inability to extend the fingers and wrist. Which nerve is involved?
- **30.** Bowel and urinary bladder control involve spinal reflex arcs that are located in the sacral region of the spinal cord. In both instances, two sphincter muscles—an inner sphincter of smooth muscle and an outer sphincter of skeletal muscle—control the passage of wastes (feces and urine) out of the body. How would a transection of the spinal cord at the L₁ segment level affect an individual's bowel and bladder control?
- **31.** Karen falls down a flight of stairs and suffers lumbar and sacral spinal cord damage due to hyperextension of her back. The injury resulted in edema around the central canal that compressed the anterior horn of the lumbar region. What signs would you expect to observe as a result of this injury?

CLINICAL CASE

Prom Night

The emergency room team "log rolls" Joe over onto his side while maintaining his spinal alignment. The abrasions and bruising of his back are obvious. The doctor can feel that Joe's spinous processes , from the 7th cervical to the 11th thoracic vertebrae are in good alignment. There is an obvious gap, however, between the 11th and 12th thoracic spinous processes. The 12th thoracic spinous process and lumbar spine are displaced lateral to the midline. Palpating in this area causes Joe a great deal of discomfort. Joe has no sensation inferior to his 11th thoracic dermatome, just below the level of the navel. Joe also has no voluntary muscle control of any muscles of his hips or inferior.

X-rays taken in the trauma room show a fracture dislocation of the thoracic spine between the 11th thoracic vertebra (T_{11}) and the 12th thoracic vertebra (T_{12}) . An MRI confirms the clinical impression that Joe's spinal cord is completely disrupted at this level.

Joe's spine is surgically realigned and stabilized (fixed in place) with internal fixation. This enables him to begin sitting within the first week after his accident. Within two

Wrap-Up

weeks he is transferred to a spinal rehabilitation facility to begin working on independence as a paraplegic—a person with loss of motor control and sensation to the lower limbs (but not the upper limbs).

- 1. Do you think Joe will regain motor or sensory activity in his lower extremities? Why or why not?
- **2.** Do you think Joe's Babinski reflexes are normal (toes plantar flexed) or abnormal (toes going up, dorsiflexed)? Why?

See the blue Answers tab at the back of the book.

The Brain and Cranial Nerves

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 14-1 Name the major brain regions, vesicles, and ventricles, and describe the locations and functions of each.
- **14-2** Explain how the brain is protected and supported, and discuss the formation, circulation, and function of cerebrospinal fluid.
- **14-3** Describe the anatomical differences between the medulla oblongata and the spinal cord, and identify the main components and functions of the medulla oblongata.
- **14-4** List the main components of the pons, and specify the functions of each.
- **14-5** List the main components of the cerebellum, and specify the functions of each.
- **14-6** List the main components of the midbrain, and specify the functions of each.
- **14-7** List the main components of the diencephalon, and specify the functions of each.
- **14-8** Identify the main components of the limbic system, and specify the locations and functions of each.
- 14-9 Identify the major anatomical subdivisions and functions of the cerebrum, and discuss the origin and significance of the major types of brain waves seen in an electroencephalogram.
- **14-10** Describe representative examples of cranial reflexes that produce somatic responses or visceral responses to specific stimuli.

SPOTLIGHT

• Formation and Circulation of Cerebrospinal Fluid p. 468

CLINICAL CASE

• The Neuroanatomist's Stroke p. 507

Clinical Notes

- Epidural and Subdural Hemorrhages p. 467
- Disconnection Syndrome p. 488
- Aphasia and Dyslexia p. 489

CLINICAL CASE

The Neuroanatomist's Stroke

Dr. Jill Bolte Taylor, a well-published neuroanatomist, was at the top of her field at age 37 when

she awoke to an evolving cerebrovascular accident (CVA), or stroke. It was caused by bleeding into her left cerebral hemisphere near her language center. The irony of her situation was not lost on her. There she was, a brain scientist witnessing a brain-centered medical emergency: her own.

Dr. Taylor's first sign that something was wrong was a throbbing, pulsating headache behind her left eye. She then noticed a shift in her perceptions and consciousness, and experienced a slowing of her thoughts and movements. By the time she was aware that her right arm was paralyzed, she was barely able to call for help. When she arrived at the hospital, she could not walk, talk, read, write, or recall anything about her life. She felt her spirit surrender and braced for death.

Dr. Taylor awoke later that day, shocked to be alive. She was unable to speak or understand speech. Sounds irritated her. She could not recognize or use numbers. Less than three weeks later, doctors performed open brain surgery to remove a large blood clot

that was pressing on the left side of her brain. **Would Dr. Taylor** ever fully recover? To find out, turn to the Clinical Case Wrap-Up on p. 507.

14

An Introduction to the Brain and Cranial Nerves

In this chapter we introduce the functional organization of the brain and cranial nerves, and describe simple cranial reflexes. The adult human brain contains almost 97 percent of the body's neural tissue. A "typical" brain weighs 1.4 kg (3 lb) and has a volume of 1200 mL (71 in.³).

Brain size varies considerably among individuals. The brains of males are, on average, about 10 percent larger than those of females, due to differences in average body size. No correlation exists between brain size and intelligence. Individuals with the smallest brains (750 mL) and the largest brains (2100 mL) are functionally normal.

14–1 The brain has several principal structures, each with specific functions

Learning Outcome Name the major brain regions, vesicles, and ventricles, and describe the locations and functions of each.

In this section we introduce the anatomical organization of the brain. We begin with an overview of the brain's major regions and landmarks. Then we discuss the brain's embryonic origins and some prominent internal cavities: the ventricles of the brain.

Major Brain Regions and Landmarks

There are six major brain regions: the cerebrum, cerebellum, diencephalon, midbrain, pons, and medulla oblongata (Figure 14–1). The largest portion of the adult brain is the **cerebrum** (se-RĒ-brum or SER-e-brum). It is made up of large, paired left and right **cerebral hemispheres**. The brain has an extensive area of **cortex**, a superficial layer of gray matter covering most of its surface. The surfaces of the cerebral hemispheres are highly folded and covered by a neural cortex called the **cerebral cortex** (*cortex*, rind or bark). This cerebral cortex forms a series of elevated ridges, or **gyri** (JĪ-rī; singular, *gyrus*). Gyri increase its surface area. The gyri are separated by shallow depressions called **sulci** (SUL-sī) or by deeper grooves called **fissures**. The cerebrum is the seat of most higher mental functions. Conscious thoughts, sensations, intellect, memory, and complex movements all originate in the cerebrum.

The **cerebellum** (ser-e-BEL-um) is the second-largest part of the brain. It is partially hidden by the cerebral hemispheres. Like the cerebrum, the cerebellum has hemispheres covered by a neural cortex called the *cerebellar cortex*. The cerebellum adjusts ongoing movements by comparing arriving sensations with previously experienced sensations, allowing you to perform the same movements over and over.

The other major anatomical regions of the brain can best be examined after the cerebral and cerebellar hemispheres have been removed (Figure 14–1). The walls of the **diencephalon** (dī-en-SEF-a-lon; *dia*, through + *encephalos*, brain) are composed of the **left thalamus** and **right thalamus** (THAL-a-mus; plural, *thalami*). Each thalamus contains relay and processing centers for sensory information. The **hypothalamus** (*hypo*-, below) is the floor of the diencephalon. It contains centers involved with emotions, autonomic function, and hormone production. The *infundibulum*, a narrow stalk, connects the hypothalamus to the **pituitary gland**, a part of the endocrine system. The hypothalamus and the pituitary gland integrate the nervous and endocrine systems.

The diencephalon is a structural and functional link between the cerebral hemispheres and the brain stem. The

Figure 14–1 An Introduction to Brain Structures and Functions.

brain stem contains a variety of important processing centers and nuclei that relay information headed to or from the cerebrum or cerebellum. As **Figure 14–1** shows, the brain stem includes the *midbrain*, *pons*, and *medulla oblongata*.¹

• The **midbrain**, or *mesencephalon*, contains nuclei that process visual and auditory information and control reflexes triggered by these stimuli. For example, your immediate,

reflexive responses to a loud, unexpected noise (eye movements and head turning) are directed by nuclei in the midbrain. This region also contains centers that help maintain consciousness.

- The **pons** of the brain connects the cerebellum to the brain stem (*pons* is Latin for "bridge"). In addition to tracts and relay centers, the pons contains nuclei involved with somatic and visceral motor control.
- The **medulla oblongata** connects the brain to the spinal cord. Near the pons, the posterior wall of the medulla oblongata is thin and membranous. The inferior portion of

¹Some sources consider the brain stem to include the diencephalon. We will use the more restrictive definition.

the medulla oblongata resembles the spinal cord in that it has a narrow central canal. The medulla oblongata relays sensory information to the thalamus and to centers in other portions of the brain stem. The medulla oblongata also contains major centers that regulate autonomic function, such as heart rate, blood pressure, and digestion.

Figure 14–1 shows the boundaries and general functions of the diencephalon and brain stem. In considering the parts of the brain, we will begin at the inferior portion of the medulla oblongata. This region has the simplest organization found anywhere in the brain. In many respects, it resembles the spinal cord. We will then ascend to regions of increasing structural and functional complexity. Finally, we will reach the cerebral cortex. The functions and capabilities of this very interesting area are as yet poorly understood.

Embryology of the Brain

14

The embryonic origins of the brain can help us understand its internal organization. The central nervous system (CNS) begins as a hollow cylinder known as the *neural tube*. This tube has a fluid-filled internal cavity, the *neurocoel*. In the cephalic portion of the neural tube, three areas enlarge rapidly through expansion of the neurocoel. This enlargement creates three prominent divisions called **primary brain vesicles**. They are named for their relative positions: the *prosencephalon* (prōz-en-SEF-a-lon; *proso*, forward + *enkephalos*, brain), or "forebrain"; the *mesencephalon*, or "midbrain"; and the *rhombencephalon* (rom-ben-SEF-a-lon), or "hindbrain."

Table 14–1 summarizes the fates of these three primary divisions of the brain. The prosencephalon and rhombencephalon are subdivided further, forming **secondary brain vesicles**. The prosencephalon forms the **telencephalon** (tel-en-SEF-a-lon; *telos*, end) and the diencephalon. The telencephalon ultimately forms the cerebrum of the brain. The walls of the mesencephalon thicken, and the neurocoel becomes a relatively narrow passageway, much like the central canal of the spinal cord. The portion of the rhombencephalon adjacent to the mesencephalon forms the **metencephalon** (met-en-SEF-a-lon; *meta*, after). The dorsal portion of the metencephalon later becomes the cerebellum, and the ventral portion develops into the pons. The portion of the rhombencephalon closer to the spinal cord forms the **myelencephalon** (mī-el-en-SEF-a-lon; *myelon*, spinal cord), which becomes the medulla oblongata. ATLAS: Embryology Summary 12: The Development of the Brain and Cranial Nerves

Ventricles of the Brain

During development, the neurocoel within the cerebral hemispheres, diencephalon, metencephalon, and medulla oblongata expands to form chambers called **ventricles** (VEN-tri-kls). Cells of the *ependyma* line the ventricles. \bigcirc p. 392

Each cerebral hemisphere contains a large **lateral ventricle** (Figure 14–2). The **septum pellucidum**, a thin medial partition, separates the two lateral ventricles. Because there are *two* lateral ventricles, the ventricle in the diencephalon is called the **third ventricle**. The two lateral ventricles are not directly connected, but each communicates with the third ventricle of the diencephalon through an **interventricular foramen** (*foramen of Monro*).

The midbrain has a slender canal known as the **cere-bral aqueduct**. This passageway connects the third ventricle with the **fourth ventricle**. The superior portion of the fourth

Figure 14–2 Ventricles of the Brain. The orientation and extent of the ventricles as they would appear if the brain were transparent. ATLAS: Plates 10; 12a–c; 13a–e

ventricle lies between the posterior surface of the pons and the anterior surface of the cerebellum. The fourth ventricle extends into the superior portion of the medulla oblongata. There this ventricle narrows and becomes continuous with the central canal of the spinal cord.

The ventricles are filled with cerebrospinal fluid (CSF). The CSF continuously circulates from the ventricles and central canal into the *subarachnoid space* of the surrounding cranial meninges. The CSF passes between the interior and exterior of the CNS through three foramina in the roof of the fourth ventricle. We will describe these foramina in a later section.

CHECKPOINT

- 1. Name the six major regions of the brain.
- 2. What brain regions make up the brain stem?
- 3. Which primary brain vesicle is destined to form the cerebellum, pons, and medulla oblongata?

See the blue Answers tab at the back of the book.

14–2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood–brain barrier

Learning Outcome Explain how the brain is protected and supported, and discuss the formation, circulation, and function of cerebrospinal fluid.

The delicate tissues of the brain are protected from physical forces by the bones of the cranium, the *cranial meninges*, and cerebrospinal fluid. In addition, the neural tissue of the brain

is biochemically isolated from the general circulation by the *blood–brain barrier*.

Refer to Figures 7–3 and 7–4 (pp. 210–213) for a review of the bones of the cranium. We will discuss the other protective factors here.

The Cranial Meninges

The layers that make up the cranial meninges—the cranial dura mater, arachnoid mater, and pia mater—are continuous with the spinal meninges. \bigcirc p. 433 However, the cranial meninges have distinctive anatomical and functional characteristics (Figure 14–3a):

- The *dura mater* consists of outer and inner fibrous layers. The outer layer is fused to the periosteum of the cranial bones. As a result, there is no epidural space superficial to the dura mater, as occurs along the spinal cord. The outer, *periosteal*, and inner, *meningeal*, layers of the cranial dura mater are typically separated by a slender gap that contains tissue fluids and blood vessels, including several large venous sinuses. The veins of the brain open into these sinuses, which deliver the venous blood to the *internal jugular veins* of the neck.
- The *arachnoid mater* consists of the arachnoid membrane (an epithelial layer) and the cells and fibers of the arachnoid trabeculae that cross the subarachnoid space to the pia mater. The arachnoid membrane covers the brain, providing a smooth surface that does not follow the brain's underlying folds. This membrane is in contact with the inner epithelial layer of the dura mater. The subarachnoid space extends between the arachnoid membrane and the pia mater.

• The *pia mater* sticks to the surface of the brain, anchored by the processes of astrocytes. It extends into every fold and fissure. It also accompanies the branches of cerebral blood vessels as they penetrate the surface of the brain to reach internal structures.

Dural Folds

In several locations, the inner layer of the dura mater extends into the cranial cavity, forming a sheet that dips inward and then returns. These **dural folds** provide additional stabilization and support to the brain. **Dural sinuses** are large collecting veins located within the dural folds. The three largest dural folds are called the falx cerebri, the tentorium cerebelli, and the falx cerebelli (Figure 14–3b):

1. The **falx cerebri** (FALKS SER-e-brī; *falx*, curving or sickleshaped) is a fold of dura mater that projects between the cerebral hemispheres in the longitudinal fissure. Its inferior portions attach anteriorly to the crista galli of the ethmoid bone and posteriorly to the *internal occipital crest*, a ridge along the inner surface of the occipital bone. The **superior sagittal sinus** and the **inferior sagittal sinus**, two large venous sinuses, lie within this dural fold. The posterior margin of the falx cerebri intersects the tentorium cerebelli.

- 2. The **tentorium cerebelli** (ten-TŌ-rē-um ser-e-BEL-ē; *tentorium*, tent) protects the cerebellum and separates the cerebral hemispheres from the cerebellum. It extends across the cranium at right angles to the falx cerebri. The **transverse sinus** lies within the tentorium cerebelli.
- 3. The **falx cerebelli** divides the two cerebellar hemispheres along the midsagittal line inferior to the tentorium cerebelli.

The Protective Function of the Cranial Meninges

The overall shape of the brain corresponds to that of the cranial cavity (Figure 14–3a). The cranial bones provide physical protection by cradling the brain, but they also pose a threat to safety that is countered by the cranial meninges and the CSF. The brain is like a person driving a car: If the car hits a tree, the car protects the driver from contact with the tree, but serious injury will occur unless a seat belt or airbag protects the driver from contact with the car. The tough, fibrous dural folds act like seat belts that hold the brain in position. The cerebrospinal fluid in the subarachnoid space acts like a bumper by cushioning the brain against sudden jolts and shocks.

Cranial trauma is a head injury resulting from impact with another object. Each year in the United States, about 8 million cases of cranial trauma occur, but only 1 case in 8 results in serious brain damage. The percentage is relatively low because the cranial meninges and CSF are so effective in protecting the brain.

Cerebrospinal Fluid

Cerebrospinal fluid (CSF) completely surrounds and bathes the exposed surfaces of the CNS. The CSF has several important functions, including the following:

- Cushioning Delicate Neural Structures.
- Supporting the Brain. In essence, the brain is suspended inside the cranium and floats in the CSF. A human brain weighs about 1400 g (3.09 lb.) in air, but only about 50 g (1.8 oz.) when supported by CSF.
- Transporting Nutrients, Chemical Messengers, and Waste Products. Except at the choroid plexus, where CSF is produced, the ependymal lining is freely permeable. The CSF is in

constant chemical communication with the interstitial fluid that surrounds the neurons and neuroglia of the CNS.

Because free exchange occurs between the interstitial fluid of the brain and the CSF, changes in CNS function can produce changes in the composition of the CSF (Spotlight Figure 14–4). As noted in Chapter 13, a *spinal tap* can provide useful clinical information about CNS injury, infection, or disease. \supset p. 434

The Formation and Circulation of CSF

A **choroid plexus** (*choroeides*, like a membrane; *plexus*, network) is an area within each ventricle that produces CSF.

Specialized ependymal cells bearing microvilli and interconnected by tight junctions surround the capillaries of a choroid plexus. The ependymal cells secrete CSF into the ventricles. They also remove waste products from the CSF and adjust its composition over time. The differences in composition between CSF and blood plasma (blood with the cellular elements removed) are quite noticeable. For example, blood plasma contains high concentrations of soluble proteins, but the CSF does not. The concentrations of individual ions and the levels of amino acids, lipids, and waste products are also different (Spotlight Figure 14–4).

If the normal circulation or resorption of CSF is interrupted, a variety of clinical problems may appear. For example, a problem with the resorption of CSF in infancy causes *hydrocephalus*, or "water on the brain." Infants with this condition have enormously expanded skulls due to the presence of an abnormally large volume of CSF. In adults, a failure of resorption or a blockage of CSF circulation can distort and damage the brain.

Epidural and Subdural Hemorrhages A severe head injury may damage meningeal blood vessels and cause bleeding into the cranial cavity. The most serious cases involve an arterial break, because arterial blood pressure is relatively high. If blood is forced between the dura mater and the skull, the condition is known as an **epidural hemorrhage**. The elevated fluid pressure then distorts the underlying tissues of the brain. The individual loses consciousness for a period lasting from minutes to hours after the injury, and death follows in untreated cases. An epidural hemorrhage involving a damaged vein does not produce massive symptoms immediately. The individual may not have neurological problems for hours, days, or even weeks after the original injury. As a result, the problem may not be noticed until the nervous tissue has been severely damaged. Epidural hemorrhages are rare, occurring in less than 1 percent of head injuries. However, the mortality rate is 100 percent in untreated cases and over 50 percent even after the blood pool has been removed and the damaged vessels have been closed.

A **subdural hemorrhage** is bleeding between the dura mater and the arachnoid mater. Subdural hemorrhages are twice as common as epidural hemorrhages. Small veins that cross the subdural space or one of the dural sinuses causes the bleeding. Because the venous blood pressure in a subdural hemorrhage is lower than that in an arterial epidural hemorrhage, the distortion produced is gradual. The effects on brain function can be quite variable and difficult to diagnose.

SPOTLIGHT Figure 14–4 Formation and Circulation of Cerebrospinal Fluid

The Blood Supply to the Brain

As noted in Chapter 12, neurons have a high demand for energy, but they have no energy reserves in the form of carbohydrates or lipids. Neurons also have no oxygen reserves in the form of myoglobin. Your brain, with billions of neurons, is an extremely active organ with a continuous demand for nutrients and oxygen. These demands are met by an extensive circulatory supply.

Arterial blood reaches the brain through the *internal carotid arteries* and the *vertebral arteries*. Most of the venous blood from the brain leaves the cranium in the *internal jugular veins*, which drain the dural sinuses. A head injury that damages cerebral blood vessels may cause bleeding into the dura mater, either near the dural epithelium or between the outer layer of the dura mater and the skull. These are serious conditions, because the blood entering these spaces compresses and distorts the soft tissues of the brain.

Cerebrovascular diseases are cardiovascular disorders that interfere with the normal blood supply to the brain. The particular distribution of the vessel involved determines the signs and symptoms. The degree of oxygen or nutrient starvation determines their severity. A **cerebrovascular accident (CVA)**, or *stroke*, occurs when the blood supply to a portion of the brain is shut off. Affected neurons begin to die in a matter of minutes.

The Blood–Brain Barrier

Neural tissue in the CNS is isolated from the general circulation by the **blood–brain barrier (BBB)**. This barrier is formed by capillary endothelial cells that are extensively interconnected by tight junctions. These junctions prevent materials from diffusing between endothelial cells. In general, only lipid-soluble compounds (including carbon dioxide; oxygen; ammonia; lipids, such as steroids or prostaglandins; and small alcohols) can diffuse across the membranes of endothelial cells into the interstitial fluid of the brain and spinal cord. Water and ions must pass through channels in the apical and basement plasma membranes. Larger, water-soluble compounds can cross the capillary walls only by active or passive transport.

The restricted permeability of the endothelial lining of brain capillaries is in some way dependent on chemicals secreted by astrocytes. \bigcirc p. 393 These glial cells play a key supporting role in the blood-brain barrier because they release chemicals that control the permeabilities of the endothelium to various substances. Astrocytes are in close contact with CNS capillaries. The processes of astrocytes cover the outer surfaces of the endothelial cells. If the astrocytes are damaged or stop stimulating the endothelial cells, the blood-brain barrier disappears.

The choroid plexus is not part of the neural tissue of the brain, so no astrocytes are in contact with the endothelial cells there. Substances do not have free access to the CNS, however, because specialized ependymal cells create a **blood–CSF barrier**. These cells, also interconnected by tight junctions, surround the capillaries of the choroid plexus.

Transport across the blood-brain and blood-CSF barriers is selective and directional. Even the passage of small ions, such as sodium, hydrogen, potassium, or chloride, is controlled. As a result, the pH and concentrations of sodium, potassium, calcium, and magnesium ions in the blood and CSF are different. Some organic compounds are readily transported, and others cross only in very small amounts.

Neurons have a constant need for glucose that must be met regardless of the concentrations in the blood and interstitial fluid. Even when circulating glucose levels are low, endothelial cells continue to transport glucose from the blood to the interstitial fluid of the brain. In contrast, only trace amounts of circulating norepinephrine, epinephrine, dopamine, and serotonin pass into the interstitial fluid or CSF of the brain. This limitation is important, because these compounds are neurotransmitters. Their entry from the bloodstream (where concentrations can be relatively high) could result in the uncontrolled stimulation of neurons throughout the brain.

The blood-brain barrier remains intact throughout the CNS except in small areas known as *circumventricular organs* (*CVOs*), which have fenestrated capillaries. Because they are outside the BBB, they provide a direct link between the CNS and the peripheral blood and they play a role in neuroendocrine function. In summary, these noteworthy exceptions include:

- Portions of the hypothalamus, where the capillary endothelium is extremely permeable. This permeability exposes hypothalamic nuclei to circulating hormones and permits hypothalamic hormones to diffuse into the circulation.
- 2. Capillaries in the posterior lobe of the pituitary gland, which is continuous with the floor of the hypothalamus. At this site, the hormones antidiuretic hormone and oxytocin, produced by hypothalamic neurons, are released into the circulation.
- **3.** Capillaries in the *pineal gland*. This endocrine gland is located on the posterior, superior surface of the diencephalon. The capillary permeability allows pineal secretions into the general circulation.
- 4. Capillaries at a choroid plexus. The capillary characteristics of the blood–brain barrier are lost there, but the transport activities of specialized ependymal cells in the choroid plexuses maintain the blood–CSF barrier.

Physicians must sometimes get specific compounds into the interstitial fluid of the brain to fight CNS infections or to treat other neural disorders. To do this, they must understand the limitations of the blood–brain barrier and blood–CSF barrier. For example, when considering possible treatments, the antibiotic *tetracycline* isn't used to treat meningitis or other CNS infections because this drug is excluded from the brain. In contrast, *sulfisoxazole* and *sulfadiazine* enter the CNS very rapidly. Sometimes, chemotherapeutic drugs or imaging dyes may be injected directly into the CSF by lumbar puncture.

CHECKPOINT

- 4. From superficial to deep, name the layers that make up the cranial meninges.
- 5. What would happen if the normal circulation or resorption of CSF were blocked?
- 6. How would decreased diffusion across the arachnoid granulations affect the volume of cerebrospinal fluid in the ventricles?
- 7. Many water-soluble molecules that are abundant in the blood occur in small amounts or not at all in the extracellular fluid (ECF) of the brain. Why?

See the blue Answers tab at the back of the book.

14–3 The medulla oblongata is continuous with the spinal cord and contains vital centers

Learning Outcome Describe the anatomical differences between the medulla oblongata and the spinal cord, and identify the main components and functions of the medulla oblongata.

The medulla oblongata is the most inferior of the brain regions. Figure 14–5 shows the position of the medulla oblongata in relation to the other components of the brain stem and the diencephalon. It also illustrates the attachment sites for 11 of the 12 pairs of cranial nerves. The individual cranial nerves are identified by a capital N followed by a Roman numeral. (We will introduce the full names and functions of these nerves in a later section.)

In sectional view, the inferior portion of the medulla oblongata resembles the spinal cord, with a small central canal. However, the gray matter and white matter organization is more complex. Ascending the medulla oblongata, the central canal opens into the fourth ventricle, and the similarity to the spinal cord all but disappears.

The medulla oblongata is a very busy place. All communication between the brain and spinal cord involves tracts that ascend or descend through the medulla oblongata. In addition, the medulla oblongata is a center for the coordination of complex autonomic reflexes and the control of visceral functions.

The medulla oblongata includes three groups of nuclei that we will discuss in later chapters (Figure 14–6a,b):

1. Autonomic Nuclei Controlling Visceral Activities. The **reticu**lar formation is a loosely organized mass of gray matter that contains embedded nuclei. It extends from the medulla oblongata to the midbrain. The portion of the reticular formation in the medulla oblongata contains nuclei and specific reflex, or processing, centers that regulate vital autonomic functions. These **reflex centers** receive inputs from cranial nerves, the cerebral cortex, and the brain stem. Their output controls or adjusts the activities of one or more peripheral systems.

There are two major groups of reflex centers in the medulla oblongata. The **cardiovascular centers** adjust the heart rate, the strength of cardiac contractions, and the flow of blood through peripheral tissues. (In terms of function, the cardiovascular centers are subdivided into **cardiac** and **vasomotor centers**, but their anatomical boundaries are difficult to determine.)

The **respiratory rhythmicity centers** set the basic pace for respiratory movements. Their activity is regulated by inputs from the apneustic and pneumotaxic respiratory centers of the pons.

- 2. Sensory and Motor Nuclei of Cranial Nerves. The medulla oblongata contains sensory and motor nuclei associated with five of the cranial nerves (VIII, IX, X, XI, and XII). These cranial nerves provide motor commands to muscles of the pharynx, neck, and back as well as to the visceral organs of the thoracic and peritoneal cavities. Cranial nerve VIII carries sensory information from receptors in the internal ear to the vestibular and cochlear nuclei, which extend from the pons into the medulla oblongata.
- 3. *Relay Stations along Sensory and Motor Pathways.* The **nucleus gracilis** and the **nucleus cuneatus** pass somatic sensory information to the thalamus. Tracts leaving these brain stem nuclei cross to the opposite side of the brain before reaching their destinations. This crossing over is called a *decussation* (dē-kuh-SĀ-shun; *decussatio*, crossing over), and the site is the **decussation of pyramids**.

The **solitary nucleus** on either side receives visceral sensory information that reaches the CNS from the spinal nerves and cranial nerves. This information is integrated and forwarded to other autonomic centers in the medulla oblongata and elsewhere.

The **olivary nuclei** relay information to the cerebellar cortex about somatic motor commands as they are issued by motor centers at higher levels. The bulk of the olivary nuclei creates the **olives**, prominent olive-shaped bulges along the ventrolateral surface of the medulla oblongata.

Figure 14–6 also contains a summary of the major components of the medulla oblongata and their functions.

14

Figure 14–6 The Medulla Oblongata. ATLAS: Plates 9a–c; 11c

CHECKPOINT

- 8. Identify the components of the medulla oblongata that are responsible for relaying somatic sensory information to the thalamus.
- 9. The medulla oblongata is one of the smallest sections of the brain, yet damage there can cause death, whereas similar damage in the cerebrum might go unnoticed. Why?

See the blue Answers tab at the back of the book.

14-4 The pons contains nuclei and tracts that carry or relay sensory and motor information

Learning Outcome List the main components of the pons, and specify the functions of each.

The pons links the cerebellum with the midbrain, diencephalon, cerebrum, and spinal cord. Important features and regions of the pons are indicated in Figures 14–5 and 14–7.

Figure 14–7 The Pons. ATLAS: Plates 9a–c; 11c

The pons contains four groups of components:

- 1. Sensory and Motor Nuclei of Cranial Nerves. These cranial nerves (V, VI, VII, and VIII) innervate the jaw muscles, the anterior surface of the face, one of the extrinsic eye muscles (the lateral rectus), and the sense organs of the internal ear (the *vestibular* and *cochlear nuclei*).
- 2. Nuclei Involved with the Control of Respiration. On each side of the pons, the reticular formation in this region contains two respiratory centers: the *apneustic center* and the *pneumotaxic center*. These centers modify the activity of the *respiratory rhythmicity centers* in the medulla oblongata.
- **3.** *Nuclei and Tracts That Process and Relay Information Sent to or from the Cerebellum.* The pons links the cerebellum with the brain stem, cerebrum, and spinal cord.
- 4. *Ascending, Descending, and Transverse Tracts.* Longitudinal tracts interconnect other portions of the CNS. The middle cerebellar peduncles are connected to the **transverse fibers**, which cross the anterior surface of the pons. These fibers are axons that link nuclei of the pons (*pontine nuclei*) with the cerebellar hemisphere of the opposite side.

Figure 14–7 also contains a summary of the major components of the pons and their functions.

	The Pons	
	Region/Nucleus	Function
	WHITE MATTER	
	Descending tracts	Carry motor commands from higher centers to nuclei of cranial or spinal nerves
	- Ascending tracts	Carry sensory information from brain stem nuclei to the thalamus
_	Transverse fibers	Interconnect cerebellar hemispheres
	GRAY MATTER	
	Apneustic and pneumotaxic centers	Adjust activities of the respiratory rhythmicity centers in the medulla oblongata
	Reticular formation	Automatic processing of incoming sensations and outgoing motor commands
	Cranial nerve nuclei N V, VI, VII, and VIII (in part)	Relay sensory information and issue somatic motor commands
	Other nuclei/relay centers	Relay sensory and motor information to the cerebellum

CHECKPOINT

- 10. Name the four groups of components found in the pons.
- 11. If the respiratory centers of the pons were damaged, what respiratory controls might be lost?
- See the blue Answers tab at the back of the book.

14–5 The cerebellum coordinates learned and reflexive patterns of muscular activity at the subconscious level

Learning Outcome List the main components of the cerebellum, and specify the functions of each.

The cerebellum is an automatic processing center (Figure 14–8). It has two primary functions:

- 1. *Adjusting the Postural Muscles of the Body.* The cerebellum coordinates rapid, automatic adjustments that maintain balance and equilibrium. It makes these alterations in muscle tone and position by modifying the activities of motor centers in the brain stem.
- 2. Programming and Fine-Tuning Movements Controlled at the Conscious and Subconscious Levels. The cerebellum refines learned movement patterns, such as riding a bicycle or

Figure 14–8 The Cerebellum.

playing the piano. It performs this function indirectly by regulating activity along motor pathways at the cerebral cortex, basal nuclei, and motor centers in the brain stem. The cerebellum compares the motor commands with proprioceptive information (position sense) and stimulates any adjustments needed to make the movement smooth.

The cerebellum has a complex, highly convoluted surface composed of neural cortex. The **folia** (FŌ-lē-uh; leaves), or folds of the cerebellum surface, are less prominent than the folds in the surfaces of the cerebral hemispheres (**Figure 14–8a**). The **primary fissure** separates the **anterior** and **posterior lobes**. Along the midline, a narrow band of cortex known as the **vermis** (VER-mis) separates the **cerebellar hemispheres**. The slender **flocculonodular** (flok-ū-lō-NOD-ū-lar) **lobe** lies between the roof of the fourth ventricle and the cerebellar hemispheres and vermis (Figure 14–8b).

Like the cerebrum, the cerebellum has a superficial layer of neural cortex. The cerebellar cortex contains relatively huge, highly branched **Purkinje** (pur-KIN-jē) **cells**. The extensive dendrites of each Purkinje cell receive input from up to 200,000 synapses— more than any other type of brain cell. The internal white matter of the cerebellum forms a branching array that in sectional view resembles a tree. Anatomists call it the **arbor vitae**, or "tree of life" (**Figure 14–8b**). It connects the cerebellar cortex and nuclei with the cerebellar peduncles, which we discuss below.

The cerebellum receives proprioceptive (position) information from the spinal cord and monitors all proprioceptive, visual, tactile, balance, and auditory sensations received by the brain. Most axons that carry sensory information do not synapse in the cerebellar nuclei but pass through the deeper layers of the cerebellum on their way to the Purkinje cells of the cerebellar cortex. Information about the motor commands issued at the conscious and subconscious levels reaches the Purkinje cells indirectly, after being relayed by nuclei in the pons or by the **cerebellar nuclei** embedded within the arbor vitae.

Tracts that link the cerebellum with the brain stem, cerebrum, and spinal cord leave the cerebellar hemispheres as the superior, middle, and inferior cerebellar peduncles:

- The superior cerebellar peduncles link the cerebellum with nuclei in the midbrain, diencephalon, and cerebrum.
- The middle cerebellar peduncles are connected to a broad band of fibers that cross the ventral surface of the pons at right angles to the axis of the brain stem. The middle cerebellar peduncles also connect the cerebellar hemispheres with sensory and motor nuclei in the pons.
- The **inferior cerebellar peduncles** communicate between the cerebellum and nuclei in the medulla oblongata and carry ascending and descending cerebellar tracts from the spinal cord.

The cerebellum can be permanently damaged by trauma or stroke. Drugs such as alcohol can also temporarily affect

it. The result is **ataxia** (a-TAK-sē-uh; *ataxia*, lack of order), a disturbance in muscular coordination. In severe ataxia, the individual cannot sit or stand without assistance.

- CHECKPOINT

- 12. Identify the components of the cerebellar gray matter.
- 13. What part of the brain has the arbor vitae? What is its function?
- See the blue Answers tab at the back of the book.

14-6 The midbrain regulates auditory and visual reflexes and controls alertness

Learning Outcome List the main components of the midbrain, and specify the functions of each.

The external anatomy of the midbrain is shown in Figures 14–5 and 14-9, and its major nuclei are listed in Figure 14-9. The tectum, or roof of the midbrain, is the region posterior to the cerebral aqueduct. It contains two pairs of sensory nuclei known collectively as the corpora quadrigemina (KOR-poruh qua-dri-JEM-i-nuh). These nuclei, the superior and inferior colliculi, process visual and auditory sensations. Each superior colliculus (ko-LIK-ū-lus; colliculus, hill) receives visual inputs from the lateral geniculate nucleus of the thalamus on that side. Each inferior colliculus receives auditory input from nuclei in the medulla oblongata and pons. Some of this information may be forwarded to the medial geniculate nucleus of the thalamus on the same side. The superior colliculi control the reflex movements of the eyes, head, and neck in response to visual stimuli, such as a bright light. The inferior colliculi control reflex movements of the head, neck, and trunk in response to auditory stimuli, such as a loud noise.

The area anterior to the cerebral aqueduct is called the **teg-mentum**. On each side, the tegmentum contains a red nucleus and the substantia nigra (Figure 14–9a,c). The **red nucleus** contains numerous blood vessels, which give it a rich red color. This nucleus receives information from the cerebrum and cerebellum and issues subconscious motor commands that affect upper limb position and background muscle tone. The **sub-stantia nigra** (NĪ-gruh; *nigra*, black) is the largest midbrain nucleus. It lies lateral to the red nucleus. The gray matter in this region contains darkly pigmented cells, giving it a black color. The pigment is melanin and here it is a byproduct of dopamine synthesis.

The substantia nigra inhibits activity of the basal nuclei in the cerebrum. The basal nuclei are involved in the subconscious control of muscle tone and learned movements. As discussed in a later section, *Parkinson's disease* is characterized by the loss of neuronal activity in the substantia nigra.
Figure 14–9 The Midbrain. ATLAS: Plates 7b; 9a–c; 11c; 12a,c

The nerve fiber bundles on the ventrolateral surfaces of the midbrain (Figures 14–5 and 14–9c) are the **cerebral peduncles** (*peduncles*, little feet). They contain (1) descending fibers that go to the cerebellum by way of the pons and (2) descending fibers that carry voluntary motor commands issued by the cerebral hemispheres.

The midbrain also contains the *reticular activating system* (*RAS*), a specialized component of the reticular formation. Stimulation of the RAS makes you more alert and attentive; damage to the RAS produces unconsciousness. We will consider the role of the RAS in maintaining consciousness in Chapter 16.

CHECKPOINT

- 14. Identify the sensory nuclei within the corpora quadrigemina.
- 15. Which area of the midbrain controls reflexive movements of the eyes, head, and neck in response to visual stimuli?

See the blue Answers tab at the back of the book.

14-7 The diencephalon integrates sensory information with motor output at the subconscious level

Learning Outcome List the main components of the diencephalon, and specify the functions of each.

The diencephalon is a division of the brain that consists of the epithalamus, thalamus, and hypothalamus. Figure 14–5 shows its position and its relationship to landmarks on the brain stem.

The *epithalamus* is the roof of the diencephalon superior to the third ventricle. The anterior portion of the epithalamus contains an extensive area of choroid plexus that extends through the interventricular foramina into the lateral ventricles. The posterior portion of the epithalamus contains the **pineal gland** (Figure 14–5c), an endocrine structure that secretes the hormone **melatonin**. Melatonin is important in regulating day–night cycles and reproductive functions. (We will describe the role of melatonin in Chapter 18.)

Most of the neural tissue in the diencephalon is concentrated in the *left thalamus* and *right thalamus*, which form the lateral walls, and the *hypothalamus*, which forms the floor. Ascending sensory information from the spinal cord and cranial nerves (other than the olfactory tract) synapses in a nucleus in the left or right thalamus before reaching the cerebral cortex and our conscious awareness. The hypothalamus contains centers involved with emotions and visceral processes that affect the cerebrum as well as other components of the brain stem. It also controls a variety of autonomic functions and forms the link between the nervous and endocrine systems.

The Thalamus

On each side of the diencephalon, the thalamus is the final relay point for sensory information ascending to the primary sensory cortex. It acts as a filter, passing on only a small portion of the arriving sensory information. The thalamus also coordinates the activities of the basal nuclei (in the cerebrum) and the cerebral cortex by relaying information between them.

The third ventricle separates the left thalamus and right thalamus. Each thalamus consists of a rounded mass of *thalamic nuclei* (Figure 14–10). Viewed in a midsagittal section through the brain (Figure 14–11a), each thalamus extends from the anterior commissure to the inferior base of the pineal gland. A projection of gray matter called an **interthalamic adhesion**

b An enlarged view of the thalamic nuclei of the left side

extends into the ventricle from the thalamus on either side (Figures 14–11b and 14–12), but no fibers cross the midline.

Functions of Thalamic Nuclei

The thalamic nuclei deal primarily with the relay of sensory information to the basal nuclei (parts of the cerebrum which we will discuss shortly) and cerebral cortex. The five major groups of thalamic nuclei are shown in Figure 14–10b and listed in Table 14–2. They are the anterior, medial, ventral, posterior, and lateral groups:

1. The *anterior group* includes the **anterior nuclei**, which are part of the *limbic system*. This system is involved with emotion and motivation. We will discuss it in a later section.

14

Table 14–2	The Thalamus			
Group/Nuclei		Function		
Anterior Group		Part of the limbic system		
Medial Group		Integrates sensory information for projection to the frontal lobes		
Ventral Group		Projects sensory information to the primary sensory cortex; relays information from cerebellum and basal nuclei to motor area of cerebral cortex		
Posterior Group				
Pulvinar nucl	ei	Integrates sensory information for projection to association areas of cerebral cortex		
Lateral genic	ulate nuclei	Project visual information to the visual cortex		
Medial genicu	ılate nuclei	Project auditory information to the auditory cortex		
Lateral Group		Integrates sensory information and influences emotional states		

- 2. The nuclei of the *medial group* provide an awareness of emotional states by connecting emotional centers in the hypothalamus with the *frontal lobes* of the cerebral hemispheres. The medial group also receives and relays sensory information from other portions of the thalamus.
- **3.** The nuclei of the *ventral group* relay information from the *basal nuclei* of the cerebrum and the cerebellum to somatic motor areas of the cerebral cortex. Ventral group nuclei also relay sensory information about touch, pressure, pain, temperature, and proprioception (position) to the sensory areas of the cerebral cortex.
- 4. The *posterior group* includes the pulvinar and geniculate nuclei. The **pulvinar nuclei** integrate sensory information for projection to the cerebral cortex. The **lateral geniculate** (je-NIK-ū-lāt; *genicula*, little knee) **nucleus** of each thalamus receives visual information over the *optic tract*, which originates at the eyes. The output of the lateral geniculate nucleus goes to the *occipital lobes* of the cerebral hemispheres and to the midbrain. The **medial geniculate nucleus** relays auditory information to the appropriate area of the cerebral cortex from specialized receptors of the internal ear.
- **5.** The nuclei of the *lateral group* form feedback loops with the limbic system and the *parietal lobes* of the cerebral hemispheres. The lateral group affects emotional states and the integration of sensory information.

The Hypothalamus

The hypothalamus extends from the area superior to the *optic chiasm*, a crossover where the optic tracts from the eyes arrive at the brain, to the posterior margins of the **mammillary** (*mammilla*, nipple) **bodies** (Figure 14–11a). The mammillary bodies

process sensory information, including olfactory sensations, and contain motor nuclei that control reflex movements associated with eating, such as chewing, licking, and swallowing. They are also involved in memory.

Immediately posterior to the optic chiasm, a narrow stalk called the **infundibulum** (in-fun-DIB-ū-lum; *infundibulum*, funnel) extends inferiorly, connecting the floor of the hypothalamus to the pituitary gland (Figure 14–11b).

The floor of the hypothalamus between the infundibulum and the mammillary bodies is the **tuberal area** (*tuber*, swelling). The tuberal area contains nuclei that are involved with the control of pituitary gland function.

Functions of the Hypothalamus

The hypothalamus contains important control and integrative centers, in addition to those associated with the limbic system. These centers are shown in Figure 14–11b, along with a summary of their functions.

Hypothalamic centers may be stimulated by (1) sensory information from the cerebrum, brain stem, and spinal cord; (2) changes in the compositions of the CSF and interstitial fluid; or (3) chemical stimuli in the circulating blood that move rapidly across highly permeable capillaries to enter the hypothalamus (where there is no blood-brain barrier).

The hypothalamus performs the following functions:

- 1. *The Subconscious Control of Skeletal Muscle Contractions.* The hypothalamus directs somatic motor patterns associated with rage, pleasure, pain, and sexual arousal by stimulating centers in other portions of the brain. For example, hypothalamic centers control the changes in facial expression that accompany rage and the basic movements associated with sexual activity.
- **2.** *The Control of Autonomic Function.* The hypothalamus adjusts and coordinates the activities of autonomic centers in the pons and medulla oblongata that regulate heart rate, blood pressure, respiration, and digestive functions.
- **3.** The Coordination of Activities of the Nervous and Endocrine *Systems*. The hypothalamus coordinates neural and endocrine activities by inhibiting or stimulating endocrine cells in the pituitary gland through the production of *regulatory hormones*. These hormones are produced at the tuberal area. They are released into local capillaries for transport to the anterior lobe of the pituitary gland.
- 4. The Secretion of Two Hormones. The hypothalamus secretes antidiuretic hormone (ADH, also called vasopressin) and oxytocin (OXT). The supraoptic nucleus produces ADH, which restricts water loss by the kidneys. The paraventricular nucleus produces oxytocin, which stimulates smooth muscle contractions in the uterus and mammary glands of females and the prostate gland of males. These hormones are transported along axons that pass through the infundibulum to the posterior lobe of the pituitary gland. There

14

Figure 14–11 The Hypothalamus in Sagittal Section.

b A diagrammatic view of the hypothalamus, showing the locations and functions of major nuclei and centers

the hormones are released into the blood for distribution throughout the body.

- 5. The Production of Emotions and Behavioral Drives. Specific hypothalamic centers produce sensations that lead to conscious or subconscious changes in behavior. For example, stimulation of the **feeding center** produces the sensation of hunger. Stimulation of the **thirst center** produces the sensation of thirst. The **satiety center** is the region that regulates food intake. These unfocused "impressions" originating in the hypothalamus are called **drives**. The conscious sensations are only part of the hypothalamic response. For instance, the thirst center also orders the release of ADH by neurons in the supraoptic nucleus.
- 6. *Coordination between Voluntary and Autonomic Functions.* When you think about a dangerous or stressful situation, your heart rate and respiratory rate go up and your body prepares for an emergency. The hypothalamus makes these autonomic adjustments.
- 7. *The Regulation of Body Temperature.* The **preoptic area** of the hypothalamus is responsible for thermoregulation. It coordinates the activities of other CNS centers and regulates other physiological systems to maintain normal body temperature. If body temperature falls, the preoptic area communicates with the *vasomotor center*, an autonomic center in the medulla oblongata that controls blood flow by regulating the diameter of peripheral blood vessels. In response, the vasomotor center decreases the blood supply to the skin, reducing the rate of heat loss.
- 8. *The Control of Circadian Rhythms*. The **suprachiasmatic nucleus** coordinates daily cycles of activity that are linked to the 24-hour day–night cycle. This nucleus receives input from the retina of the eye. The output of this nucleus adjusts the activities of other hypothalamic nuclei, the pineal gland, and the reticular formation.

CHECKPOINT

- 16. Name the main components of the diencephalon.
- 17. Damage to the lateral geniculate nuclei of the thalamus would interfere with the functions of which special sense?
- **18**. Which component of the diencephalon is stimulated by changes in body temperature?

See the blue Answers tab at the back of the book.

14-8 The limbic system is a group of tracts and nuclei that function in emotion, motivation, and memory

Learning Outcome Identify the main components of the limbic system, and specify the locations and functions of each.

The **limbic system** (*limbus*, border) includes nuclei and tracts along the border between the cerebrum and diencephalon. This system is a functional grouping rather than an anatomical one. Functions of the limbic system include (1) establishing emotional states; (2) linking the conscious, intellectual functions of the cerebral cortex with the unconscious and autonomic functions of the brain stem; and (3) facilitating memory storage and retrieval. The sensory cortex, motor cortex, and association areas of the cerebral cortex enable you to perform complex tasks, but it is largely the limbic system that makes you *want* to do them. For this reason, the limbic system is also known as the *motivational system*.

Figure 14–12 focuses on major components of the limbic system. The **amygdaloid** (ah-MIG-da-loyd; *amygdale*, almond) **body** is commonly referred to as the *amygdala* (**Figure 14–12b**). It appears to act as an interface between the limbic system, the cerebrum, and various sensory systems. It plays a role in regulating heart rate, in responding to fear and anxiety and controlling the "fight or flight" response by the sympathetic division of the ANS, and in linking emotions with specific memories.

The **limbic lobe** of the cerebral hemisphere consists of the superficial folds, or *gyri*, and underlying structures adjacent to the diencephalon. The gyri curve along the *corpus callosum*, a fiber tract that links the two cerebral hemispheres The gyri then continue on to the medial surface of the cerebrum lateral to the diencephalon (Figure 14–12a). There are three gyri in the limbic lobe. The **cingulate** (SIN-gū-lāt) **gyrus** (*cingulum*, girdle or belt) sits superior to the corpus callosum. The **dentate gyrus** and the **parahippocampal** (pa-ra-hip-ō-KAM-pal) **gyrus** form the posterior and inferior portions of the limbic lobe (Figure 14–12b). These gyri conceal the **hippocampus**, a nucleus inferior to the floor of the lateral ventricle. To early anatomists, this structure resembled a sea horse (*hippocampus*). This nucleus is important in learning, especially in the storage and retrieval of new long-term memories.

The **fornix** (FOR-niks, arch) is a tract of white matter that connects the hippocampus with the hypothalamus (Figures 14–12 and 14–15b). From the hippocampus, the fornix curves medially, meeting its counterpart from the opposing hemisphere. The fornix proceeds anteriorly, inferior to the corpus callosum, before curving toward the hypothalamus. Many fibers of the fornix end in the mammillary bodies of the hypothalamus.

In the diencephalon, several other nuclei in the wall (thalamus) and floor (hypothalamus) are components of the limbic system. The *anterior nucleus* of the thalamus (Figure 14–12b) relays information from the mammillary body (of the hypothalamus) to the cingulate gyrus on that side. The boundaries between the hypothalamic nuclei of the limbic system are often poorly defined, but experimental stimulation has outlined a number of important hypothalamic

Figure 14–12 The Limbic System.

centers responsible for the emotions of rage, fear, pain, sexual arousal, and pleasure. The stimulation of specific regions of the hypothalamus can also produce heightened alertness and a generalized excitement or generalized lethargy and sleep. These responses are caused by the stimulation or inhibition of the reticular formation. Although the reticular formation extends the length of the brain stem, its headquarters reside in the midbrain.

CHECKPOINT

- 19. What are the primary functions of the limbic system?
- **20**. Damage to the amygdaloid body would interfere with regulation of what division of the autonomic nervous system (ANS)?

See the blue Answers tab at the back of the book.

14-9 The cerebrum, the largest region of the brain, contains motor, sensory, and association areas

Learning Outcome Identify the major anatomical subdivisions and functions of the cerebrum, and discuss the origin and significance of the major types of brain waves seen in an electroencephalogram.

The cerebrum is the largest region of the brain. Conscious thoughts and all intellectual functions originate in the cerebral hemispheres. Much of the cerebrum is involved in processing somatic sensory and motor information. Gray matter in the cerebrum is located in the *cerebral cortex* and in deeper *basal nuclei*. The white matter of the cerebrum lies deep to the cerebral cortex and around the basal nuclei.

The Cerebral Cortex

A layer of cerebral cortex ranging from 1 to 4.5 mm thick covers the paired cerebral hemispheres, which dominate the superior and lateral surfaces of the cerebrum. The gyri increase the surface area of the cerebral hemispheres, and thus the number of cortical neurons they contain. The total surface area of the cerebral hemispheres is roughly equivalent to 2200 cm² (2.5 ft²) of flat surface.

The entire brain has enlarged over the course of human evolution, but the cerebral hemispheres have enlarged at a much faster rate than has the rest of the brain. This enlargement reflects the large numbers of neurons needed for complex analytical and integrative functions. Since the neurons involved are in the superficial layer of cortex, it is there that the expansion has been most pronounced. The only solution available, other than an enlargement of the entire skull, was for the cortical layer to fold like a crumpled piece of paper.

Landmarks and features on the surface of one cerebral hemisphere are shown in Figure 14–13a,b. (The two cerebral hemispheres are almost completely separated by a deep **lon-gitudinal fissure**, seen in Figure 14–14b.) Each cerebral hemisphere can be divided into *lobes*, or regions, named after the overlying bones of the skull.

Your brain has a unique pattern of sulci and gyri, as individual as a fingerprint, but the boundaries between lobes are reliable landmarks. On each hemisphere, the **central sulcus**, a deep groove, divides the anterior **frontal lobe** from the more posterior **parietal lobe**. The horizontal **lateral sulcus** separates the frontal lobe from the **temporal lobe**. The **insula** (IN-sū-luh; *insula*, island), an "island" of cortex, lies medial to the lateral sulcus separates the parietal lobe from the **occipital lobe** (Figure 14–13d).

Each lobe contains functional regions whose boundaries are less clearly defined. Some of these regions deal with sensory information and others with motor commands. Keep in mind three points about the cerebral lobes:

- 1. Each cerebral hemisphere receives sensory information from, and sends motor commands to, the opposite side of the body. For example, the motor areas of the left cerebral hemisphere control muscles on the right side, and the right cerebral hemisphere controls muscles on the left side. This crossing over has no known functional significance.
- 2. The two hemispheres have different functions, even though they look almost identical. We discuss these differences in a later section.
- 3. The correspondence between a specific function and a specific region of the cerebral cortex is imprecise. Because the boundaries are indistinct and have considerable overlap, one region may have several functions. Some aspects of cortical function, such as consciousness, cannot easily be assigned to any single region. However, we know that normal individuals use all portions of the brain.

The White Matter of the Cerebrum

The interior of the cerebrum consists mostly of white matter. We can classify the axons of white matter as association fibers, commissural fibers, and projection fibers (Figure 14–14).

- **Association fibers** interconnect areas of cerebral cortex within a single cerebral hemisphere. Shorter association fibers are called **arcuate** (AR-kū-āt) **fibers**, because they curve in an arc to pass from one gyrus to another. Longer association fibers are organized into discrete bundles, or *fasciculi*. The **longitudinal fasciculi** connect the frontal lobe to the other lobes of the same hemisphere.
- **Commissural** (kom-i-SŪR-ul; *commissura*, crossing over) **fibers** interconnect and permit communication between the cerebral hemispheres. Bands of commissural fibers linking the hemispheres include the **corpus callosum** and the **anterior commissure**. The corpus callosum alone contains more than 200 million axons, carrying some 4 billion impulses per second!
- **Projection fibers** link the cerebral cortex to the diencephalon, brain stem, cerebellum, and spinal cord. All projection fibers pass through the diencephalon. There, axons heading to sensory areas of the cerebral cortex pass among the axons descending from motor areas of the cortex. In gross dissection, the ascending fibers and descending fibers look alike. The entire collection of projection fibers is known as the **internal capsule**.

The Basal Nuclei

While your cerebral cortex is consciously directing a complex movement or solving some intellectual puzzle, other centers of your cerebrum, diencephalon, and brain stem are processing

sensory information and issuing motor commands outside your conscious awareness. Many of these activities, which occur at the subconscious level, are directed by the basal nuclei.

Anatomy of the Basal Nuclei

The **basal nuclei** are masses of gray matter that lie within each hemisphere deep to the floor of the lateral ventricle (Figure 14–15). They are embedded in the white matter of the cerebrum. The radiating projection fibers and commissural fibers travel around or between these nuclei.

Historically, the basal nuclei have been considered part of a larger functional group known as the *basal ganglia*. This group included the basal nuclei of the cerebrum and the associated motor nuclei in the diencephalon and midbrain. We will consider the functional interactions among these components in Chapter 15, but we will avoid the term "basal ganglia" because ganglia are otherwise restricted to the PNS.

The **caudate nucleus** has a massive head and a slender, curving tail that follows the curve of the lateral ventricle. The head of the caudate nucleus lies anterior to the **lentiform**

nucleus. The lentiform nucleus consists of a medial **globus pallidus** (GLŌ-bus PAL-i-dus; pale globe) and a lateral **puta-men** (pū-TĀ-men). The term *corpus striatum* (striated body) has been used to refer to the caudate and lentiform nuclei, or to the caudate nucleus and putamen. The name refers to the striated (striped) appearance of the internal capsule as its fibers pass among these nuclei. The amygdaloid body, part of the limbic system, lies anterior to the tail of the caudate nucleus and inferior to the lentiform nucleus.

Functions of the Basal Nuclei

The basal nuclei are involved with the subconscious control of skeletal muscle tone and the coordination of learned movement patterns. Under normal conditions, these nuclei do not initiate particular movements. But once a movement is under way, the basal nuclei provide the general pattern and rhythm, especially for movements of the trunk and proximal limb muscles. For example:

- When you walk, the basal nuclei control the cycles of arm and thigh movements that occur between the time you decide to "start" walking and the time you give the "stop" order.
- As you begin a voluntary movement, the basal nuclei control and adjust muscle tone, particularly in the appendicular muscles, to set your body position. When you decide to pick up a pencil, you consciously reach and grasp with your forearm, wrist, and hand while the basal nuclei operate at the

486 UNIT 3 Control and Regulation

subconscious level to position your shoulder and stabilize vour arm.

How do the basal nuclei carry out their functions? They alter the motor commands issued by the cerebral cortex through a feedback loop. Information arrives at the caudate nucleus and putamen from sensory, motor, and integrative areas of the cerebral cortex. Lateral processing then takes place in these nuclei and in the adjacent globus pallidus. Most of the output of the basal nuclei leaves the globus pallidus and synapses in the thalamus. Nuclei in the thalamus then project the information to appropriate areas of the cerebral cortex.

Activity of the basal nuclei is inhibited by neurons in the substantia nigra of the midbrain, which release the neurotransmitter *dopamine*. \supset p. 417 If the substantia nigra is damaged or the neurons secrete less dopamine, basal nuclei become more active. The result is a gradual, generalized increase in muscle tone and the appearance of symptoms characteristic of Parkinson's disease. **D** p. 108 People with Parkinson's disease have difficulty starting voluntary movements, because opposing muscle groups do not relax. Instead, they must be overpowered. Once a movement is under way, every aspect must be voluntarily controlled through intense effort and concentration.

Motor and Sensory Areas of the Cortex

The major motor and sensory regions of the cerebral cortex are shown in Figure 14–16 and listed in Table 14–3. The central

ALL LOBES				
Association areas	5	Integration and processing of sensory data; processing and initiation of motor activities		

sulcus separates the motor and sensory areas of the cortex. The **precentral gyrus** of the frontal lobe forms the anterior border of the central sulcus. The surface of this gyrus is the **primary motor cortex**. Neurons of the primary motor cortex direct voluntary movements by controlling somatic motor neurons in the brain stem and spinal cord. These cortical neurons are called **pyramidal cells**, because their cell bodies resemble little pyramids.

The primary motor cortex is like the keyboard of a piano. If you strike a specific piano key, you produce a specific sound. Similarly, if you stimulate a specific motor neuron in the primary motor cortex, you generate a contraction in a specific skeletal muscle.

Like the monitoring gauges in the dashboard of a car, the sensory areas of the cerebral cortex report key information. At each location, sensory information is reported in the pattern of neuron activity in the cortex. The **postcentral gyrus** of the parietal lobe forms the posterior border of the central sulcus, and its surface contains the **primary sensory cortex**. Neurons in this region receive general somatic sensory information from receptors for touch, pressure, pain, vibration, or temperature. You are aware of these sensations only when nuclei in the thalamus relay the information to the primary sensory cortex.

Sensations of sight, sound, smell, and taste arrive at other portions of the cerebral cortex (Figure 14–16a). The **visual cortex** of the occipital lobe receives visual information. The **auditory cortex** and **olfactory cortex** of the temporal lobe receive information about hearing and smell, respectively. The **gustatory cortex**, which receives information from taste receptors of the tongue and pharynx, lies in the anterior portion of the insula and adjacent portions of the frontal lobe.

Association Areas

The sensory and motor regions of the cortex are connected to nearby **association areas**, regions of the cortex that interpret incoming data or coordinate a motor response (Figure 14–16a). Like the information provided by the gauges in a car, the arriving information must be noticed and interpreted before the driver can take appropriate action. *Sensory association areas* are cortical regions that monitor and interpret the information that arrives at the sensory areas of the cortex. Examples include the somatic sensory association area, visual association area, and auditory association area.

The **somatic sensory association area** monitors activity in the primary sensory cortex. The somatic sensory association area allows you to recognize a touch as light as a mosquito landing on your arm (and gives you a chance to swat the mosquito before it bites).

The special senses of smell, sight, and hearing involve separate areas of the sensory cortex, and each has its own association area. These areas monitor and interpret arriving sensations. For example, the **visual association area** monitors the patterns of activity in the visual cortex and interprets the results. You see the symbols *c*, *a*, and *r* when the stimulation of receptors in your eyes leads to the stimulation of neurons in your visual cortex. Your visual association area recognizes that these are letters and that c + a + r = car. An individual with a damaged visual association area could scan the lines of a printed page and see rows of symbols that are clear, but would perceive no meaning from the symbols. Similarly, the **auditory association area** monitors sensory activity in the auditory cortex. Word recognition takes place in this association area.

The premotor cortex, or somatic motor association area, coordinates learned movements. The primary motor cortex does nothing on its own, any more than a piano keyboard can play itself. The neurons in the primary motor cortex must be stimulated by neurons in other parts of the cerebrum. When you perform a voluntary movement, the premotor cortex relays the instructions to the primary motor cortex. With repetition, the proper pattern of stimulation becomes stored in your premotor cortex. You can then perform the movement smoothly and easily by triggering the *pattern* rather than by controlling the individual neurons. This principle applies to any learned movement, from something as simple as picking up a glass to something as complex as playing the piano. One area of the premotor cortex, the frontal eye field, controls learned eye movements, such as when you scan these lines of type (Figure 14–16b). Individuals with damage to the frontal eve field can understand written letters and words but cannot read, because their eyes cannot follow the lines on a printed page.

Integrative Centers

Integrative centers are areas that receive information from many association areas and direct extremely complex motor activities.

These centers also perform complicated analytical functions. For example, consider the *prefrontal cortex* of the frontal lobe (Figure 14–16b). It integrates information from sensory association areas and performs abstract intellectual functions, such as predicting the consequences of possible responses.

Integrative centers are located in the lobes and cortical areas of both cerebral hemispheres. Integrative centers concerned with complex processes, such as speech, writing, mathematical computation, and understanding spatial relationships, are largely restricted to either the left or the right hemisphere. These centers include the *general interpretive area* and the *speech center*. The corresponding regions on the opposite hemisphere are also active, but their functions are less well defined.

The General Interpretive Area. The **general interpretive area** also called the *Wernicke's area*, is present in only one hemisphere, typically the left (Figure 14–16b). This analytical center receives information from all the sensory association areas. It plays an essential role in your personality by integrating

🔶 Clinical Note

Disconnection Syndrome The functional differences between the hemispheres become apparent if the corpus callosum is cut. Such a procedure is sometimes performed to treat epileptic seizures that cannot be controlled by other methods. This surgery produces symptoms of **disconnection syndrome**. In this condition, the two hemispheres function independently, each "unaware" of stimuli or motor commands that involve the other.

Individuals with this syndrome exhibit some rather interesting changes in their mental abilities. For example, they can recognize but cannot verbally identify objects that they touch with the left hand, because the sensory information arrives at the right hemisphere but the speech center is on the left. They can verbally identify the object if they feel it with the right hand, but they cannot say whether it is the same object they previously touched with the left hand. Sensory information from the left side of the body arrives at the right hemisphere and cannot reach the general interpretive area. For this reason, conscious decisions are made without regard to sensations from the left side.

Two years after a surgical sectioning of the corpus callosum, the most striking behavioral abnormalities have disappeared. The person may test normally. In addition, individuals born without a functional corpus callosum do not have sensory, motor, or intellectual problems. In some way, the CNS adapts to these situations, probably by increasing the amount of information transferred across the anterior commissure. sensory information and coordinating access to complex visual and auditory memories.

Damage to the general interpretive area affects your ability to interpret what you see or hear, even though you understand the words as individual entities. For example, if your general interpretive area were damaged, you might still understand the meaning of the spoken words *sit* and *here*, because word recognition takes place in the auditory association areas. But you would be totally bewildered by the request *sit here*. Damage to another portion of the general interpretive area might leave you able to see a chair clearly, and to know that you recognize it, but you would be unable to name it because the connection to your visual association area has been disrupted.

The Speech Center. Some of the neurons in the general interpretive area innervate the **speech center**, also called the *Broca's area* or the *motor speech area* (Figure 14–16b). This center lies along the edge of the premotor cortex in the same hemisphere as the general interpretive area (usually the left). The speech center regulates the patterns of breathing and vocalization needed for normal speech. This regulation involves coordinating the activities of the respiratory muscles, the laryngeal and pharyngeal muscles, and the muscles of the tongue, cheeks, lips, and jaws. A person with a damaged speech center can make sounds but not words.

The motor commands issued by the speech center are adjusted by feedback from the auditory association area, also called the *receptive speech area*. Damage to the related sensory areas can cause a variety of speech-related problems. (See the discussion of *aphasia* on p. 489.) Some affected individuals have difficulty speaking although they know exactly which words to use. Others talk constantly but use all the wrong words.

The Prefrontal Cortex. The **prefrontal cortex** of the frontal lobe coordinates information relayed from the association areas of the entire cortex (**Figure 14–16b**). In doing so, it performs such abstract intellectual functions as predicting the consequences of events or actions. The prefrontal cortex doesn't fully develop until the early 20s. Damage to the prefrontal cortex leads to difficulties in estimating temporal relationships between events. Questions such as "How long ago did this happen?" or "What happened first?" become difficult to answer.

The prefrontal cortex has extensive connections with other cortical areas and with other portions of the brain. Feelings of frustration, tension, and anxiety are generated as the prefrontal cortex interprets ongoing events and makes predictions about future situations or consequences. If the connections between the prefrontal cortex and other brain regions are physically severed, the frustrations, tensions, and anxieties are removed. During the middle of the 20th century, this rather drastic procedure, called **prefrontal lobotomy**, was used to "cure" a variety of mental illnesses, especially those associated with violent or antisocial behavior. After a lobotomy, the patient would no longer be concerned about what had previously been a major problem, whether psychological (hallucinations) or physical (severe pain). However, the individual was often equally unconcerned about tact, decorum, and toilet training. Since then, drugs that target specific pathways and regions of the CNS have been developed, so lobotomies are no longer used to change behavior.

Brodmann Areas. Early in the 20th century, numerous researchers attempted to describe and classify regional differences in the histological organization of the cerebral cortex. They hoped to correlate the patterns of cellular organization with specific functions. By 1919, at least 200 patterns had been described, but most of the classification schemes have since been abandoned. However, the cortical map prepared by Korbinian Brodmann in 1909 has proved useful to neuroanatomists. Brodmann, a German neurologist, described about 50 patterns of cellular organization in the cerebral cortex.

Several of these *Brodmann areas* are shown in Figure 14–16c. Some correspond to known functional areas. For example, Brodmann area 44 corresponds to the speech center, and area 41 to the auditory cortex. Area 4 follows the contours of the primary motor cortex. In other cases, the correspondence is less precise. For instance, Brodmann area 42 forms only a small portion of the auditory association area.

Hemispheric Lateralization

Each of the two cerebral hemispheres is responsible for specific functions that are not ordinarily performed by the opposite hemisphere. This regional specialization is called *hemispheric lateralization*. Figure 14–17 indicates the major functional differences between the hemispheres. In most people, the left hemisphere contains the general interpretive and speech centers and is responsible for language-based skills. For example, reading, writing, and speaking depend on processing done in the left cerebral hemisphere. In addition, the premotor cortex involved with the control of hand movements is larger on the left side for right-handed individuals than for left-handed ones. The left hemisphere is also important in performing analytical tasks, such as mathematical calculations and logical decision-making. For these reasons, the left cerebral hemisphere has been called the *dominant hemisphere*.

The right cerebral hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit you to identify familiar objects by touch, smell, sight, taste, or feel. For example, the right hemisphere plays a dominant role in recognizing faces and in understanding three-dimensional relationships. It is also important in analyzing the emotional context of a conversation—for instance, distinguishing between the threat "Get lost!" and the question "Get lost?" Individuals with a damaged Clinical Note

Aphasia and Dyslexia Aphasia (*a*-, without + *phasia*, speech) is a disorder affecting the ability to speak or read. *Global aphasia* results from extensive damage to the general interpretive area or to the associated sensory tracts. Affected individuals are unable to speak, read, or understand speech. Global aphasia often accompanies a severe stroke or tumor that affects a large area of cortex, including the speech and language areas. Recovery is possible when the condition results from edema or hemorrhage, but the process often takes months or even years.

Dyslexia (*dys*-, difficult, faulty + *lexis*, diction) is a disorder affecting the comprehension and use of written words. *Developmental dyslexia* affects children. Estimates are that up to 15 percent of children in the United States have some degree of dyslexia. Children with dyslexia have difficulty reading and writing, although their other intellectual functions may be normal or above normal. Their writing looks uneven and disorganized. They typically write letters in the wrong order (*dig* becomes *gid*) or reverse them (*E* becomes 3). Recent evidence suggests that at least some forms of dyslexia result from problems in processing, sorting, and integrating visual or auditory information.

right hemisphere may be unable to add emotional inflections to their own words.

Left-handed people represent 9 percent of the human population. In most cases, the primary motor cortex of the right hemisphere controls motor function for the dominant (left) hand. However, the centers involved with speech and analytical function are in the left hemisphere, just as they are in righthanded people. Interestingly, an unusually high percentage of musicians and artists are left-handed. The complex motor activities performed by these individuals are directed by the primary motor cortex and association areas of the right cerebral hemisphere, near the association areas involved with spatial visualization and emotions.

Monitoring Brain Activity: The Electroencephalogram

Various methods have led to maps of brain activity and brain function. The primary sensory cortex and the primary motor cortex have been mapped by direct stimulation in patients undergoing brain surgery. The functions of other regions of the cerebrum can be revealed by the behavioral changes that follow localized injuries or strokes. The activities of specific regions can be visualized by a PET scan or through functional magnetic resonance imaging (fMRI). \supset p. 21

Clinicians commonly monitor the electrical activity of the brain to assess brain activity. Neural function depends on electrical events of the plasma membrane of neurons.

Figure 14–17 Hemispheric Lateralization. Functional differences between the left and right cerebral hemispheres.

The brain contains billions of neurons, and their activity generates an electrical field that can be measured by electrodes placed on the brain or on the outer surface of the skull. The electrical activity changes constantly, as nuclei and cortical areas are stimulated or quiet down. A printed recording of the electrical activity of the brain is called an **electroencephalogram (EEG)**. The electrical patterns observed are called *brain waves*.

Typical brain waves are shown in **Figure 14–18a–d**. **Alpha waves** occur in the brains of healthy, awake adults who are resting with their eyes closed. Alpha waves disappear during sleep, but they also vanish when the individual begins to concentrate on some specific task.

During attention to stimuli or tasks, higher-frequency **beta waves** replace alpha waves. Beta waves are typical of individuals who are either concentrating on a task, under stress, or in a state of psychological tension.

Theta waves may appear transiently during sleep in normal adults but are most often observed in children and in intensely frustrated adults. The presence of theta waves under other circumstances may indicate the presence of a brain disorder, such as a tumor.

Delta waves are very-large-amplitude, low-frequency waves. They are normally seen during deep sleep in individuals of all ages. Delta waves are also seen in the brains of infants (whose brains are still developing) and in awake adults when a tumor, vascular blockage, or inflammation has damaged portions of the brain.

Electrical activity in the two hemispheres is generally synchronized by a "pacemaker" mechanism that appears to **Figure 14–18 Brain Waves.** The four electrical patterns revealed by electroencephalograms (EEGs). The heights (amplitudes) of the four waves are not drawn to the same scale.

involve the thalamus. Asynchrony between the hemispheres can indicate localized damage or other cerebral abnormalities. For example, a tumor or injury affecting one hemisphere typically changes the pattern in that hemisphere, and the patterns of the two hemispheres are no longer aligned.

A **seizure** is a temporary cerebral disorder accompanied by abnormal movements, unusual sensations, inappropriate behavior, or some combination of these symptoms. Clinical conditions characterized by seizures are known as seizure disorders, or *epilepsies*. Seizures of all kinds are accompanied by a marked change in the pattern of electrical activity recorded in an electroencephalogram. The change begins in one portion of the cerebral cortex but may then spread across the entire cortical surface, like a wave on the surface of a pond.

The nature of the signs and symptoms produced depends on the region of the cortex involved. If a seizure affects the primary motor cortex, movements will occur. If it affects the auditory cortex, the individual will hear strange sounds.

CHECKPOINT

- 21. What name is given to fibers carrying information between the brain and spinal cord, and through which brain regions do they pass?
- 22. What symptoms would you expect to observe in an individual who has damage to the basal nuclei?
- 23. A patient suffers a head injury that damages her primary motor cortex. Where is this area located?
- 24. Which senses would be affected by damage to the temporal lobes of the cerebrum?
- 25. After suffering a stroke, a patient is unable to speak. He can understand what is said to him, and he can understand written messages, but he cannot express himself verbally. Which part of his brain has been affected by the stroke?
- **26**. A patient is having a difficult time remembering facts and recalling long-term memories. Which part of his cerebrum is probably involved?

- See the blue Answers tab at the back of the book.

Focus Cranial Nerves

Cranial nerves are PNS components that connect directly to the brain. The 12 pairs of cranial nerves are visible on the ventral surface of the brain (Figure 14–19). Each has a name related to its distribution or its function.

The number assigned to a cranial nerve corresponds to the nerve's position along the longitudinal axis of the brain, beginning at the cerebrum. Roman numerals preceded by the letter N are usually used. (You may sometimes encounter these numerals preceded by the letters CN.)

Each cranial nerve attaches to the brain near the associated sensory or motor nuclei. The sensory nuclei act as switching centers, with the postsynaptic neurons relaying the information to other nuclei or to processing centers in the cerebral or cerebellar cortex. In a similar way, the motor nuclei receive convergent inputs from higher centers or from other nuclei along the brain stem.

In this section, we classify cranial nerves as primarily sensory, special sensory, motor, or mixed (sensory and motor). In this classification, sensory nerves carry somatic sensory information, including touch, pressure, vibration, temperature, or pain. Special sensory nerves carry the sensations of smell, sight, hearing, or balance. Motor nerves are dominated by the axons of somatic motor neurons. Mixed nerves have a mixture of sensory and motor fibers. This classification scheme is useful, but it is based

Figure 14–19 Origins of the Cranial Nerves. An inferior view of the brain.

on the primary function, and a cranial nerve can have important secondary functions. Three examples are worth noting:

- 1. The olfactory receptors, the visual receptors, and the receptors of the internal ear are innervated by cranial nerves that are dedicated almost entirely to carrying special sensory information. In contrast, the sensation of taste, considered to be one of the special senses, is carried by axons that form only a small part of large cranial nerves that have other primary functions.
- 2. As elsewhere in the PNS, a nerve containing tens of thousands of motor fibers that lead to a skeletal muscle also contains sensory fibers from muscle spindles and Golgi tendon organs (proprioceptive sensory nerve endings) in that muscle. We assume that these sensory fibers are present but ignore them in classifying the nerve.
- **3.** Regardless of their other functions, several cranial nerves (III, VII, IX, and X) distribute autonomic fibers to peripheral ganglia, just as spinal nerves deliver them to ganglia along the spinal cord. We will note the presence of small numbers of autonomic fibers (and will discuss them further in Chapter 16) but ignore them in the classification of the nerve.

Cranial nerves are clinically important, in part because they can provide clues to underlying CNS problems. Clinicians assess cranial nerve function with a number of standardized tests.

TIPS&TRICKS

Two useful mnemonics for remembering the names of the cranial nerves in order are "Oh Oh Oh, To Touch And Feel Very Green Vegetables, Ah Heaven!" and "Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly!"

The Olfactory Nerves (I)

Primary function: Special sensory (smell)

Origin: Receptors of olfactory epithelium

Pass through: Olfactory foramina in cribriform plate of ethmoid > pp. 213, 218

Destination: Olfactory bulbs

The first pair of cranial nerves carries special sensory information responsible for the sense of smell (Figure 14–20). The olfactory receptors are specialized neurons in the epithelium covering the roof of the nasal cavity, the superior nasal conchae, and the

5. 8.0.0

Olfactory

epithelium

Cribriform plate

of ethmoid bone

A 400 200

superior parts of the nasal septum. Axons from these sensory neurons collect to form 20 or more bundles that penetrate the cribriform plate of the ethmoid bone. These bundles are components of the **olfactory nerves** (I). Almost at once these bundles enter the **olfactory bulbs**, neural masses on either side of the crista galli. The olfactory afferents synapse within the olfactory bulbs. The axons of the postsynaptic neurons proceed to the cerebrum along the slender **olfactory tracts** (Figures 14–19 and 14–20).

Because the olfactory tracts look like typical peripheral nerves, anatomists about a century ago misidentified these tracts as the first cranial nerve. Later studies demonstrated that the olfactory tracts and bulbs are part of the cerebrum, but by then the numbering system was already firmly established. Anatomists were left with a forest of tiny olfactory nerve bundles lumped together as cranial nerve I.

The olfactory nerves are the only cranial nerves attached directly to the cerebrum. The rest originate or terminate within nuclei of the diencephalon or brain stem, and the ascending sensory information synapses in the thalamus before reaching the cerebrum.

Figure 14–20 The Olfactory Nerve.

The Optic Nerves (II)

Primary function: Special sensory (vision)

Origin: Retina of eye

Pass through: Optic canals of sphenoid **D p**. 217

Destination: Diencephalon by way of the optic chiasm

The **optic nerves** (II) carry visual information from special sensory ganglia in the eyes (Figure 14–21). These nerves contain about 1 million sensory nerve fibers. The optic nerves pass through the optic canals of the sphenoid. Then they converge at the ventral, anterior margin of the diencephalon, at the **optic chiasm** (*chiasma*, a crossing). At the optic chiasm, fibers from the medial half of each retina cross over to the opposite side of the brain.

Figure 14–21 The Optic Nerve.

The reorganized axons continue toward the lateral geniculate nuclei of the thalamus as the **optic tracts** (Figures 14–19 and 14–21). After synapsing in the lateral geniculates, projection fibers deliver the information to the visual cortex of the occipital lobes. With this arrangement, each cerebral hemisphere receives visual information from the lateral half of the retina of the eye on that side and from the medial half of the retina of the eye of the opposite side (Figure 14–17). A few axons in the optic tracts bypass the lateral geniculate nuclei and synapse in the superior colliculi of the midbrain. We will consider that pathway in Chapter 17.

The Oculomotor Nerves (III)

Primary function: Motor (eye movements)

Origin: Midbrain

Pass through: Superior orbital fissures of sphenoid **D** pp. 211, 218, 220, 223

Destination: *Somatic motor:* superior, inferior, and medial rectus muscles; inferior oblique muscle; levator palpebrae superioris muscle. *Visceral motor:* intrinsic eye muscles

The midbrain contains the motor nuclei controlling the third and fourth cranial nerves. Each **oculomotor nerve** (III) innervates four of the six extrinsic muscles that move the eye, and the levator palpebrae superioris muscle, which raises the upper eyelid (Figure 14–22). On each side of the brain, nerve III emerges from the ventral surface of the midbrain and penetrates the posterior wall of the orbit at the superior orbital fissure. Individuals with damage to this nerve often complain of pain over the eye, droopy eyelids, and double vision, because the movements of the left and right eyes cannot be coordinated properly.

The oculomotor nerve also delivers preganglionic autonomic fibers to neurons of the **ciliary ganglion**. These neurons control intrinsic eye muscles. These muscles change the diameter of the pupil, adjusting the amount of light entering the eye. They also change the shape of the lens to focus images on the retina.

Figure 14–22 Cranial Nerves Controlling the Extrinsic Eye Muscles. ATLAS: Plates 16a,b

The Trochlear Nerves (IV)

Primary function: Motor (eye movements)

Origin: Midbrain

Pass through: Superior orbital fissures of sphenoid ⇒ pp. 211, 217, 220, 223

Destination: Superior oblique muscle

A **trochlear** (TROK-Iē-ar; *trochlea*, a pulley) **nerve** (IV), the smallest cranial nerve, innervates the superior oblique muscle of each eye (Figure 14–22). The trochlea is a pulley-shaped, ligamentous sling. Each superior oblique muscle passes through a trochlea on its way to its insertion on the surface of the eye. An individual with damage to cranial nerve IV or to its nucleus has difficulty looking down and to the side.

The Abducens Nerves (VI)

Primary function: Motor (eye movements)

Origin: Pons

Pass through: Superior orbital fissures of sphenoid **D** pp. 211, 217, 220, 223

Destination: Lateral rectus muscle

The **abducens** (ab-DŪ-senz) **nerves** (VI) innervate the lateral rectus muscles, the sixth pair of extrinsic eye muscles. Contraction of the lateral rectus muscle makes the eye look to the side. In essence, the *abducens* causes *abduction* of the eye. Each abducens nerve emerges from the inferior surface of the brain stem at the border between the pons and the medulla oblongata (Figure 14–22). Along with the oculomotor and trochlear nerves from that side, it reaches the orbit through the superior orbital fissure.

The Trigeminal Nerves (V)

Primary function: Mixed (sensory and motor) to face

Origin: Ophthalmic branch (sensory): orbital structures, cornea, nasal cavity, skin of forehead, upper eyelid, eyebrow, nose (part). *Maxillary branch* (sensory): lower eyelid, upper lip, gums, and teeth; cheek; nose, palate, and pharynx (part). *Mandibular branch* (mixed): sensory from lower gums, teeth, and lips; palate and tongue (part); motor from motor nuclei of pons

Pass through (on each side): Ophthalmic branch through superior orbital fissure, maxillary branch through foramen rotundum, mandibular branch through foramen ovale ⊃ pp. 211, 213, 217, 223

Destination: Ophthalmic, maxillary, and mandibular branches to sensory nuclei in pons; mandibular branch also innervates muscles of mastication \bigcirc **p.** 348

The pons contains the nuclei associated with three cranial nerves (V, VI, and VII) and contributes to a fourth (VIII). The **trigeminal** (trī-JEM-i-nal) **nerves** (V), the largest cranial nerves, are mixed

nerves. Each provides both somatic sensory information from the head and face, and motor control over the muscles of mastication. Sensory (dorsal) and motor (ventral) roots originate on the lateral surface of the pons (Figure 14–23). The sensory branch is larger, and the enormous **semilunar ganglion** contains the cell bodies of the sensory neurons.

As the name implies, the trigeminal has three major branches. The small motor root contributes to only one of the three. **Tic douloureux** (doo-luh-ROO; *douloureux*, painful), or *trigeminal neuralgia*, is a painful condition affecting the area innervated by the maxillary and mandibular branches of the trigeminal nerve. Sufferers complain of debilitating pain triggered by contact with the lip, tongue, or gums. The cause of the condition is unknown.

The trigeminal nerve branches are associated with the *ciliary*, *sphenopalatine*, *submandibular*, and *otic ganglia*. These are autonomic (parasympathetic) ganglia whose neurons innervate structures of the face. Although its nerve fibers may pass around or through these ganglia, the trigeminal nerve does not contain visceral motor fibers. We discussed the ciliary ganglion on page 494 and will describe the other ganglia next, with the branches of the *facial nerves* (VII) and the *glossopharyngeal nerves* (IX).

Figure 14–23 The Trigeminal Nerve.

The Facial Nerves (VII)

Primary function: Mixed (sensory and motor) to face

Origin: *Sensory*: taste receptors on anterior two-thirds of tongue. *Motor*: motor nuclei of pons

Pass through: Internal acoustic meatus to canals leading to the stylomastoid foramina **pp. 211, 213, 217**

Destination: Sensory: sensory nuclei of pons. Somatic motor: muscles of facial expression. **D p. 344** Visceral motor: lacrimal (tear) gland and nasal mucous glands by way of the pterygopalatine ganglion; submandibular and sublingual salivary glands by way of the submandibular ganglion

The **facial nerves** (VII) are mixed nerves. The cell bodies of the sensory neurons are located in the **geniculate ganglia**, and the motor nuclei are in the pons. On each side, the sensory and motor roots emerge from the pons and enter the internal acoustic meatus of the temporal bone. Each facial nerve then passes through the facial canal to reach the face by way of the stylomastoid foramen. The nerve then splits to form the temporal, zygomatic, buccal, mandibular, and cervical branches (Figure 14–24).

The sensory neurons monitor proprioceptors in the facial muscles and provide deep pressure sensations over the face. They also receive taste information from receptors along the anterior two-thirds of the tongue. Somatic motor fibers control the superficial muscles of the scalp and face and deep muscles near the ear.

The facial nerves carry preganglionic autonomic fibers to the pterygopalatine and submandibular ganglia. Postganglionic fibers from the **pterygopalatine ganglia** innervate the lacrimal glands and small glands of the nasal cavity and pharynx. The **submandibular ganglia** innervate the *submandibular* and *sub-lingual* (*sub-*, under + *lingual*, pertaining to the tongue) *salivary glands*.

Bell's palsy is a cranial nerve disorder that results from an inflammation of a facial nerve. The condition is probably due to a viral infection. Signs and symptoms include paralysis of facial muscles on the affected side and loss of taste sensations from the anterior two-thirds of the tongue. The condition is usually painless. In most cases the symptoms fade after a few weeks or months.

Figure 14–24 The Facial Nerve.

The Vestibulocochlear Nerves (VIII)

Primary function: Special sensory: balance and equilibrium (vestibular branch) and hearing (cochlear branch)

Origin: Monitor receptors of the internal ear (vestibule and cochlea)

Pass through: Internal acoustic meatus of temporal bones > pp. 213, 217

Destination: Vestibular and cochlear nuclei of pons and medulla oblongata

The **vestibulocochlear nerves** (VIII) are also known as the *acoustic nerves*, the *auditory nerves*, and the *stato-acoustic nerves*. We will use *vestibulocochlear*, because this term indicates the names of the two major branches: the vestibular branch and the cochlear branch. Each vestibulocochlear nerve lies posterior to the origin of the facial nerve, straddling the boundary between the pons and the medulla oblongata (Figure 14–25). This nerve

reaches the sensory receptors of the internal ear by entering the internal acoustic meatus in company with the facial nerve.

Each vestibulocochlear nerve has two distinct bundles of sensory fibers. The vestibular (vestibulum, cavity) branch originates at the receptors of the vestibule, the portion of the internal ear concerned with balance sensations. The sensory neurons are located in an adjacent sensory ganglion, and their axons target the **vestibular nuclei** of the pons and medulla oblongata. These afferents convey information about the orientation and movement of the head. The cochlear (cochlea, snail shell) branch monitors the receptors in the *cochlea*, the portion of the internal ear that provides the sense of hearing. The cell bodies of the sensory neurons are located within a peripheral ganglion (the spiral ganglion), and their axons synapse within the cochlear nuclei of the pons and medulla oblongata. Axons leaving the vestibular and cochlear nuclei relay the sensory information to other centers or initiate reflexive motor responses. We discuss balance and the sense of hearing in Chapter 17.

Figure 14–25 The Vestibulocochlear Nerve.

The Glossopharyngeal Nerves (IX)

Primary function: Mixed (sensory and motor) to head and neck

Origin: *Sensory*: posterior one-third of the tongue, part of the pharynx and palate, carotid arteries of the neck. *Motor*: motor nuclei of medulla oblongata

Pass through: Jugular foramina between the occipital bone and the temporal bones \bigcirc pp. 211, 213

Destination: Sensory: sensory nuclei of medulla oblongata. Somatic motor: pharyngeal muscles involved in swallowing. Visceral motor: parotid salivary gland by way of the otic ganglion

The medulla oblongata contains the sensory and motor nuclei of cranial nerves IX, X, XI, and XII, in addition to the vestibular nucleus of nerve VIII. The **glossopharyngeal** (glos-ō-fah-RIN-jē-al; *glossum*, tongue) **nerves** (IX) innervate the tongue and pharynx. Each glossopharyngeal nerve penetrates the cranium within the jugular foramen, with cranial nerves X and XI. The glossopharyngeal nerves are mixed nerves, but sensory fibers are most abundant. The sensory neurons on each side are in the **superior** (*jugular*) **ganglion** and **inferior** (*petrosal*) **ganglion** (Figure 14–26). The sensory fibers carry general sensory information from the lining of the pharynx and the soft palate to a nucleus in the medulla oblongata. These nerves also provide taste sensations from the posterior third of the tongue. Additionally, they have special receptors that monitor the blood pressure and dissolved gas concentrations in the carotid arteries, major blood vessels in the neck.

The somatic motor fibers control the pharyngeal muscles involved in swallowing. Visceral motor fibers synapse in the **otic ganglion**. Postganglionic fibers innervate the parotid salivary gland of the cheek.

The Vagus Nerves (X)

Primary function: Mixed (sensory and motor), widely distributed in the thorax and abdomen

Origin: Sensory: pharynx (part), auricle and external acoustic

meatus (a portion of the external ear), diaphragm, and visceral

Figure 14–26 The Glossopharyngeal Nerve.

Destination: Sensory: sensory nuclei and autonomic centers of medulla oblongata. Visceral motor: muscles of the palate, pharynx, digestive, respiratory, and cardiovascular systems in the thoracic and

The **vagus** (VĀ-gus) **nerves** (X) arise immediately posterior to the attachment of the glossopharyngeal nerves. Many small rootlets contribute to their formation. Developmental studies indicate that these nerves probably represent the fusion of several smaller cranial nerves during our evolutionary history. Vagus means wandering, and the vagus nerves branch and radiate extensively. Figure 14–27 shows only the general pattern of

Sensory neurons are located in the **superior** (jugular) ganglion and the inferior (nodose; NO-dos) ganglion. Each vagus nerve provides somatic sensory information about the external acoustic meatus and the diaphragm, and special sensory information from pharyngeal taste receptors. But most of the vagal afferents carry visceral sensory information from receptors along the esophagus, respiratory tract, and abdominal viscera as distant as the last portions of the large intestine. This visceral sensory information is vital to the autonomic control of visceral function.

The motor components of the vagus are equally diverse. Each vagus nerve carries preganglionic autonomic (parasympathetic) fibers that affect the heart and control smooth muscles and glands within the areas monitored by its sensory fibers, including the stomach, intestines, and gallbladder. Difficulty in swallowing is one of the most common signs of damage to either nerve IX or X. Damage to either one prevents the coordination of the swallowing reflex.

The Accessory Nerves (XI)

Primary function: Motor to muscles of the neck and upper back

Origin: Motor nuclei of spinal cord and medulla oblongata

Pass through: Jugular foramina between the occipital bone and the temporal bones \bigcirc pp. 211, 213

Destination: Internal branch innervates voluntary muscles of palate, pharynx, and larynx; external branch controls sternocleidomastoid and trapezius muscles

The **accessory nerves** (XI) are also known as the *spinal accessory nerves* or the *spinoaccessory nerves*. Unlike other cranial nerves, each accessory nerve has some motor fibers that originate in the lateral part of the anterior gray horns of the first five cervical segments of the spinal cord (Figure 14–28). These somatic motor

fibers form the **spinal root** of nerve XI. They enter the cranium through the foramen magnum. They then join the motor fibers of the **cranial root**, which originates at a nucleus in the medulla oblongata. The composite nerve leaves the cranium through the jugular foramen and divides into two branches.

The **internal branch** of nerve XI joins the vagus nerve and innervates the voluntary swallowing muscles of the soft palate and pharynx and the intrinsic muscles that control the vocal cords. The **external branch** of nerve XI controls the sternocleidomastoid and trapezius muscles of the neck and back. \bigcirc pp. 351, 358 The motor fibers of this branch originate in the lateral gray part of the anterior horns of cervical spinal nerves C₁ to C₅.

The Hypoglossal Nerves (XII)

Primary function: Motor (tongue movements)

Origin: Motor nuclei of medulla oblongata

Pass through: Hypoglossal canals of occipital bone **Dpp. 212**, 213, 214

Destination: Muscles of the tongue \bigcirc p. 349

Figure 14–28 The Accessory and Hypoglossal Nerves. ATLAS: Plates 18a-c; 25

Each **hypoglossal** (hī-pō-GLOS-al) **nerve** (XII) leaves the cranium through the hypoglossal canal. The nerve then curves to reach the skeletal muscles of the tongue (Figure 14–28). This cranial nerve provides voluntary motor control over movements of the tongue. Its condition is checked by having you stick out your tongue. Damage to one hypoglossal nerve or to its associated nuclei causes the tongue to veer toward the affected side.

 Table 14–4 summarizes the basic distribution and function of each cranial nerve.

Table 14–4	Cranial Nerve Branches and Functions				
Cranial Nerve (Number)	Sensory Ganglion	Branch	Primary Function	Foramen	Innervation
Olfactory (N I)			Special sensory	Olfactory foramina of ethmoid	Olfactory epithelium
Optic (N II)			Special sensory	Optic canal	Retina of eye
Oculomotor (N III))		Motor	Superior orbital fissure	Inferior, medial, superior rectus, inferior oblique and levator palpebrae superioris muscles; intrinsic eye muscles
Trochlear (N IV)			Motor	Superior orbital fissure	Superior oblique muscle
Trigeminal (N V)	Semilunar		Mixed	Superior orbital fissure	Areas associated with the jaws
		Ophthalmic	Sensory	Superior orbital fissure	Orbital structures, nasal cavity, skin of forehead, upper eyelid, eyebrows, nose (part)
		Maxillary	Sensory	Foramen rotundum	Lower eyelid; superior lip, gums, and teeth; cheek, nose (part), palate, and pharynx (part)
		Mandibular	Mixed	Foramen ovale	<i>Sensory</i> : inferior gums, teeth, lips, palate (part), and tongue (part) <i>Motor</i> : muscles of mastication
Abducens (N VI)			Motor	Superior orbital fissure	Lateral rectus muscle
Facial (N VII)	Geniculate		Mixed	Internal acoustic meatus to facial canal; exits at stylomastoid foramen	<i>Sensory</i> : taste receptors on anterior 2/3 of tongue <i>Motor</i> : muscles of facial expression, lacrimal gland, submandibular gland, sublingual salivary glands
Vestibulocochlea (N VIII)	r	Cochlear Vestibular	Special sensory	Internal acoustic meatus	Cochlea (receptors for hearing) Vestibule (receptors for motion and balance)
Glossopharyngea (N IX)	l Superior (jugular) and inferior (petrosal)		Mixed	Jugular foramen	<i>Sensory</i> : posterior 1/3 of tongue; pharynx and palate (part); receptors for blood pressure, pH, oxygen, and carbon dioxide concentrations <i>Motor</i> : pharyngeal muscles and parotid salivary gland
Vagus (N X)	Superior (jugular) and inferior (nodose)		Mixed	Jugular foramen	Sensory: pharynx; auricle and external acoustic meatus; diaphragm; visceral organs in thoracic and abdominopelvic cavities Motor: palatal and pharyngeal muscles and visceral organs in thoracic and abdominopelvic cavities
Accessory (N XI)		Internal	Motor	Jugular foramen	Skeletal muscles of palate, pharynx, and larynx (with vagus nerve)
		External	Motor	Jugular foramen	Sternocleidomastoid and trapezius muscles
Hypoglossal (N XI	I)		Motor	Hypoglossal canal	Tongue musculature

14–10 Cranial reflexes involve sensory and motor fibers of cranial nerves

Learning Outcome Describe representative examples of cranial reflexes that produce somatic responses or visceral responses to specific stimuli.

Cranial reflexes are automatic responses to stimuli that involve the sensory and motor fibers of cranial nerves. They include both monosynaptic and polysynaptic reflex arcs. Later chapters contain numerous examples of cranial reflexes. In this section we will simply provide an overview and general introduction.

Table 14–5 lists representative examples of cranial reflexes and their functions. These reflexes are clinically important because they provide a quick and easy method for observing the condition of cranial nerves and specific nuclei and tracts in the brain. The somatic reflexes mediated by the cranial nerves are seldom more complex than the somatic reflexes of the spinal cord that we discussed in Chapter 13. ⊃ p. 452 These cranial reflexes are often used to check for damage to the cranial nerves or the associated processing centers in the brain.

The brain stem contains many reflex centers that control visceral motor activity. The motor output of these reflexes is distributed by the autonomic nervous system. As you will see in Chapter 16, the cranial nerves carry most of the commands issued by the parasympathetic division of the ANS. Spinal nerves T_1-L_2 carry the sympathetic commands. Many of the centers that coordinate autonomic reflexes are located in the medulla oblongata. These centers can direct very complex visceral motor responses that are essential to the control of respiratory, digestive, and cardiovascular functions.

CHECKPOINT

- 27. What are cranial reflexes?
- 28. Which reflex and type are you testing if you shine a light in a person's eye?
- See the blue Answers tab at the back of the book.

Table 14–5	Cranial Reflexes					
Reflex	Stimulus	Afferents	Central Synapse	Efferents	Response	
SOMATIC REFLEXES						
Corneal reflex	Contact with corneal surface	N V (trigeminal)	Motor nucleus for N VII (facial)	N VII (facial)	Blinking of eyelids	
Tympanic reflex	Loud noise	N VIII (vestibulocochlear)	Inferior colliculus	N VII (facial)	Reduced movement of auditory ossicles	
Auditory reflexes	Loud noise	N VIII (vestibulocochlear)	Motor nuclei of brain stem and spinal cord	N III, IV, VI, VII, X, and cervical nerves	Eye and/or head movements triggered by sudden sounds	
Vestibulo-ocular reflexes	Rotation of head	N VIII (vestibulocochlear)	Motor nuclei controlling eye muscles	N III, IV, VI	Opposite movement of eyes to stabilize field of vision	
VISCERAL REFLEX	ES					
Direct light reflex	Light striking photoreceptors	N II (optic)	Superior colliculus	N III (oculomotor)	Constriction of ipsilateral pupil	
Consensual light reflex	Light striking photoreceptors	N II (optic)	Superior colliculus	N III (oculomotor)	Constriction of contralateral pupil	

Related Clinical Terms

- **attention deficit hyperactivity disorder (ADHD):** Disorder occurring mainly in children characterized by hyperactivity, inability to concentrate, and impulsive or inappropriate behavior.
- **autism:** Any of a range of behavioral disorders occurring primarily in children, including such symptoms as poor concentration, hyperactivity, and impulsivity.
- **concussion:** A brain injury often caused by a hit to the head that may result in a bad headache, altered levels of alertness, loss of memory, or unconsciousness.
- **Creutzfeldt-Jakob disease (CJD):** A rare, degenerative, invariably fatal brain disorder that is marked by rapid mental deterioration. The disease, which is caused by a prion (an infectious protein particle),

typically starts by causing mental and emotional problems, then progresses to affect motor skills, such as walking and talking.

- **delirium:** An acutely disturbed state of mind that occurs in fever, intoxication, and other disorders and is characterized by restlessness, hallucinations, and incoherence of thought and speech.
- **dementia:** A chronic or persistent disorder of the mental processes caused by brain disease or injury and marked by memory disorders, personality changes, and impaired reasoning.
- **Glasgow coma scale:** The most widely used scoring system to quantify the level of consciousness of a victim of a traumatic brain injury. It rates three functions: eye opening, verbal response, and motor response.

- **migraine:** A type of headache marked by severe debilitating head pain lasting several hours or longer.
- **myoclonus:** A quick, involuntary muscle jerk or contraction; persistent myoclonus usually indicates a nervous system disorder.
- **pallidectomy:** The destruction of all or part of the globus pallidus by chemicals or freezing; used in the treatment of Parkinson's disease.
- **prosopagnosia:** The inability to recognize other humans by their faces.

An Introduction to the Brain and Cranial Nerves p. 462

- 1. The adult human brain contains almost 97 percent of the body's neural tissue and averages 1.4 kg (3 lb) in weight and 1200 mL (71 in.³) in volume.
- 14-1 The brain has several principal structures, each with specific functions p. 462
- 2. The six regions in the adult brain are the **cerebrum**, **cerebellum**, **diencephalon**, **midbrain** (mesencephalon), **pons**, and **medulla oblongata**. (*Figure 14–1*)
- The brain contains extensive areas of neural cortex, a layer of gray matter on the surfaces of the cerebrum (cerebral cortex) and cerebellum.
- 4. The brain forms from three swellings at the superior tip of the developing *neural tube*: the *prosencephalon*, the *mesencephalon*, and the *rhombencephalon*. The prosencephalon ("forebrain") forms the **telencephalon** (which becomes the cerebrum) and diencephalon; the rhombencephalon ("hindbrain") forms the **metencephalon** (cerebellum and pons) and **myelencephalon** (medulla oblongata). (*Table 14–1*)
- 5. During development, the central passageway of the brain expands to form chambers called **ventricles**, which contain cerebrospinal fluid (CSF). (*Figure 14–2*)

14-2 The brain is protected and supported by the cranial meninges, cerebrospinal fluid, and the blood-brain barrier p. 465

6. The cranial meninges (the *dura mater, arachnoid mater,* and *pia mater*) are continuous with the meninges of the spinal cord.

- **psychosis:** A severe mental disorder in which thought and emotions are so impaired that contact with reality is lost.**stupor:** A state of near-unconsciousness or insensibility.
- **transient ischemic attack (TIA):** An episode in which a person has stroke-like symptoms that last less than 24 hours and result in no permanent injury to the brain, but may be a warning sign of the potential for a major stroke.

- Folds of dura mater, including the falx cerebri, tentorium cerebelli, and falx cerebelli, stabilize the position of the brain. (*Figure 14–3*)
- 8. Cerebrospinal fluid (CSF) (1) protects delicate neural structures, (2) supports the brain, and (3) transports nutrients, chemical messengers, and waste products.
- Cerebrospinal fluid is produced at the choroid plexuses, reaches the subarachnoid space through the lateral and median apertures, and diffuses across the arachnoid granulations into the superior sagittal sinus. (Spotlight Figure 14–4)
- **10.** The **blood–brain barrier (BBB)** isolates neural tissue from the general circulation.
- 11. The blood-brain barrier is incomplete in parts of the **hypothalamus**, the **pituitary gland**, the **pineal gland**, and the **choroid plexus**.
- **14-3** The medulla oblongata is continuous with the spinal cord and contains vital centers p. 470
- 12. The medulla oblongata connects the brain and spinal cord. It contains relay stations such as the **olivary nuclei**, and **re-flex centers**, including the **cardiovascular** and **respiratory rhythmicity centers**. The **reticular formation** begins in the medulla oblongata and extends into more superior portions of the brain stem. (*Figures 14–5, 14–6*)
- **14-4** The pons contains nuclei and tracts that carry or relay sensory and motor information p. 472
- **13.** The pons contains (1) sensory and motor nuclei for four cranial nerves; (2) nuclei that help control respiration; (3) nuclei and tracts linking the cerebellum with the brain stem, cerebrum, and spinal cord; and (4) ascending, descending, and transverse tracts. (*Figure* 14–7)

14-5 The cerebellum coordinates learned and reflexive patterns of muscular activity at the subconscious level p. 473

- 14. The cerebellum adjusts postural muscles and programs and tunes ongoing movements. The two **cerebellar hemispheres** consist of the **anterior** and **posterior lobes**, the **vermis**, and the **flocculonodular lobe**. (*Figure 14–8*)
- **15.** The **superior**, **middle**, and **inferior cerebellar peduncles** link the cerebellum with the brain stem, diencephalon, cerebrum, and spinal cord and interconnect the two cerebellar hemispheres.

- 14-6 The midbrain regulates auditory and visual reflexes and controls alertness p. 475
- 16. The tectum (roof of the midbrain) contains the corpora quadrigemina (superior colliculi and inferior colliculi). The tegmentum contains the red nucleus, the substantia nigra, the cerebral peduncles, and the headquarters of the reticular activating system (RAS). (*Figure 14–9*)
- 14-7 The diencephalon integrates sensory information with motor output at the subconscious level p. 477
- **17.** The diencephalon is composed of the epithalamus, the hypothalamus, and the thalamus. (*Figures* 14–10, 14–11)
- **18.** The thalamus is the final relay point for ascending sensory information and coordinates the activities of the basal nuclei and cerebral cortex. (*Figures 14–10, 14–11; Table 14–2*)
- The hypothalamus can (1) control somatic motor activities at the subconscious level, (2) control autonomic function, (3) coordinate activities of the nervous and endocrine systems, (4) secrete certain hormones, (5) produce emotions and behavioral **drives**, (6) coordinate voluntary and autonomic functions, (7) regulate body temperature, and (8) coordinate circadian cycles of activity. (*Figure 14–11*)
- **14-8** The limbic system is a group of tracts and nuclei that function in emotion, motivation, and memory p. 480
- 20. The **limbic system**, or *motivational system*, includes the **amygdaloid body, cingulate gyrus, dentate gyrus, parahippocampal gyrus, hippocampus, and fornix**. The functions of the limbic system involve emotional states, behavioral drives, and memory. (*Figure 14–12*)
- 14-9 The cerebrum, the largest region of the brain, contains motor, sensory, and association areas p. 482
- 21. The cortical surface contains **gyri** (elevated ridges) separated by **sulci** (shallow depressions) or **fissures** (deeper grooves). The **longitudinal fissure** separates the two **cerebral hemispheres**. The **central sulcus** separates the **frontal** and **parietal lobes**. Other sulci form the boundaries of the **temporal** and **occipital lobes**. (*Figure 14–13*)
- **22.** The white matter of the cerebrum contains **association fibers**, **commissural fibers**, and **projection fibers**. (*Figure* 14–14)
- 23. The **basal nuclei** include the **caudate nucleus**, **globus pallidus**, and **putamen**; they control muscle tone and coordinate learned movement patterns and other somatic motor activities. (*Figure 14–15*)
- 24. The **primary motor cortex** of the **precentral gyrus** directs voluntary movements. The **primary sensory cortex** of the **postcentral gyrus** receives somatic sensory information from touch, pressure, pain, vibration, taste, and temperature receptors. (*Figure 14–16; Table 14–3*)
- **25. Association areas**, such as the **somatic sensory association area**, **visual association area**, and **premotor cortex (so-matic motor association area)**, control our ability to understand sensory information and coordinate a motor response. (*Figure 14–16*)
- **26.** The **general interpretive area** receives information from all the sensory association areas. It is present in only one hemisphere—generally the left. (*Figures 14–16b, 14–17*)
- **27.** The **speech center** regulates the patterns of breathing and vocalization needed for normal speech. (*Figures 14–16b, 14–17*)

- **28.** The **prefrontal cortex** coordinates information from the secondary and special association areas of the entire cortex and performs abstract intellectual functions. (*Figure 14–16*)
- **29.** The left hemisphere typically contains the general interpretive and speech centers and is responsible for language-based skills. The right hemisphere is typically responsible for spatial relationships and analyses. (*Figure 14–17*)
- 30. Brain activity is measured using an electroencephalogram. Alpha waves appear in healthy resting adults; beta waves occur when adults are concentrating; theta waves appear in children; and delta waves are normal during sleep. (*Figure 14–18*)

Focus: Cranial Nerves p. 492

- **31.** We have 12 pairs of cranial nerves. Except for N I and N II, each nerve attaches to the ventrolateral surface of the brain stem near the associated sensory or motor nuclei. (*Figure* 14–19)
- **32.** The **olfactory nerves** (N I) carry sensory information responsible for the sense of smell. The olfactory afferents synapse within the **olfactory bulbs**. (*Figures 14–19, 14–20*)
- **33.** The **optic nerves** (N II) carry visual information from special sensory receptors in the eyes. (*Figures 14–19, 14–21*)
- **34.** The **oculomotor nerves** (N III) are the primary source of innervation for four of the extrinsic eye muscles. (*Figure 14–22*)
- **35.** The **trochlear nerves** (N IV), the smallest cranial nerves, innervate the superior oblique muscles of the eyes. (*Figure 14–22*)
- **36.** The **trigeminal nerves** (N V), the largest cranial nerves, are mixed nerves with *ophthalmic*, *maxillary*, and *mandibular branches*. (*Figure 14–23*)
- **37.** The **abducens nerves** (N VI) innervate the lateral rectus muscles of the eyes. (*Figure 14–22*)
- **38.** The **facial nerves** (N VII) are mixed nerves that control muscles of the scalp and face. They provide pressure sensations over the face and receive taste information from the tongue. (*Figure 14–24*)
- **39.** The **vestibulocochlear nerves** (N VIII) contain the **vestibular branch**, which monitors sensations of balance, position, and movement, and the **cochlear branch**, which monitors hearing receptors. (*Figure 14–25*)
- **40.** The **glossopharyngeal nerves** (N IX) are mixed nerves that innervate the tongue and pharynx and control the action of swallowing. (*Figure 14–26*)
- 41. The **vagus nerves** (N X) are mixed nerves that are vital to the autonomic control of visceral function in the thorax and abdomen. (*Figure 14–27*)
- **42.** The **accessory nerves** (N XI) have **internal branches**, which innervate voluntary swallowing muscles of the soft palate and pharynx, and **external branches**, which control muscles associated with the pectoral girdle. (*Figure 14–28*)
- **43.** The **hypoglossal nerves** (N XII) provide voluntary motor control over tongue movements. (*Figure 14–28*)
- 44. The branches and functions of the cranial nerves are summarized in *Table 14–4*.
- 14-10 Cranial reflexes involve sensory and motor fibers of cranial nerves p. 503
- 45. Cranial reflexes are monosynaptic and polysynaptic reflex arcs that involve sensory and motor fibers of cranial nerves. *(Table 14–5)*

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the six major regions of the brain in the following diagram.

2. Identify the layers of the cranial meninges in the following diagram.

- **3.** The term *higher brain centers* refers to those areas of the brain involved in higher-order functions. These centers would probably include nuclei, centers, and cortical areas of **(a)** the cerebrum, **(b)** the cerebellum, **(c)** the diencephalon, **(d)** all of these, **(e)** a and c only.
- 4. Which of the following is the site of cerebrospinal fluid production?
 (a) dural sinus, (b) choroid plexus, (c) falx cerebri, (d) tentorium cerebelli, (e) insula.
- The pons contains (a) sensory and motor nuclei for six cranial nerves, (b) nuclei concerned with control of blood pressure, (c) tracts that link the cerebellum with the brain stem, (d) no ascending or descending tracts, (e) both a and b.
- 6. The dural fold that divides the two cerebellar hemispheres is the (a) transverse sinus, (b) falx cerebri, (c) tentorium cerebelli, (d) falx cerebelli.

- Cerebrospinal fluid is produced and secreted by (a) neurons,
 (b) ependymal cells, (c) Purkinje cells, (d) basal nuclei.
- The primary purpose of the blood–brain barrier (BBB) is to

 (a) provide the brain with oxygenated blood, (b) drain venous blood by the internal jugular veins, (c) isolate neural tissue in the CNS from the general circulation, (d) do all of these.
- The centers in the pons that modify the activity of the respiratory rhythmicity centers in the medulla oblongata are the (a) apneustic and pneumotaxic centers, (b) inferior and superior peduncles, (c) cardiac and vasomotor centers, (d) nucleus gracilis and nucleus cuneatus.
- 10. The final relay point for ascending sensory information that will be projected to the primary sensory cortex is the (a) hypothalamus, (b) thalamus, (c) spinal cord, (d) medulla oblongata.
- The establishment of emotional states is a function of the
 (a) limbic system, (b) tectum, (c) mammillary bodies, (d) thalamus.
- 12. Coordination of learned movement patterns at the subconscious level is performed by (a) the cerebellum, (b) the substantia nigra, (c) association fibers, (d) the hypothalamus.
- **13.** The two cerebral hemispheres are functionally different, even though anatomically they appear the same. **(a)** true, **(b)** false.
- 14. What are the three important functions of the CSF?
- **15.** Which three areas in the brain are not isolated from the general circulation by the blood–brain barrier?
- **16.** Using the mnemonic device "Oh, Once One Takes The Anatomy Final, Very Good Vacations Are Heavenly," list the names of the 12 pairs of cranial nerves.

LEVEL 2 Reviewing Concepts

- 17. Why can the brain respond to stimuli with greater versatility than the spinal cord?
- **18.** Briefly summarize the overall function of the cerebellum.
- 19. The only cranial nerves that are attached to the cerebrum are the ______ nerves. (a) optic, (b) oculomotor, (c) trochlear, (d) olfactory, (e) abducens.
- **20.** If symptoms characteristic of Parkinson's disease appear, which part of the midbrain is inhibited from secreting a neurotransmitter? Which neurotransmitter is it?
- 21. What varied roles does the hypothalamus play in the body?
- **22.** Stimulation of which part of the brain would produce sensations of hunger and thirst?
- **23.** Which structure in the brain would your A&P instructor be referring to when talking about a nucleus that resembles a sea horse and that is important in the storage and retrieval of long-term memories? In which functional system of the brain is it located?
- 24. What are the principal functional differences between the right and left cerebral hemispheres?
- 25. Damage to the vestibular nucleus would lead to (a) loss of sight,(b) loss of hearing, (c) inability to sense pain, (d) difficulty in maintaining balance, (e) inability to swallow.
- 26. A cerebrovascular accident occurs when (a) the reticular activating system fails to function, (b) the prefrontal lobe is damaged, (c) the blood supply to a portion of the brain is cut off, (d) a descending tract in the spinal cord is severed, (e) brain stem nuclei hypersecrete dopamine.
- **27.** What kinds of problems are associated with the presence of lesions in the Wernicke's area and the Broca's area?

LEVEL 3 Critical Thinking and Clinical Applications

28. Smelling salts can sometimes help restore consciousness after a person has fainted. The active ingredient of smelling salts is ammonia, and it acts by irritating the lining of the nasal cavity. Propose a mechanism

by which smelling salts would raise a person from the unconscious state to the conscious state.

- **29.** A police officer has just stopped Bill on suspicion of driving while intoxicated. The officer asks Bill to walk the yellow line on the road and then to place the tip of his index finger on the tip of his nose. How would these activities indicate Bill's level of sobriety? Which part of the brain is being tested by these activities?
- **30.** Colleen falls down a flight of stairs and bumps her head several times. Soon after, she develops a headache and blurred vision. Diagnostic tests at the hospital reveal an epidural hematoma in the temporoparietal area. The hematoma is pressing against the brain stem. What other signs and symptoms might she experience as a result of the injury?
- **31.** Cerebral meningitis is a condition in which the meninges of the brain become inflamed as the result of viral or bacterial infection. This condition can be life threatening. Why?
- **32.** Infants have little to no control of the movements of their head. One of the consequences of this is that they are susceptible to shaken baby syndrome, caused by vigorous shaking of an infant or young child by the arms, legs, chest, or shoulders. Forceful shaking can cause brain damage leading to mental retardation, speech and learning disabilities, paralysis, seizures, hearing loss, and even death. Damage to which areas of the brain would account for the clinical signs observed in this syndrome?

CLINICAL CASE

The Neuroanatomist's Stroke

Dr. Taylor's full recovery took about eight years. While the left side of her brain was injured and

shut down, the right side continued functioning. Because language and thoughts are controlled in the left hemisphere, Dr. Taylor "sat in an absolutely silent mind" for the first month after her stroke. Similarly, since the general interpretive center for mathematical calculation is in the left hemisphere, she had to learn to use numbers all over again. And because the primary motor cortex governing the right side of the body resides in the precentral gyrus of the left hemisphere, she had to learn to use her right arm again.

The stroke had injured some cells in her brain beyond repair. But some cells were dormant, capable of recovery and of making new neuronal connections. This ability of nerve cells to make these new connections is neuroplasticity, which permits healing as the brain reorganizes itself after an injury.

Dr. Taylor wants anatomy and physiology students to know two things. First, "if you study the brain, you will never be bored."

Wrap-Up

Second, "if you treat stroke patients like they will recover, they are more likely to recover."

She has written a best-selling memoir about her personal experience with stroke, *My Stroke of Insight: A Brain Scientist's Personal Journey.* She of-

fers suggestions for the stroke survivor, caregiver, and everyone who deals with stroke.

- 1. How would you know, just based on signs and symptoms, which side of Dr. Taylor's brain has been injured by a stroke?
- 2. What is neuroplasticity and why was it important in Dr. Taylor's recovery?

See the blue Answers tab at the back of the book.

15

Sensory Pathways and the Somatic Nervous System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **15-1** Specify the components of the afferent and efferent divisions of the nervous system, and explain what is meant by the somatic nervous system.
- 15-2 Explain why receptors respond to specific stimuli, and how the organization of a receptor affects its sensitivity.
- 15-3 Identify the receptors for the general senses, and describe how they function.
- 15-4 Identify the major sensory pathways, and explain how it is possible to distinguish among sensations that originate in different areas of the body.

15-5 Describe the components, processes, and functions of the somatic motor pathways, and the levels of information processing involved in motor control.

SPOTLIGHT

• Somatic Sensory Pathways pp. 520–521

CLINICAL CASE

• Living with Cerebral Palsy p. 509

Clinical Notes

- Assessment of Tactile Sensitivities p. 517
- Amyotrophic Lateral Sclerosis p. 526
- Cerebral Palsy p. 527

CLINICAL CASE

Living with Cerebral Palsy

Michael Ward had a challenging start in life. His mother had a difficult and prolonged labor in the

days when cesarean sections were rarely performed. Michael was a large baby and suffered brain damage from inadequate oxygen during birth, requiring an extended resuscitation. The lack of oxygen to his brain caused a condition known as *cerebral palsy* (CP).

Michael was critically ill as a newborn and remained hospitalized for weeks. Because of swallowing difficulties, he had aspiration pneumonia (lung inflammation from inhaling food) three times in his first year of life. He was delayed in reaching gross and fine motor developmental milestones, and although he had plenty to say, his speech was difficult to understand. When he was finally able to walk, by age four, he used crutches or held a parent's hand. His gait was slow, unsteady, and crouched. He fell often. He has used a wheelchair regularly since high school.

Cerebral palsy is the most common congenital neurological condition, affecting as many as 1 million Americans. In spite of advances in obstetric and neonatal care, the incidence of CP has not changed in the past half century. Cerebral palsy is caused by an injury to the developing

brain, and can occur before, during, or within a few years after birth. It is not contagious. It is not progressive. It is a condition, not a disease. How did Michael's life turn out? See the Clinical Case Wrap-Up on p. 530.

An Introduction to Sensory Pathways and the Somatic Nervous System

In this chapter we examine how the nervous system works as an integrated unit. We consider sensory receptors, sensory processing centers in the brain, and conscious and subconscious motor functions. The basic events that occur along sensory and motor pathways are shown in Figure 15–1. In our discussion, we will focus on the "general senses" that provide information about the body and its environment. The "special senses"—smell, taste, sight, equilibrium (balance), and hearing—are considered in Chapter 17.

15-1 Sensory information from all parts of the body is routed to the somatosensory cortex

Learning Outcome Specify the components of the afferent and efferent divisions of the nervous system, and explain what is meant by the somatic nervous system.

Sensory receptors are specialized cells or cell processes that monitor specific conditions in the body or the external environment. When stimulated, a receptor passes information to the CNS in the form of action potentials along the axon of a sensory neuron. Such axons are parts of *sensory pathways*—the nerves, nuclei, and tracts that deliver somatic and visceral sensory information to their final destinations inside the CNS. Taken together, the receptors, sensory neurons, and sensory pathways make up the afferent division of the nervous system. \bigcirc p. 387 Somatic and visceral sensory information often travels along the same pathway. Somatic sensory information is distributed to *sensory processing centers in the brain*—either the primary sensory cortex of the cerebral hemispheres or appropriate areas of the cerebellar hemispheres. Visceral sensory information is distributed primarily to reflex centers in the brain stem and diencephalon.

In this chapter we also consider the somatic motor portion of the efferent division—the nuclei, motor tracts, and motor neurons that control peripheral effectors. Whether somatic motor commands arise at the conscious or subconscious levels, they travel from motor centers in the brain along *somatic motor pathways*, which consist of motor nuclei, tracts, and nerves. The motor neurons and pathways that control skeletal muscles form the somatic nervous system (SNS).

In Chapter 16, we will discuss the visceral motor portion of the efferent division. All visceral motor commands are carried into the PNS by the autonomic nervous system (ANS). Both somatic and visceral motor commands may be issued in response to arriving sensory information. These commands may be modified on the basis of planning, memories, and learning—the so-called *higher-order functions* of the brain. We will also consider these higher-order functions in Chapter 16.

CHECKPOINT

- 1. What do we call the body's specialized cells that monitor specific internal or external conditions?
- 2. Is it possible for somatic motor commands to occur at the subconscious level?
- See the blue Answers tab at the back of the book.

Figure 15–1 An Overview of Events Occurring Along the Sensory and Motor Pathways.

15-2 Sensory receptors connect our internal and external environments with the nervous system

Learning Outcome Explain why receptors respond to specific stimuli, and how the organization of a receptor affects its sensitivity.

As we noted, sensory receptors are specialized cells or cell processes that provide your central nervous system with information about conditions inside or outside the body. We use the term **general senses** to describe our sensitivity to temperature, pain, touch, pressure, vibration, and proprioception (body position). You have general sensory receptors throughout your body. They are fairly simple in structure. Some of the information they send to the CNS reaches the primary sensory cortex and your awareness.

As noted in Chapter 12, the CNS interprets sensory information on the basis of the frequency of arriving action potentials. \bigcirc **p**. 423 For example, when pressure sensations are arriving, the harder the pressure, the higher the frequency of action potentials. The arriving information is called a **sensation**. The conscious awareness of a sensation is called a **perception**.

The **special senses** are **olfaction** (smell), **vision** (sight), **gustation** (taste), **equilibrium** (balance), and **hearing**. These

sensations are provided by receptors that are structurally more complex than those of the general senses. Special sensory receptors are located in **sense organs** such as the eye or ear, where surrounding tissues protect the receptors. The information these receptors provide is distributed to specific areas of the cerebral cortex (the auditory cortex, the visual cortex, and so forth) and to centers throughout the brain stem. We consider the special senses in Chapter 17.

Sensory receptors represent the interface between your nervous system and your internal and external environments. A sensory receptor detects an arriving stimulus and translates it into an action potential that can be conducted to the CNS. This translation, or conversion, process is called *transduction*. If transduction does not take place, then as far as you are concerned, the stimulus doesn't exist. For example, bees can see ultraviolet light that you can't see. Dogs can respond to sounds you can't hear. In each case the stimuli are there—but your receptors cannot detect them. Now let's examine the basic concepts of receptor function and sensory processing.

The Detection of Stimuli

How do receptors detect stimuli? Each receptor has a characteristic sensitivity. For example, a touch receptor is very sensitive to pressure but relatively insensitive to chemical stimuli. A taste receptor is sensitive to dissolved chemicals but insensitive to pressure. This feature is called *receptor specificity*.

Specificity may result from the structure of the receptor cell, or from the presence of accessory cells or structures that shield the receptor cell from other stimuli. The simplest receptors are the dendrites of sensory neurons. The branching tips of these dendrites, called **free nerve endings**, are not protected by accessory structures. Free nerve endings extend through a tissue the way grass roots extend into the soil. Many different stimuli can stimulate them. For this reason, free nerve endings show little receptor specificity. For example, chemicals, pressure, temperature changes, or trauma may stimulate free nerve endings that respond to tissue damage by providing pain sensations.

Complex receptors, such as the eye's visual receptors, are protected by accessory cells and connective tissue layers. These cells are seldom exposed to any stimulus other than light and so provide very specific information.

The area monitored by a single receptor cell is its *receptive field* (Figure 15–2). Whenever a sufficiently strong stimulus arrives in the receptive field, the CNS receives the information "stimulus arriving at receptor X." The larger the receptive field, the poorer your ability to localize a stimulus. A touch receptor on the general body surface, for example, may have a receptive field 7 cm (2.5 in.) in diameter. As a result, you can describe a light touch there as affecting only a general area, not an exact spot. On your tongue or fingertips, the receptive fields are less than a millimeter in diameter. In these areas, you can be very precise about the location of a stimulus.

An arriving stimulus can take many forms. It may be a physical force (such as pressure), a dissolved chemical, a sound, or light. Regardless of the nature of the stimulus, however,

Figure 15–2 Receptors and Receptive Fields. Each receptor cell monitors a specific area known as the receptive field.

sensory information is sent to the CNS only in the form of action potentials, which are electrical events.

As noted earlier, transduction is the translation of an arriving stimulus into an action potential by a sensory receptor. Transduction begins when a stimulus changes the membrane potential of the receptor cell. This change, called a *receptor potential*, is either a graded depolarization or a graded hyperpolarization. The stronger the stimulus, the larger the receptor potential.

The typical receptors for the general senses are the dendrites of sensory neurons. In these cases, the sensory neuron is the receptor cell. Any receptor potential that depolarizes the plasma membrane will bring the membrane closer to threshold. A depolarizing receptor potential in a neural receptor is called a *generator potential*.

Specialized receptor cells that communicate with sensory neurons across chemical synapses give us sensations of taste, hearing, equilibrium, and vision. In these cases, the receptor potential and the generator potential occur in different cells. The receptor potential develops in the receptor cell, and the generator potential appears later, in the sensory neuron. The receptor cells develop graded receptor potentials in response to stimulation, and the change in membrane potential alters the rate of neurotransmitter release at the synapse. The result is a depolarization or hyperpolarization of the sensory neuron. If sufficient depolarization occurs, an action potential appears in the sensory neuron.

Whenever a sufficiently large generator potential appears, action potentials develop in the axon of a sensory neuron. For reasons discussed in Chapter 12, the greater the degree of sustained depolarization at the axon hillock, the higher the frequency of action potentials in the afferent fiber. \bigcirc p. 410 The CNS then processes and interprets this arriving information at the conscious and subconscious levels.

The Interpretation of Sensory Information

Sensory information that arrives at the CNS is routed according to the location and nature of the stimulus. In previous chapters we emphasized the fact that axons in the CNS are organized in bundles with specific origins and destinations. Along sensory pathways, a series of neurons relays information from one point (the receptor) to another (a neuron at a specific site in the cerebral cortex). For example, sensations of touch, pressure, pain, and temperature arrive at the primary sensory cortex. Visual, auditory, gustatory (taste), and olfactory (smell) sensations reach their respective visual, auditory, gustatory, and olfactory regions of the cortex.

The link between peripheral receptor and cortical neuron is called a **labeled line**. Each labeled line consists of axons carrying information about one *modality*, or type of stimulus (touch, pressure, light, and sound). The CNS interprets the modality
entirely on the basis of the labeled line over which it arrives. For this reason, you cannot tell the difference between a true sensation and a false one generated somewhere along the line. For example, when you rub your eyes, you commonly see flashes of light. The stimulus is mechanical (pressure) rather than visual, but *any* activity along the optic nerve is projected to the visual cortex. You experience it as a visual perception.

The identity of the active labeled line indicates the type of stimulus. Where it arrives within the sensory cortex determines its perceived location. For example, if activity in a labeled line that carries touch sensations stimulates the facial region of your primary sensory cortex, you perceive a touch on the face.

All other characteristics of the stimulus—its strength, duration, and variation—are conveyed by the frequency and pattern of action potentials. The translation of complex sensory information into meaningful patterns of action potentials is called *sensory coding*.

Receptors can be categorized by the nature of their response to stimulation (Figure 15–3). Some sensory neurons, called **tonic receptors**, are always active (Figure 15–3a). Other receptors, called **phasic receptors**, are usually not active. Phasic receptors provide information about the intensity and rate of change of a stimulus (Figure 15–3b). Receptors that combine phasic and tonic coding can convey extremely complicated sensory information.

Adaptation

Adaptation is a reduction in sensitivity in the presence of a constant stimulus. You seldom notice the rumble of the tires when you ride in a car, or the background noise of the air conditioner. The reason is that your nervous system quickly adapts to stimuli that are painless and constant. *Peripheral adaptation*

occurs when the level of receptor activity changes. The receptor responds strongly at first, but then its activity gradually declines, in part because the size of the generator potential gradually decreases. This response is characteristic of phasic receptors, which are also called **fast-adapting receptors**. For example, temperature receptors (*thermoreceptors*) are phasic receptors. You seldom notice room temperature unless it changes suddenly.

Tonic receptors show little peripheral adaptation and so are called **slow-adapting receptors**. Pain receptors (*nociceptors*) are slow-adapting receptors. This is one reason why pain sensations remind you of an injury long after the initial damage has taken place.

Adaptation also occurs along sensory pathways inside the CNS. For example, a few seconds after you have been exposed to a new smell, awareness of the stimulus virtually disappears, although the sensory neurons are still quite active. This process is known as *central adaptation*. Central adaptation generally involves the inhibition of nuclei along a sensory pathway.

Peripheral adaptation reduces the amount of information that reaches the CNS. Central adaptation at the subconscious level further restricts the amount of detail that arrives at the cerebral cortex. Most of the incoming sensory information is processed in centers along the spinal cord or brain stem at the subconscious level. This processing can produce reflexive motor responses, but you are seldom consciously aware of either the stimuli or the responses.

The output from higher centers can increase receptor sensitivity or facilitate transmission along a sensory pathway. The reticular activating system in the midbrain helps focus our attention and heightens or reduces our awareness of arriving sensations. \bigcirc p. 476 This adjustment of sensitivity can take place under conscious or subconscious direction. When you "listen

rate of action potential generation changes accordingly.

Figure 15–3 Tonic and Phasic Sensory Receptors.

carefully," your sensitivity and awareness of auditory stimuli increase. Output from higher centers can also inhibit transmission along a sensory pathway. Such inhibition occurs when you enter a noisy factory or walk along a crowded city street. You automatically tune out the high level of background noise. Next let's consider how these basic concepts of receptor function and sensory processing apply to the general senses.

CHECKPOINT

- 3. Receptor A has a circular receptive field on the skin surface with a diameter of 2.5 cm. Receptor B has a circular receptive field 7.0 cm in diameter. Which receptor provides more precise sensory information?
- 4. Define adaptation.

See the blue Answers tab at the back of the book.

15-3 General sensory receptors are classified by the type of stimulus that excites them

Learning Outcome Identify the receptors for the general senses, and describe how they function.

Receptors for the general senses are scattered throughout the body. They are simple in structure. Using the simple classification scheme introduced in Chapter 12, we divide them into three types. **D p. 391** *Exteroceptors* provide information about the external environment. *Proprioceptors* report the positions and movements of skeletal muscles and joints. *Interoceptors* monitor visceral organs and functions.

Using a more detailed classification system, we can divide the general sensory receptors into four types by the nature of the stimulus that excites them: *nociceptors* (pain), *thermoreceptors* (temperature), *mechanoreceptors* (physical distortion), and *chemoreceptors* (chemical concentration). Each class of receptors has distinct structural and functional characteristics. The difference between a somatic receptor and a visceral receptor is its location, not its structure. A pain receptor in the gut looks and acts like a pain receptor in the skin, but the two sensations are delivered to separate locations in the CNS.

Proprioception, however, is a purely somatic sensation. There are no proprioceptors in the visceral organs of the thoracic and abdominopelvic cavities. Your mental map of your body doesn't include these organs. You cannot tell, for example, where your spleen, appendix, or pancreas is at the moment. The visceral organs also have fewer pain, temperature, and touch receptors than we find elsewhere in the body. The sensory information you receive is poorly localized because the receptive fields are very large and may be widely separated.

General sensations are widely distributed in the CNS, but most of the processing takes place in centers along the sensory pathways in the spinal cord or brain stem. Only about 1 percent of the information provided by afferent fibers reaches the cerebral cortex and our awareness. For example, you usually do not feel the clothes you wear or hear the hum of the engine when riding in a car.

Nociceptors

Pain receptors, or **nociceptors** (*noxa*, harm), are especially common in the superficial portions of the skin, in joint capsules, within the periostea of bones, and around the walls of blood vessels. Other deep tissues and most visceral organs have few nociceptors. Pain receptors are free nerve endings with large receptive fields (Figure 15–2). As a result, it is often difficult to determine the exact source of a painful sensation.

Different nociceptors may be sensitive to (1) extremes of temperature, (2) mechanical damage, and (3) dissolved chemicals, such as chemicals released by injured cells. Very strong stimuli, however, will excite all three receptor types. For that reason, people describing very painful sensations—whether caused by acids, heat, or a deep cut—use similar descriptive terms, such as "burning."

Stimulation of the dendrites of a nociceptor causes depolarization. When the initial segment of the axon reaches threshold, an action potential heads toward the CNS.

Two types of axons—Type A and Type C fibers—carry painful sensations. **D p. 413** Myelinated Type A fibers carry sensations of **fast pain**, or *prickling pain*. An injection or a deep cut produces this type of pain. These sensations reach the CNS quickly, where they often trigger somatic reflexes. They are also relayed to the primary sensory cortex and so receive conscious attention. In most cases, the arriving information allows you to localize the stimulus to an area several inches in diameter.

Slower, Type C fibers carry sensations of **slow pain**, or *burning and aching pain*. These sensations cause a generalized activation of the reticular formation and thalamus. You become aware of the pain but only have a general idea of the area affected.

Pain receptors are tonic receptors (Figure 15–3a). Significant peripheral adaptation does not occur, and the receptors continue to respond as long as the painful stimulus remains. Painful sensations stop only after tissue damage has ended. However, central adaptation may reduce the *perception* of the pain while pain receptors remain stimulated. This effect involves the inhibition of centers in the thalamus, reticular formation, lower brain stem, and spinal cord.

An understanding of the origins of pain sensations and an ability to control or reduce pain levels have always been among the most important aspects of medical treatment. After all, it is usually pain that causes us to seek treatment. We usually tolerate or ignore conditions that are not painful. Although we often use the term *pain pathways*, it is clear that pain distribution and perception are extremely complex.

The sensory neurons that bring pain sensations into the CNS release *glutamate* and/or *substance P* as neurotransmitters.

These neurotransmitters facilitate neurons along the pain pathways. As a result, the level of pain experienced (especially chronic pain) can be out of proportion to the amount of painful stimuli or the apparent tissue damage. This effect may be one reason why people differ so widely in their perception of the pain associated with childbirth, headaches, or back pain. This facilitation is also presumed to play a role in phantom limb pain (discussed shortly): the sensory neurons may be inactive, but the hyperexcitable interneurons may continue to generate pain sensations.

The release of endorphins and enkephalins within the CNS can reduce the level of pain that a person feels. As noted in Chapter 12, endorphins and enkephalins are neuromodulators that inhibit activity along pain pathways in the brain. ⊃ p. 417 These compounds are structurally similar to morphine. They are found in the limbic system, hypothalamus, and reticular formation. The pain centers in these areas also use substance P as a neurotransmitter. Endorphins bind to the presynaptic membrane and prevent the release of substance P, reducing the conscious perception of pain, although the painful stimulus remains.

TIPS&TRICKS

The **P** in substance **P** stands for **p**eptide and is involved with **p**ain, which it transmits **p**eripherally.

Thermoreceptors

Temperature receptors, or **thermoreceptors**, are free nerve endings located in the dermis, in skeletal muscles, in the liver, and in the hypothalamus. Cold receptors are three or four times more numerous than warm receptors. There are no structural differences between warm and cold thermoreceptors. Temperature sensations are conducted along the same pathways that carry pain sensations. They are sent to the reticular formation, the thalamus, and (to a lesser extent) the primary sensory cortex.

Thermoreceptors are phasic receptors (Figure 15–3b). They are very active when the temperature is changing, but they quickly adapt to a stable temperature. When you enter an air-conditioned classroom on a hot summer day or a warm lecture hall on a brisk fall evening, the temperature change seems extreme at first, but you quickly become comfortable as adaptation occurs.

Mechanoreceptors

Mechanoreceptors are sensitive to stimuli that distort their plasma membranes. These membranes contain *mechanically gated ion channels*. The gates open or close in response to stretching, compression, twisting, or other distortions of the membrane. There are three classes of mechanoreceptors:

1. **Tactile receptors** provide the closely related sensations of touch, pressure, and vibration. Touch sensations provide

information about shape or texture, whereas pressure sensations indicate the degree of mechanical distortion. Vibration sensations indicate a pulsing pressure. The receptors involved may be specialized in some way. For example, rapidly adapting tactile receptors are best suited for detecting vibration. But your interpretation of a sensation as touch rather than pressure is typically a matter of the degree of stimulation, and not of differences in the type of receptor stimulated.

- Baroreceptors (bar-ō-rē-SEP-torz; *baro-*, pressure) detect pressure changes in the walls of blood vessels and in portions of the digestive, respiratory, and urinary tracts.
- Proprioceptors monitor the positions of joints and skeletal muscles. They are the most structurally and functionally complex of the general sensory receptors.

Tactile Receptors

Fine touch and pressure receptors provide detailed information about a source of stimulation, including its exact location, shape, size, texture, and movement. These receptors are extremely sensitive and have narrow receptive fields. **Crude touch and pressure receptors** provide poor localization. They give little additional information about the stimulus because they have large receptive fields.

Tactile receptors range in complexity from free nerve endings to specialized sensory complexes with accessory cells and supporting structures. Figure 15–4 shows six types of tactile receptors in the skin:

- 1. *Free nerve endings* sensitive to touch and pressure are located between epidermal cells (Figure 15–4a). There appear to be no structural differences between these receptors and the free nerve endings that provide temperature or pain sensations. These are the only sensory receptors on the corneal surface of the eye, but in other portions of the body surface, more specialized tactile receptors are probably more important. Free nerve endings that provide touch sensations are tonic receptors with small receptive fields.
- 2. Wherever hairs are located, the nerve endings of the **root hair plexus** monitor distortions and movements across the body surface (Figure 15–4b). When a hair is displaced, the movement of its follicle distorts the sensory dendrites and produces action potentials. These receptors adapt rapidly, so they are best at detecting initial contact and subsequent movements. For example, you generally feel your clothing only when you move or when you consciously focus on tactile sensations from the skin.
- Tactile discs, or *Merkel* (MER-kel) *discs*, are fine touch and pressure receptors associated with sensitivity to shape and texture (Figure 15–4c). They are extremely sensitive tonic receptors, with very small receptive fields. The flattened dendritic processes of a single myelinated afferent fiber

b Root hair plexus

a Free nerve endings

make close contact with unusually large epithelial cells in the stratum basale of the skin. We described these *Merkel cells* in Chapter 5. \bigcirc p. 153

4. Tactile corpuscles, or *Meissner's* (MĪS-nerz) *corpuscles*, give us sensations of fine touch and pressure and low-frequency vibration. They adapt to stimulation within a second after contact. Tactile corpuscles are fairly large structures, measuring about 100 μm in length and 50 μm in width. These receptors are most abundant in the eyelids, lips, fingertips, nipples, and external genitalia. The dendrites are highly coiled and interwoven, and modified Schwann cells surround them. A fibrous capsule surrounds the entire complex and anchors it within the dermis (Figure 15–4d).

TIPS&TRICKS

To remember that Meissner's corpuscles perceive pressure sensations, associate the *m* and *ss* in "*M*ei*ss*ner" with *mass*age.

- 5. Lamellated (LAM-e-lat-ed; lamella, thin plate) corpuscles, or pacinian (pa-SIN-ē-an) corpuscles, are sensitive to deep pressure. Because they are fast-adapting receptors, they are most sensitive to pulsing or high-frequency vibrating stimuli. A single dendrite lies within a series of concentric layers of collagen fibers and supporting cells (specialized fibroblasts) (Figure 15-4e). The entire corpuscle may reach 4 mm in length and 1 mm in diameter. The concentric layers, separated by interstitial fluid, shield the dendrite from virtually every source of stimulation other than direct pressure. Lamellated corpuscles adapt quickly because distortion of the capsule soon relieves pressure on the sensory process. Somatic sensory information is provided by lamellated corpuscles located throughout the dermis, notably in the fingers, mammary glands, and external genitalia; in the superficial and deep fasciae; and in joint capsules. Visceral sensory information is provided by lamellated corpuscles in mesenteries, in the pancreas, and in the walls of the urethra and urinary bladder.
- 6. Ruffini (rū-FĒ-nē) corpuscles are also sensitive to pressure and distortion of the skin, but they are located in the reticular (deep) dermis. These receptors are tonic and show little if any adaptation. The capsule surrounds a core of collagen fibers that are continuous with those of the surrounding dermis (Figure 15–4f). In the capsule, a network of dendrites is intertwined with the collagen fibers. Any tension or distortion of the dermis tugs or twists the capsular fibers, stretching or compressing the attached dendrites and altering the activity in the myelinated afferent fiber.

Your sensitivity to tactile sensations may be altered by infection, disease, or damage to sensory neurons or pathways. For this reason, mapping tactile responses can sometimes aid clinical assessment. Sensory losses with clear regional boundaries indicate trauma to spinal nerves. For example, sensory loss within the boundaries of a dermatome can help identify the affected spinal nerve. (Figure 13–7, p. 439)

Tickle and itch sensations are closely related to the sensations of touch and pain. The receptors involved are free nerve endings. Unmyelinated Type C fibers carry the information. People usually (but not always) describe tickle sensations as pleasurable. A light touch that moves across the skin typically produces a tickle sensation. Psychological factors influence the interpretation of tickle sensations, and tickle sensitivity differs greatly from person to person.

Itching is probably produced by the stimulation of the same receptors. Specific "itch spots" can be mapped in the skin, the inner surfaces of the eyelids, and the mucous membrane of the nose. Itch sensations are absent from other mucous membranes and from deep tissues and viscera. Itching is extremely unpleasant, even more unpleasant than pain. Individuals with extreme itching will scratch even when pain is the result. Itch receptors can be stimulated by the injection of histamine or proteolytic enzymes into the epidermis and superficial dermis. The precise receptor mechanism is unknown.

Baroreceptors

Baroreceptors monitor changes in pressure in an organ. A baroreceptor consists of free nerve endings that branch within the elastic tissues in the wall of a distensible organ, such as a blood vessel or a portion of the respiratory, digestive, or urinary tract. When the pressure changes, the elastic walls of the tract recoil or expand. This movement distorts the dendritic branches and alters the rate of action potential generation. Baroreceptors respond immediately to a change in pressure, but they adapt rapidly, and the output along the afferent fibers gradually returns to normal.

Baroreceptors monitor blood pressure in the walls of major vessels. These vessels include the carotid arteries (at the *carotid sinuses*) and the aorta (at the *aortic sinuses*). The information plays a major role in regulating cardiac function and adjusting blood flow to vital tissues.

Baroreceptors in the lungs monitor the degree of lung expansion. This information is relayed to the respiratory rhythmicity centers, which set the pace of respiration. Comparable stretch receptors at various sites in the digestive and urinary tracts trigger a variety of visceral reflexes, including urination and defecation reflexes. We describe those baroreceptor reflexes in the digestive and urinary system chapters.

Proprioceptors

Proprioceptors monitor the position of joints, the tension in tendons and ligaments, and the state of muscular contraction. There are three major groups of proprioceptors:

1. *Muscle Spindles*. Muscle spindles monitor skeletal muscle length and trigger stretch reflexes. ⊃ p. 453

- 2. *Golgi Tendon Organs.* **Golgi tendon organs** are similar in function to Ruffini corpuscles but are located at the junction between a skeletal muscle and its tendon. In a Golgi tendon organ, dendrites branch repeatedly and wind around the densely packed collagen fibers of the tendon. These receptors are stimulated by tension in the tendon. They monitor the external tension developed during muscle contraction.
- **3.** *Receptors in Joint Capsules.* Joint capsules are richly innervated by free nerve endings that detect pressure, tension, and movement at the joint. Your sense of body position results from the integration of information from these receptors with information provided by muscle spindles, Golgi tendon organs, and the receptors of the internal ear.

Proprioceptors do not adapt to constant stimulation, and each receptor continuously sends information to the CNS. Most proprioceptive information is processed at subconscious levels. Only a small proportion of the arriving proprioceptive information reaches your awareness.

Chemoreceptors

Specialized nerve cells, called **chemoreceptors**, can detect small changes in the concentration of specific chemicals or compounds. In general, chemoreceptors respond only to water-soluble and lipid-soluble substances that are dissolved in body fluids (interstitial fluid, blood plasma, and CSF). These receptors exhibit peripheral adaptation over a period of seconds. Central adaptation may also take place.

The chemoreceptors included in the general senses do not send information to the primary sensory cortex, so you are not consciously aware of the sensations they provide. The arriving sensory information is routed to brain stem centers that deal with the autonomic control of respiratory and cardiovascular functions. Neurons in the respiratory centers of the brain respond to the concentration of hydrogen ions (pH) and levels of carbon dioxide molecules in the cerebrospinal fluid.

Chemoreceptors are also located in the **carotid bodies**, near the origin of the internal carotid arteries on each side of the neck, and in the **aortic bodies**, between the major branches of the aortic arch. These receptors monitor the pH and the carbon dioxide and oxygen levels in arterial blood. The afferent fibers leaving the carotid or aortic bodies reach the respiratory centers by traveling within cranial nerves IX (glossopharyngeal) and X (vagus).

CHECKPOINT

- 5. List the four types of general sensory receptors, and identify the nature of the stimulus that excites each type.
- 6. Identify the three classes of mechanoreceptors.
- 7. What would happen to you if the information from proprioceptors in your legs were blocked from reaching the CNS?
- See the blue Answers tab at the back of the book.

Clinical Note

Assessment of Tactile Sensitivities Regional sensitivity to light touch can be checked by gentle contact with a fingertip or a slender wisp of cotton. The **two-point discrimination test** provides a more detailed sensory map of tactile receptors. Two fine points of a bent paper clip or another object are applied to the skin surface simultaneously. The person then describes the contact. When the points fall within a single receptive field, the person will report only one point of contact. A normal person loses two-point discrimination at 1 mm (0.04 in.) on the surface of the tongue, at 2–3 mm (0.08–0.12 in.) on the lips, at 3–5 mm (0.12–0.20 in.) on the backs of the hands and feet, and at 4–7 cm (1.6–2.75 in.) over the general body surface.

Applying the base of a tuning fork to the skin tests vibration receptors. Damage to an individual spinal nerve produces insensitivity to vibration along the paths of the related sensory nerves. If the sensory loss results from spinal cord damage, the injury site can typically be located by walking the tuning fork down the spinal column, resting its base on the vertebral spinous processes.

Various descriptive terms indicate the degree of sensitivity in an area. *Anesthesia* implies a total loss of sensation. The person cannot perceive touch, pressure, pain, or temperature sensations in that area. *Hypesthesia* (hypoesthesia) is a reduc-

tion in sensitivity. *Par-esthesia* is the presence of abnormal sensations such as the pricking sensation when an arm or leg "falls asleep" as a result of pressure on a peripheral nerve.

15-4 Separate pathways carry somatic sensory and visceral sensory information

Learning Outcome Identify the major sensory pathways, and explain how it is possible to distinguish among sensations that originate in different areas of the body.

A sensory neuron that delivers sensations to the CNS is called a **first-order neuron**. The cell body of a first-order general sensory neuron is located in a dorsal root ganglion or cranial nerve ganglion. In the CNS, the axon of that sensory neuron synapses on an interneuron known as a **second-order neuron**, which may be located in the spinal cord or brain stem. If the sensation is to reach our awareness, the second-order neuron synapses on a **third-order neuron** in the thalamus.

Somewhere along its length, the axon of the second-order neuron crosses over to the opposite side of the CNS. As a result, the right side of the thalamus receives sensory information from the left side of the body, and the left side of the thalamus receives sensory information from the right side of the body. The reason for this crossover is unknown. Although it has no apparent functional benefit, crossover occurs along sensory and motor pathways in all vertebrates.

The axon of the third-order neuron then ascends (without crossing back over) and synapses on neurons of the primary sensory cortex of the cerebral hemisphere. As a result, the right cerebral hemisphere receives sensory information from the left side of the body, and the left cerebral hemisphere receives sensations from the right side.

Somatic Sensory Pathways

Somatic sensory pathways carry sensory information from the skin and muscles of the body wall, head, neck, and limbs. We will consider three major somatic sensory pathways: (1) the *spinothalamic pathway*, (2) the *posterior column pathway*, and (3) the *spinocerebel lar pathway*. These pathways are made up of pairs of spinal tracts, symmetrically arranged on opposite sides of the spinal cord. All the axons within a tract share a common origin and destination.

Figure 15–5 shows the relative positions of the spinal tracts in each somatic sensory pathway. Note that tract names often give clues to their function. For example, if the name of a tract begins with *spino-*, the tract *starts* in the spinal cord and *ends* in the brain. It must therefore be an ascending tract that carries sensory information. The rest of the name indicates the tract's destination. Thus, a *spinothalamic tract* begins in the spinal cord and carries sensory information to the thalamus.

If, on the other hand, the name of a tract ends in *-spinal*, the tract *ends* in the spinal cord and *starts* in a higher center of the brain. It must therefore be a descending tract that carries motor commands. The first part of the name indicates the nucleus or cortical area of the brain where the tract originates. For example, a *corticospinal tract* carries motor commands from the cerebral cortex to the spinal cord. We consider such tracts later in the chapter. **Table 15–1** summarizes the somatic sensory pathways discussed in this section.

The Spinothalamic Pathway

The *spinothalamic pathway* carries sensations of poorly localized touch, pressure, pain, and temperature. This pathway includes

Figure 15–5 Sensory Pathways and Ascending Tracts in the Spinal Cord. A cross-sectional view of the spinal cord showing the locations of the major ascending (sensory) tracts. For information about these tracts, see Table 15–1.

small tracts that deliver sensations to reflex centers in the brain stem as well as larger tracts that carry sensations destined for the cerebral cortex. We will ignore the smaller tracts in this discussion.

Sensations bound for the cerebral cortex ascend within the anterior spinothalamic tract or lateral spinothalamic tract. These tracts end at third-order neurons in the ventral nucleus group of the thalamus. After the sensations have been sorted and processed, they are relayed to the primary sensory cortex (Spotlight Figure 15–6).

The perception that an arriving stimulus is painful rather than cold, hot, or vibrating depends on which second-order and third-order neurons are stimulated. The ability to localize that stimulus to a specific location in the body depends on the stimulation of an appropriate area of the primary sensory cortex. Any abnormality along the pathway can result in inappropriate sensations or inaccurate localization of the source. Consider these examples:

- A person can experience painful sensations that are not real. For example, a person may continue to experience pain in an amputated limb. This **phantom limb pain** is caused by activity in the sensory neurons or interneurons along the spinothalamic pathway. The neurons involved were once part of the labeled line that monitored conditions in the intact limb. These labeled lines and pathways are developmentally programmed. For this reason, even people born without limbs can have phantom limb pain.
- A person can feel pain in an uninjured part of the body when the pain actually originates at another location. For example, strong visceral pain sensations arriving at a segment of the spinal cord can stimulate interneurons that

Table 15–1	Principal Ascending (Sensory) Pathways						
			Location of Neuron Cell Bodies			Location of Neuron Cell Bodies	
Pathway/Tract		Sensation(s)	First-Order	Second-Order	Third-Order	Final Destination	Site of Crossover
SPINOTHALAMIC	PATHWA	Y					
Lateral spinothal tracts	lamic	Pain and temperature	Dorsal root ganglia; axons enter CNS in dorsal roots	Interneurons in posterior gray horn; axons enter lateral spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second- order neurons at level of entry
Anterior spinothalamic tracts		Crude touch and pressure	Dorsal root ganglia; axons enter CNS in dorsal roots	Interneurons in posterior gray horn; axons enter anterior spinothalamic tract on opposite side	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second- order neurons at level of entry
POSTERIOR COLU	JMN PATI	IWAY					
Fasciculus gracili	is	Proprioception and fine touch, ventral pressure, and vibration from inferior half of body	Dorsal root ganglia of inferior half of body; axons enter CNS in dorsal roots and join fasciculus gracilis	Nucleus gracilis of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second- order neurons before entering the medial lemniscus
Fasciculus cuneatus		Proprioception and fine touch, ventral pressure, and vibration from superior half of body	Dorsal root ganglia of superior half of body; axons enter CNS in dorsal roots and join fasciculus cuneatus	Nucleus cuneatus of medulla oblongata; axons cross over before entering medial lemniscus	Ventral nuclei of thalamus	Primary sensory cortex on side opposite stimulus	Axons of second- order neurons before entering the medial lemniscus
SPINOCEREBELLAR PATHWAY							
Posterior spinocerebellar t	tracts	Proprioception	Dorsal root ganglia; axons enter CNS in dorsal roots	Interneurons in posterior gray horn; axons enter posterior spinothalamic tract on same side	Not present	Cerebellar cortex on side of stimulus	None
Anterior spinocerebellar t	tracts	Proprioception	Dorsal root ganglia; axons enter CNS in dorsal roots	Interneurons in same spinal section; axons enter anterior spinocerebellar tract on the same or opposite side	Not present	Cerebellar cortex on side opposite (and side of) stimulus	Axons of most second-order neurons cross over before entering tract; many re-cross at cerebellum

SPOTLIGHT Figure 15-6 Somatic Sensory Pathways

SPINOTHALAMIC PATHWAY

The spinothalamic pathway provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature. In this pathway, the axons of first-order neurons enter the spinal cord and synapse on second-order neurons within the posterior gray horns. The axons of these interneurons cross to the opposite side of the spinal cord before ascending to the thalamus. The third-order neuron synapses in the primary sensory cortex.

POSTERIOR COLUMN PATHWAY

The **posterior column pathway** carries sensations of highly localized ("fine") touch, pressure, vibration, and proprioception. This pathway is also known as the dorsal column-medial lemniscus pathway. It begins at a peripheral receptor and ends at the primary sensory cortex of the cerebral hemispheres.

sensations from right side of body

SPINOCEREBELLAR PATHWAY

The cerebellum receives proprioceptive information about the position of skeletal muscles, tendons, and joints along the **spinocerebellar pathway**. The **posterior spinocerebellar tracts** contain axons that do not cross over to the opposite side of the spinal cord. These axons reach the cerebellar cortex by the inferior cerebellar peduncle of that side. The **anterior spinocerebellar tracts** are dominated by axons that have crossed over to the opposite side of the spinal cord.

are part of the spinothalamic pathway. Activity in these interneurons leads to the stimulation of the primary sensory cortex, so the individual feels pain in a specific part of the body surface. This phenomenon is called **referred pain**. One familiar example is the pain of a heart attack, which is frequently felt in the left arm. Women may experience pain in the jaw, neck, shoulder, stomach, or back. Another is the pain of appendicitis, which is generally felt first in the area around the navel and then in the right lower quadrant. These and additional examples for both anterior and posterior aspects are shown in Figure 15–7.

The Posterior Column Pathway

The *posterior column pathway* carries sensations of precise touch and vibrations, and proprioception. The spinal tracts involved are the left and right **fasciculus gracilis** (*gracilis*, slender) and the left and right **fasciculus cuneatus** (*cuneus*, wedge-shaped). On each side of the posterior median sulcus, the fasciculus gracilis is medial to the fasciculus cuneatus (**Figure 15–5**).

The axons of the first-order neurons reach the CNS within the dorsal roots of spinal nerves and the sensory roots of cranial nerves. The axons ascending within the posterior column are organized according to the region innervated. Axons carrying sensations from the inferior half of the body ascend within the fasciculus gracilis and synapse in the nucleus gracilis of the medulla oblongata. Axons carrying sensations from the superior half of the trunk, upper limbs, and neck ascend in the fasciculus cuneatus and synapse in the nucleus cuneatus. \bigcirc p. 470

Axons of the second-order neurons of the nucleus gracilis and nucleus cuneatus ascend to the thalamus. As they ascend, these axons cross over to the opposite side of the brain stem. The crossing of an axon from the left side to the right side, or from the right side to the left side, is called **decussation**. Once on the opposite side of the brain, the axons enter a tract called the **medial lemniscus** (*lemniskos*, ribbon). As it ascends, the medial lemniscus runs alongside a smaller tract that carries sensory information from the face, relayed from the sensory nuclei of the trigeminal nerve (V) (**Spotlight Figure 15–6**).

The axons in these tracts synapse on third-order neurons in one of the ventral nuclei of the thalamus. \bigcirc **p**. 477 These nuclei sort the arriving information according to (1) the nature of the stimulus and (2) the region of the body involved. Processing in the thalamus determines whether you perceive a given sensation as fine touch, pressure, or vibration.

Our ability to localize the sensation—to determine precisely where on the body a specific stimulus originated depends on the projection of information from the thalamus to the primary sensory cortex. Sensory information from the toes arrives at the medial end of the primary sensory cortex, and information from the head arrives at the lateral end. When **Figure 15–7 Referred Pain.** Pain sensations from visceral organs are often perceived as arising from areas distant from the actual origin, because the body surface is innervated by the same spinal segments. Each region of perceived pain is labeled according to the organ at which the pain originates.

neurons in one portion of your primary sensory cortex are stimulated, you become aware of sensations originating at a specific location. If your primary sensory cortex were damaged or the projection fibers were cut, you could detect a light touch but would be unable to determine its source.

The same sensations are reported whether the cortical neurons are activated by axons ascending from the thalamus or by direct electrical stimulation. Researchers have electrically stimulated the primary sensory cortex in awake individuals during brain surgery and asked the subjects where they thought the stimulus originated. The results were used to create a functional map of the primary sensory cortex known as a *sensory homunculus*.

In a sensory homunculus, the body features are distorted. For example, the face is huge, with enormous lips and tongue, but the back is relatively tiny. These distortions take place because the area of sensory cortex devoted to a particular body region is proportional to the *number of sensory neurons* in the region, not to the region's absolute size. In other words, many more cortical neurons are required to process sensory information from the tongue, which has tens of thousands of taste and touch receptors, than to process sensations from the back, where touch receptors are few and far between.

The Spinocerebellar Pathway

The *spinocerebellar pathway* conveys information about muscle, tendon, and joint positions from the spine to the cerebellum (**Spotlight Figure 15-6**). This information does not reach our awareness. The axons of first-order sensory neurons synapse on interneurons in the dorsal gray horns of the spinal cord. The axons of these second-order neurons ascend in one of the spinocerebellar tracts: the posterior spinocerebellar tracts or the anterior spinocerebellar tracts.

The sensations carried by the anterior spinocerebellar tracts reach the cerebellar cortex by the superior cerebellar peduncle. Interestingly, many of the axons that cross over and ascend to the cerebellum then cross over again within the cerebellum, synapsing on the same side as the original stimulus. The functional significance of this "double cross" is unknown.

The information carried by the spinocerebellar pathway ultimately arrives at the *Purkinje cells* of the cerebellar cortex. **D p**. 475 Proprioceptive information from each part of the body is relayed to a specific portion of the cerebellar cortex. We will consider the integration of proprioceptive information and the role of the cerebellum in somatic motor control in a later section.

Visceral Sensory Pathways

Visceral sensory information is collected by interoceptors monitoring visceral tissues and organs, primarily within the thoracic and abdominopelvic cavities. These interoceptors include nociceptors, thermoreceptors, tactile receptors, baroreceptors, and chemoreceptors, although none of them is as numerous as they are in somatic tissues. The axons of the first-order neurons usually travel in company with autonomic motor fibers innervating the same visceral structures.

Cranial nerves V, VII, IX, and X carry visceral sensory information from the mouth, palate, pharynx, larynx, trachea, esophagus, and associated vessels and glands. \bigcirc pp. 496–501 This information is delivered to the **solitary nucleus**, a large nucleus on each side of the medulla oblongata. The solitary nucleus is a major processing and sorting center for visceral sensory information. It has extensive connections with the various cardiovascular and respiratory centers as well as with the reticular formation.

The dorsal roots of spinal nerves T_1-L_2 carry visceral sensory information provided by receptors in organs located between the diaphragm and the pelvic cavity. The dorsal roots of spinal nerves S_2-S_4 carry visceral sensory information from organs in the inferior portion of the pelvic cavity. These organs include the last segment of the large intestine, the urethra and base of the urinary bladder, and the prostate gland (males) or the cervix of the uterus and adjacent portions of the vagina (females).

The first-order neurons deliver the visceral sensory information to interneurons whose axons ascend within the spinothalamic pathway. Most of the sensory information is delivered to the solitary nucleus. Because it never reaches the primary sensory cortex, you remain unaware of these sensations.

CHECKPOINT

- 8. As a result of pressure on her spinal cord, Jill cannot feel fine touch or pressure on her lower limbs. Which spinal tract is being compressed?
- 9. Which spinal tract carries action potentials generated by nociceptors?
- **10**. Which cerebral hemisphere receives impulses carried by the right fasciculus gracilis?

See the blue Answers tab at the back of the book.

15-5 The somatic nervous system is an efferent division that controls skeletal muscles

Learning Outcome Describe the components, processes, and functions of the somatic motor pathways, and the levels of information processing involved in motor control.

Motor commands issued by the CNS are distributed by the somatic nervous system (SNS) and the autonomic nervous system (ANS). The somatic nervous system, also called the *somatic motor system*, controls the contractions of skeletal muscles. The output of the SNS is under voluntary control.

The autonomic nervous system, or *visceral motor system*, controls visceral effectors, such as smooth muscle, cardiac muscle, glands, and adipocytes. We examine the organization of the ANS in Chapter 16. Our interest here is the structure of the SNS. Throughout this discussion we will use the terms *motor neuron* and *motor control* to refer specifically to somatic motor neurons and pathways that control skeletal muscles.

Somatic motor pathways always involve at least two motor neurons: an **upper motor neuron**, whose cell body lies in a CNS processing center, and a **lower motor neuron**, whose cell body lies in a nucleus of the brain stem or spinal cord. The upper motor neuron synapses on the lower motor neuron, which in turn innervates a single motor unit in a skeletal muscle. \bigcirc p. 312

Activity in the upper motor neuron may facilitate or inhibit the lower motor neuron. Activation of the lower motor neuron triggers a contraction in the innervated muscle. Only the axon of the lower motor neuron extends outside the CNS. Destruction of or damage to a lower motor neuron eliminates voluntary and reflex control over the innervated motor unit. **Figure 15–8** indicates the positions of the associated motor (descending) tracts in the spinal cord. Conscious and subconscious motor commands control skeletal muscles by traveling over three integrated motor pathways: the *corticospinal pathway*, the *medial pathway*, and the *lateral pathway*. The basal nuclei and cerebellum monitor and adjust activity within these motor pathways. The output of these centers stimulates or inhibits the activity of either (1) motor nuclei or (2) the primary motor cortex. **Table 15–2** summarizes the descending (motor) tracts discussed in this section.

The Corticospinal Pathway

The **corticospinal pathway** (Figure 15–9), sometimes called the *pyramidal system*, provides voluntary control over skeletal muscles. This system begins at the *pyramidal cells* of the primary motor cortex. **D** p. 487 The axons of these upper motor neurons descend into the brain stem and spinal cord to synapse on lower motor neurons that control skeletal muscles. In general, the corticospinal pathway is direct: The upper motor neurons synapse directly on the lower motor neurons. However, the corticospinal pathway also works indirectly, as it innervates centers of the medial and lateral pathways.

The corticospinal pathway contains three pairs of descending tracts: (1) the *corticobulbar tracts*, (2) the *lateral corticospinal tracts*, and (3) the *anterior corticospinal tracts*. These tracts enter the white matter of the internal capsule, descend into the brain stem, and emerge on either side of the midbrain as the *cerebral peduncles* \bigcirc p. 476. **Figure 15–8 Descending (Motor) Tracts in the Spinal Cord.** A cross-sectional view showing the locations of the major descending (motor) tracts that contain the axons of upper motor neurons. The origins and destinations of these tracts are listed in **Table 15–2**. Ascending sensory tracts (shown in *Figure 15-5*) appear in dashed outline.

The Corticobulbar Tracts

Axons in the **corticobulbar** (kor-ti-kō-BUL-bar; bulbar, brain stem) **tracts** synapse on lower motor neurons in the motor nuclei of cranial nerves III, IV, V, VI, VII, IX, XI, and XII. The corticobulbar tracts provide conscious control over skeletal muscles that move the eye, jaw, and face, and some muscles of the neck and pharynx. The corticobulbar tracts also innervate the motor centers of the medial and lateral pathways.

Table 15–2	Principal D	Descending (Motor) Pathways			
Tract		Location of Upper Motor Neurons	Destination	Site of Crossover	Action
CORTICOSPINAL P	PATHWAY				
Corticobulbar tra	cts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of cranial nerve nuclei in brain stem	Brain stem	Conscious motor control of skeletal muscles
Lateral corticospi	nal tracts	Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior gray horns of spinal cord	Pyramids of medulla oblongata	Conscious motor control of skeletal muscles
Anterior corticospinal tracts		Primary motor cortex (cerebral hemisphere)	Lower motor neurons of anterior gray horns of spinal cord	Level of lower motor neuron	Conscious motor control of skeletal muscles
MEDIAL PATHWAY	1				
Vestibulospinal tı	racts	Vestibular nuclei (at border of pons and medulla oblongata)	Lower motor neurons of anterior gray horns of spinal cord	None (uncrossed)	Subconscious regulation of balance and muscle tone
Tectospinal tracts	;	Tectum (midbrain: superior and inferior colliculi)	Lower motor neurons of anterior gray horns (cervical spinal cord only)	Brain stem (midbrain)	Subconscious regulation of eye, head, neck, and upper limb position in response to visual and auditory stimuli
Reticulospinal tra	icts	Reticular formation (network of nuclei in brain stem)	Lower motor neurons of anterior gray horns of spinal cord	None (uncrossed)	Subconscious regulation of reflex activity
LATERAL PATHWA	Y				
Rubrospinal tracts		Red nuclei of midbrain	Lower motor neurons of anterior gray horns of spinal cord	Brain stem (midbrain)	Subconscious regulation of upper limb muscle tone and movement

Figure 15–9 The Corticospinal Pathway. The corticospinal pathway originates at the primary motor cortex. The corticobulbar tracts end at the motor nuclei of cranial nerves on the opposite side of the brain. Most fibers in this pathway cross over in the medulla and enter the lateral corticospinal tracts; the rest descend in the anterior corticospinal tracts and cross over after reaching target segments in the spinal cord.

The Corticospinal Tracts

Axons in the **corticospinal tracts** synapse on lower motor neurons in the anterior gray horns of the spinal cord. As they descend, the corticospinal tracts are visible along the ventral surface of the medulla oblongata as a pair of thick bands, the **pyramids**. Along the length of the pyramids, roughly 85 percent of the axons cross the midline (decussate) to enter the descending **lateral corticospinal tracts** on the opposite side of the spinal cord.

The other 15 percent continue uncrossed along the spinal cord as the **anterior corticospinal tracts**. Then, at the spinal segment it targets, an axon in the anterior corticospinal tract

crosses over to the opposite side of the spinal cord in the anterior white commissure. The axon synapses on lower motor neurons in the anterior gray horns.

The Motor Homunculus

The activity of pyramidal cells in a specific portion of the primary motor cortex results in the contraction of specific peripheral muscles. Which muscles are stimulated depends on the region of motor cortex that is active. As in the primary sensory cortex, the primary motor cortex corresponds point by point with specific regions of the body. The cortical areas have been mapped out in diagrammatic form, creating a **motor homunculus**. **Figure 15–9** shows the motor homunculus of the left cerebral hemisphere and the corticospinal pathway controlling skeletal muscles on the right side of the body.

The proportions of the motor homunculus are quite different from those of the actual body, because the area of primary motor cortex devoted to a specific body region is proportional to the number of motor units involved in the region's control, not to the region's actual size. For this reason, the homunculus indicates the degree of fine motor control available. For example, the hands, face, and tongue are all capable of varied and complex movements, so they appear very large. In contrast, the trunk is relatively small. These proportions are similar to those of the sensory homunculus (Spotlight Figure 15–6).

The sensory and motor homunculi differ, however, with respect to some other areas of the body. For example, some highly sensitive regions, such as the sole of the foot, contain few motor units. Also, some areas with an abundance of motor units, such as the eye muscles, are not particularly sensitive.

The Medial and Lateral Pathways

Several centers in the cerebrum, diencephalon, and brain stem may issue somatic motor commands as a result of processing performed at a subconscious level. These centers and their associated tracts were long known as the *extrapyramidal system* (*EPS*). It was thought that they operated independently of, and in parallel with, the *pyramidal system* (corticospinal pathway). This classification scheme is both inaccurate and misleading, because motor control is integrated at all levels through extensive feedback loops and interconnections.

Instead, it is more appropriate to group these nuclei and tracts in terms of their primary functions: The components of the **medial pathway** help control gross movements of the

Clinical Note

Amyotrophic Lateral Sclerosis Amyotrophic lateral sclerosis (ALS) is a progressive, degenerative disorder that affects motor neurons in the spinal cord, brain stem, and cerebral hemispheres. The degeneration affects both upper and lower motor neurons. A defect in axonal transport is thought to underlie the disease. Because a motor neuron and its dependent muscle fibers are so intimately related, the destruction of CNS neurons causes the associated skeletal muscles to atrophy. ALS is commonly known as Lou Gehrig's disease, named after the famous New York Yankees player who died of the disorder. Noted physicist Stephen Hawking is also afflicted with this condition.

trunk and proximal limb muscles, and those of the **lateral pathway** help control the distal limb muscles that perform more precise movements.

The medial and lateral pathways can modify or direct skeletal muscle contractions by stimulating, facilitating, or inhibiting lower motor neurons. Note that the axons of upper motor neurons in the medial and lateral pathways synapse on the same lower motor neurons innervated by the corticospinal pathway. This means that the various motor pathways interact not only within the brain, through connections between the primary motor cortex and motor centers in the brain stem, but also at the level of the lower motor neuron, through excitatory or inhibitory interactions.

The Medial Pathway

The medial pathway is primarily concerned with the control of muscle tone and gross movements of the neck, trunk, and proximal limb muscles. The upper motor neurons of the medial pathway are located in the *vestibular nuclei*, the *superior* and *inferior colliculi*, and the *reticular formation*.

The vestibular nuclei (located at the border of the pons and medulla) receive information over the vestibulocochlear nerve (N VIII). This nerve has receptors in the internal ear that monitor the position and movement of the head. These nuclei respond to changes in the orientation of the head, sending motor commands that alter the muscle tone, extension, and position of the neck, eyes, head, and limbs. The primary goal is to maintain posture and balance. The descending fibers in the spinal cord constitute the **vestibulospinal tracts** (Figure 15–8).

The superior and inferior colliculi are located in the *tectum*, or roof of the midbrain (Figure 14–9, p. 476). The superior colliculi receive visual sensations and the inferior colliculi receive auditory sensations. Axons of upper motor neurons in the colliculi descend in the **tectospinal tracts**. These axons cross to the opposite side immediately, before descending to synapse

on lower motor neurons in the brain stem or spinal cord. Axons in the tectospinal tracts direct reflexive changes in the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises.

The reticular formation is a loosely organized network of neurons that extends throughout the brain stem. \bigcirc p. 470 The reticular formation receives input from almost every ascending and descending pathway. It also has extensive interconnections with the cerebrum, the cerebellum, and brain stem nuclei. Axons of upper motor neurons in the reticular formation descend into the **reticulospinal tracts** without crossing to the opposite side. The region stimulated determines the effects of reticular formation stimulation. For example, the stimulation of upper motor neurons in one portion of the reticular formation produces eye movements. The stimulation of another portion activates respiratory muscles.

The Lateral Pathway

The lateral pathway is primarily concerned with the control of muscle tone and the more precise movements of the distal parts of the limbs. The upper motor neurons of the lateral pathway lie within the red nuclei of the midbrain. ⊃ p. 472 Axons of upper motor neurons in the red nuclei cross to the opposite side of the brain and descend into the spinal cord in the **rubrospinal tracts** (*ruber*, red). In humans, the rubrospinal tracts are small and extend only to the cervical spinal cord. There they provide motor control over distal muscles of the upper limbs. Normally, their role is insignificant as compared with that of the lateral corticospinal tracts can be important in maintaining motor control and muscle tone in the upper limbs if the lateral corticospinal tracts are damaged.

The Basal Nuclei and Cerebellum

The basal nuclei and cerebellum are responsible for coordination and feedback control over muscle contractions. Those contractions can be consciously or subconsciously directed.

The Basal Nuclei

The basal nuclei provide the background patterns of movement involved in voluntary motor activities. For example, they may control muscles that determine the background position of the trunk or limbs, or they may direct rhythmic cycles of movement, as in walking or running. These nuclei do not exert direct control over lower motor neurons. Instead, they adjust the activities of upper motor neurons in the various motor pathways based on input from all portions of the cerebral cortex, as well as from the substantia nigra.

The basal nuclei adjust or establish patterns of movement by two major pathways:

1. One group of axons synapses on thalamic neurons, whose axons extend to the premotor cortex, the motor association

Clinical Note

Cerebral Palsy The term cerebral palsy (CP) refers to a number of disorders that affect voluntary motor performance. The motor dysfunction is not progressive. It appears during infancy or childhood and persists throughout life. The cause may be trauma due to premature or unusually stressful birth, maternal exposure to drugs (including alcohol), or a genetic defect that causes the motor pathways to develop improperly. Problems during labor and delivery may compress or interrupt placental circulation or oxygen supplies. If the oxygen concentration in fetal blood declines significantly for as little as 5-10 minutes, CNS function can be permanently impaired. The cerebral cortex, cerebellum, basal nuclei, hippocampus, and thalamus are likely to be affected. The result is difficulty with motor skills, posture and balance, memory, speech, and learning.

area that directs activities of the primary motor cortex. This arrangement creates a feedback loop that changes the sensitivity of the pyramidal cells and alters the pattern of instructions carried by the corticospinal tracts.

2. A second group of axons synapses in the reticular formation, altering the excitatory or inhibitory output of the reticulospinal tracts.

Two distinct populations of interneurons exist in the basal nuclei: one that stimulates neurons by releasing acetylcholine (ACh), and another that inhibits neurons by releasing gamma aminobutyric acid (GABA). Under normal conditions, the excitatory interneurons are kept inactive, and the axons leaving the basal nuclei have an inhibitory effect on upper motor neurons. In *Parkinson's disease*, the excitatory neurons become more active, leading to problems with the voluntary control of movement. \bigcirc p. 108

If the primary motor cortex is damaged, the person loses fine motor control over skeletal muscles. However, the basal nuclei can still control some voluntary movements. In effect, the medial and lateral pathways function as they usually do, but the corticospinal pathway cannot fine-tune the movements. For example, after damage to the primary motor cortex, the basal nuclei can still receive information about planned movements from the prefrontal cortex and can perform preparatory movements of the trunk and limbs. But because the corticospinal pathway is inoperative, precise movements of the forearms, wrists, and hands cannot occur. An individual in this condition can stand, maintain balance, and even walk, but all movements are hesitant, awkward, and poorly controlled.

The Cerebellum

The cerebellum monitors proprioceptive (position) sensations, visual information from the eyes, and vestibular (balance) sensations from the internal ear as movements are under way. Axons within the spinocerebellar tracts deliver proprioceptive information to the cerebellar cortex. Visual information is relayed from the superior colliculi, and balance information is relayed from the vestibular nuclei. The output of the cerebellum affects upper motor neuron activity in the corticospinal, medial, and lateral pathways.

All motor pathways send information to the cerebellum when motor commands are issued. As the movement proceeds, the cerebellum monitors proprioceptive and vestibular information, comparing the arriving sensations with those experienced during previous movements. It then adjusts the activities of the upper motor neurons involved. In general, any voluntary movement begins with the activation of far more motor units than are required. The cerebellum acts like a brake, inhibiting the number of motor commands used for that movement. The pattern and degree of inhibition changes from moment to moment, making the movement efficient, smooth, and precisely controlled.

The patterns of cerebellar activity are learned by trial and error, over many repetitions. Many of the basic patterns are established early in life. Examples include the fine balancing adjustments you make while standing and walking. The ability to fine-tune a complex pattern of movement improves with practice, until the movements become fluid and automatic. Consider the relaxed, smooth movements of acrobats, golfers, and sushi chefs. These people move without thinking about the details of their movements. Think about what happens when you concentrate on voluntary control of various movements. The rhythm and pattern of the movement usually fall apart as your primary motor cortex starts overriding the commands of the basal nuclei and cerebellum.

Levels of Processing and Motor Control

All sensory and motor pathways involve a series of synapses, one after the other. Along the way, the information is distributed to processing centers operating at the subconscious level. Consider what happens when you stumble. You often recover your balance even as you become aware that a problem exists. Long before your cerebral cortex could assess the situation, evaluate possible responses (shift weight *here*, move leg *there*, and so on), and issue appropriate motor commands, monosynaptic and polysynaptic reflexes, perhaps adjusted by the brain stem and cerebellum, successfully prevent a fall. This is a general pattern: Spinal and cranial reflexes provide rapid, involuntary, preprogrammed responses that preserve homeostasis over the short term. Voluntary responses are more complex and require more time to prepare and execute. Cranial and spinal reflexes control the most basic motor activities. Integrative centers in the brain perform more elaborate processing. As we move from the medulla oblongata to the cerebral cortex, the motor patterns become increasingly complex and variable. The primary motor cortex of the cerebral hemispheres directs the most complex and variable motor activities.

During development, the spinal reflexes and cranial reflexes appear first. More complex reflexes and motor patterns develop as CNS neurons multiply, enlarge, and interconnect. The process proceeds slowly, as billions of neurons establish trillions of synaptic connections. At birth, neither the cerebral nor the cerebellar cortex is fully functional. Centers in the diencephalon and brain stem primarily direct the behavior of newborn infants.

CHECKPOINT

- 11. What is the anatomical basis for the fact that the left side of the brain controls motor function on the right side of the body?
- 12. An injury involving the superior portion of the motor cortex affects which region of the body?
- **13**. What effect would increased stimulation of the motor neurons of the red nucleus have on muscle tone?

See the blue Answers tab at the back of the book.

Related Clinical Terms

analgesia: The inability to feel pain while still conscious. **flaccid paralysis:** Weakness or loss of muscle tone as a result of disease or injury to the nerves innervating the muscles.

- **hyperalgesia:** Increased sensitivity to pain that may be caused by damage to nociceptors or peripheral nerves.
- **pain threshold:** The lowest intensity of stimulation at which pain is experienced. It can vary among individuals.
- **pain tolerance:** The maximum pain level an individual can withstand. It can vary among individuals.
- **spastic paralysis:** The chronic pathological condition in which muscles are affected by persistent spasms and exaggerated tendon reflexes due to damage to motor nerves of the central nervous system.
- **syphilis:** A sexually transmitted disease (STD) caused by the bacterium *Treponema pallidum*. Many of the signs and symptoms are indistinguishable from those of other diseases. Late-stage untreated syphilis can cause progressive degeneration of the posterior column pathway, spinocerebellar pathway, and dorsal roots of the spinal cord.

An Introduction to Sensory Pathways and the Somatic Nervous System p. 509

- The nervous system works as an integrated unit. This chapter considers sensory pathways (sensory receptors and sensory processing centers in the brain) and motor pathways (including both conscious and subconscious motor functions). (*Figure 15–1*)
- **15-1** Sensory information from all parts of the body is routed to the somatosensory cortex **p**. 509
- **2.** The brain, spinal cord, and peripheral nerves continuously communicate with each other and with the internal and

external environments. Information arrives by sensory receptors and ascends within the afferent division, while motor commands descend and are distributed by the efferent division.

15-2 Sensory receptors connect our internal and external environments with the nervous system p. 510

- **3.** A sensory receptor is a specialized cell or cell process that monitors specific conditions within the body or in the external environment. Arriving information is a **sensation**; awareness of a sensation is a **perception**.
- 4. The general senses are our sensitivity to pain, temperature, touch, pressure, vibration, and proprioception. Receptors for these senses are distributed throughout the body. Special senses, located in specific sense organs, are structurally more complex.
- 5. Each receptor cell monitors a specific *receptive field*. *Transduction* begins when a large enough stimulus depolarizes the *receptor potential* or *generator potential* to the point where action potentials are produced. (*Figure 15–2*)
- 6. A **labeled line** is a link between a peripheral receptor and a cortical neuron. **Tonic receptors** are always active. **Phasic receptors** provide information about the intensity and rate of change of a stimulus. **Adaptation** is a reduction in sensitivity in the presence of a constant stimulus. Tonic receptors are

slow-adapting receptors, while phasic receptors are **fast-adapting receptors**. (*Figure 15–3*)

- 15-3 General sensory receptors are classified by the type of stimulus that excites them p. 513
- 7. Three types of **nociceptors** in the body provide information on pain as related to extremes of temperature, mechanical damage, and dissolved chemicals. Myelinated Type A fibers carry **fast pain**. Slower Type C fibers carry **slow pain**.
- 8. Thermoreceptors are found in the dermis. Mechanoreceptors are sensitive to distortion of their membranes, and include tactile receptors, baroreceptors, and proprioceptors. There are six types of tactile receptors in the skin, and three kinds of proprioceptors. Chemoreceptors include carotid bodies and aortic bodies. (*Figure 15–4*)
- 15-4 Separate pathways carry somatic sensory and visceral sensory information p. 518
- 9. Sensory neurons that deliver sensation to the CNS are referred to as first-order neurons. These synapse on second-order neurons in the brain stem or spinal cord. The next neuron in this chain is a third-order neuron, found in the thalamus.
- **10.** Three major somatic sensory pathways carry sensory information from the skin and musculature of the body wall, head, neck, and limbs: the *spinothalamic pathway*, the *posterior column pathway*, and the *spinocerebellar pathway*. (*Figure 15–5*)
- 11. The **spinothalamic pathway** carries poorly localized ("crude") sensations of touch, pressure, pain, and temperature. The axons involved decussate in the spinal cord and ascend within the **anterior** and **lateral spinothalamic tracts** to the ventral nuclei of the thalamus. Abnormalities along the spinothalamic pathway can lead to **phantom limb pain**, painful sensations that are perceived as real, and **referred pain**, inaccurate localizations of the source of pain. (*Spotlight Figure 15–6, Figure 15–7; Table 15–1*)
- 12. The posterior column pathway carries fine touch, pressure, and proprioceptive sensations. The axons ascend within the fasciculus gracilis and fasciculus cuneatus and relay information to the thalamus by the medial lemniscus. Before the axons enter the medial lemniscus, they cross over to the opposite side of the brain stem. This crossing over is called decussation. (Spotlight Figure 15–6; Table 15–1)
- 13. The **spinocerebellar pathway**, including the **posterior** and **anterior spinocerebellar tracts**, carries sensations to the cerebellum concerning the position of muscles, tendons, and joints. (*Spotlight Figure 15–6; Table 15–1*)
- 14. Visceral sensory pathways carry information collected by interoceptors. Sensory information from cranial nerves V, VII, IX, and X is delivered to the **solitary nucleus** in the medulla oblongata. Dorsal roots of spinal nerves T₁-L₂ carry visceral

sensory information from organs between the diaphragm and the pelvic cavity. Dorsal roots of spinal nerves S_2-S_4 carry sensory information from more inferior structures.

15-5 The somatic nervous system is an efferent division that controls skeletal muscles p. 523

- 15. Somatic motor (descending) pathways always involve an **upper motor neuron** (whose cell body lies in a CNS processing center) and a **lower motor neuron** (whose cell body is located in a nucleus of the brain stem or spinal cord). (*Figure 15–8*)
- 16. The neurons of the primary motor cortex are *pyramidal cells*. The **corticospinal pathway** provides voluntary skeletal muscle control. The **corticospinal tracts** end at the cranial nerve nuclei. The **corticospinal tracts** synapse on lower motor neurons in the anterior gray horns of the spinal cord. The corticospinal tracts are visible along the medulla oblongata as a pair of thick bands, the **pyramids**, where most of the axons decussate to enter the descending **lateral corticospinal tracts**. Those that do not cross over enter the **anterior corticospinal tracts**. The corticospinal pathway provides a rapid, direct mechanism for controlling skeletal muscles. (*Figure 15–9; Table 15–2*)
- 17. The **medial** and **lateral pathways** include several other centers that issue motor commands as a result of processing performed at a subconscious level. (*Table 15–2*)
- 18. The medial pathway primarily controls gross movements of the neck, trunk, and proximal limbs. It includes the vestibulospinal, tectospinal, and reticulospinal tracts. The **vestibulospinal tracts** carry information related to maintaining balance and posture. Commands carried by the **tectospinal tracts** change the position of the head, neck, and upper limbs in response to bright lights, sudden movements, or loud noises. Motor commands carried by the **reticulospinal tracts** vary according to the region stimulated. (*Table 15–2*)
- **19.** The lateral pathway consists of the **rubrospinal tracts**, which primarily control muscle tone and movements of the distal muscles of the upper limbs. (*Table 15–2*)
- **20.** The basal nuclei adjust the motor commands issued in other processing centers and provide background patterns of movement involved in voluntary motor activities.
- 21. The cerebellum monitors proprioceptive sensations, visual information, and vestibular (balance) sensations. The integrative activities performed by neurons in the cortex and nuclei of the cerebellum are essential for the precise control of movements.
- **22.** Spinal and cranial reflexes provide rapid, involuntary, preprogrammed responses that preserve homeostasis. Voluntary responses are more complex and require more time to prepare and execute.
- **23.** During development, the spinal and cranial reflexes are first to appear. Complex reflexes develop over years, as the CNS matures and the brain grows in size and complexity.

Review Questions

LEVEL 1 Reviewing Facts and Terms

 The larger the receptive field, the (a) larger the stimulus needed to stimulate a sensory receptor, (b) fewer sensory receptors there are, (c) harder it is to locate the exact point of stimulation, (d) larger the area of the somatosensory cortex in the brain that deals with the area, (e) closer together the receptor cells.

See the blue Answers tab at the back of the book.

- 2. _____ receptors are normally inactive, but become active for a short time whenever there is a change in the modality that they monitor.
- 3. The CNS interprets information entirely on the basis of the (a) number of action potentials that it receives, (b) kind of action potentials that it receives, (c) line over which sensory information arrives, (d) intensity of the sensory stimulus, (e) number of sensory receptors that are stimulated.

- 4. The area of primary sensory cortex devoted to a body region is relative to the (a) size of the body area, (b) distance of the body area from the brain, (c) number of motor units in the area of the body, (d) number of sensory receptors in the area of the body, (e) size of the nerves that serve the area of the body.
- 5. Identify and shade in the locations of all the ascending sensory tracts in the following diagram of the spinal cord.

- 6. Identify six types of tactile receptors located in the skin, and describe their sensitivities.
- 7. What three types of mechanoreceptors respond to stretching, compression, twisting, or other distortions of their plasma membrane?
- 8. What are the three major somatic sensory pathways and their functions?
- 9. Which three pairs of descending tracts make up the corticospinal pathway?
- **10.** Which three motor tracts make up the medial pathway?
- 11. What are the two primary functional roles of the cerebellum?
- The corticospinal tract (a) carries motor commands from the cerebral cortex to the spinal cord, (b) carries sensory information from the spinal cord to the brain, (c) starts in the spinal cord and ends in the brain, (d) does all of these.
- 13. What three steps are necessary for transduction to occur?

LEVEL 2 Reviewing Concepts

- 14. Differentiate between a tonic receptor and a phasic receptor.
- 15. What is a motor homunculus? How does it differ from a sensory homunculus?
- **16**. Describe the relationship among first-, second-, and third-order neurons in a sensory pathway.
- **17.** Damage to the posterior spinocerebellar tract on the left side of the spinal cord at the L₁ level would interfere with the coordinated movement of which limb(s)?
- **18.** What effect does injury to the primary motor cortex have on peripheral muscles?
- **19.** By which structures and in which part of the brain is the level of muscle tone in the body's skeletal muscles controlled? How is this control exerted?
- **20.** Explain the phenomenon of *referred pain* in terms of labeled lines and organization of sensory tracts and pathways.

LEVEL 3 Critical Thinking and Clinical Applications

- **21.** Kayla is having difficulty controlling her eye movements and has lost some control of her facial muscles. After an examination and testing, Kayla's physician tells her that her cranial nerves are perfectly normal but that a small tumor is putting pressure on certain fiber tracts in her brain. This pressure is the cause of Kayla's symptoms. Where is the tumor most likely located?
- **22.** Harry, a construction worker, suffers a fractured skull when a beam falls on his head. Diagnostic tests indicate severe damage to the motor cortex. His wife is anxious to know if he will ever be able to move or walk again. What would you tell her?
- **23.** Denzel had to have his arm amputated at the elbow after an accident. He tells you that he can sometimes still feel pain in his fingers even though the hand is gone. He says this is especially true when he bumps the stub. How can this be?

CLINICAL CASE

Living with Cerebral Palsy

Communication between the periphery and the central nervous system follows neural pathways. Somatic sensory tracts are ascending, ending in the brain. Somatic motor tracts are descending, beginning in the brain. Between the input and the output, nerve impulses are analyzed, influenced, and modified in various parts of the brain, including the cerebrum, cerebellum, basal nuclei, hippocampus, and thalamus. These were the very areas of Michael's brain that were injured during birth.

The damage affected the sensory and motor processing centers in the brain. As a result, Michael's voluntary movements, muscle tone, postural muscle control, and balance were all affected. These deficits were stable and did not get worse. There was no limit to the development of the rest of Michael's brain, or how brilliant he could become.

In spite of his disabilities, Michael chose to define himself in terms of his abilities. He earned his Ph.D. in special education.

He was a pioneer and became a catalyst in introducing the concept of self-determination to the field of education. He has been an educator, writer, and motivator his entire life. He is not just living, but thriving despite his cerebral palsy.

Wrap-Up

- 1. Name the principal descending motor pathways that carry information that would be affected by the brain damage causing Michael's cerebral palsy.
- **2.** Besides aspiration pneumonia, what other difficulties could result from poor motor control of the muscles used in swallowing?

See the blue Answers tab at the back of the book.

The Autonomic Nervous System and Higher-Order Functions

Learning Outcomes

16

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **16-1** Compare the organization of the autonomic nervous system with that of the somatic nervous system.
- **16-2** Describe the structures and functions of the sympathetic division of the autonomic nervous system.
- **16-3** Describe the mechanisms of sympathetic neurotransmitter release and their effects on target organs and tissues.
- **16-4** Describe the structures and functions of the parasympathetic division of the autonomic nervous system.
- **16-5** Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues.
- **16-6** Discuss the functional significance of dual innervation and autonomic tone.
- **16-7** Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes.
- **16-8** Explain how memories are created, stored, and recalled, and distinguish among the levels of consciousness and unconsciousness.
- **16-9** Describe some of the ways in which the interactions of neurotransmitters influence brain function.
- **16-10** Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems.

CLINICAL CASE

The First Day in Anatomy Lab

It is Tim's first day in anatomy lab and he is very excited. He has been dreaming of this day for

years. He has a new, white lab coat and a great anatomy and physiology textbook, and he is ready to go.

The first thing Tim notices upon entering the lab is the body lying on the table. A human cadaver certainly resembles a human being, but there is no mistaking the two. There are bright lights and a smothering smell of formaldehyde from the embalming fluid used in the cadaver.

Tim suddenly feels hot and sweaty. He has a vague discomfort in his chest and feels sick to his stomach. His instructor says something to him but he cannot understand the words. He tries to respond, but is unable to speak. When his instructor looks at him, Tim appears pale and confused. Then he becomes light-headed. His vision blurs and he hears ringing in his ears. The last thing Tim remembers is a sensation of profound weakness.

Tim hits the floor with a thud, landing in a crumpled, prone position. His instructor rolls him over, loosens his tie and belt, and props his lower legs up on a chair. Within ten seconds

Tim regains consciousness but feels exhausted. It is as if he is climbing out of a very deep sleep. He is very embarrassed. What happened to Tim? To find out, turn to the Clinical Case Wrap-Up on p. 562.

An Introduction to the Autonomic Nervous System and Higher-Order Functions

In this chapter we focus on the autonomic nervous system (ANS), which adjusts our basic life support systems without our conscious control. We also consider aspects of higher-order functions such as consciousness, learning, and intelligence. Finally, we look at the effects of aging on the nervous system and conclude with an overview of interactions between the nervous system and other body systems.

16-1 The autonomic nervous system is involved in the unconscious regulation of visceral functions and has sympathetic and parasympathetic divisions

Learning Outcome Compare the organization of the autonomic nervous system with that of the somatic nervous system.

Your conscious thoughts, plans, and actions are a tiny fraction of what the nervous system does. If all consciousness were eliminated, your vital physiological processes would continue virtually unchanged. After all, a night's sleep is not a life-threatening event. Longer, deeper states of unconsciousness are not necessarily more dangerous, as long as you get nourishment and other basic care. People with severe brain injuries can survive in a coma for decades.

How do people survive under these conditions? Their survival is possible because the **autonomic nervous system**

(ANS) makes routine homeostatic adjustments in physiological systems. The ANS coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions. It adjusts internal water, electrolyte, nutrient, and dissolved gas concentrations in body fluids—without instructions or interference from the conscious mind.

The practice of medicine has benefitted greatly from our understanding of the ANS. For example, in 1960, the five-year survival rate for patients after their first heart attack was very low. The problem was that it was difficult and sometimes impossible to control high blood pressure. Today, many heart attack survivors lead normal lives. What changed? We learned to manipulate the ANS with medicine and clinical procedures. Let's begin our examination of the ANS by comparing its organization with that of the somatic nervous system (SNS).

Organization of the ANS

Figure 16–1 compares the organization of the somatic and autonomic nervous systems. Both are efferent divisions that carry motor commands. The SNS controls skeletal muscles, and the ANS controls visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The primary structural difference between the two is that in the SNS, motor neurons of the central nervous system exert direct control over skeletal muscles (Figure 16–1a). In the ANS, by contrast, motor neurons of the central nervous system synapse on visceral motor neurons in autonomic ganglia, and these ganglionic neurons control visceral effectors (Figure 16–1b).

The hypothalamus contains the integrative centers for autonomic activity. The neurons in these centers are comparable to the upper motor neurons in the SNS. Visceral motor neurons

Figure 16–1 The Organization of the Somatic and Autonomic Nervous Systems.

in the brain stem and spinal cord are known as **preganglionic neurons** because they extend to ganglia. These neurons are part of visceral reflex arcs. Most of their activities represent direct reflex responses, rather than responses to commands from the hypothalamus. The axons of preganglionic neurons are called **preganglionic fibers**.

Preganglionic fibers leave the CNS and synapse on **ganglionic neurons**—visceral motor neurons in peripheral ganglia. These ganglia, which contain hundreds to thousands of ganglionic neurons, are called **autonomic ganglia**. Ganglionic neurons innervate visceral effectors such as smooth muscle, glands, cardiac muscle, and adipocytes. The axons of ganglionic neurons are called **postganglionic fibers**, because they begin at the autonomic ganglia and extend to the peripheral target organs.

Somatic or visceral sensory information can trigger visceral reflexes, and the ANS distributes the motor commands of those reflexes. Sometimes those motor commands control the activities of target organs. For example, in cold weather, the ANS stimulates the arrector pili muscles and gives you "goosebumps." \bigcirc p. 163 In other cases, the motor commands may alter some ongoing activity. A sudden, loud noise can startle

you and make you jump, but thanks to the ANS, that sound can also increase your heart rate dramatically and temporarily stop all digestive gland secretion. These changes in visceral activity take place in response to neurotransmitters released by postganglionic fibers. As noted in Chapter 12, a specific neurotransmitter may stimulate or inhibit activity, depending on the response of particular plasma membrane receptors. We consider the major types of receptors later in the chapter. Now let's turn to the anatomy and physiology of the ANS.

TIPS & TRICKS

Each autonomic ganglion functions somewhat like a baton handoff in a relay race. Within the ganglion, one runner (the preganglionic fiber) hands off the baton (a neurotransmitter) to the next runner (the postganglionic fiber), who then continues on toward the finish line (the target effector).

Divisions of the ANS

You are probably already familiar with the names of the two main subdivisions of the ANS: the *sympathetic division* and the *parasympathetic division* (Spotlight Figure 16-2).

AUTONOMIC NERVOUS SYSTEM

Consists of two divisions

Sympathetic Division (Thoracolumbar)

Preganglionic fibers from both the thoracic and upper lumbar spinal segments synapse in ganglia near the spinal cord. These axons and ganglia are part of the **sympathetic division**, or thoracolumbar (thor-a-kō-LUM-bar) division, of the ANS. In this division, the preganglionic fibers are short, and the postganglionic fibers are long. The sympathetic division brings about what is often called the "fight or flight" response because it readies the body for a crisis that may require sudden, intense physical activity.

Parasympathetic Division (Craniosacral)

Preganglionic fibers originating in either the brain stem (cranial nerves III, VII, IX, and X) or the sacral segments of the spinal cord are part of the **parasympathetic division**, or **craniosacral division**, of the ANS. The preganglionic fibers synapse in terminal ganglia, located close to the target organs, or intramural (*murus*, wall) ganglia, within the tissues of the target organs. In this division, the preganglionic fibers are long, and the postganglionic fibers are short. The parasympathetic division brings about what is often called the "rest and digest" response because it conserves energy and promotes sedentary activities, such as digestion.

The two divisions work in several ways:

- 1. Most often, these two divisions have opposing effects. If the sympathetic division causes excitation, the parasympathetic causes inhibition.
- **2.** The two divisions may also work independently. Only one division innervates some structures.
- **3.** The two divisions may work together, with each controlling one stage of a complex process.

In general, the sympathetic division "kicks in" only during exertion, stress, or emergency, and the parasympathetic division predominates under resting conditions (Spotlight Figure 16–2).

An increase in sympathetic activity prepares the body to deal with emergencies. Imagine walking down a long, dark alley and hearing strange noises in the darkness ahead. Your body responds right away, and you become more alert and aware of your surroundings. Your metabolic rate rises quickly, up to twice its resting level. Your digestive and urinary processes stop temporarily, and more blood flows to your skeletal muscles. You begin breathing more quickly and more deeply. Both your heart rate and blood pressure increase, circulating your blood more rapidly. You feel warm and begin to perspire.

We can summarize this general pattern of responses to increased levels of sympathetic activity as follows: (1) heightened mental alertness, (2) increased metabolic rate, (3) reduced digestive and urinary functions, (4) activation of energy reserves, (5) increased respiratory rate and dilation of respiratory passageways, (6) increased heart rate and blood pressure, and (7) activation of sweat glands.

The parasympathetic division stimulates visceral activity. For example, it brings about the state of "rest and digest" after you eat a big dinner. Your body relaxes, energy demands are minimal, and both your heart rate and blood pressure are relatively low. Meanwhile, your digestive organs are highly stimulated.

The overall pattern of responses to increased parasympathetic activity is as follows: (1) decreased metabolic rate, (2) decreased heart rate and blood pressure, (3) increased secretion by salivary and digestive glands, (4) increased motility and blood flow in the digestive tract, and (5) stimulation of urination and defecation.

The ANS also includes a third division: the **enteric ner-vous system (ENS)**. The ENS is an extensive network of neurons and nerve networks in the walls of the digestive tract. The sympathetic and parasympathetic divisions both influence the enteric nervous system, but many complex visceral reflexes are initiated and coordinated locally. They operate without instructions from the CNS. Altogether, the ENS has roughly 100 million neurons—at least as many as the spinal cord. It also uses the same neurotransmitters found in the brain.

In this chapter, we focus on the sympathetic and parasympathetic divisions, which integrate and coordinate visceral functions throughout the body. We consider the enteric nervous system later in this chapter, when we discuss visceral reflexes, and again when we examine the control of digestion in Chapter 24.

CHECKPOINT

- 1. Identify the two major divisions of the autonomic nervous system.
- 2. How many motor neurons are needed to carry an action potential from the spinal cord to smooth muscles in the wall of the intestine?
- 3. While out for a walk, Julie suddenly meets an angry dog. Which division of the autonomic nervous system is responsible for the physiological changes that occur in Julie as she turns and runs?
- 4. On the basis of anatomy, how could you distinguish the sympathetic division from the parasympathetic division of the ANS?
- See the blue Answers tab at the back of the book.

16-2 The sympathetic division consists of preganglionic neurons and ganglionic neurons involved in using energy and increasing metabolic rate

Learning Outcome Describe the structures and functions of the sympathetic division of the autonomic nervous system.

Spotlight Figure 16–2 shows the overall organization of the sympathetic division of the ANS. Its preganglionic neurons are located between segments T_1 and L_2 of the spinal cord, and its ganglionic neurons are located in ganglia near the vertebral column. The cell bodies of the preganglionic neurons are in the lateral gray horns, and their axons enter the ventral roots of these segments. The ganglionic neurons are in three locations (Figure 16–3):

- Sympathetic Chain Ganglia. Sympathetic chain ganglia, also called *paravertebral ganglia*, lie on both sides of the vertebral column (Figure 16–3a). Neurons in these ganglia control effectors in the body wall, inside the thoracic cavity, and in the head and limbs.
- Collateral Ganglia. Collateral ganglia, also known as prevertebral ganglia, are anterior to the vertebral bodies (Figure 16–3b). Collateral ganglia contain ganglionic neurons that innervate tissues and organs in the abdominopelvic cavity.
- Adrenal Medullae. The center of each adrenal (ad-, near + renal, kidney) gland is known as the adrenal medulla, or suprarenal medulla. It is a modified sympathetic ganglion (Figure 16–3c). The ganglionic neurons of the adrenal medullae have very short axons. When stimulated, they release their neurotransmitters into the bloodstream, not at a

Figure 16–3 Sites of Ganglia in Sympathetic Pathways. Superior views of sections through the thoracic spinal cord, showing the three major patterns of distribution for preganglionic and postganglionic fibers.

synapse. This mode of release allows the neurotransmitters to function as hormones, affecting target cells throughout the body.

In the sympathetic division, the preganglionic fibers are relatively short because the ganglia are located near the spinal cord. In contrast, the postganglionic fibers are relatively long, except at the adrenal medullae.

Organization and Anatomy of the Sympathetic Division

The ventral roots of spinal segments T₁ to L₂ contain sympathetic preganglionic fibers that originate from the lateral gray horns. We described the basic pattern of sympathetic innervation in these regions in Spotlight Figure 13-8, pp. 440-441. After passing through the intervertebral foramen, each ventral root gives rise to a myelinated white ramus, which carries myelinated preganglionic fibers into a nearby sympathetic chain ganglion. These fibers may synapse within the sympathetic chain ganglia, and/ or at one of the collateral ganglia, or in the adrenal medullae (Figure 16-3). They diverge extensively, with one preganglionic fiber synapsing on two dozen or more ganglionic neurons. Preganglionic fibers running between the sympathetic chain ganglia interconnect them, making the chain look like a string of pearls. Each ganglion in the sympathetic chain innervates a particular body segment or group of segments.

Sympathetic Chain Ganglia

If a preganglionic fiber carries motor commands targeting structures in the body wall, thoracic cavity, head, neck, or limbs, it synapses in one or more sympathetic chain ganglia. The unmyelinated postganglionic

fibers then follow differing paths, depending on where their targets lie:

- Postganglionic fibers that control visceral effectors in the body wall, head, neck, or limbs enter the *gray ramus* and return to the spinal nerve for subsequent distribution (Figure 16–3a, right). These postganglionic fibers innervate sweat glands, smooth muscles in superficial blood vessels, and arrector pili muscles.
- Postganglionic fibers innervating structures in the thoracic cavity, such as the heart and lungs, form bundles known as sympathetic nerves (Figure 16–3a).

For the sake of clarity, **Figure 16–3a** shows sympathetic nerves on the left side and spinal nerve distribution on the right but in reality *both* innervation patterns occur on *each* side of the body.

Figure 16–4 provides a more detailed view of the structure of the ganglion chain and the sympathetic division as a whole. The left side of the figure shows the distribution to the skin (and to skeletal muscles and other tissues of the body wall). The right side shows the innervation of visceral organs.

Each sympathetic chain contains 3 cervical, 10–12 thoracic, 4–5 lumbar, and 4–5 sacral ganglia, plus 1 coccygeal ganglion. (The numbers vary because adjacent ganglia sometimes fuse.) Preganglionic neurons are limited to spinal cord segments T_1-L_2 , and these spinal nerves have both white rami (myelinated preganglionic fibers) and gray rami (unmyelinated postganglionic fibers). The neurons in the cervical, inferior lumbar, and sacral sympathetic chain ganglia are innervated by preganglionic fibers that run along the axis of the chain. In turn, these chain ganglia provide postganglionic fibers, through gray rami, to the cervical, lumbar, and sacral spinal nerves. As a result, only spinal nerves T_1-L_2 have white rami, and every spinal nerve has a gray ramus that carries sympathetic postganglionic fibers for distribution in the body wall.

The spinal nerves provide somatic motor innervation to skeletal muscles of the body wall and limbs, but they also distribute sympathetic postganglionic fibers (Figures 16–3a and 16–4). About 8 percent of the axons in each spinal nerve are sympathetic postganglionic fibers. In the head and neck, sympathetic postganglionic fibers leaving the superior cervical sympathetic ganglia supply the regions and structures innervated by cranial nerves III, VII, IX, and X. \bigcirc pp. 494, 497, 499

In summary:

- The cervical, inferior lumbar, and sacral chain ganglia receive preganglionic fibers from spinal segments T₁-L₂.
- Only the thoracic and superior lumbar ganglia (T₁-L₂) receive preganglionic fibers from white rami.
- Every spinal nerve receives a gray ramus from a ganglion of the sympathetic chain.

Collateral Ganglia

The abdominopelvic viscera receive sympathetic innervation by sympathetic preganglionic fibers that synapse in separate collateral ganglia (Figures 16–3b). These fibers pass through the sympathetic chain without synapsing. They form the **splanchnic** (SPLANK-nik) **nerves**, which lie in the posterior wall of the abdominal cavity. In adults the collateral ganglia are typically single rather than paired. They originate as paired ganglia (left and right), but the two usually fuse.

Postganglionic fibers leaving the collateral ganglia extend throughout the abdominopelvic cavity, innervating a variety of visceral tissues and organs. The general function is to (1) reduce blood flow and energy use by organs that are not important to immediate survival (such as the digestive tract) and (2) release stored energy.

The splanchnic nerves innervate three collateral ganglia (Figure 16–3). Preganglionic fibers from the seven inferior thoracic spinal segments end at either the **celiac** (SĒ-lē-ak) **ganglion** or the **superior mesenteric ganglion**. These ganglia are embedded in an extensive network of autonomic nerves. Preganglionic fibers from the lumbar segments form splanchnic nerves that end at the **inferior mesenteric ganglion**. All three ganglia are named after nearby arteries:

- The celiac ganglion is named after the *celiac trunk*, a major artery and its branches supplying the stomach, spleen, and liver. The celiac ganglion commonly consists of a pair of interconnected masses of gray matter located at the base of that artery. The celiac ganglion may also form a single mass or many small, interwoven masses. Postganglionic fibers from this ganglion innervate the stomach, liver, gallbladder, pancreas, and spleen.
- The superior mesenteric ganglion is found near the base of the *superior mesenteric artery*, which provides blood to the stomach, small intestine, and pancreas. Postganglionic fibers leaving the superior mesenteric ganglion innervate the small intestine and the proximal two-thirds of the large intestine.
- The inferior mesenteric ganglion is located near the base of the *inferior mesenteric artery*, which supplies the large intestine and other organs in the inferior portion of the abdominopelvic cavity. Postganglionic fibers from this ganglion provide sympathetic innervation to the kidney, urinary bladder, the terminal portions of the large intestine, and the sex organs.

Adrenal Medullae

Preganglionic fibers entering an adrenal gland proceed to its center, a region called the adrenal medulla (Figures 16–3c and 16–4). The adrenal medulla is a modified sympathetic ganglion where preganglionic fibers synapse on *neuroendocrine cells*, specialized neurons that secrete hormones (chemical messengers) into the bloodstream. These neuroendocrine cells secrete the

neurotransmitters *epinephrine* (*E*) and *norepinephrine* (*NE*). Epinephrine, or *adrenaline*, makes up 75–80 percent of the secretory output. The rest is NE, or *noradrenaline*.

The bloodstream carries the neurotransmitters throughout the body, where they cause changes in the metabolic activities of many different cells. These effects resemble those produced by the stimulation of sympathetic postganglionic fibers. They differ, however, in two respects: (1) Cells not innervated by sympathetic postganglionic fibers are affected; and (2) the effects last much longer than those produced by direct sympathetic innervation, because the hormones continue to diffuse out of the bloodstream for an extended period.

Sympathetic Activation

The sympathetic division can change the activities of tissues and organs by releasing NE at peripheral synapses, and by distributing E and NE throughout the body in the bloodstream. The visceral motor fibers that target specific effectors, such as smooth muscle fibers in blood vessels of the skin, can be activated in reflexes that do not involve other visceral effectors. In a crisis, however, the entire division responds. This event, called **sympathetic activation**, is controlled by sympathetic centers in the hypothalamus. The effects are not limited to peripheral tissues, because sympathetic activation also alters CNS activity.

When sympathetic activation occurs, a person experiences the following changes:

- Increased alertness by stimulation of the reticular activating system, causing the individual to feel "on edge."
- A feeling of energy and euphoria, often associated with a disregard for danger and a temporary insensitivity to painful stimuli.
- Increased activity in the cardiovascular and respiratory centers of the pons and medulla oblongata, which increases blood pressure, heart rate, breathing rate, and depth of respiration.
 - A general elevation in muscle tone through stimulation of the medial and lateral pathways, so the individual *looks* tense and may begin to shiver.
 - The mobilization of energy reserves, through the accelerated breakdown of glycogen in muscle and liver cells and the release of lipids by adipose tissues.

These changes, plus the peripheral changes already noted, prepare the individual to cope with a stressful situation.

CHECKPOINT

5. Where do the nerves that synapse in collateral ganglia originate?

See the blue Answers tab at the back of the book.

16–3 Stimulation of sympathetic neurons leads to the release of various neurotransmitters

Learning Outcome Describe the mechanisms of sympathetic neurotransmitter release and their effects on target organs and tissues.

We have examined the structure of the sympathetic division of the ANS and the general effects of sympathetic activation. Now let's consider the cellular basis of these effects on peripheral organs.

When stimulated, sympathetic preganglionic neurons release ACh at synapses with ganglionic neurons. Synapses that use ACh as a transmitter are called *cholinergic*. \bigcirc **p**. 414 The effect on the ganglionic neurons is always excitatory.

These ganglionic neurons then release neurotransmitters at specific target organs. The axon terminals differ from neuromuscular junctions of the somatic nervous system. In the sympathetic nervous system, the telodendria form a branching network, with each branch resembling a string of pearls. Each "pearl" is a swollen segment called a **varicosity** and is packed with neurotransmitter vesicles (Figure 16–5). Chains of varicosities pass along or near the surfaces of effector cells. These cells have no specialized postsynaptic membranes, such as the motor end plates in skeletal muscle cells. Instead, membrane receptors are scattered across the surfaces of the target cells.

Most sympathetic ganglionic neurons release NE at their varicosities. Neurons that release NE are called *adrenergic*. **D** p. 417 A small but significant number of ganglionic neurons in the sympathetic division release ACh rather than NE. Varicosities releasing ACh are located in the body wall, the skin, the brain, and skeletal muscles.

Figure 16–5 Sympathetic Varicosities.

The NE released by varicosities affects its targets until it is reabsorbed or inactivated by enzymes. Fifty to 80 percent of the NE is reabsorbed by varicosities and is either reused or broken down by the enzyme *monoamine oxidase (MAO)*. The rest of the NE diffuses out of the area or is broken down by the enzyme *catechol-O-methyltransferase (COMT)* in surrounding tissues.

In general, the effects of NE on the postsynaptic membrane last for a few seconds, significantly longer than the 20-msec duration of ACh effects. (As usual, the responses of the target cells vary with the nature of their receptors.) When the adrenal medullae release NE or E into the bloodstream, the effects last even longer because (1) the bloodstream does not contain MAO or COMT, and (2) most tissues contain relatively low concentrations of those enzymes. After the adrenal medullae are stimulated, tissue concentrations of NE and E throughout the body may remain elevated for as long as 30 seconds, and the effects may persist for several minutes.

Sympathetic Stimulation and the Release of NE and E

The effects of sympathetic stimulation result primarily from the interactions of NE and E with adrenergic membrane receptors. There are two classes of these receptors: *alpha receptors* and *beta receptors*. In general, norepinephrine (NE) stimulates alpha receptors to a greater degree than it does beta receptors, and epinephrine (E) stimulates both classes of receptors. For this reason, localized sympathetic activity, involving the release of NE at varicosities, primarily affects nearby alpha receptors. By contrast, generalized sympathetic activation and the release of E by the adrenal medullae affect alpha and beta receptors throughout the body.

Alpha receptors and beta receptors are *G* protein-coupled receptors. As we saw in Chapter 12, the effects of stimulating such a receptor depend on the production of second messengers, intracellular intermediaries with varied functions. \bigcirc p. 420

The stimulation of **alpha** (α) **receptors** activates their associated G proteins on the cytoplasmic surface of the plasma membrane. There are two types of alpha receptors: alpha-1 (α_1) and alpha-2 (α_2).

- α_1 is the more common type of alpha receptor. Its stimulation results in G protein activation that brings about the release of intracellular calcium ions into the cytosol from reserves in the endoplasmic reticulum. This action generally has an excitatory effect on the target cell. For example, the stimulation of α_1 receptors on smooth muscle cells causes peripheral blood vessels to constrict and sphincters along the digestive tract and urinary bladder to close.
- Stimulation of α₂ receptors and G protein activation results in a lowering of cyclic-AMP (cAMP) levels in the cytoplasm. Cyclic-AMP is an important second messenger that can activate or inactivate key enzymes. D p. 420 This reduction generally has an inhibitory effect on the cell. The presence

of α_2 receptors in the parasympathetic division helps coordinate sympathetic and parasympathetic activities. When the sympathetic division is active, the NE released binds to α_2 receptors at parasympathetic neuromuscular and neuroglandular junctions and inhibits their activity.

Beta (β) **receptors** are located on the plasma membranes of cells in many organs, including skeletal muscles, the lungs, the heart, and the liver. The stimulation of beta receptors and G protein activation triggers changes in the metabolic activity of the target cell. These changes occur indirectly, as G protein activation results in an increase in intracellular cAMP levels. There are three major types of beta receptors: beta-1 (β_1), beta-2 (β_2), and beta-3 (β_3).

- The stimulation of β_1 receptors leads to an increase in metabolic activity. For example, the stimulation of β_1 receptors in skeletal muscles accelerates the metabolic activities of the muscles. The stimulation of β_1 receptors in the heart increases heart rate and force of contraction.
- The stimulation of β₂ receptors causes inhibition, triggering a relaxation of smooth muscles along the respiratory tract. As a result, respiratory passageways dilate, making breathing easier. The inhalers used to treat asthma trigger this response.
- A third type of beta receptor, beta-3 (β₃), is found in adipose tissue. Stimulation of β₃ receptors leads to *lipolysis*, the breakdown of triglycerides stored within adipocytes. The fatty acids generated through lipolysis are released into the bloodstream for use by other tissues.

Sympathetic Stimulation and the Release of ACh and NO

The vast majority of sympathetic postganglionic fibers are adrenergic (release NE), but as we noted, a few are cholinergic (release ACh). These postganglionic fibers innervate skin sweat glands and the blood vessels to skeletal muscles and the brain. The activation of these sympathetic fibers stimulates sweat gland secretion and dilates the blood vessels.

In other regions of the body, the parasympathetic division (rather than the sympathetic division) releases ACh. However, neither the body wall nor skeletal muscles are innervated by the parasympathetic division, and in these areas both ACh and NE are needed to regulate visceral functions with precision. For example, ACh causes most small peripheral arteries to dilate (*vasodilation*), and NE causes them to constrict (*vasoconstriction*). This means that the sympathetic division can increase blood flow to skeletal muscles, by releasing ACh to activate cholinergic terminals. At the same time, it can reduce the blood flow to other tissues in the body wall, by releasing NE to stimulate adrenergic terminals.

The sympathetic division also includes *nitroxidergic* synapses, which release *nitric oxide* (*NO*) as a neurotransmitter. Such synapses occur where neurons innervate smooth muscles in the walls of blood vessels in many regions, notably in skeletal

muscles and the brain. The activity of these synapses produces vasodilation and increased blood flow through these regions.

Summary: The Sympathetic Division

To summarize our discussion of the sympathetic division:

- 1. The sympathetic division of the ANS includes two sets of sympathetic chain ganglia, one on each side of the vertebral column; three collateral ganglia anterior to the vertebral column; and two adrenal medullae.
- The preganglionic fibers are short, because the ganglia are close to the spinal cord. The postganglionic fibers are longer and extend a considerable distance to their target organs. (In the case of the adrenal medullae, very short axons end at capillaries that carry their secretions to the bloodstream.)
- 3. The sympathetic division shows extensive divergence. That is, a single preganglionic fiber may innervate two dozen or more ganglionic neurons in different ganglia. As a result, a single sympathetic motor neuron in the CNS can control a variety of visceral effectors and can produce a complex and coordinated response.
- 4. All preganglionic neurons release ACh at their synapses with ganglionic neurons. Most postganglionic fibers release NE, but a few release ACh or NO.
- 5. The effector response depends on the second messengers triggered by G protein activation when NE or E binds to alpha receptors or beta receptors.

CHECKPOINT

- 6. How would a drug that stimulates acetylcholine receptors affect the sympathetic nervous system?
- 7. An individual with high blood pressure is given a medication that blocks beta receptors. How could this medication help correct that person's condition?

See the blue Answers tab at the back of the book.

16-4 The parasympathetic division consists of preganglionic neurons and ganglionic neurons involved in conserving energy and lowering metabolic rate

Learning Outcome Describe the structures and functions of the parasympathetic division of the autonomic nervous system.

The parasympathetic division of the ANS (Figure 16–6) consists of:

1. Preganglionic Neurons in the Brain Stem and in Sacral Segments of the Spinal Cord. The midbrain, pons, and medulla oblongata contain autonomic nuclei associated with cranial nerves III, VII, IX, and X. In sacral segments of the spinal cord, the parasympathetic nuclei lie in the lateral gray horns of spinal segments S_2 - S_4 .

2. *Ganglionic Neurons in Peripheral Ganglia within or Adjacent to the Target Organs.* Preganglionic fibers of the parasympathetic division do not diverge as extensively as do those of the sympathetic division. A typical preganglionic fiber synapses on six to eight ganglionic neurons. All are in the same ganglion. The postganglionic fibers then extend to the same target organ. The ganglion may be a **terminal ganglion**, located near the target organ, or an **intramural** (*murus*, wall) **ganglion**, embedded in the tissues of the target organ. Note that this pattern makes the effects of parasympathetic stimulation very specific and localized. Terminal ganglia are usually paired. Examples include the parasympathetic ganglia associated with the cranial nerves. Intramural ganglia typically consist of interconnected masses and clusters of ganglion cells.

Organization and Anatomy of the Parasympathetic Division

Parasympathetic preganglionic fibers leave the brain in cranial nerves III (oculomotor), VII (facial), IX (glossopharyngeal), and X (vagus) (Figure 16–6). These fibers carry the cranial parasympathetic output to visceral structures in the head. These fibers synapse in the *ciliary, pterygopalatine, submandibular,* and *otic ganglia.* \supset pp. 494, 496, 497 Short postganglionic fibers continue to their peripheral targets.

The vagus nerve alone provides roughly 75 percent of all parasympathetic outflow. It supplies preganglionic parasympathetic innervation to structures in the neck and in the thoracic and abdominopelvic cavities as distant as the distal portion of the large intestine. The many branches of the vagus nerve mingle with preganglionic and postganglionic fibers of the sympathetic division, forming plexuses comparable to those formed by spinal nerves innervating the limbs. We consider these plexuses in a later section.

The preganglionic fibers in the sacral segments of the spinal cord carry the sacral parasympathetic output. These fibers do not join the ventral roots of the spinal nerves. Instead, they form distinct **pelvic nerves**, which innervate intramural ganglia in the walls of the kidneys, urinary bladder, terminal portions of the large intestine, and sex organs.

Parasympathetic Activation

The functions of the parasympathetic division center on relaxation, food processing, and nutrient absorption. This division has been called the *anabolic system* (*anabole*, a raising up), because its stimulation leads to a general increase in the nutrient content of the blood. In response to this increase, cells throughout the body absorb nutrients and use them to support growth

Figure 16–6 The Distribution of Parasympathetic Innervation.

and cell division and to create energy reserves in the form of lipids or glycogen.

The major effects of the parasympathetic division include the following:

- Constriction of the pupils (to restrict the amount of light that enters the eyes) and focusing of the lenses of the eyes on nearby objects.
- Secretion by digestive glands, including salivary glands, gastric glands, duodenal glands, intestinal glands, the pancreas (exocrine and endocrine), and the liver.
- The secretion of hormones that promote the absorption and use of nutrients by peripheral cells.
- Changes in blood flow and glandular activity associated with sexual arousal.

- An increase in smooth muscle activity along the digestive tract.
- The stimulation and coordination of defecation.
- Contraction of the urinary bladder during urination.
- Constriction of the respiratory passageways.
- A reduction in heart rate and force of contraction.

CHECKPOINT

- 8. Which nerve is responsible for the parasympathetic innervation of the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines?
- 9. Why is the parasympathetic division sometimes referred to as the anabolic system?

See the blue Answers tab at the back of the book.

16–5 Stimulation of parasympathetic neurons leads to the release of the neurotransmitter ACh

Learning Outcome Describe the mechanisms of parasympathetic neurotransmitter release and their effects on target organs and tissues.

All parasympathetic neurons release ACh as a neurotransmitter. The effects on the postsynaptic cell can vary widely, however, due to different types of receptors or to the nature of the second messenger involved.

Neurotransmitter Release

The neuromuscular (neuron to muscle) and neuroglandular (neuron to effector) junctions of the parasympathetic division have narrow synaptic clefts. The effects of stimulation are short-lived. Most of the ACh released is inactivated at the synapse by *acetylcholinesterase (AChE)*. Any ACh diffusing into the surrounding tissues is inactivated by the enzyme *tissue cholinester-ase*. As a result, the effects of parasympathetic stimulation are quite localized, and they last a few seconds.

Membrane Receptors and Responses

The parasympathetic division uses the same transmitter, ACh, at all of its synapses (neuron to neuron) and neuromuscular or neuroglandular junctions. Two types of ACh receptors occur on the postsynaptic membranes:

1. Nicotinic (nik-ō-TIN-ik) receptors occur on ganglion cells of both the parasympathetic and sympathetic divisions. They also occur at neuromuscular junctions of the somatic nervous system. ACh always causes excitation of the ganglionic neuron or muscle fiber. It works by opening chemically gated Na⁺ channels in the postsynaptic membrane.

2. **Muscarinic** (mus-ka-RIN-ik) **receptors** occur at cholinergic neuromuscular or neuroglandular junctions in the parasympathetic division. They also occur at the few cholinergic junctions in the sympathetic division. Muscarinic receptors are G protein–coupled receptors. Their stimulation and G protein activation produces longer-lasting effects than does the stimulation of nicotinic receptors. The response can be excitatory or inhibitory, depending on the activation or inactivation of specific enzymes.

The names *nicotinic* and *muscarinic* originated with researchers who found that dangerous environmental toxins bind to these receptor sites. Nicotinic receptors bind *nicotine*, a powerful toxin obtained from a variety of sources, including tobacco leaves. (The highest nicotine levels in tobacco are about 3 mg per gram.) Muscarinic receptors are stimulated by *muscarine*, a toxin produced by some poisonous mushrooms.

These toxins have completely separate actions. Nicotine targets the autonomic ganglia and skeletal neuromuscular junctions. Muscarine acts at the parasympathetic neuromuscular or neuroglandular junctions. They produce dangerously exaggerated, uncontrolled responses due to abnormal stimulation of cholinergic or adrenergic receptors.

Nicotine poisoning occurs if as little as 50 mg of the compound is ingested or absorbed through the skin. The signs reflect widespread autonomic activation. They include vomiting, diarrhea, high blood pressure, rapid heart rate, sweating, and profuse salivation. Convulsions occur because the neuromuscular junctions of the somatic nervous system are stimulated. In severe cases, the stimulation of nicotinic receptors inside the CNS can lead to coma and death within minutes.

The signs and symptoms of muscarine poisoning are almost entirely restricted to the parasympathetic division. They include salivation, nausea, vomiting, diarrhea, constriction of respiratory passages, low blood pressure, and an abnormally slow heart rate (bradycardia). Sweating, a sympathetic response, is also prominent. For this reason, *Amanita muscaria*, commonly known as the fly-agaric mushroom, is used in some Native American sweat lodge rituals.

 Table 16–1 summarizes details about the adrenergic and cholinergic receptors of the ANS.

Summary: The Parasympathetic Division

In summary:

- The parasympathetic division includes visceral motor nuclei associated with cranial nerves III, VII, IX, and X, and with sacral segments S₂–S₄.
- Ganglionic neurons are located in ganglia within or next to their target organs.
- The parasympathetic division innervates areas serviced by the cranial nerves and organs in the thoracic and abdominopelvic cavities.

Table 16–1	Adrenergic and Cholinergic Receptors of the ANS				
Receptor	Location	Response	Mechanism		
ADRENERGIC					
α ₁	Widespread, found in most tissues	Excitation, stimulation of metabolism	Enzyme activation; intracellular release of ${\rm Ca}^{2+}$		
α ₂	Sympathetic neuromuscular or neuroglandular junctions	Inhibition of effector cell	Reduction of cAMP concentrations		
α ₂	Parasympathetic neuromuscular or neuroglandular junctions	Inhibition of neurotransmitter release	Reduction of cAMP concentrations		
β_1	Heart, kidneys, liver, adipose tissue*	Stimulation, increased energy consumption	Enzyme activation		
β_2	Smooth muscle in vessels of heart and skeletal muscle; smooth muscle layers in intestines, lungs, bronchi	Inhibition, relaxation	Enzyme activation		
CHOLINERGIC					
Nicotinic	All autonomic synapses between preganglionic and ganglionic neurons; neuromuscular junctions of SNS	Stimulation, excitation; muscular contraction	Opening of chemically gated Na ⁺ channels		
Muscarinic	All parasympathetic and cholinergic sympathetic neuromuscular or neuroglandular junctions	Variable	Enzyme activation causing changes in membrane permeability to K^+		

*Adipocytes also contain an additional receptor type, β_3 , not found in other tissues. Stimulation of β_3 receptors causes lipolysis.

- All parasympathetic neurons are cholinergic. Ganglionic neurons have nicotinic receptors, which are excited by ACh. Muscarinic receptors at neuromuscular or neuroglandular junctions produce either excitation or inhibition, depending on the action of enzymes triggered by G protein activation when ACh binds to the receptor.
- The effects of parasympathetic stimulation are generally brief and restricted to specific organs and sites.

CHECKPOINT

- **10**. What neurotransmitter is released by all parasympathetic neurons?
- 11. Name the two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons.
- **12**. How would the stimulation of muscarinic receptors in cardiac muscle affect the heart?

See the blue Answers tab at the back of the book.

16-6 The sympathetic and parasympathetic divisions interact, creating dual innervation

Learning Outcome Discuss the functional significance of dual innervation and autonomic tone.

Figure 16–7 and **Table 16–2** compare key structural features of the sympathetic and parasympathetic divisions of the ANS. The differences in structure lead to differences in functions. The sympathetic division has widespread impact, reaching

organs and tissues throughout the body. The parasympathetic division innervates only visceral structures that are supplied by the cranial nerves or that lie within the abdominopelvic cavity.

Some organs are innervated by just one division, but most vital organs receive **dual innervation**, so they receive instructions from both the sympathetic and parasympathetic divisions. Where dual innervation exists, the two divisions commonly have opposing effects. Dual innervation with opposing effects is most obvious in the digestive tract, heart, and lungs. At other sites, the responses may be separate or complementary. Table 16–3 provides a functional comparison of the two divisions, noting the effects of sympathetic or parasympathetic activity on specific organs and systems.

Anatomy of Dual Innervation

Parasympathetic postganglionic fibers from the ciliary, pterygopalatine, submandibular, and otic ganglia of the head travel by the cranial nerves to their peripheral destinations. Sympathetic innervation reaches the same structures by traveling directly from the superior cervical ganglia of the sympathetic chain.

In the thoracic and abdominopelvic cavities, the sympathetic postganglionic fibers mingle with parasympathetic preganglionic fibers, forming a series of nerve networks collectively called *autonomic plexuses*. They include the cardiac plexus, the pulmonary plexus, the esophageal plexus, the celiac plexus, the inferior mesenteric plexus, and the hypogastric plexus (Figure 16–8). Nerves leaving these networks travel with the blood vessels and lymphatic vessels that supply visceral organs.

Autonomic fibers entering the thoracic cavity intersect at the **cardiac plexus** and the **pulmonary plexus**. These plexuses contain sympathetic and parasympathetic fibers to the heart and lungs, respectively, as well as the parasympathetic ganglia whose output affects those organs. The **esophageal plexus** contains descending branches of the vagus nerves and splanchnic nerves leaving the sympathetic chain on either side.

Parasympathetic preganglionic fibers of the vagus nerves enter the abdominopelvic cavity with the esophagus. There the fibers enter the **celiac plexus**, also known as the *solar plexus*. The celiac plexus and associated smaller plexuses, such as the **inferior mesenteric plexus**, innervate viscera within the abdominal cavity. The **hypogastric plexus** innervates the digestive, urinary, and reproductive organs of the pelvic cavity. This plexus contains the parasympathetic outflow of the pelvic nerves, sympathetic postganglionic fibers from the inferior mesenteric ganglion, and splanchnic nerves from the sacral sympathetic chain. Figure 16–7 Summary: The Anatomical Differences between the Sympathetic and Parasympathetic Divisions.

Autonomic Tone

16

Even without stimuli, autonomic motor neurons show a resting level of spontaneous activity. This background level of activity determines an individual's **autonomic tone**. Autonomic tone is an important aspect of ANS function, just as muscle tone is a key aspect of SNS function. If a nerve is absolutely inactive under normal conditions, then all it can do is increase its activity on demand. But if the nerve maintains a background level

of activity, then it can increase or decrease its activity, providing a greater range of control options.

Autonomic tone is significant where dual innervation occurs and the two ANS divisions have opposing effects. It is even more important where dual innervation does not occur. To

Table 16–2	A Structural Comparison of the Sympathetic and Parasympathetic Divisions of the ANS			
Characteristic		Sympathetic Division	Parasympathetic Division	
Location of CNS visceral motor neurons		Lateral gray horns of spinal segments T_1-L_2	Brain stem and spinal segments $\rm S_2–S_4$	
Location of PNS ganglia		Near vertebral column	Typically intramural	
Preganglionic fib	pers			
Length		Relatively short	Relatively long	
Neurotransmitter released		Acetylcholine	Acetylcholine	
Postganglionic fi	ibers			
Length		Relatively long	Relatively short	
Neurotransmitter released		Normally NE; sometimes NO or ACh	Acetylcholine	
Neuromuscular or neuroglandular junction		Varicosities and enlarged axonic terminals that release transmitter near target cells	Junctions that release transmitter to special receptor surface	
Degree of divergence from CNS to ganglion cells		Approximately 1:32	Approximately 1:6	
General function		Stimulates metabolism; increases alertness; prepares for emergency ("fight or flight")	Promotes relaxation, nutrient uptake, energy storage ("rest and digest")	

Table 16–3	A Functional Comparison of the Sympathetic and Parasympathetic Divisions of the ANS			
Structure		Sympathetic Effects (receptor or synapse type)	Parasympathetic Effects (all muscarinic receptors)	
EYE		Dilation of pupil (α_1); accommodation for distance vision (β_2)	Constriction of pupil; accommodation for close vision	
Lacrimal glands		None (not innervated)	Secretion	
SKIN				
Sweat glands		Increased secretion, palms and soles (α_1); generalized increase in secretion (cholinergic)	None (not innervated)	
Arrector pili mus	cles	Contraction; erection of hairs (α_1)	None (not innervated)	
CARDIOVASCUL	AR SYSTEM			
Blood vessels			None (not innervated)	
To skin		Dilation (β_2 and cholinergic); constriction (α_1)	None (not innervated)	
To skeletal mus	cles	Dilation (β_2 and cholinergic; nitroxidergic)	None (not innervated)	
To heart		Dilation (β_2); constriction (α_1, α_2)	None (not innervated)	
To lungs		Dilation (α_2); constriction (α_1)	None (not innervated)	
To digestive vis	cera	Constriction (β_2); dilation (α_2)	None (not innervated)	
To kidneys		Constriction, decreased urine production (α_1, α_2); dilation, increased urine production (β_1, β_2)	None (not innervated)	
To brain		Dilation (cholinergic and nitroxidergic)	None (not innervated)	
Veins		Constriction (α_1 , β_2)	None (not innervated)	
Heart		Increased heart rate, force of contraction, and blood pressure (α_1, β_1)	Decreased heart rate, force of contraction, and blood pressure	
ENDOCRINE SYS	TEM			
Adrenal gland		Secretion of epinephrine, norepinephrine by adrenal medulla	None (not innervated)	
Posterior lobe of pituitary gland		Secretion of ADH (β_1, β_2)	None (not innervated)	
Pancreas		Decreased insulin secretion (α_2)	Increased insulin secretion	
Pineal gland		Increased melatonin secretion (β_1 , β_2)	Inhibition of melatonin synthesis	
RESPIRATORY SY	YSTEM			
Airways		Increased airway diameter (β_2)	Decreased airway diameter	
Secretory glands	5	Mucous secretion (α_1)	None (not innervated)	
DIGESTIVE SYST	EM			
Salivary glands		Production of viscous secretion (α_1 , β_1) containing mucins and enzymes	Production of copious, watery secretion	
Sphincters		Constriction (α_1)	Dilation	
General level of activity		Decreased (α_2, β_2)	Increased	
Secretory glands		Inhibition (α_2)	Stimulation	
Liver		Glycogen breakdown, glucose synthesis and release (α_1, β_2)	Glycogen synthesis	
Pancreas		Decreased exocrine secretion (α_1)	Increased exocrine secretion	
SKELETAL MUSC	LES			
		Increased force of contraction, glycogen breakdown (β_2)	None (not innervated)	
		Facilitation of ACh release at neuromuscular junction (α_2)	None (not innervated)	
ADIPOSETISSUE		Lipolysis, fatty acid release ($\alpha_1, \beta_1, \beta_3$)	None (not innervated)	
URINARY SYSTE	M			
Kidneys		Secretion of renin (β_1)	Uncertain effects on urine production	
Urinary bladder		Construction of internal sphincter; relaxation of urinary bladder (α_1, β_2)	rensing of urinary bladder, relaxation of internal sphincter to eliminate urine	
MALE REPRODU	CTIVE SYSTEM	Increased glandular secretion and ejaculation (α_1)	Erection	
FEMALE REPROI	DUCTIVE SYSTEM			
		Increased glandular secretion; contraction of pregnant uterus (α_1)	Variable (depending on hormones present)	
		Relaxation of nonpregnant uterus (β_2)	Variable (depending on hormones present)	

demonstrate how autonomic tone affects ANS function, let's consider one example of each situation.

The heart receives dual innervation. Recall that the heart consists of cardiac muscle tissue, and that specialized pacemaker cells trigger its contractions. **D** p. 142 The two autonomic divisions have opposing effects on heart function. Acetylcholine, released by postganglionic fibers of the parasympathetic division, causes a reduction in heart rate. Norepinephrine, released by varicosities of the sympathetic division, accelerates heart rate. Small amounts of both of these neurotransmitters are released continuously, creating autonomic tone. However, the parasympathetic division dominates under resting conditions. Heart rate can be controlled very precisely to meet the demands

of active tissues through small adjustments in the balance between parasympathetic stimulation and sympathetic stimulation. In a crisis, stimulation of the sympathetic innervation and inhibition of the parasympathetic innervation accelerate the heart rate to the maximum extent possible.

The sympathetic control of blood vessel diameter demonstrates how autonomic tone allows fine adjustment of peripheral activities in target organs that are innervated by only one ANS division. Blood flow to specific organs must be controlled to meet the tissue demands for oxygen and nutrients. When a blood vessel dilates, blood flow through it increases, and when it constricts, blood flow is reduced. Sympathetic postganglionic fibers release NE at the smooth muscle cells in the walls of peripheral vessels. This background sympathetic tone keeps these muscles partially contracted, so the blood vessels are ordinarily at about half their maximum diameter. When increased blood flow is needed, the rate of NE release decreases and sympathetic cholinergic fibers are stimulated. As a result, the smooth muscle cells relax, the vessels dilate, and blood flow increases. By adjusting sympathetic tone and the activity of cholinergic fibers, the sympathetic division can exert precise control of vessel diameter over its entire range.

CHECKPOINT

- 13. What effect would the loss of sympathetic tone have on blood flow to a tissue?
- 14. What physiological changes would you expect in a patient who is about to undergo a dental root canal and is quite anxious about the procedure?

See the blue Answers tab at the back of the book.

16-7 Visceral reflexes play a role in the integration and control of autonomic functions

Learning Outcome Describe the hierarchy of interacting levels of control in the autonomic nervous system, including the significance of visceral reflexes.

Recall that centers involved in somatic motor control are found in all portions of the CNS. The lowest level of regula-

tory control consists of the lower motor neurons involved in cranial and spinal reflex arcs. The highest level consists of the pyramidal motor neurons of the primary motor cortex, operating with feedback from the cerebellum and basal nuclei.

Similarly, the ANS is also organized into a series of interacting levels. At the bottom are visceral motor neurons in the lower brain stem and spinal cord that are involved in cranial and spinal visceral reflexes. **Visceral reflexes** are autonomic reflexes initiated in the viscera. They provide automatic motor responses that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus.

For example, when a light is shone in one of your eyes, a visceral reflex constricts the pupils of *both* eyes (the *consensual light reflex*). The visceral motor commands are distributed by parasympathetic fibers. In darkness, your pupils dilate, but this *pupillary reflex* is directed by sympathetic fibers. However, the motor nuclei directing pupillary constriction or dilation are also controlled by hypothalamic centers concerned with emotional states. For example, when you are queasy or nauseated, your pupils constrict. When you are sexually aroused, your pupils dilate.

Visceral Reflexes

Each **visceral reflex arc** consists of a receptor, a sensory neuron, a processing center (one or more interneurons), and two visceral motor neurons (Figure 16–9). All visceral reflexes are polysynaptic. They can be long reflexes or short reflexes.

Long reflexes are the autonomic equivalents of the polysynaptic reflexes introduced in Chapter 13. ⁵ p. 454 Visceral sensory neurons deliver information to the CNS. It travels along the dorsal roots of spinal nerves, within the sensory branches of cranial nerves, and within the autonomic nerves that innervate visceral effectors. The processing steps involve interneurons within the CNS. The ANS then carries the motor commands to the appropriate visceral effectors. Long reflexes typically coordinate the activities of an entire organ.

Short reflexes bypass the CNS entirely. They involve sensory neurons and interneurons whose cell bodies lie in autonomic ganglia. These interneurons synapse on ganglionic neurons, and then postganglionic fibers distribute the motor commands. Short reflexes control very simple motor responses with localized effects. In general, short reflexes may control patterns of activity in one small part of a target organ.

In most organs, long reflexes are most important in regulating visceral activities, but this is not the case with the digestive

Figure 16–9 Visceral Reflexes. Visceral reflexes have the same basic components as somatic reflexes, but all visceral reflexes are polysynaptic. Note that short visceral reflexes bypass the CNS altogether.

tract and its associated glands. In these areas, short reflexes provide most of the control and coordination for normal functioning. The neurons involved form the *enteric nervous system*, introduced on p. 536. The ganglia in the walls of the digestive tract contain the cell bodies of visceral sensory neurons, interneurons, and visceral motor neurons, and all their axons form extensive nerve nets. Parasympathetic innervation by the visceral motor neurons can stimulate and coordinate various digestive activities, but the enteric nervous system is quite capable of controlling digestive functions independent of the central nervous system. We consider the functions of the enteric nervous system further in Chapter 24.

As we examine other body systems in later chapters, you will come across many examples of autonomic reflexes involved in respiration, cardiovascular function, and other visceral activities. Look at Table 16–4 to preview some of the most important ones. Notice that the parasympathetic division participates in a variety of reflexes that affect individual organs and systems. This specialization reflects its relatively specific and restricted pattern of innervation.

16

In contrast, fewer sympathetic reflexes exist. The sympathetic division is typically activated as a whole. One reason is that it has such a high degree of divergence. Another reason is that the release of hormones by the adrenal medullae produces widespread peripheral effects.

Higher Levels of Autonomic Control

Centers in the brain stem that regulate specific visceral functions control the levels of activity in the sympathetic and parasympathetic divisions of the ANS. As in the SNS, in the ANS simple reflexes based in the spinal cord provide rapid and automatic responses to stimuli. Processing centers in the medulla oblongata coordinate more complex sympathetic and parasympathetic reflexes. In addition to the cardiovascular and respiratory centers, the medulla oblongata contains centers and nuclei involved with salivation, swallowing, digestive secretions, peristalsis, and urinary function. These centers are in turn subject to regulation by the hypothalamus. D p. 478

The term *autonomic* was originally applied because the regulatory centers involved with the control of visceral function were thought to operate autonomously—that is, independent of other CNS activities. This view has been drastically revised in light of later research. Because the hypothalamus interacts with all other portions of the brain, activity in the limbic system,

Table 16–4	Representative Visceral Reflexes				
Reflex		Stimulus	Response	Comments	
PARASYMPATHETIC REFLEXES					
Gastric and intestinal reflexes (Chapter 24)		Pressure and physical contact	Smooth muscle contractions that propel food materials and mix with secretions	By vagus nerves	
Defecation (Chapter 24)		Distention of rectum	Relaxation of internal anal sphincter	Requires voluntary relaxation of external anal sphincter	
Urination (Chapter 26)		Distention of urinary bladder	Contraction of walls of urinary bladder; relaxation of internal urethral sphincter	Requires voluntary relaxation of external urethral sphincter	
Direct light and consensual light reflexes (Chapter 14)		Bright light shining in eye(s)	Constriction of pupils of both eyes		
Swallowing reflex (Chapter 24)		Movement of food and liquids into pharynx	Smooth muscle and skeletal muscle contractions	Coordinated by medullary swallowing center	
Coughing reflex (Chapter 23)		Irritation of respiratory tract	Sudden explosive ejection of air	Coordinated by medullary coughing center	
Baroreceptor reflex (Chapters 17, 20, 21)		Sudden rise in carotid blood pressure	Reduction in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata	
Sexual arousal (Chapter 28)		Erotic stimuli (visual or tactile)	Increased glandular secretions, sensitivity, erection		
SYMPATHETIC REFLEXES					
Cardioacceleratory reflex (Chapter 21)		Sudden decline in blood pressure in carotid artery	Increase in heart rate and force of contraction	Coordinated in cardiac centers of medulla oblongata	
Vasomotor reflexes (Chapter 21)		Changes in blood pressure in major arteries	Changes in diameter of peripheral vessels	Coordinated in vasomotor center in medulla oblongata	
Pupillary reflex (Chapter 17)		Low light level reaching visual receptors	Dilation of pupil		
Ejaculation (in males) (Chapter 28)		Erotic stimuli (tactile)	Skeletal muscle contractions ejecting semen		

Table 16–5	A Compariso	on of the ANS and SNS		
Characteristic		ANS	SNS	
Innervation		Visceral effectors, including cardiac muscle, smooth muscle, glands, fat cells	Skeletal muscles	
Activation		In response to sensory stimuli or from commands of higher centers	In response to sensory stimuli or from commands of higher centers	
Relay and processing centers		Brain stem	Brain stem and thalamus	
Headquarters		Hypothalamus	Cerebral cortex	
Feedback received from		Limbic system and thalamus	Cerebellum and basal nuclei	
Control method		Adjustment of activity in brain stem processing centers that innervate preganglionic neurons	Direct (corticospinal) and indirect (medial and lateral) pathways that innervate lower motor neurons	
Reflexes		Polysynaptic (short and long)	Monosynaptic and polysynaptic (always long)	

thalamus, or cerebral cortex can have dramatic effects on autonomic function. For example, what happens when you become angry? Your heart rate accelerates, your blood pressure rises, and your respiratory rate increases. What happens when you think about your next meal? Your stomach "growls" and your mouth waters.

The Integration of SNS and ANS Activities

Figure 16–10 and Table 16–5 show how the activities of the somatic nervous system (discussed in Chapter 15) and the autonomic nervous system are integrated. We have considered somatic and visceral motor pathways separately, but the two have many parallels, in terms of both organization and function. Integration takes place at the level of the brain stem, and both systems are under the influence of higher centers.

CHECKPOINT

- 15. Define visceral reflex.
- 16. Luke has a brain tumor that is interfering with the function of his hypothalamus. Explain why this tumor would interfere with autonomic function.

See the blue Answers tab at the back of the book.

Figure 16–10 A Comparison of Somatic and Autonomic Function. The SNS and ANS have parallel organization and are integrated at the level of the brain stem. Blue arrows indicate ascending sensory information; red arrows, descending motor commands; dashed lines indicate pathways of communication and feedback among higher centers.

16-8 Higher-order functions include memory and states of consciousness

Learning Outcome Explain how memories are created, stored, and recalled, and distinguish among the levels of consciousness and unconsciousness.

Higher-order functions share three characteristics:

- 1. The cerebral cortex is required for their performance. They involve complex interactions among areas of the cortex and between the cerebral cortex and other areas of the brain.
- 2. They involve both conscious and unconscious information processing.
- **3.** They are not part of the programmed "wiring" of the brain. For this reason, higher-order functions are subject to adjustment over time.

In Chapter 14, we considered functional areas of the cerebral cortex and the regional specializations of the left and right cerebral hemispheres. \bigcirc pp. 486–487 In this section, we consider the mechanisms of memory and learning. We also describe the neural interactions responsible for consciousness, sleep, and arousal.

Memory

What was the topic of the last sentence you read? What is your social security number? What does a hot dog taste like? To answer these questions, you access *memories*, stored bits of information gathered through experience. **Fact memories** are specific bits of information, such as the color of a stop sign or the smell of a perfume. **Skill memories** are learned motor behaviors. You can probably remember how to light a match or open a screw-top jar, for example. With repetition, skill memories become incorporated at the unconscious level. Examples include the complex motor patterns involved in skiing, playing the violin, and similar activities. Skill memories related to programmed behaviors, such as eating, are stored in appropriate portions of the brain stem. Complex skill memories involve the integration of motor patterns in the basal nuclei, cerebral cortex, and cerebellum.

Two classes of memories are recognized. **Short-term memories** do not last long, but while they persist the information can be recalled immediately. Short-term memories contain small bits of information, such as a person's name or a telephone number. Repeating a phone number or other bit of information reinforces the original short-term memory and helps to make sure it gets converted to a long-term memory.

Long-term memories last much longer, in some cases for an entire lifetime. The conversion from short-term to long-term memory is called **memory consolidation**. There are two types of long-term memory: (1) *Secondary memories* are long-term memories that fade with time and may require considerable effort to recall. (2) *Tertiary memories* are long-term memories that are with you for a lifetime, such as your name or the contours of your own body. Relationships among these memory classes are diagrammed in **Figure 16–11**.

Figure 16–11 Memory Storage. Steps in the storage of memories and the conversion from short-term memory to long-term memory.

Brain Regions Involved in Memory Consolidation and Access

The amygdaloid body (amygdala) and the hippocampus, two components of the limbic system (Figure 14–12, p. 481), are essential to memory consolidation. Damage to the hippocampus leads to an inability to convert short-term memories to new longterm memories, although existing long-term memories remain intact and accessible. Tracts leading from the amygdaloid body to the hypothalamus may link memories to specific emotions.

The **nucleus basalis**, a cerebral nucleus near the diencephalon, plays an uncertain role in memory storage and retrieval. Tracts connect this nucleus with the hippocampus, amygdaloid body, and all areas of the cerebral

cortex. Damage to this nucleus is associated with changes in emotional states, memory, and intellectual function (as we will see in the discussion of Alzheimer's disease later in this chapter).

Most long-term memories are stored in the cerebral cortex. Conscious motor and sensory memories are referred to the appropriate association areas. For example, visual memories are stored in the visual association area, and memories of voluntary motor activity are stored in the premotor cortex. Special portions of the occipital and temporal lobes are crucial to the memories of faces, voices, and words.

In at least some cases, a specific memory probably depends on the activity of a single neuron. For example, in one portion of the temporal lobe an individual neuron responds to the sound of one word and ignores others. A specific neuron may also be activated by the proper combination of sensory stimuli associated with a particular individual, such as your grandmother. As a result, these neurons are called "grandmother cells."

Information on one subject is parceled out to many different regions of the brain. Your memories of cows are stored in the visual association area (what a cow looks like, that the letters *c-o-w* mean "cow"), the auditory association area (the "moo" sound and how the word *cow* sounds), the speech center (how to say the word *cow*), and the frontal lobes (how big cows are, what they eat). Related information, such as how you feel about cows and what milk tastes like, is stored in other locations. If one of those storage areas is damaged, your memory will be incomplete in some way. How these memories are accessed and assembled on demand remains a mystery.

Cellular Mechanisms of Memory Formation and Storage

Memory consolidation at the cellular level involves anatomical and physiological changes in neurons and synapses. For legal, ethical, and practical reasons, scientists do not conduct much research on these mechanisms with human subjects. Research on other animals, commonly those with relatively simple nervous systems, has indicated that the following mechanisms may be involved:

- *Increased Neurotransmitter Release*. A synapse that is frequently active increases the amount of neurotransmitter it stores, and it releases more with each stimulation. The more neurotransmitter released, the greater the effect on the postsynaptic neuron.
- *Facilitation at Synapses.* When a neural circuit is repeatedly activated, the axon terminals begin continuously releasing neurotransmitter in small quantities. The neurotransmitter binds to receptors on the postsynaptic membrane, producing a graded depolarization that brings the membrane closer to threshold. The facilitation that results affects all neurons in the circuit.
- *The Formation of Additional Synaptic Connections*. Evidence indicates that when one neuron repeatedly communicates with another, the axon tip branches and forms additional synapses on the postsynaptic neuron. As a result, the presynaptic neuron has a greater effect on the membrane potential of the postsynaptic neuron.

These processes create anatomical changes that facilitate communication along a specific neural circuit. This facilitated

Clinical Note

Amnesia Amnesia is the loss of memory as a result of trauma or disease. The type of memory loss depends on the specific regions of the brain affected. For example, damage to the auditory association areas can make it difficult to remember sounds. Recovery may be partial or complete. In *retrograde amnesia (retro-*, behind), the person loses memories of events that occurred before the trauma or the onset of the disease. Some degree of retrograde amnesia commonly follows a head injury. After a fall or a car wreck, many victims are unable to remember the moments preceding the accident. In *anterograde amnesia (antero-*, ahead), a person is unable to store additional memories, but earlier memories remain intact and accessible. The problem appears to involve an inability to generate long-term memories. Some degree of anterograde amnesia is a common sign of senility, a condition discussed

further on p. 557. At least two drugs—*diazepam (Valium)* and *triazolam (Halcion)*—have been known to cause brief periods of anterograde amnesia. Brain injuries can cause more prolonged memory problems. A person with permanent anterograde amnesia lives in surroundings that are always new. The person can read magazines, chuckle over them, and reread them a few minutes later with equal pleasure. Clinicians must introduce themselves at every meeting, even if they have been treating the patient for years.

In *post-traumatic amnesia (PTA)*, a head injury produces a combination of retrograde and anterograde amnesias. The individual can neither remember the past nor consolidate memories of the present. The extent and duration of the amnesia varies with the severity of the injury. communication is thought to be the basis of memory storage. A single circuit that corresponds to a single memory has been called a **memory engram**. This definition is based on function rather than structure. We know too little about the organization and storage of memories to be able to describe the neural circuits involved. Memory engrams form as the result of experience and repetition. Repetition is crucial—that's why you probably need to read these chapters more than once before an exam.

Efficient conversion of a short-term memory into a memory engram takes time, usually at least an hour. Whether that conversion will occur depends on several factors. They include the nature, intensity, and frequency of the original stimulus. Very strong, repeated, or exceedingly pleasant or unpleasant events are most likely to be converted to long-term memories. Drugs that stimulate the CNS, such as caffeine and nicotine, may enhance memory consolidation through facilitation. We discussed the membrane effects of those drugs in Chapter 12.

D pp. 419, 422

The hippocampus plays a key role in consolidating memories. The mechanism remains unknown, but it is linked to the presence of *NMDA* (N-methyl D-aspartate) *receptors*, which are chemically gated calcium channels. When activated by the neurotransmitter *glutamate*, the gates open and calcium enters the cell. Blocking NMDA receptors in the hippocampus prevents long-term memory formation.

States of Consciousness

The difference between a conscious individual and an unconscious one might seem obvious. A conscious individual is alert and attentive, and an unconscious individual is not. Yet there are many degrees of both states. *Conscious* implies an awareness of and attention to external events and stimuli, but a healthy conscious person can be nearly asleep, wide awake, or highstrung and jumpy. *Unconscious* can refer to conditions ranging from the deep, unresponsive state induced by anesthesia before major surgery, to deep sleep, to the light, drifting "nod" that occasionally plagues students who are reading anatomy and physiology textbooks.

A person's degree of wakefulness at any moment indicates the level of ongoing CNS activity. When you are asleep, you are unconscious but can still be awakened by normal sensory stimuli. Healthy individuals cycle between the alert, conscious state and sleep each day. When CNS function becomes abnormal or depressed, the state of wakefulness can be affected. An individual in a *coma*, for example, is unconscious and cannot be awakened, even by strong stimuli.

Sleep

We recognize two general levels of sleep, each with characteristic patterns of brain wave activity (Figure 16–12a):

a An EEG of the various sleep states. The EEG pattern during REM sleep resembles the alpha waves typical of awake adults.

Typical pattern of sleep stages in a healthy young adult during a single night's sleep.

- 1. In **deep sleep**, also called *slow wave* or *non-REM* (*NREM*) *sleep*, your entire body relaxes, and activity at the cerebral cortex is at a minimum. Heart rate, blood pressure, respiratory rate, and energy use decline by up to 30 percent.
- 2. During **rapid eye movement (REM) sleep**, you dream actively and your blood pressure and respiratory rate change. Although the EEG resembles that of the awake state, you become even less receptive to outside stimuli than in deep sleep, and your muscle tone decreases markedly. Intense inhibition of somatic motor neurons probably prevents you from acting out the responses you envision while dreaming. The neurons controlling your eye muscles escape this inhibitory influence, and your eyes move rapidly as dream events unfold.

Periods of REM and deep sleep alternate throughout the night, beginning with deep sleep for about an hour and a half (Figure 16–12b). Rapid eye movement periods initially average about 5 minutes, but over an eight-hour night they gradually increase to about 20 minutes. Each night we probably spend less than two hours dreaming, but variation among individuals is significant. For example, children spend more time in REM sleep than do adults, and extremely tired individuals have very short and infrequent REM periods.

Sleep produces only minor changes in the physiological activities of other organs and systems, and none of these changes appear to be essential to normal function. The significance of sleep must lie in its impact on the CNS, but the physiological or biochemical basis remains to be determined. We do know that protein synthesis in neurons increases during sleep.

Extended periods without sleep lead to a variety of disturbances in mental function. Roughly 25 percent of the U.S. population experiences some form of *sleep disorder*. Examples include abnormal patterns or duration of REM sleep or unusual

Categorizing Nervous System Disorders Neural tissue is extremely delicate. The characteristics of its extracellular environment must be kept within narrow homeostatic limits. Signs and symptoms of neurological disorders appear when homeostatic regulatory mechanisms break down. This may happen under the stress of genetic or environmental factors, infection, or trauma.

Literally hundreds of disorders affect the nervous system. They can be categorized as:

- Infections, which include diseases such as rabies, meningitis, and polio
- Congenital disorders, such as spina bifida and hydrocephalus
- Degenerative disorders, such as Parkinson's disease and Alzheimer's disease
- Tumors of neural origin
- Trauma, such as spinal cord injuries and concussions
- Toxins, such as heavy metals and the neurotoxins found in certain seafoods
- Secondary disorders, which are problems resulting from dysfunction in other systems, for example, strokes and several demyelination disorders

A standard physical examination includes a neurological component. The physician checks the general status of the CNS and PNS. In *neurological examinations*, a physician attempts to trace the location of a specific problem by evaluating the sensory, motor, behavioral, and cognitive functions of the nervous system. behaviors during sleep, such as sleepwalking. In some cases, these problems affect the individual's conscious activities. Slowed reaction times, irritability, and behavioral changes may result. Memory loss has also been linked to sleep disorders.

Arousal and the Reticular Activating System

Arousal, or awakening from sleep, appears to be one of the functions of the reticular formation. The reticular formation is especially well suited for providing "watchdog" services, because it has extensive interconnections with the sensory, motor, and integrative nuclei and pathways all along the brain stem.

Your state of consciousness results from complex interactions between the reticular formation and the cerebral cortex. One of the most important brain stem components is a diffuse network in the reticular formation known as the **reticular activating system (RAS)**. ⊃ p. 476 This network extends from the medulla oblongata to the midbrain (Figure 16–13). The output of the RAS projects to thalamic nuclei that influence large areas of the cerebral cortex. When the RAS is inactive, so is the cerebral cortex, and stimulation of the RAS produces a widespread activation of the cerebral cortex.

The midbrain portion of the RAS appears to be the "headquarters" of the system. Stimulating this area produces the most pronounced and long-lasting effects on the cerebral cortex. Stimulating other portions of the RAS seems to have an effect only to the degree that it changes the activity of the midbrain

Figure 16–13 The Reticular Activating System. The midbrain "headquarters" of the reticular formation receives collateral inputs from a variety of sensory pathways. Stimulation of this region produces arousal and heightened states of attentiveness.

region. The greater the stimulation to the midbrain region of the RAS, the more alert and attentive the individual will be to incoming sensory information. The thalamic nuclei associated with the RAS may also play an important role in focusing attention on specific mental processes.

Sleep may be ended by any stimulus sufficient to activate the reticular formation and RAS. Arousal occurs rapidly, but the effects of a single stimulation of the RAS last less than a minute. After that, consciousness can be maintained by positive feedback, because activity in the cerebral cortex, basal nuclei, and sensory and motor pathways will continue to stimulate the RAS.

After many hours of activity, the reticular formation becomes less responsive to stimulation. You become less alert and more lethargic. The precise mechanism remains unknown, but neural fatigue probably plays a relatively minor role in the decreasing RAS activity. Evidence suggests that the regulation of sleep–wake cycles involves an interplay between brain stem nuclei that use different neurotransmitters. One group of nuclei stimulates the RAS with norepinephrine and maintains the awake, alert state. Another group depresses RAS activity with serotonin, promoting deep sleep. These "dueling" nuclei are located in the brain stem.

CHECKPOINT

- 17. List three characteristics of higher-order functions.
- 18. As you recall facts while you take your A&P test, which type of memory are you using?
- **19**. Name the two general levels of sleep that have characteristic patterns of brain wave activity.
- 20. You are asleep. What would happen if your reticular activating system (RAS) were suddenly stimulated?

See the blue Answers tab at the back of the book.

16-9 Neurotransmitters influence brain chemistry and behavior

Learning Outcome Describe some of the ways in which the interactions of neurotransmitters influence brain function.

Changes in the normal balance between two or more neurotransmitters can profoundly affect brain function. Recall from the previous section that the interplay between populations of neurons releasing norepinephrine and serotonin appears to be involved in regulating sleep–wake cycles. Another example concerns *Huntington's disease*. The primary problem in this inherited disease is the destruction of ACh-secreting and GABA-secreting neurons in the basal nuclei. The reason for this destruction is unknown. Symptoms appear as the basal nuclei and frontal lobes slowly degenerate. An individual with

Huntington's disease has difficulty controlling movements, and intellectual abilities gradually decline. In many cases, the importance of a specific neurotransmitter was revealed while searching for the mechanism of action for other drugs. Three examples follow.

- 1. It is now clear that an extensive network of tracts delivers serotonin to nuclei and higher centers throughout the brain, and variations in serotonin levels affect sensory interpretation and emotional states. Compounds that enhance the effects of serotonin produce hallucinations. For instance, lysergic acid diethylamide (LSD) is a powerful hallucinogenic drug that activates serotonin receptors in the brain stem, hypothalamus, and limbic system. Compounds that merely enhance the effects of serotonin also produce hallucinations, whereas compounds that inhibit serotonin production or block its action cause severe depression and anxiety. An effective antidepressive drug now in widespread use, fluoxetine (Prozac), slows the removal of serotonin at synapses, causing an increase in serotonin concentrations at the postsynaptic membrane. Such drugs are classified as selective serotonin reuptake inhibitors (SSRIs). Other important SSRIs include Celexa, Luvox, Paxil, and Zoloft.
- 2. Norepinephrine is another important neurotransmitter with pathways throughout the brain. Drugs that stimulate NE release cause exhilaration, and those that depress NE release cause depression. One inherited form of depression has been linked to a defective enzyme involved in NE synthesis.
- 3. Disturbances in dopamine transmission have been linked to several neurological disorders. We have already seen that inadequate dopamine causes the motor problems of Parkinson's disease. ⊃ p. 486 Excessive production of dopamine may be associated with *schizophrenia*, a psychological disorder marked by pronounced disturbances of mood, thought patterns, and behavior. Amphetamines, or "speed," stimulate dopamine secretion and, in large doses, can produce symptoms resembling those of schizophrenia. Dopamine is thus important not only in the nuclei involved in the control of intentional movements, but in many other centers of the diencephalon and cerebrum.

- CHECKPOINT

- **21**. What would be an effect of a drug that substantially increases the amount of serotonin released in the brain?
- **22**. Identify the neurotransmitters thought to be involved with the regulation of sleep-wake cycles.
- **23**. Amphetamines stimulate the secretion of which neurotransmitter?
- See the blue Answers tab at the back of the book.

16–10 Aging produces various structural and functional changes in the nervous system

Learning Outcome Summarize the effects of aging on the nervous system and give examples of interactions between the nervous system and other organ systems.

The aging process affects all body systems, and the nervous system is no exception. Anatomical and physiological changes probably begin by age 30 and accumulate over time. An estimated 85 percent of people above age 65 lead relatively normal lives, but they exhibit noticeable changes in mental performance and in CNS function. Common age-related anatomical changes in the nervous system include the following:

- A *Reduction in Brain Size and Weight.* This reduction results primarily from a decrease in the volume of the cerebral cortex. The brains of elderly individuals have narrower gyri and wider sulci than do those of young people, and the subarachnoid space is larger.
- A *Reduction in the Number of Neurons*. Brain shrinkage has been linked to a loss of cortical neurons, although evidence indicates that neurons are not lost (at least to the same degree) in brain stem nuclei.
- A Decrease in Blood Flow to the Brain. With age, fatty deposits gradually build up in the walls of blood vessels. Just as

a clog in a drain reduces water flow, these deposits reduce the rate of blood flow through arteries. (This process, called *arteriosclerosis*, affects arteries throughout the body, as we discuss further in Chapter 21.) Even if the reduction in blood flow is not large enough to damage neurons, arteriosclerosis increases the chances that the affected vessel wall will rupture, damaging the surrounding neural tissue and producing signs and symptoms of a *cerebrovascular accident* (*CVA*), also called a stroke.

- *Changes in the Synaptic Organization of the Brain.* In many areas, the number of dendritic branches, spines, and interconnections appears to decrease. Synaptic connections are lost, and the rate of neurotransmitter production declines.
- Intracellular and Extracellular Changes in CNS Neurons. Many neurons in the brain accumulate abnormal intracellular deposits, including lipofuscin and neurofibrillary tangles. Lipofuscin is a granular pigment with no known function. Neurofibrillary tangles are masses of neurofibrils that form dense mats inside the cell body and axon. Plaques are extracellular accumulations of fibrillar proteins, surrounded by abnormal dendrites and axons. Both plaques and tangles contain deposits of several peptides—primarily two forms of amyloid β (Aβ) protein, fibrillar and soluble. They appear in brain regions such as the hippocampus, specifically associated with memory

Alzheimer's Disease Alzheimer's disease (AD) is a progressive disorder characterized by the loss of higher-order cerebral functions. It is the most common cause of senility. Symptoms may appear at 50–60 years of age or later, although the disease occasionally affects younger people. Alzheimer's disease has widespread impact. An estimated 5.2 million people in the United States—including about 11 percent of those over age 65, and 38 percent over age 85—have some form of the condition. It causes approximately 100,000 deaths each year.

The link is uncertain, but microscopic examination of the brain shows abnormal plaques and neurofibrillary tangles in regions involved with memory, emotions, and intellectual function. It is still unknown whether these deposits cause AD or are secondary signs of ongoing metabolic alterations with an environmental, hereditary, or infectious basis.

Genetic factors certainly play a major role. The late-onset form of AD has been traced to a gene on chromosome 19

that codes for proteins involved in cholesterol transport. Fewer than 5 percent of people with Alzheimer's disease have the early-onset form, which may develop before age 50. This form of AD has been linked to genes on chromosomes 1, 14, 19, and 21. Interestingly, the majority of individuals with *Down's syndrome* develop AD relatively early in life. (Down's syndrome results from an extra copy of chromosome 21. We discuss this condition further in Chapter 29.)

There is no cure for Alzheimer's disease. A few medications and supplements slow its progress in many patients. Diagnosis involves excluding metabolic disorders, chemical/ drug interactions, nutritional deficiencies, and anatomical conditions that can mimic dementia; taking a detailed history and doing a thorough physical exam; and evaluating mental function and mood (depression may mimic dementia).

The Nervous System

The nervous system is closely integrated with other body systems. Every moment of your life, billions of neurons in your nervous system are exchanging information across trillions of synapses and performing the most complex integrative functions in the body. As part of this process, the nervous system monitors all other systems and issues commands that adjust their activities. However, the significance and impact of these commands varies greatly from one system to another. The normal functions of the muscular system, for example, simply cannot be performed without instructions from the nervous system. By contrast, the cardiovascular system is relatively independent—the nervous system merely coordinates and adjusts cardiovascular activities to meet the circulatory demands of other systems. In the final analysis, the nervous system is like the conductor of an orchestra, directing the rhythm and balancing the performances of each section to produce a symphony, instead of simply a very loud noise.

Figure 16–14 diagrams the functional relationships between the nervous system and other body systems we have studied so far.

processing. Their significance is unknown. Evidence indicates that they appear in all aging brains. In excess, they seem to be associated with clinical abnormalities.

The anatomical changes associated with aging of the nervous system affect all neural functions. For example, memory consolidation typically becomes more difficult, and secondary memories, especially those of the recent past, become harder to access. The sensory systems of elderly people—notably, hearing, balance, vision, smell, and taste—become less sensitive. Lights must be brighter, sounds louder, and smells stronger before they are perceived. Reaction rates are slowed, and reflexes—even some withdrawal reflexes—weaken or disappear. The precision of motor control decreases, and it takes longer for an elderly person to perform a given motor pattern than it did 20 years earlier.

For roughly 85 percent of the elderly population, these changes do not interfere with their abilities to function in society. But for reasons yet unknown, some elderly individuals become incapacitated by progressive CNS changes. These degenerative changes, which can include memory loss, anterograde amnesia, and emotional disturbances, are often lumped together as *senile dementia*, or **senility**. By far the most common and disabling form of senile dementia is Alzheimer's disease. The relationships between the nervous system and the integumentary, skeletal, and muscular systems are shown in Figure 16–14.

CHECKPOINT

- 24. Memory retrieval deteriorates with aging. What are some possible reasons for these changes?
- **25**. Identify several common age-related anatomical changes in the nervous system.
- 26. Name the most common form of senile dementia.
- **27**. Identify the relationships between the nervous system and the body systems studied so far.

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **alpha₁-receptor agonists:** Drugs used to treat hypotension (low-blood pressure) by stimulating α_1 receptors to cause vasoconstriction of blood vessels.
- **alpha₂-receptor agonists:** Drugs used to treat hypertension (high blood pressure) by stimulating α_2 adrenergic receptors to inhibit sympathetic vasomotor centers.
- **beta-adrenergic blockers:** Drugs that decrease heart rate and force of contraction, lowering peripheral blood pressure by acting on beta adrenergic receptors to diminish the effects of epinephrine.

parasympathetic blocking agents: Drugs that target the muscarinic receptors at neuromuscular or neuroglandular junctions.

parasympathomimetic drugs: Drugs that mimic parasympathetic stimulation and increase the activity along the digestive tract.

- **sympathetic blocking agents:** Drugs that bind to receptor sites, preventing a normal response to neurotransmitters or sympathomimetic drugs.
- **sympathomimetic drugs:** Drugs that mimic the effects of sympathetic stimulation.

- An Introduction to the Autonomic Nervous System and Higher-Order Functions p. 532
 - 1. The autonomic nervous system (ANS) adjusts our basic life support systems without conscious control.
- 16-1 The autonomic nervous system is involved in the unconscious regulation of visceral functions and has sympathetic and parasympathetic divisions p. 532
- 2. The **autonomic nervous system (ANS)** coordinates cardiovascular, respiratory, digestive, urinary, and reproductive functions.
- **3. Preganglionic neurons** in the CNS send axons to synapse on **ganglionic neurons** in **autonomic ganglia** outside the CNS. (*Figure 16–1*)

4. Preganglionic fibers from the thoracic and lumbar segments form the **sympathetic division**, or *thoracolumbar division* ("fight or flight" system), of the ANS. Preganglionic fibers leaving the brain and sacral segments form the **parasympathetic division**, or *craniosacral division* ("rest and digest" system) (*Spotlight Figure 16–2*).

16-2 The sympathetic division consists of preganglionic neurons and ganglionic neurons involved in using energy and increasing metabolic rate p. 536

- 5. The sympathetic division consists of preganglionic neurons between segments T_1 and L_2 , ganglionic neurons in ganglia near the vertebral column, and specialized neurons in the adrenal glands. (*Spotlight Figure 16–2*)
- 6. The two types of sympathetic ganglia are **sympathetic chain ganglia** (*paravertebral ganglia*) and **collateral ganglia** (*prevertebral ganglia*). (*Figure 16–3*)
- 7. In spinal segments T_1-L_2 , ventral roots give rise to the myelinated white ramus, which, in turn, leads to the sympathetic chain ganglia. (*Figures 16–3, 16–4*)
- 8. **Postganglionic fibers** targeting structures in the body wall and limbs rejoin the spinal nerves and reach their destinations by way of the dorsal and ventral rami. (*Figures 16–3, 16–4*)
- 9. Postganglionic fibers targeting structures in the thoracic cavity form **sympathetic nerves**, which go directly to their visceral destinations. Preganglionic fibers run between the sympathetic chain ganglia and interconnect them. (*Figures 16–3, 16–4*)
- 10. The abdominopelvic viscera receive sympathetic innervation by preganglionic fibers that synapse within collateral ganglia. The preganglionic fibers that innervate the collateral ganglia form the **splanchnic nerves**. (*Figures 16–3, 16–4*)
- 11. The **celiac ganglion** innervates the stomach, liver, gallbladder, pancreas, and spleen; the **superior mesenteric ganglion** innervates the small intestine and initial segments of the large intestine; and the **inferior mesenteric ganglion** innervates the kidneys, urinary bladder, the terminal portions of the large intestine, and the sex organs. (*Figures* 16–4, 16–8)
- **12.** Preganglionic fibers entering an adrenal gland synapse within the **adrenal medulla**. (*Figures* 16–3, 16–4)
- 13. In a crisis, the entire sympathetic division responds—an event called **sympathetic activation**. Its effects include increased alertness, a feeling of energy and euphoria, increased cardiovascular and respiratory activities, a general elevation in muscle tone, and a mobilization of energy reserves.

16-3 Stimulation of sympathetic neurons leads to the release of various neurotransmitters p.540

- 14. The stimulation of the sympathetic division has two distinctive results: the release of either ACh or *norepinephrine (NE)* at specific locations, and the secretion of *epinephrine (E)* and NE into the general circulation.
- 15. Sympathetic ganglionic neurons end in telodendria studded with **varicosities** containing neurotransmitters. (*Figure 16–5*)
- **16.** The two types of sympathetic receptors are **alpha receptors** and **beta receptors**.
- **17.** Most postganglionic fibers are *adrenergic*; a few are *cholinergic* or *nitroxidergic*. (*Table 16–1*)
- **18.** The sympathetic division includes two sympathetic chain ganglia, three collateral ganglia, and two adrenal medullae. (*Figure 16–7; Tables 16–2, 16–3*)

- **16-4** The parasympathetic division consists of preganglionic neurons and ganglionic neurons involved in conserving energy and lowering metabolic rate p. 542
- The parasympathetic division includes preganglionic neurons in the brain stem and sacral segments of the spinal cord, and ganglionic neurons in peripheral ganglia located within (intramural) or next to (terminal) target organs. (*Spotlight Figure 16–2*)
- **20.** Preganglionic fibers leave the brain as components of cranial nerves III, VII, IX, and X. Those leaving the sacral segments form **pelvic nerves**. (*Figure 16–6*)
- **21.** The effects produced by the parasympathetic division center on relaxation, food processing, and energy absorption.

16-5 Stimulation of parasympathetic neurons leads to the release of the neurotransmitter ACh p. 542

- 22. All parasympathetic preganglionic and postganglionic fibers release ACh. The effects are short-lived, because ACh is inactivated by *acetylcholinesterase (AChE)* and by *tissue cholinesterase*. (*Figure 16–7*)
- **23.** Postsynaptic membranes have two types of ACh receptors. The stimulation of **muscarinic receptors** produces a longerlasting effect than does the stimulation of **nicotinic receptors**. (*Table 16–1*)
- 24. The parasympathetic division innervates areas serviced by cranial nerves and organs in the thoracic and abdominopelvic cavities. (*Figure 16–6*)

16-6 The sympathetic and parasympathetic divisions interact, creating dual innervation p. 544

- **25.** The sympathetic division has widespread influence on visceral and somatic structures.
- **26.** The parasympathetic division innervates only visceral structures that are serviced by cranial nerves or lying within the abdominopelvic cavity. Organs with dual innervation receive input from both divisions. (*Tables 16–2, 16–3*)
- 27. The parasympathetic and sympathetic nerves intermingle in the thoracic and abdominopelvic cavities to form a series of characteristic *autonomic plexuses* (nerve networks): the **cardiac**, **pulmonary**, **esophageal**, **celiac**, **inferior mesenteric**, and **hypogastric plexuses**. (*Figure 16–8*)
- **28.** Important physiological and functional differences exist between the sympathetic and parasympathetic divisions. (*Figure 16–7; Tables 16–2, 16–3*)
- **29.** Even when stimuli are absent, autonomic motor neurons show a resting level of activation, the **autonomic tone**.

16-7 Visceral reflexes play a role in the integration and control of autonomic functions p. 545

- **30. Visceral reflex arcs** perform the simplest function of the ANS, and can be either **long reflexes** (with interneurons) or **short reflexes** (bypassing the CNS). (*Figure 16–9*)
- **31.** Parasympathetic reflexes govern respiration, cardiovascular functions, and other visceral activities. (*Table 16–4*)
- **32.** Levels of activity in the sympathetic and parasympathetic divisions of the ANS are controlled by centers in the brain stem that regulate specific visceral functions.
- **33.** The SNS and ANS are organized in parallel. Integration occurs at the level of the brain stem and higher centers. (*Figure 16–10; Table 16–5*)

16-9 Neurotransmitters influence brain chemistry and

40. Changes in the normal balance between two or more neu-

rotransmitters can profoundly affect brain function.

neurons, a decrease in blood flow to the brain, changes in the

synaptic organization of the brain, and intracellular and extra-

commands that adjust their activities. The efficiency of these

changes in the nervous system p. 557

16-8 Higher-order functions include memory and states of consciousness p. 552

- 34. Higher-order functions (1) are performed by the cerebral cortex and involve complex interactions among areas of the cerebral cortex and between the cortex and other areas of the brain, (2) involve conscious and unconscious information processing, and (3) are subject to modification and adjustment over time.
- 35. Memories can be classified as **short term** or **long term**.
- **36.** The conversion from short-term to long-term memory is **memory consolidation**. (*Figure 16–11*)
- 37. Amnesia is the loss of memory as a result of disease or trauma.
- In deep sleep (*slow wave* or *non-REM sleep*), the body relaxes and cerebral cortex activity is low. In rapid eye movement (REM) sleep, active dreaming occurs. (*Figure 16–12*)
- **39.** The **reticular activating system (RAS)**, a network in the reticular formation, is most important to arousal and the maintenance of consciousness. (*Figure 16–13*)

Review Questions

cellular changes in CNS neurons.

behavior p. 556

LEVEL 1 Reviewing Facts and Terms

 The preganglionic and ganglionic neurons are missing from the diagram below showing the distribution of sympathetic innervation. Indicate their distribution using red for the preganglionic neurons and black for the ganglionic neurons.

The autonomic division of the nervous system directs (a) voluntary motor activity, (b) conscious control of skeletal muscles, (c) unconscious control of skeletal muscles, (d) processes that maintain homeostasis, (e) sensory input from the skin.

The division of the autonomic nervous system that prepares the body for activity and stress is the ______ division. (a) sympathetic, (b) parasympathetic, (c) craniosacral, (d) intramural, (e) somatomotor.

See the blue Answers tab at the back of the book.

- Effects produced by the parasympathetic branch of the autonomic nervous system include (a) dilation of the pupils, (b) increased secretion by digestive glands, (c) dilation of respiratory passages, (d) increased heart rate, (e) increased breakdown of glycogen by the liver.
- A progressive disorder characterized by the loss of higher-order cerebral functions is (a) Parkinson's disease, (b) parasomnia, (c) Huntington's disease, (d) Alzheimer's disease.
- 6. Starting in the spinal cord, trace an impulse through the sympathetic division of the ANS until it reaches a target organ in the abdominopelvic region.
- 7. Which four ganglia serve as origins for postganglionic fibers involved in control of visceral structures in the head?
- 8. What are the components of a visceral reflex arc?
- 9. What cellular mechanisms identified in animal studies are thought to be involved in memory formation and storage?
- **10**. What physiological activities distinguish non-REM sleep from REM sleep?
- 11. What anatomical and functional changes in the brain are linked to alterations that occur with aging?
- 12. All preganglionic autonomic fibers release ______ at their axon terminals, and the effects are always ______. (a) norepinephrine, inhibitory, (b) norepinephrine, excitatory, (c) acetylcholine, excitatory, (d) acetylcholine, inhibitory.
- The neurotransmitter at all synapses and neuromuscular or neuroglandular junctions in the parasympathetic division of the ANS is
 (a) epinephrine, (b) norepinephrine, (c) cyclic-AMP, (d) acetylcholine.
- 14. How does the emergence of sympathetic fibers from the spinal cord differ from the emergence of parasympathetic fibers?
- **15.** Which three collateral ganglia serve as origins for ganglionic neurons that innervate organs or tissues in the abdominopelvic region?
- **16.** What two distinctive results are produced by the stimulation of sympathetic ganglionic neurons?
- 17. Which four pairs of cranial nerves are associated with the cranial segment of the parasympathetic division of the ANS?
- 18. Which six plexuses in the thoracic and abdominopelvic cavities innervate visceral organs, and what are the effects of sympathetic versus parasympathetic stimulation?
- 19. What three characteristics are shared by higher-order functions?

LEVEL 2 Reviewing Concepts

- 20. Dual innervation refers to situations in which (a) vital organs receive instructions from both sympathetic and parasympathetic fibers,
 (b) the atria and ventricles of the heart receive autonomic stimulation from the same nerves, (c) sympathetic and parasympathetic fibers have similar effects, (d) a, b, and c are correct.
- Damage to the hippocampus, a component of the limbic system, leads to (a) a loss of emotion due to forgetfulness, (b) a loss of consciousness, (c) a loss of long-term memory, (d) an immediate loss of short-term memory.
- **22.** Why does sympathetic function remain intact even when the ventral roots of the cervical spinal nerves are damaged?
- 23. During sympathetic stimulation, a person may begin to feel "on edge"; this is the result of (a) increased energy metabolism by muscle tissue, (b) increased cardiovascular activity, (c) stimulation of the reticular activating system, (d) temporary insensitivity to painful stimuli, (e) decreased levels of epinephrine in the blood.
- 24. Under which of the following circumstances would the diameter of peripheral blood vessels be greatest? (a) increased sympathetic stimulation, (b) decreased sympathetic stimulation, (c) increased parasympathetic stimulation, (e) both increased parasympathetic and sympathetic stimulation.
- **25.** A possible side effect of a drug used to open the airways of some one suffering from an asthma attack is (a) decreased activity of the

digestive system, (b) diarrhea, (c) profuse urination, (d) increased blood pressure, (e) decreased heart rate.

- **26.** You are home alone at night when you hear what sounds like breaking glass. What physiological effects would this experience probably produce, and what would be their cause?
- 27. Why is autonomic tone a significant part of ANS function?
- **28.** Nicotine stimulates cholinergic receptors of the ANS. Based on this information, how would cigarette smoking affect the cardiovascular system?
- **29.** The condition known as shock is characterized in part by a decreased return of venous blood to the heart. How could an upsetting situation, such as the sight of a tragic accident or very bad news, produce some temporary symptoms of shock?

LEVEL 3 Critical Thinking and Clinical Applications

- **30.** Phil is stung on his cheek by a wasp. Because Phil is allergic to wasp venom, his throat begins to swell and his respiratory passages constrict. Would acetylcholine or epinephrine be more helpful in relieving his condition? Why?
- **31.** While studying the activity of smooth muscle in blood vessels, Shelly discovers that, when applied to a muscle plasma membrane, a molecule chemically similar to a neurotransmitter triggers an increase in intracellular calcium ions. Which neurotransmitter is the molecule mimicking, and to which receptors is it binding?

CLINICAL CASE Wrap-Up

The First Day in Anatomy Lab

Tim has suffered a vasovagal (*vaso,* vascular; *vagal,* vagus nerve) loss of consciousness, commonly

known as fainting. Environmental triggers, including the smell of the anatomy lab and the sight of the cadaver, caused a momentary malfunction of his autonomic nervous system (ANS). The sympathetic division of the ANS, sometimes called the "fight or flight" division, failed him. The parasympathetic division of the ANS, sometimes called the "rest and digest" or "faint and freeze" division, went into overdrive.

Parasympathetic stimulation of the vagus nerve caused it to release ACh at the cardiac plexus. Meanwhile, there was no counteracting stimulation from the sympathetic nervous system. This caused Tim's heart rate to slow, the force of contractions to decrease, and his blood pressure to drop. As a result, blood flow to the brain decreased, causing the fainting episode. If the brain does not get enough blood, it shuts down quickly. Tim's rapid recovery begins as soon as the sympathetic division of the ANS takes over. Norepinephrine is released at the cardiac plexus and throughout the body. His heart rate and blood pressure increase, as does his level of consciousness.

"Don't worry, Tim," says his instructor. "Everybody is allowed one fainting episode. And everybody can overcome this. Next time just lie down before you fall down."

- 1. Why would the instructor tell Tim to lie down, or want him to get his head below his heart, the next time he feels faint?
- 2. In addition to the cardiac plexus, where else in the body would the sympathetic nervous system act during Tim's recovery?

See the blue Answers tab at the back of the book.

The Special Senses

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- 17-1 Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination.
- 17-2 Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination.
- 17-3 Identify the internal and accessory structures of the eye, and explain the functions of each.
- **17-4** Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain.
- 17-5 Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain.

Clinical Notes

- Diabetic Retinopathy p. 574
- Detached Retina p. 574
- Glaucoma p. 577
- Motion Sickness p. 593

SPOTLIGHTS

- Olfaction and Gustation pp. 566–567
- Refractive Problems p. 582
- Photoreception pp. 584–585

CLINICAL CASE

• A Chance to See p. 564

CLINICAL CASE

A Chance to See

Makena is a 12-year-old Kenyan girl living with her family in a small village in sub-Saharan Africa.

Their village is miles away from roads, electricity, and health care. Her family is very poor, and lives on less than \$1.25 per day. Makena's daily chores include walking two hours to collect water, every morning before school and again after school. Water is so precious in this part of the world that nobody in Makena's village has ever taken a shower.

Makena is a bright girl, but she does not do well in school. She can't see the chalkboard in her classroom. She can't see the soccer ball when she tries to play with her classmates. She even has trouble seeing the path that leads to the dry riverbed where she collects water from a deep hole. She has no idea that other people can see these things better.

No one in Makena's village wears eyeglasses, and most do not even know what they are. Makena's teacher, however, studied at the University of Nairobi and knows that glasses can correct vision problems.

The teacher thinks perhaps nearsightedness is a problem for Makena. Can a desperately poor child, many miles away from health care of any kind, obtain glasses to correct her poor vision? To find out, turn to the Clinical Case Wrap-Up on p. 607.

An Introduction to the Special Senses

Our knowledge of the world around us is limited to those characteristics that stimulate our sensory receptors. We may not realize it, but our picture of the environment is incomplete. Colors we cannot see guide insects to flowers. Sounds we cannot hear and smells we cannot detect give dolphins, dogs, and cats key information about their surroundings.

What we *do* perceive varies considerably with the state of our nervous system. For example, during sympathetic activation, you experience a heightened awareness of sensory information. You hear sounds that normally you would not notice. Yet, when concentrating on a difficult problem, you may be unaware of fairly loud noises.

Finally, our perception of any stimulus reflects activity in the cerebral cortex, but that activity can be inappropriate. In cases of phantom limb pain, for example, a person feels pain in a missing limb. During an epileptic seizure, a person may experience sights, sounds, or smells that have no physical basis.

In our discussion of the general senses and sensory pathways in Chapter 15, we introduced basic principles of receptor function and sensory processing. We now turn to the five *special senses*: olfaction (smell), gustation (taste), vision, equilibrium (balance), and hearing. The sense organs involved are structurally more complex than those of the general senses, but the same basic principles of receptor function apply. ATLAS: Embryology Summary 13: The Development of Special Sense Organs

17-1 Olfaction, the sense of smell, involves olfactory receptors responding to chemical stimuli

Learning Outcome Describe the sensory organs of smell, trace the olfactory pathways to their destinations in the brain, and explain the physiological basis of olfactory discrimination.

The sense of smell, called *olfaction*, is made possible by paired **olfactory organs**. These organs are located in the nasal cavity on either side of the nasal septum (Figure 17–1a). The olfactory organs are made up of two layers: the olfactory epithelium and the lamina propria.

The **olfactory epithelium** contains the **olfactory receptor cells**, supporting cells, and regenerative **basal cells** (*stem cells*) (Figure 17–1b). This epithelium covers the inferior surface of the cribriform plate, the superior portion of the perpendicular plate, and the superior nasal conchae of the ethmoid. \bigcirc p. 218

The second layer, the underlying lamina propria, consists of areolar tissue, numerous blood vessels, and nerves. This layer also contains **olfactory glands**. Their secretions absorb water and form thick, pigmented mucus.

What happens when you inhale through your nose? The air swirls within your nasal cavity. This turbulence brings airborne compounds to your olfactory organs. A normal, relaxed inhalation carries a small sample (about 2 percent) of the inhaled air to the olfactory organs. If you sniff repeatedly, you increase the flow of air across the olfactory epithelium, increasing the stimulation of the olfactory receptors. However, only the molecules of water-soluble and lipid-soluble materials that can diffuse into the overlying mucus can stimulate those receptors.

Olfactory Receptors

Olfactory receptor cells are highly modified neurons. The exposed tip of each receptor cell forms a prominent knob that projects beyond the epithelial surface (Figure 17–1b). The knob is a base for up to 20 cilia-shaped dendrites that extend into the surrounding mucus. These dendrites lie parallel to the epithelial surface, exposing their considerable surface area to dissolved compounds called *odorants*. Olfactory reception begins

Figure 17–1 The Olfactory Organs.

with the binding of an odorant to a G protein-coupled receptor in the plasma membrane of an olfactory receptor cell dendrite (Spotlight Figure 17–2).

Between 10 and 20 million olfactory receptors fill an area of roughly 5 cm² (0.8 in.²). If we take into account the exposed dendritic surfaces, the actual sensory area probably approaches that of the entire body surface. Yet, our olfactory sensitivities cannot compare with those of other vertebrates such as dogs, cats, or fishes. A German shepherd dog sniffing for smuggled drugs or explosives has an olfactory receptor surface 72 times greater than that of the nearby customs inspector!

Olfactory Pathways

The olfactory system is very sensitive. However, the activation of an afferent fiber does not guarantee an awareness of the stimulus. Considerable convergence takes place along the olfactory pathway, and inhibition at the intervening synapses can prevent the sensations from reaching the *olfactory cortex* of the cerebral hemispheres. \bigcirc **p.** 487 The olfactory receptors themselves adapt very little to an ongoing stimulus. Rather, central adaptation ensures that you quickly lose awareness of a new smell but remain sensitive to others.

Axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid bone to reach the *olfactory bulbs* of the cerebrum, where the first synapse occurs (Figure 17–1). Efferent fibers from nuclei elsewhere in the brain also innervate neurons of the olfactory bulbs. This arrangement provides a mechanism for central adaptation or facilitation of olfactory sensitivity. Axons leaving the olfactory bulb travel along the olfactory tract to the olfactory cortex, the hypothalamus, and portions of the limbic system.

Olfactory stimulation is the only type of sensory information that reaches the cerebral cortex directly. All other sensations are relayed from processing centers in the thalamus. Certain smells can trigger profound emotional and behavioral responses, as well as the memories, due to the parallel distribution of olfactory information to the limbic system and hypothalamus. The perfume industry understands the practical implications of these connections and works to develop odors that trigger sexual responses.

Olfactory Discrimination

The human olfactory system can make subtle distinctions among 2000–4000 chemical stimuli. No apparent structural differences exist among the olfactory receptor cells, but the epithelium as a whole contains receptor populations with distinct sensitivities. At least 50 "primary smells" are known. It is almost impossible to describe these sensory impressions

SPOTLIGHT Figure 17–2 Olfaction and Gustation

Olfaction and gustation are special senses that give us vital information about our

environment. Although the sensory information is diverse and complex, each special sense originates at receptor cells that may be neurons or specialized receptor cells that communicate with

sensory neurons.

FACTION

Olfactory receptors are the dendrites of specialized neurons. When dissolved chemicals contact the dendritic processes, there is a depolarization, called a generator potential. This graph shows the action potentials produced by a generator potential.

Stimulus removed Action potentials +30 0 ž Stimulus Threshold -60 -70 Generator potential 0 Time (msec) –

The receptors for the senses of taste, vision, equilibrium, and hearing are specialized cells that have unexcitable membranes and form synapses with the processes of sensory neurons. When stimulated, the membrane of the receptor cell undergoes a graded depolarization that triggers the release of chemical transmitters at the synapse. These transmitters then depolarize the sensory neuron, creating a generator potential and action potentials that are propagated to the CNS. Because a synapse is involved, there is a slight synaptic delay. However, this arrangement permits modification of the sensitivity of the receptor cell by presynaptic facilitation or inhibition.

Olfactory reception occurs on the surface membranes of the olfactory dendrites. **Odorants**—dissolved chemicals that stimulate olfactory receptors—interact with receptors called odorant-binding proteins on the membrane surface.

In general, odorants are small organic molecules. The strongest smells are associated with molecules of either high water or high lipid solubilities. As few as four odorant molecules can activate an olfactory receptor.

Some 90 percent of the gustatory receptor cells respond to two or more different taste stimuli. The different tastes involve different receptor mechanisms. A salty stimulus involves the diffusion of Na⁺ ions through a sodium ion leak channel common in epithelial cells. Stimuli for a sour or acidic taste include H⁺ ions that diffuse through the same epithelial Na⁺ channel. The intracellular increase in cations leads to depolarization and neurotransmitter release. Sweet, bitter, and umami stimuli bind to specific G protein-coupled receptors. The resulting multiple chemical pathways lead to depolarization and neurotransmitter release.

Salt and Sour Channels

The diffusion of sodium ions from salt solutions or hydrogen ions from acids or sour solutions into the receptor cell leads to depolarization.

Depolarization of membrane stimulates release of chemical neurotransmitters.

Sweet, Bitter, and Umami Receptors

Receptors responding to stimuli that produce sweet, bitter, and umami sensations are linked to G proteins called **gustducins** (GUST-doosinz)—protein complexes that use second messengers to produce their effects.

release of chemical neurotransmitters.

effectively. It appears likely that the CNS interprets each smell on the basis of the overall pattern of receptor activity.

The human olfactory organs can discriminate among many smells, but acuity varies widely, depending on the nature of the odorant. We detect many odorants in amazingly small concentrations. One example is mercaptan, an odorant commonly added to natural gas, propane, and butane, which are otherwise odorless. Because we can smell mercaptan in extremely low concentrations (a few parts per billion), its addition enables us to detect a gas leak almost at once and take steps to prevent an explosion.

The olfactory receptor population undergoes considerable turnover. Basal cells in the epithelium divide and differentiate to produce new receptor cells. This turnover is one of the few examples of neuronal replacement in adult humans. Despite this process, the total number of receptors declines with age, and those that remain become less sensitive. As a result, elderly people have difficulty detecting odors in low concentrations. This decline in the number of receptors accounts for Grandma's tendency to use too much perfume and explains why Grandpa's aftershave seems so strong: They must apply more to be able to smell it.

CHECKPOINT

- 1. Define olfaction.
- 2. Trace the olfactory pathway, beginning at the olfactory epithelium.
- 3. When you first enter the A&P lab for dissection, you are very aware of the odor of preservatives. By the end of the lab period, the smell doesn't seem to be nearly as strong. Why?

See the blue Answers tab at the back of the book.

17-2 Gustation, the sense of taste, involves taste receptors responding to chemical stimuli

Learning Outcome Describe the sensory organs of taste, trace the gustatory pathways to their destinations in the brain, and explain the physiological basis of gustatory discrimination.

Gustation, or taste, provides information about the foods and liquids we eat and drink. **Taste receptors**, or *gustatory* (GUS-tator- \bar{e}) *receptors*, are distributed over the superior surface of the tongue and adjacent portions of the pharynx and larynx. The most important taste receptors are on the tongue. By the time we reach adulthood, the taste receptors on the pharynx, larynx, and epiglottis have decreased in number. Taste receptors and specialized epithelial cells form sensory structures called **taste buds**. An adult has about 10,000 taste buds.

The surface of the tongue has numerous variously shaped epithelial projections called *lingual papillae* (pa-PIL-ē; *papilla*, a

nipple-shaped mound). The human tongue has four types of lingual papillae (Figure 17–3b,c): (1) filiform (*filum*, thread) **papillae**, (2) fungiform (*fungus*, mushroom) **papillae**, (3) **vallate** (VAL-āt; *vallum*, wall) **papillae**, and (4) foliate (FŌ-lē-āt) **papillae**.

The distribution of these lingual papillae varies by region. Filiform papillae provide friction that helps the tongue move objects around in the mouth, but do not contain taste buds. Each small fungiform papilla contains about five taste buds. There are up to 12 vallate papillae that form a V near the posterior margin of the tongue. Each large vallate papilla contains as many as 100 taste buds. The foliate papillae are folds found on the lateral margins of the posterior tongue.

Taste Receptors

Taste buds are recessed into the surrounding epithelium, isolated from the unprocessed contents of the mouth. Each taste bud contains about 40–100 receptor cells and many small stem cells, called basal cells (Figure 17–3b,c). The basal cells continually divide to produce daughter cells that mature in stages. The cells of the last stage are called **gustatory receptor cells**. Cells at all three stages—basal, transitional, and mature—are innervated by sensory neurons. Each gustatory receptor cell extends microvilli, sometimes called *taste hairs*, into the surrounding fluids through the **taste pore**, a narrow opening. Despite this relatively protected position, it's still a hard life: A typical gustatory receptor cell survives for only about 10 days before it is replaced.

Gustatory Pathways

Taste buds are innervated by cranial nerves VII (facial), IX (glossopharyngeal), and X (vagus). The facial nerve innervates all the taste buds located on the anterior two-thirds of the tongue, from the tip to the line of vallate papillae. The glossopharyngeal nerve innervates the vallate papillae and the posterior one-third of the tongue. The vagus nerve innervates taste buds scattered on the surface of the epiglottis.

The sensory afferent fibers carried by these cranial nerves synapse in the solitary nucleus of the medulla oblongata. The axons of the postsynaptic neurons then enter the medial lemniscus. There, the neurons join axons that carry somatic sensory information on touch, pressure, and proprioception. After another synapse in the thalamus, the information is projected to the appropriate portions of the gustatory cortex of the insula.

You have a conscious perception of taste as the brain correlates information received from the taste buds with other sensory data. Information about the texture of food, along with taste-related sensations such as "peppery" or "burning hot," comes from sensory afferents in the trigeminal cranial nerve (V).

In addition, the level of stimulation from the olfactory receptors plays an overwhelming role in taste perception. The combination of taste and smell is what provides the *flavor*, or

17

Figure 17–3 Gustatory Receptors.

b The structure and representative locations of the four types of lingual papillae. Taste receptors are located in taste buds, which form pockets in the epithelium of fungiform, foliate, and vallate papillae.

distinctive quality of a particular food or drink. You are several thousand times more sensitive to "tastes" when your olfactory organs are fully functional. By contrast, when you have a cold and your nose is stuffed up, airborne molecules cannot reach your olfactory receptors, so meals taste dull and unappealing. The reduction in flavor takes place even though the taste buds may be responding normally. Without accompanying olfactory sensations, you are now limited to the basic taste sensations provided by your gustatory receptors.

Gustatory Discrimination

You are probably already familiar with the four **primary taste sensations**: sweet, salty, sour, and bitter. There is some evidence for differences in sensitivity to tastes along the axis of the tongue, with greatest sensitivity to salty–sweet anteriorly and sour–bitter posteriorly. However, there are no differences

in the structure of the taste buds. Taste buds in all portions of the tongue provide all four primary taste sensations.

Humans have two additional taste sensations that are less widely known:

- Umami. Umami (oo-MAH-mē, derived from Japanese meaning "deliciousness") is a pleasant, savory taste corresponding to the flavor of beef broth, chicken broth, and Parmesan cheese. Umami is due to the presence of free glutamates (an amino acid) in food. The distribution of these receptors is not known in detail, but they are present in taste buds of the vallate papillae.
- Water. Most people say that water has no flavor. However, research on humans and other vertebrates has demonstrated the presence of water receptors, especially in the pharynx. The sensory output of these receptors is processed in the hypothalamus and affects several systems that affect

water balance and the regulation of blood volume. For example, minor reductions in the secretion of antidiuretic hormone (a hormone that regulates urination) occur each time you take a long drink.

Gustation reception is described in **Spotlight Figure 17–2**. The threshold for receptor stimulation varies for each of the primary taste sensations. Also, the taste receptors respond more readily to unpleasant than to pleasant stimuli. For example, we are almost a thousand times more sensitive to acids, which taste sour, than to either sweet or salty chemicals. We are a hundred times more sensitive to bitter compounds than to acids. This sensitivity has survival value, because acids can damage the mucous membranes of the mouth and pharynx, and many potent biological toxins have an extremely bitter taste.

Taste sensitivity differs significantly among individuals. Many conditions related to taste sensitivity are inherited. The best-known example involves sensitivity to the compound *phenylthiocarbamide* (PTC). This substance tastes bitter to some people, but is tasteless to others. PTC is not found in foods, but compounds related to PTC are found in Brussels sprouts, broccoli, cabbage, and cauliflower.

Our tasting abilities change with age. Many elderly people find that their food tastes bland and unappetizing, while children tend to find the same foods too spicy. What accounts for these differences?

We begin life with more than 10,000 taste buds, but the number begins declining dramatically by age 50. The sensory loss becomes especially significant because, as we have already noted, older individuals also experience a decline in the number of olfactory receptors.

- CHECKPOINT

- 4. Define gustation.
- 5. If you completely dry the surface of your tongue and then place salt or sugar crystals on it, you can't taste them. Why not?
- 6. Your grandfather can't understand why foods he used to enjoy just don't taste the same anymore. How would you explain this to him?

See the blue Answers tab at the back of the book.

17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection

Learning Outcome Identify the internal and accessory structures of the eye, and explain the functions of each.

We rely more on vision than on any other special sense. Our eyes contain our visual receptors. The eyes are elaborate structures that enable us not only to detect light, but also to create detailed visual images. We begin our discussion of these fascinating organs with the *accessory structures* of the eye, which provide protection, lubrication, and support.

Accessory Structures of the Eye

The **accessory structures** of the eye include the eyelids and the superficial epithelium of the eye, as well as the structures involved with the production, secretion, and removal of tears. **Figure 17–4** shows the superficial anatomy of the eye and its accessory structures.

Eyelids and Superficial Epithelium of the Eye

The eyelids, or **palpebrae** (pal-PĒ-brē), are a continuation of the skin. Their continual blinking keeps the surface of the eye lubricated. They also act like windshield wipers, removing dust and debris. The eyelids can also close firmly to protect the delicate surface of the eye.

The **palpebral fissure** is the gap that separates the free margins of the upper and lower eyelids. The two eyelids are connected, however, at the **medial canthus** (KAN-thus) and the **lateral canthus** (Figure 17–4a). The **eyelashes**, along the margins of the eyelids, are very robust hairs. They help prevent foreign matter (including insects) from reaching the surface of the eye.

The eyelashes are associated with unusually large sebaceous glands. Along the inner margin of the lid are small, modified sebaceous glands called **tarsal glands**, or *Meibomian* (mī-BŌ-mē-an) *glands*. They secrete a lipid-rich product that helps keep the eyelids from sticking together. At the medial canthus, the **lacrimal caruncle** (KAR-ung-kul), a mass of soft tissue, contains glands producing the thick secretions that contribute to the gritty deposits that sometimes appear after a good night's sleep.

Bacteria occasionally invade and infect these various glands. A *chalazion* (kah-LĀ-zē-on; small lump) is a cyst that results from an infection of a tarsal gland. An infection in a sebaceous gland associated with an eyelash produces a painful localized swelling known as a *sty*.

The skin covering the visible surface of the eyelid is very thin. Deep to the skin lie the muscle fibers of the *orbicularis oculi* and *levator palpebrae superioris muscles.* \bigcirc p. 347 These skeletal muscles close the eyelids and raise the upper eyelid, respectively.

The epithelium covering the inner surfaces of the eyelids and the outer surface of the eyeball is called the **conjunctiva** (kon-junk-TĪ-vuh). It is a mucous membrane covered by a specialized stratified squamous epithelium. The **palpebral conjunctiva** covers the inner surface of the eyelids. The **ocular conjunctiva**, or *bulbar conjunctiva*, covers the anterior surface of the eye (Figure 17–4b).

b The organization of the lacrimal apparatus

The ocular conjunctiva extends to the edges of the **cornea** (KOR-nē-uh), a transparent part of the outer fibrous layer of the eye. The cornea is covered by a very delicate squamous *corneal epithelium*, five to seven cells thick, that is continuous with the ocular conjunctiva. A constant supply of fluid washes over the surface of the eyeball, keeping the ocular conjunctiva and cornea moist and clean. Mucous cells in the epithelium assist the accessory glands in lubricating the surfaces of the conjunctiva to prevent drying out and friction.

Conjunctivitis, or *pinkeye*, is an inflammation of the conjunctiva. The most obvious sign, redness, is due to the dilation of blood vessels deep to the conjunctival epithelium. This condition may be caused by pathogenic infection or by physical, allergic, or chemical irritation of the conjunctival surface.

The Lacrimal Apparatus

A constant flow of tears keeps conjunctival surfaces moist and clean. Tears reduce friction, remove debris, prevent bacterial infection, and provide nutrients and oxygen to portions of the conjunctival epithelium. The **lacrimal apparatus** produces, distributes, and removes tears. The lacrimal apparatus of each eye consists of (1) a *lacrimal gland* with associated ducts,

(2) paired *lacrimal canaliculi*, (3) a *lacrimal sac*, and (4) a *naso-lacrimal duct* (Figure 17–4b).

The **fornix** of the eye is a pocket created where the palpebral conjunctiva becomes continuous with the ocular conjunctiva (**Figure 17–5a**). The lateral portion of the superior fornix receives 10–12 ducts from the **lacrimal gland**, or tear gland (**Figure 17–4b**). This gland is about the size and shape of an almond, measuring roughly 12–20 mm (0.5–0.75 in.). It nestles within a depression in the frontal bone, just inside the orbit and superior and lateral to the eyeball. ⁽⁺⁾ p. 215

The lacrimal gland normally provides the key ingredients and most of the volume of the tears that bathe the conjunctival surfaces. The lacrimal secretions supply nutrients and oxygen to the corneal cells by diffusion. The lacrimal secretions are watery and slightly alkaline. They contain the antibacterial enzyme **lysozyme** and antibodies that attack pathogens before they enter the body.

The lacrimal gland produces about 1 mL of tears each day. Once the lacrimal secretions have reached the ocular surface, they mix with the products of accessory glands and the oily secretions of the tarsal glands. The result is a superficial "oil slick" that aids lubrication and slows evaporation.

572 UNIT 3 Control and Regulation

Figure 17–5 The Sectional Anatomy of the Eye. ATLAS: Plates 12a; 16a,b

17

Blinking sweeps the tears across the ocular surface. Tears accumulate at the medial canthus in an area known as the *lacrimal lake*, or "lake of tears." The lacrimal lake covers the lacrimal caruncle, which bulges anteriorly. The **lacrimal puncta** (singular, *punctum*), two small pores, drain the lacrimal lake. They empty into the **lacrimal canaliculi**, small canals that in turn lead to the **lacrimal sac**, which nestles within the lacrimal sulcus of the orbit (Figure 17–4b). \supset p. 221

From the inferior portion of the lacrimal sac, the **nasolacrimal duct** passes through the *nasolacrimal canal*, formed by the lacrimal bone and the maxilla. This duct delivers tears to the nasal cavity on that side. The duct empties into the *inferior meatus*, a narrow passageway inferior and lateral to the inferior nasal concha. When a person cries, tears rushing into the nasal cavity produce a runny nose. If the lacrimal puncta can't provide enough drainage, the lacrimal lake overflows and tears stream across the face.

The Eye

Your eyes are extremely sophisticated visual instruments. They are more versatile and adaptable than the most expensive cameras, yet compact and durable. Each eye is a slightly irregular spheroid, a little smaller than a Ping-Pong ball. An eye has an average diameter of 24 mm (almost 1 inch) and a weight of about 8 g (0.28 oz). Within the orbit, the eyeball shares space with the extrinsic eye muscles, the lacrimal gland, and the cranial nerves and blood vessels that supply the eye and adjacent portions of the orbit and face. **Orbital fat** cushions and insulates the eye (Figures 17–4b and 17–5c).

The wall of the eye has three distinct layers, formerly called tunics (Figure 17–5b): (1) an outer *fibrous layer*, (2) an intermediate *vascular layer (uvea)*, and (3) a deep *inner layer (retina)*. The visual receptors, or *photoreceptors*, are located in the inner layer.

The eyeball itself is hollow and filled with fluid. Its interior can be divided into two cavities, anterior and posterior (Figure 17–5c). The **anterior cavity** has two chambers, the **anterior chamber** (between the cornea and the colored portion known as the iris) and the **posterior chamber** (between the iris and the lens). A clear, watery fluid called *aqueous humor* fills the entire anterior cavity. The **posterior cavity**, or *vitreous chamber*, contains a gelatinous substance called the *vitreous body*. The fluid part of this body is *vitreous humor*. The vitreous body and the aqueous humor help to stabilize the shape of the eye.

The Fibrous Layer

The **fibrous layer**, the outermost layer of the eye, consists of the *sclera* (SKLER-uh) and the *cornea*. The fibrous layer (1) supports and protects, (2) serves as an attachment site for the

extrinsic eye muscles, and (3) contains structures that assist in focusing.

The **sclera**, or "white of the eye," covers most of the ocular surface (Figure 17–5b,c). The sclera consists of a dense fibrous connective tissue containing both collagen and elastic fibers. This layer is thickest over the posterior surface of the eye, near the exit of the optic nerve. The sclera is thinnest over the anterior surface. The six extrinsic eye muscles insert on the sclera, blending their collagen fibers with those of the fibrous layer. **D p**. 344

The surface of the sclera contains small blood vessels and nerves that penetrate the sclera to reach internal structures. The network of small vessels interior to the ocular conjunctiva generally does not carry enough blood to lend an obvious color to the sclera. On close inspection, however, the vessels are visible as red lines against the white background of collagen fibers.

The transparent cornea is structurally continuous with the sclera. The border between the two is called the **corneal limbus** (Figures 17–4a and 17–5a,c). Deep to the delicate corneal epithelium, the cornea consists primarily of a dense matrix containing multiple layers of collagen fibers, organized so as not to interfere with the passage of light. The cornea has no blood vessels. Its superficial epithelial cells obtain oxygen and nutrients by diffusion from the tears that flow across their free surfaces. The cornea also has numerous free nerve endings, making it the most sensitive portion of the eye.

Damage to the cornea may cause blindness even though the functional components of the eye—including the photoreceptors are perfectly normal. The cornea has a very restricted ability to repair itself. For this reason, corneal injuries must be treated immediately to prevent serious vision losses.

Restoring vision after corneal scarring generally requires replacing the cornea through a corneal transplant. Corneal replacement is probably the most common form of transplant surgery. Such transplants can be performed between unrelated individuals, because there are no blood vessels to carry white blood cells, which attack foreign tissues, into the area. Corneal grafts are obtained from donor eyes. For best results, the tissues must be removed within five hours after the donor's death.

The Vascular Layer

The **vascular layer**, or **uvea** (Ū-vē-uh), is a pigmented region that includes the iris, ciliary body, and choroid (**Figure 17–5b,c**). It contains numerous blood vessels, lymphatic vessels, and the intrinsic (smooth) muscles of the eye. This middle layer (1) provides a route for blood vessels and lymphatics that supply tissues of the eye; (2) regulates the amount of light that enters the eye; (3) secretes and reabsorbs the aqueous humor that circulates within the chambers of the eye; and (4) controls the shape of the lens, an essential part of the focusing process.

Clinical Note

Diabetic Retinopathy A retinopathy is a disease of the retina. **Diabetic retinopathy** develops in many people with diabetes mellitus, an endocrine disorder that interferes with glucose metabolism. Diabetes affects many systems, but serious cardiovascular problems are particularly common. Diabetic retinopathy develops over years. It results from the blockage of small retinal blood vessels, followed by excessive growth of abnormal blood vessels. These blood vessels invade the retina (inner layer) and extend into the space between its two parts—the outer pigmented part and the inner neural part. Visual acuity is gradually lost through damage to photoreceptors (which are deprived of oxygen and nutrients), leakage of blood into the posterior cavity, and the overgrowth of blood vessels. Laser therapy can seal leaking vessels and block new vessel growth. The posterior cavity can be drained and the cloudy fluid replaced by a suitably clear substitute. This procedure is called a vitrectomy. These are only temporary, imperfect fixes. Diabetic retinopathy is a leading cause of blindness in the United States.

The Iris. The **iris** is visible through the transparent corneal surface. The iris contains blood vessels, pigment cells, and two layers of smooth muscle fibers called *pupillary muscles*. When these muscles contract, they change the diameter of the **pupil**, the central opening of the iris. There are two types of pupillary muscles: dilators and constrictors (Figure 17–6).

Clinical Note

Detached Retina Photoreceptors depend entirely on the diffusion of oxygen and nutrients from blood vessels in the choroid. In a **detached retina**, the neural part of the retina becomes separated from the pigmented part. This condition can result from a variety of factors, including a sudden hard impact to the eye. Unless the two parts of the inner layer (retina) are reattached, the photoreceptors will degenerate and vision will be lost. Reattachment involves "welding" the two parts together using laser beams focused through the cornea. These beams heat the two parts, fusing them together at several points around the retina. However, the procedure destroys the photoreceptors and other cells at the "welds," producing permanent blind spots.

The autonomic nervous system controls both muscle groups. For example, parasympathetic activation in response to bright light causes the pupils to constrict (the *consensual light reflex*). Sympathetic activation in response to dim light causes the pupils to dilate. \bigcirc p. 545

The body of the iris consists of highly vascular, pigmented, loose connective tissue. The anterior surface has no epithelial covering. Instead, it has an incomplete layer of fibroblasts and melanocytes. Melanocytes are also scattered within the body of the iris. The posterior surface is covered by a pigmented epithelium that is part of the inner layer and contains melanin granules.

Figure 17–6 The Pupillary Muscles.

How is eye color determined? Our genes influence the density and distribution of melanocytes on the anterior surface and interior of the iris, as well as the density of the pigmented epithelium. When the connective tissue of the iris contains few melanocytes, light passes through it and bounces off the pigmented epithelium. The eye then appears blue. Individuals with green, brown, or black eyes have increasing numbers of melanocytes in the body and on the surface of the iris. The eyes of people with albinism, whose cells do not produce melanin, appear a very pale gray or blue-gray.

The Ciliary Body. At its periphery, the iris attaches to the anterior portion of the **ciliary body**, a thickened region that begins deep to the junction between the cornea and the sclera. The ciliary body extends posteriorly to the level of the **ora serrata** (\overline{O} -ra ser-RA-tuh; serrated mouth), the serrated anterior edge of the thick, neural part of the inner layer, or retina (**Figure 17–5a,c**). The bulk of the ciliary body consists of the **ciliary muscle**, a ring of smooth muscle that projects into the interior of the eye. The epithelium covering this muscle has numerous folds called **ciliary processes**. The **ciliary zonule** (*suspensory ligament*) is the ring of fibers that attaches the lens to the ciliary processes. The connective tissue fibers hold the lens in place posterior to the iris and centered on the pupil. As a result, any light passing through the pupil also passes through the lens.

The Choroid. The **choroid** is a vascular layer that separates the fibrous layer and the inner layer posterior to the ora serrata (**Figure 17–5c**). The choroid is covered by the sclera and attached to the outermost layer of the retina. An extensive capillary network in the choroid delivers oxygen and nutrients to the retina. The choroid also contains melanocytes, which are especially numerous near the sclera.

The Inner Layer

The **inner layer**, or **retina**, is the innermost layer of the eye. It consists of a thin, outer layer called the *pigmented part*, and a thick, inner layer called the *neural part*. The pigmented part of the retina absorbs light that passes through the neural part, preventing light from bouncing back through the neural part and producing visual "echoes." The pigment cells also have important biochemical interactions with the retina's light receptors, which are located in the neural part of the retina. In addition to light receptors, the neural part of the retina contains supporting cells and neurons that do preliminary processing and integration of visual information.

The two layers of the retina are normally very close together, but not tightly interconnected. The pigmented part of the retina continues over the ciliary body and iris, but the neural part extends anteriorly only as far as the ora serrata. The neural part of the retina forms a cup that establishes the posterior and lateral boundaries of the posterior cavity (Figure 17–5b,c).

Organization of the Retina. In sectional view, the neural part of the retina contains several layers of cells (Figure 17–7a). The outermost layer, closest to the pigmented part of the retina, contains the **photoreceptors**, the cells that detect light.

The eve has two main types of photoreceptors: rods and cones. Rods do not discriminate among colors of light. Highly sensitive to light, they enable us to see in dimly lit rooms, at twilight, and in pale moonlight. Cones give us color vision. We have three types of cones, and each type contains a different visual pigment: red, green, and blue. A person who sees these three primary colors has normal color vision and thus is referred to as a *trichromat* (*tri-*, three + *chroma*, color). Their stimulation in various combinations enables us to perceive different colors. Cones give us sharper, clearer images than rods do, but cones require more intense light. If you sit outside at sunset with your textbook open to a colorful illustration, you can detect the gradual shift in your visual system from conebased vision (a clear image in full color) to rod-based vision (a relatively grainy image in black and white). A third type of photoreceptor is the intrinsically photosensitive retinal ganglion cell (ipRGC). The photopigment in the ipRGC is melanopsin. These cells are known to respond to different levels of brightness and influence the body's 24-hour circadian rhythm (biological clock).

TIPS&TRICKS

Associate the "r" in **r**od with the "r" in da**r**k, and associate the "c" in **c**ones with the "c" in **c**olor and in a**c**uity.

Rods and cones are not evenly distributed across the retina. Approximately 125 million rods form a broad band around the periphery of the retina. As you move away from the periphery, toward the center of the retina, the density of rods gradually decreases. In contrast, most of the roughly 6 million cones are concentrated in the area where a visual image arrives after it passes through the cornea and lens. This region, known as the macula (MAK-ū-luh; spot), has no rods. The very highest concentration of cones occurs at the center of the macula, an area called the **fovea centralis** (FO-vē-uh; shallow depression). It is usually simply referred to as the **fovea** (Figure 17–7c). The fovea is the site of sharpest vision. When you look directly at an object, its image falls on this portion of the retina. An imaginary line drawn from the center of that object through the center of the lens to the fovea establishes the visual axis of the eye (Figure 17–5c).

What are some of the visual consequences of this distribution of photoreceptors? When you look directly at an object, you are placing its image on the fovea, the center of color vision. You see a very good image as long as there is enough light to stimulate the cones. But in very dim light, cones cannot function. That is why you can't see a dim star if you stare directly at it,

but you can see it if you shift your gaze to one side or the other. Shifting your gaze moves the image of the star from the fovea, where it does not provide enough light to stimulate the cones, to the periphery, where it can affect the more sensitive rods.

Rods and cones synapse with about 6 million neurons called **bipolar cells** (Figure 17–7a). These cells in turn synapse within the layer of neurons called **ganglion cells**, which lie

adjacent to the posterior cavity. A network of **horizontal cells** extends across the neural part of the retina at the level of the synapses between photoreceptors and bipolar cells. A comparable layer of **amacrine** (AM-a-krin) **cells** occurs where bipolar cells synapse with ganglion cells. Horizontal and amacrine cells can facilitate or inhibit communication between photoreceptors and ganglion cells, altering the sensitivity of the retina.

These cells play an important role in the eye's adjustment to dim or brightly lit environments.

The Optic Disc. Axons from an estimated 1 million ganglion cells converge on the **optic disc**, a circular region just medial to the fovea. The optic disc is the origin of the optic nerve (N II). From this point, the axons turn, penetrate the wall of the eve, and proceed toward the diencephalon (Figure 17–7b). The central retinal artery and central retinal vein, which supply the retina, pass through the center of the optic nerve and emerge on the surface of the optic disc (Figure 17–7b,c). The optic disc has no photoreceptors or other structures typical of the rest of the retina. The optic disc is commonly called the **blind spot** because light striking this area goes unnoticed. Why don't you see a blank spot in your field of vision? The reason is that involuntary eye movements keep the visual image moving and allow your brain to fill in the missing information. However, try the simple activity in Figure 17-8 to prove that a blind spot really exists in your field of vision.

The Chambers of the Eye

Recall that the ciliary body and lens divide the interior of the eye into a large posterior cavity and a smaller anterior cavity made up of anterior and posterior chambers (Figure 17–5c). Both chambers are filled with the fluid *aqueous humor*. The posterior cavity also contains aqueous humor, but a gelatinous substance known as the *vitreous body* takes up most of its volume.

Aqueous Humor. Aqueous humor is a fluid that circulates within the anterior cavity. It passes from the posterior chamber to the anterior chamber through the pupil (Figure 17–9). It also freely diffuses through the posterior cavity and across the

Figure 17–8 A Demonstration of the Presence of a Blind

Spot. Close your left eye and stare at the plus sign with your right eye, keeping the plus sign in the center of your field of vision. Begin with the page a few inches away from your eye, and gradually increase the distance. The dot will disappear when its image falls on the blind spot, at your optic disc. To check the blind spot in your left eye, close your right eye and repeat the sequence while you stare at the dot.

surface of the retina. Its composition resembles that of cerebrospinal fluid.

Aqueous humor forms through active secretion by epithelial cells of the ciliary body's ciliary processes. The epithelial cells regulate its composition. Because aqueous humor circulates, it provides an important route for nutrient and waste transport. It also serves as a fluid cushion.

The eye is filled with fluid, and fluid pressure provided by the aqueous humor helps retain the eye's shape. Fluid pressure also stabilizes the position of the retina, pressing the neural part against the pigmented part. In effect, the aqueous humor acts like the air inside a balloon.

The eye's **intraocular pressure** can be measured in the anterior chamber, where the fluid pushes against the inner surface of the cornea. Intraocular pressure is most often checked by applanation tonometry. This procedure involves placing a small, flat disk on the anesthetized cornea to measure the tension. Normal intraocular pressure ranges from 12 to 21 mm Hg.

Aqueous humor is secreted into the posterior chamber at a rate of 1–2 mL per minute. It leaves the anterior chamber at the same rate. After filtering through a network of connective tissues located near the base of the iris, aqueous humor enters the **scleral venous sinus** (*canal of Schlemm*), a passageway that

Clinical Note

Glaucoma If aqueous humor cannot drain into the scleral venous sinus, intraocular pressure rises due to the continued production of aqueous humor, and **glaucoma** results. The sclera is a fibrous coat, so it cannot expand like an inflating balloon, but it does have one weak point—the optic disc, where the optic nerve penetrates the wall of the eye. Gradually the increasing pressure pushes the optic nerve outward, damaging its nerve fibers. When intraocular pressures have risen to roughly twice normal levels, the distortion of the optic nerve fibers begins to interfere with the propagation of action potentials, and peripheral vision begins to deteriorate. If this condition is not corrected, tunnel vision and then complete blindness may result.

Glaucoma affects about 2 percent of people over age 35. In most cases, the primary factors responsible cannot be determined. Glaucoma is a relatively common condition, with more than 2 million cases in the United States alone. For this reason, most eye exams include a test of intraocular pressure. Glaucoma may be treated by the topical application of drugs that constrict the pupil and tense the edge of the iris, making the surface more permeable to aqueous humor. Surgical correction involves perforating the wall of the anterior chamber to encourage drainage. This procedure is now performed by laser surgery on an outpatient basis.

Figure 17–9 The Circulation of Aqueous Humor. Aqueous humor, which is secreted at the ciliary body, circulates through the posterior and anterior chambers before it is reabsorbed through the scleral venous sinus.

extends completely around the eye at the level of the corneal limbus. Collecting channels deliver the aqueous humor from this channel to veins in the sclera.

Aqueous humor is removed and recycled within a few hours of its formation. The rate of removal normally keeps pace with the rate of generation at the ciliary processes.

The Vitreous Body. The posterior cavity of the eye contains the **vitreous body**, a gelatinous mass. Its fluid portion is called *vitreous humor*. The vitreous body helps stabilize the shape of the eye. Otherwise, the eye might distort as the extrinsic eye muscles change its position within the orbit. Specialized cells embedded in the vitreous body produce the collagen fibers and proteoglycans that account for the gelatinous consistency of this mass. Unlike the aqueous humor, the vitreous body is formed during development of the eye and is not replaced.

The Lens

The **lens** lies posterior to the cornea and is held in place by the ciliary zonule that originates on the ciliary body of the choroid (Figures 17–5b and 17–9). The primary function of the lens is to focus the visual image on the photoreceptors. The lens does so by changing its shape.

The lens consists of concentric layers of cells that are precisely organized. A dense fibrous capsule covers the entire lens. Many of the capsular fibers are elastic. Unless an outside force is applied, they will contract and make the lens spherical. Around the edges of the lens, these capsular fibers intermingle with those of the ciliary zonule. The cells in the interior of the lens are called **lens fibers**. These highly specialized cells have lost their nuclei and other organelles. They are long and slender and are filled with transparent proteins called **crystallins**. These proteins give the lens both its clarity and its focusing power. Crystallins are extremely stable proteins. They remain intact and functional for a lifetime.

The transparency of the lens depends on the crystallin proteins maintaining a precise combination of structural and biochemical characteristics. Because these proteins are not renewed, any modifications they undergo over time can accumulate and result in the lens losing its transparency. This abnormality is known as a **cataract**. Cataracts can result from injuries, radiation, or reaction to drugs. **Senile cataracts**, however, are a natural consequence of aging and are the most common form.

Over time, the lens turns yellowish and eventually begins to lose its transparency. As the lens becomes "cloudy," the individual needs brighter and brighter light for reading. Visual clarity begins to fade. If the lens becomes completely opaque, the person will be functionally blind, even though the photoreceptors are normal.

Cataract surgery involves removing the lens, either intact or after it has been shattered with high-frequency sound waves. The missing lens is then replaced by an artificial substitute. Vision is then fine-tuned with glasses or contact lenses.

Refraction. The retina has about 130 million photoreceptors. Each one monitors the light striking a specific site on the retina. The processing of information from all the receptors produces a visual image.

The eye is often compared to a camera. To provide useful information, the lens of the eye, like a camera lens, must focus the arriving image. To say that an image is "in focus" means that the rays of light arriving from an object strike the sensitive surface of the retina (or the semiconductor device that records light electronically in digital cameras) in precise order so as to form a miniature image of the object. If the rays are not perfectly focused, the image is blurry. Focusing normally occurs in two steps, as light passes first through the cornea and then the lens.

Light is **refracted**, or bent, when it passes from one medium to another medium with a different density. You can see this effect if you stick a pencil into a glass of water. Notice that the shaft of the pencil appears to bend sharply at the air–water interface. This effect occurs when light is refracted as it passes into the air from the much denser water.

In the human eye, the greatest amount of refraction occurs when light passes from the air into the corneal tissues, which have a density close to that of water. When you open your eyes under water, you cannot see clearly because refraction at the corneal surface has been largely eliminated. Light passes unbent from one watery medium to another.

Additional refraction takes place when the light passes from the aqueous humor into the relatively dense lens. The lens provides the extra refraction needed to focus the light rays from an object toward a **focal point**—a specific point of intersection on the retina.

The distance between the center of the lens and its focal point is the **focal distance** of the lens. Whether in the eye or in a camera, the focal distance is determined by two factors:

- The distance of the object from the lens. The closer an object is to the lens, the greater the focal distance (Figure 17–10a,b).
- The shape of the lens. The rounder the lens, the more refraction occurs. So, a very round lens has a shorter focal distance than a flatter one (Figure 17–10b,c).

Accommodation. Accommodation is the automatic adjustment of the eye to give us clear vision (Figure 17–11). During accommodation, the lens becomes rounder to focus the image

Figure 17–10 Factors Affecting Focal Distance. Light rays from a source are refracted when they reach the lens of the eye. The rays are then focused onto a single focal point.

Figure 17–11 Accommodation. For the eye to form a sharp image, the focal distance must equal the distance between the center of the lens and the retina.

of a nearby object on the retina. The lens becomes flatter to focus the image of a distant object on the retina.

How does the lens change shape? The lens is held in place by the ciliary zonule that originates at the ciliary body. Smooth muscle fibers in the ciliary body act like sphincter muscles. When the ciliary muscle contracts, the ciliary body moves toward the lens, thereby reducing the tension in the ciliary zonule. The elastic capsule then pulls the lens into a rounder shape that increases the refractive (bending) power of the lens. This enables it to bring light from nearby objects into focus on the retina (Figure 17–11a). When the ciliary muscle relaxes, the ciliary zonule pulls at the circumference of the lens, making the lens flatter (Figure 17–11b).

The greatest amount of refraction is required to view objects that are very close to the lens. The inner limit of clear vision, known as the *near point of vision*, is determined by the degree of elasticity in the lens. Children can usually focus on something 7–9 cm (3–4 in.) from the eye, but over time the lens tends to become stiffer and less responsive. A young adult can usually focus on objects 15–20 cm (6–8 in.) away. As we age, this distance gradually increases. The near point at age 60 is typically about 83 cm (33 in.).

If light passing through the cornea and lens is not refracted properly, the visual image will be distorted. In the condition called **astigmatism**, the degree of curvature in the cornea or lens varies from one axis to another. Minor astigmatism is very common. The image distortion may be so minimal that people are unaware of the condition.

Image Reversal. We have been discussing light that originates at a single point, either near or far from the viewer. An object we see is really a complex light source that must be treated as a number of individual points. Light from each point is focused on the retina as in Figure 17–12a,b. The result is a miniature image of the original, but the image arrives upside down and reversed from left to right.

Why does an image arrive upside down? Consider **Figure 17–12c**, a sagittal section through an eye that is looking at a telephone pole. The image of the top of the pole lands at the bottom of the retina, and the image of the bottom hits the top of the retina. Now consider **Figure 17–12d**, a horizontal section through an eye that is looking at a picket fence. The image of the left edge of the fence falls on the right side of the retina, and the image of the retina.

Figure 17–12 Image Formation.

b Light from a point at the bottom of an object is focused on the upper retinal surface.

The brain compensates for this image reversal, so you are not aware of any difference between the orientation of the image on the retina and that of the object. (Note that these illustrations are not drawn to scale because the fovea occupies a small area of the retina, and the projected images are very tiny. As a result, the cross-over of light rays is shown in the lens, but it actually occurs very close to the fovea.)

Visual Acuity. How well you see, or your **visual acuity**, is rated by comparison to a "normal" standard. The standard vision rating of 20/20 is defined as the level of detail seen at a distance of 20 feet by a person with normal vision. That is, a person with a visual acuity of 20/20 sees clearly at 20 feet what should normally be seen at 20 feet. Vision rated as 20/15 is better than average, because at 20 feet the person is able to see details that would be clear to a normal eye only at a distance of 15 feet. Conversely, a person with 20/30 vision must be 20 feet from an object to discern details that a person with normal vision could make out at a distance of 30 feet.

When visual acuity falls below 20/200, even with the help of glasses or contact lenses, the individual is considered to be legally blind. There are probably fewer than 400,000 legally blind people in the United States, and more than half are over 65 years old. The term *blindness* implies a total absence of vision due to damage to the eyes or to the optic pathways. Common causes of blindness include diabetes mellitus, cataracts, glaucoma, corneal scarring, retinal detachment, accidental injuries, and hereditary factors that are still not understood.

An abnormal blind spot, or **scotoma** (skō-TO-muh), may appear in the field of vision at positions other than at the optic disc. A scotoma is permanent and may result from compression of the optic nerve, damage to photoreceptors, or central damage along the visual pathway.

Floaters are small spots that drift across the field of vision. They are generally temporary and result from blood cells or cellular debris in the vitreous body. You may have seen floaters if you have ever stared at a blank wall or a white sheet of paper and noticed these little spots. **Spotlight Figure 17–13** describes common visual abnormalities.

- CHECKPOINT

- 7. Which layer of the eye would be affected first by inadequate tear production?
- 8. When the lens of your eye is more rounded, are you looking at an object that is close to you or far from you?
- 9. As Sue enters a dimly lit room, most of the available light becomes focused on the fovea of her eye. Will she be able to see very clearly?
- 10. How would a blockage of the scleral venous sinus affect your vision?

See the blue Answers tab at the back of the book.

17-4 Photoreceptors respond to light and change it into electrical signals essential to visual physiology

Learning Outcome Explain color and depth perception, describe how light stimulates the production of nerve impulses, and trace the visual pathways to their destinations in the brain.

How does our special sense of vision work? Let's begin to answer this question by examining visual physiology, the way in which photoreceptors function. Then we will consider the structure and function of the visual pathways.

Visual Physiology

The rods and cones of the retina are called *photoreceptors* because they detect *photons*, basic units of visible light. Light energy is a form of *radiant energy* that travels in waves with characteristic *wavelengths* (distances between wave peaks).

Our eyes are sensitive to wavelengths of 700–400 nm, the spectrum of visible light. Remember this spectrum, as seen in a rainbow, with the acronym ROY G. BIV (*Red*, *Orange*, *Yellow*, *Green*, *Blue*, *Indigo*, *Violet*). Photons of red light carry the least energy and have the longest wavelength. Photons from the violet portion of the spectrum contain the most energy and have the shortest wavelength.

Rods provide the central nervous system with information about the presence or absence of photons, with little regard to their wavelength. Cones provide information about the wavelength of arriving photons, giving us the perception of color.

Anatomy of Rods and Cones

Figure 17–14a compares the structures of rods and cones. The names *rod* and *cone* refer to the shape of each photoreceptor's outer segment.

Visual Pigments. Both rods and cones contain special organic compounds called **visual pigments**. These pigments are located in each photoreceptor's outer segment, in flattened membranous plates called *discs*.

The first key step in the process of *photoreception*—the detection of light—is the absorption of photons by visual pigments. Visual pigments are derivatives of the compound **rhodopsin** (rō-DOP-sin), or *visual purple*, the visual pigment found in rods (Figure 17–14b). Rhodopsin consists of a protein, **opsin**, bound to the pigment **retinal** (RET-i-nal), or *retinene*, which is synthesized from **vitamin A**. All rods contain the same form of opsin. Cones contain the same retinal pigment that rods do, but the retinal is attached to different forms of opsin.

We have three types of cones—**blue cones**, **green cones**, and **red cones**. Each type has a different form of opsin and is sensitive to a different range of wavelengths. Their stimulation

SPOTLIGHT Figure 17–13 Refractive Problems

A camera focuses an image by moving the lens toward or away from the film. This method cannot work in our eyes, because the distance from the lens to the macula cannot change. We focus images on the retina by changing the shape of the lens to keep the focal distance constant.

Emmetropia (normal vision) In the healthy eye, when the ciliary muscle is relaxed and the lens is flattened, a distant image will be focused on the retina's surface. This condition is called emmetropia (emmetro-, proper + opia, vision).

The eye has a fixed focal distance and focuses by varying the shape of the lens.

A camera lens has a fixed size and shape and focuses by varying the distance to the film.

Myopia (nearsightedness)

If the eyeball is too deep or the resting curvature of the lens is too great, the image of a distant object is projected in front of the retina. Myopic people see distant objects as blurry and out of focus. Vision at close range will be normal because the lens is able to round as needed to focus the image on the retina.

Hyperopia (farsightedness)

If the eyeball is too shallow or the lens is too flat, hyperopia results. The ciliary muscle must contract to focus even a distant object on the retina. And at close range the lens cannot provide enough refraction to focus an image on the retina. Older people become farsighted as their lenses lose elasticity, a form of hyperopia called **presbyopia** (presbys, old man).

Surgical Correction

Variable success at correcting myopia and hyperopia has been achieved by surgery that reshapes the cornea. In photorefractive

keratectomy (PRK)

a computer-guided laser shapes the cornea to exact specifications. The entire procedure can be done in less than a minute. A variation on PRK is called LASIK (Laser-Assisted in-Situ Keratomileusis). In this procedure the interior layers of the cornea are reshaped and then re-covered by the flap of original outer corneal epithelium. Roughly 70 percent of LASIK patients achieve normal vision, and LASIK has become the most common form of refractive surgery.

Even after surgery, many patients still need reading glasses, and both immediate and long-term visual problems can occur.

Figure 17–14 Structure of Rods, Cones, and Rhodopsin Molecule.

a Structure of rods and cones

in various combinations is the basis for color vision. In an individual with normal vision, the cone population consists of 16 percent blue cones, 10 percent green cones, and 74 percent red cones. Their sensitivities overlap, but each type is most sensitive to a specific portion of the visual spectrum (Figure 17–15).

New discs containing visual pigment are continuously assembled at the base of the outer segment of both rods and cones. A completed disc then moves toward the tip of the segment. After about 10 days, the disc is shed in a small droplet of cytoplasm. The pigment cells absorb droplets with shed discs, break down the disc membrane's components, and reconvert the retinal to vitamin A. The pigment cells then store the vitamin A for later transfer to the photoreceptors.

Photoreceptor functioning is described in **Spotlight Figure 17–16**.

Figure 17–15 Cone Types and Sensitivity to Color. This graph compares the absorptive characteristics of blue, green, and red cones with those of typical rods.

Gated

Na+ Channel

RESTING STATE DARKNESS

Sodium entry through gated channels produces dark current

The plasma membrane in the outer segment of the photoreceptor contains chemically gated sodium ion channels. In darkness, these gated channels are kept open in the presence of cGMP (cyclic guanosine monophosphate), a derivative of the high-energy compound guanosine triphosphate (GTP). Because the channels are open, the membrane potential is approximately -40 mV, rather than the -70 mV typical of resting neurons. At the -40 mV membrane potential, the photoreceptor is continuously releasing neurotransmitters (in this case, glutamate) across synapses at the inner segment. The inner segment also continuously pumps sodium ions out of the cytoplasm.

The movement of ions into the outer segment, on to the inner segment, and out of the cell is known as the dark current.

Na+

Rod

Bipolar cell

Rhodopsin

0-

Disc

Neurotransmitter Release **Opsin activation occurs**

1

The bound retinal molecule has two possible configurations: the 11-*cis* form and the 11-*trans* form.

Normally, the molecule is in the curved 11-*cis* form; on absorbing light it changes to the more linear 11-*trans* form. This change activates the opsin molecule.

ACTIVE STATE

2

Transducin is a G protein—a membrane-bound enzyme complex

In this case, opsin activates transducin, and transducin in turn activates **phosphodiesterase** (**PDE**). Cyclic GMP levels decline and gated sodium channels close

3

Phosphodiesterase is an enzyme that breaks down cGMP.

The removal of cGMP from the gated sodium channels results in their inactivation. The rate of Na⁺ entry into the cytoplasm then decreases.

Dark current is reduced and rate of neurotransmitter release declines

4

The reduction in the rate of Na⁺ entry reduces the dark current. At the same time, active transport continues to export Na⁺ from the cytoplasm. When the sodium channels close, the membrane potential drops toward -70 mV. As the plasma membrane hyperpolarizes, the rate of neurotransmitter release decreases. This decrease signals the adjacent bipolar cell that the photoreceptor has absorbed a photon. After absorbing a photon, retinal does not spontaneously revert to the 11-cis form. Instead, the entire rhodopsin molecule must be broken down into retinal and opsin, in a process called bleaching. It is then reassembled.

Na

Bleaching and Regeneration of Visual Pigments. Rhodopsin is broken down through a process called **bleaching** (**Figure 17–17**). Before it can recombine with opsin, the retinal must be enzymatically converted from the 11-*trans* form to the 11-*cis* form. This conversion requires energy in the form of ATP (adenosine triphosphate), and it takes time.

Bleaching contributes to the lingering visual impression you have after you see a camera's flash. Following intense exposure to light, a photoreceptor cannot respond to further stimulation until its rhodopsin molecules have been regenerated. As a result, a "ghost" image remains on the retina. We seldom notice bleaching under ordinary circumstances, because our eyes are constantly making small, involuntary changes in position that move the image across the retina's surface.

While the rhodopsin molecule is being reassembled, membrane permeability of the outer segment is returning to normal. Opsin is inactivated when bleaching occurs, and the breakdown of cGMP halts as a result. As other enzymes generate cGMP in the cytoplasm, the chemically gated sodium channels reopen.

As previously noted, the visual pigments of the photoreceptors are synthesized from vitamin A. The body contains vitamin A reserves sufficient for several months. A significant amount is stored in the cells of the pigmented part of the retina. If dietary sources are inadequate, these reserves are gradually used up and the amount of visual pigment in the photoreceptors begins to decline. Daylight vision is affected, but in daytime the light is usually bright enough to stimulate any visual pigments that remain within the densely packed cone population of the fovea. As a result, the problem first becomes apparent at night, when the dim light proves insufficient to activate the rods. This condition, known as **night blindness** or **nyctalopia**, can be treated by eating a diet rich in vitamin A. The body can convert the carotene pigments in many vegetables to vitamin A. Carrots are a particularly good source of carotene, leading to the old adage that carrots are good for your eyes.

Light and Dark Adaptation

The sensitivity of your visual system varies with the intensity of illumination. After 30 minutes or more in the dark, almost all visual pigments will have recovered from photobleaching. They are fully receptive to stimulation. This is the **dark-adapted state**. When dark-adapted, the visual system is extremely sensitive. For example, a single rod will hyperpolarize in response to a single photon of light. Even more remarkable, if as few as seven rods absorb photons at one time, you will see a flash of light.

When the lights come on, at first they seem almost unbearably bright, but over the next few minutes your sensitivity decreases as bleaching occurs. Eventually, the rate of bleaching is balanced by the rate at which the visual pigments reassemble. This condition is the **light-adapted state**. If you moved from the depths of a cave to the full sunlight of midday, your receptor sensitivity would decrease by a factor of 25,000.

A variety of central responses further adjust light sensitivity. The pupils constrict, by the *pupillary constrictor reflex*, reducing the amount of light entering your eye to one-thirtieth the maximum dark-adapted level. Dilating the pupil fully can produce a thirtyfold increase in the amount of light entering the eye, and facilitating some of the synapses along the visual pathway can perhaps triple its sensitivity. In these ways, the sensitivity of the entire system may increase by a factor of more than 1 million.

Retinitis pigmentosa (RP) is an inherited disease characterized by progressive retinal degeneration. As the visual receptors gradually deteriorate, blindness eventually results. The mutations that are responsible change the structure of the photoreceptors—specifically, the visual pigments of the membrane discs. We do not know how the altered pigments lead to the destruction of photoreceptor cells.

Color Vision

An ordinary lightbulb or the sun emits photons of all wavelengths. These photons stimulate both rods and cones. Your eyes also detect photons that reach your retina after they bounce off objects around you. If photons of all colors bounce off an object, the object will appear white to you. If the object absorbs all the photons (so that none reaches the retina), the object will appear black.

An object appears to have a particular color when it reflects (or transmits) photons from one portion of the visible spectrum and absorbs the rest. Color discrimination takes place through the integration of information arriving from all three **Figure 17–18** A Standard Test for Color Vision. People who lack one or more types of cones cannot see the number 12 in this pattern.

types of cones. For example, you perceive yellow from a combination of inputs from highly stimulated green cones, less strongly stimulated red cones, and relatively unaffected blue cones (Figure 17–15, p. 583). If all three cone populations are stimulated, we perceive the color as white. We also perceive white if rods, rather than cones, are stimulated. For this reason, everything appears black-and-white when you enter dimly lit surroundings or walk by starlight.

Persons who are unable to distinguish certain colors have a form of **color blindness**. The standard tests for color vision involve picking numbers or letters out of a complex colored picture such as the one in Figure 17-18. Color blindness occurs when one or more types of cones are nonfunctional. The cones may be absent, or they may be present but unable to manufacture the necessary visual pigments. In the most common type of color blindness (red-green color blindness), the red cones are missing, so the individual cannot distinguish red light from green light. Inherited color blindness involving one or two cone pigments is not unusual. Ten percent of all males show some color blindness, but only about 0.67 percent of all females have color blindness. Total color blindness is extremely rare. Only 1 person in 300,000 does not manufacture any cone pigments. We consider the inheritance of color blindness in Chapter 29.

The Visual Pathways

The visual pathways begin at the photoreceptors and end at the visual cortex of the cerebral hemispheres. In other sensory pathways we have examined, only one synapse lies between a receptor and a sensory neuron that delivers information to the CNS. In the visual pathways, the message must cross two synapses (photoreceptor to bipolar cell, and bipolar cell to ganglion cell). Only then does it head toward the brain. The extra synapse increases the synaptic delay, but it provides an opportunity for the processing and integration of visual information before it leaves the retina.

Processing by the Retina

Each photoreceptor in the retina monitors a specific receptive field. The retina contains about 130 million photoreceptors, 6 million bipolar cells, and 1 million ganglion cells. Thus, a considerable amount of convergence takes place at the start of the visual pathway. The degree of convergence differs between rods and cones. Regardless of the amount of convergence, each ganglion cell monitors a specific portion of the field of vision.

17

As many as a thousand rods may pass information by their bipolar cells to a single ganglion cell. The fairly large ganglion cells that monitor rods are called **M cells** (*magnocells; magnus*, great). They provide information about the general form of an object, motion, and shadows in dim lighting. Because so much convergence occurs, the activation of an M cell indicates that light has arrived in a general area rather than at a specific location.

The loss of specificity due to convergence is partially overcome by the fact that the activity of ganglion cells varies according to the pattern of activity in their receptive field, which is usually shaped like a circle. Typically, a ganglion cell responds differently to stimuli that arrive in the center of its receptive field than to stimuli that arrive at the edges (Figure 17-19). Some ganglion cells, called on-center neu**rons**, are excited by light arriving in the center of their sensory field and are inhibited when light strikes the edges of their receptive field. Others, known as off-center neurons, are inhibited by light in the central zone, but are stimulated by illumination at the edges. On-center and off-center neurons provide information about which portion of their receptive field is illuminated. This kind of retinal processing within ganglion receptive fields improves the detection of the edges of objects within the visual field.

Cones typically show very little convergence. In the fovea, the ratio of cones to ganglion cells is 1:1. The ganglion cells that monitor cones, called **P cells** (*parvo cells; parvus*, small), are smaller and more numerous than M cells. P cells are active in bright light, and they provide information about edges, fine detail, and color. Because little convergence occurs, the activation of a P cell means that light has arrived at one specific location. As a result, cones provide more precise information about a visual image than do rods. We could say that images formed

Figure 17–19 Convergence and Ganglion Cell Function. Photoreceptors are organized in groups within a receptive field. Each ganglion cell monitors a well-defined portion of that field. Some ganglion cells (on-center neurons, labeled A) respond strongly to light arriving at the center of their receptive field. Others (off-center neurons, labeled B) respond most strongly to illumination of the edges of their receptive field.

by rods have a coarse, grainy, pixelated appearance that blurs details. By contrast, images produced by cones are sharp, clear, and of high resolution.

Central Processing of Visual Information

Axons from the entire population of ganglion cells converge on the optic disc, penetrate the wall of the eye, and proceed toward the diencephalon as the optic nerve (II). The two optic nerves, one from each eye, reach the diencephalon at the optic chiasm (Figure 17–20). From that point, approximately half the fibers proceed toward the lateral geniculate nucleus of the same side of the brain, whereas the other half cross over to reach the lateral geniculate nucleus of the opposite side. \bigcirc p. 475 From each lateral geniculate nucleus, visual information travels to the occipital cortex of the cerebral hemisphere on that side.

Figure 17–20 The Visual Pathways. The crossover of some nerve fibers occurs at the optic chiasm. As a result, each hemisphere receives visual information from the medial half of the field of vision of the eye on that side, and from the lateral half of the field of vision of the eye on the opposite side. Visual association areas integrate this information to develop a composite picture of the entire field of vision.

The bundle of projection fibers linking the lateral geniculates with the visual cortex is known as the **optic radiation**. Collaterals from the fibers synapsing in the lateral geniculate continue to subconscious processing centers in the diencephalon and brain stem. For example, the pupillary reflexes and reflexes that control eye movement are triggered by collaterals carrying information to the superior colliculi.

The Field of Vision. You perceive a visual image due to the integration of information that arrives at the visual cortex of the occipital lobes. Each eye receives a slightly different visual image. One reason is that the foveae in your two eyes are 5–7.5 cm (2–3.0 in.) apart. Another reason is that your nose and eye socket block the view of the opposite side. **Depth perception** is the ability to judge depth or distance by interpreting the three-dimensional relationships among objects in view. Your brain obtains it by comparing the relative positions of objects within the images received by your two eyes.

When you look straight ahead, the visual images from your left and right eyes overlap (Figure 17–20). The image received by the fovea of each eye lies in the center of the region of overlap. A vertical line drawn through the center of this region marks the division of visual information at the optic chiasm. Visual information from the left half of the combined field of vision reaches the visual cortex of your right occipital lobe. Visual information from the right half of the combined field of vision arrives at the visual cortex of your left occipital lobe.

The cerebral hemispheres thus contain a map of the entire field of vision. As in the case of the primary sensory cortex, the map does not faithfully duplicate the areas within the sensory field. For example, the area assigned to the macula and fovea covers about 35 times the surface it would cover if the map were proportionally accurate. The map is also upside down and reversed, duplicating the orientation of the visual image at the retina.

The Brain Stem and Visual Processing. Many centers in the brain stem receive visual information, either from the lateral geniculate nuclei or through collaterals from the optic tracts. Collaterals that bypass the lateral geniculates synapse in the superior colliculi or in the hypothalamus. The superior colliculi of the midbrain issue motor commands that control unconscious eye, head, or neck movements in response to visual stimuli.

Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brain stem nuclei. \bigcirc **p**. 480 The suprachiasmatic nucleus and the *pineal gland* of the epithalamus receive visual information and use it to establish a **circadian rhythm** (*circa*, about + *dies*, day), which is a daily pattern of visceral activity that is tied to the day–night cycle. This circadian rhythm affects your metabolic rate, endocrine function, blood pressure, digestive activities, sleep–wake cycle, and other physiological and behavioral processes.

CHECKPOINT

- 11. If you had been born without cones in your eyes, would you still be able to see? Explain.
- 12. How could a diet deficient in vitamin A affect vision?
- **13**. What effect would a decrease in phosphodiesterase activity in photoreceptor cells have on vision?

See the blue Answers tab at the back of the book.

17-5 Equilibrium sensations originate within the internal ear, while hearing involves the detection and interpretation of sound waves

Learning Outcome Describe the structures of the external, middle, and internal ear, explain their roles in equilibrium and hearing, and trace the pathways for equilibrium and hearing to their destinations in the brain.

The special senses of equilibrium and hearing are provided by the *internal ear*, a receptor complex located in the petrous part of the temporal bone of the skull. *Equilibrium* sensations inform us of the position of the head in space by monitoring gravity, linear acceleration, and rotation. *Hearing* enables us to detect and interpret sound waves.

The basic receptor mechanism for both senses is the same. The receptors, called *hair cells*, are mechanoreceptors. The complex structure of the internal ear and the different arrangement of accessory structures enable hair cells to respond to different stimuli, providing the input for both senses.

Anatomy of the Ear

The ear is divided into three anatomical regions: the external ear, the middle ear, and the internal ear (Figure 17–21). The *external ear*—the visible portion of the ear—collects and directs sound waves toward the *middle ear*, a chamber located within the petrous portion of the temporal bone. Structures of the middle ear collect sound waves and transmit them to an appropriate portion of the *internal ear*, which contains the sensory organs for both hearing and equilibrium.

Figure 17–21 The Anatomy of the Ear. The dashed lines indicate the boundaries separating the three anatomical regions of the ear (external, middle, and internal).

The External Ear

The **external ear** includes the outer fleshy and cartilaginous **auricle**, or *pinna*, which surrounds a passageway called the **external acoustic meatus**, or *auditory canal*. The auricle protects the opening of the canal and provides directional sensitivity. Sounds coming from behind the head are blocked by the auricle, but sounds coming from the side or front are collected and channeled into the external acoustic meatus. (When you "cup" your ear with your hand to hear a faint sound more clearly, you are exaggerating this effect.) The external acoustic meatus ends at the **tympanic membrane** (*tympanon*, drum) or *eardrum*. This thin, semitransparent sheet separates the external ear from the middle ear.

The tympanic membrane is very delicate. The auricle and the narrow external acoustic meatus provide some protection from accidental injury. In addition, **ceruminous glands** integumentary glands along the external acoustic meatus secrete a waxy material that helps keep out foreign objects or small insects. The canal is also lined with many small, outwardly projecting hairs. These hairs trap debris and also provide increased tactile sensitivity through their root hair plexuses. The slightly waxy secretion of the ceruminous glands, called **cerumen**, also slows the growth of microorganisms and reduces the chances of infection.

The Middle Ear

The middle ear, or tympanic cavity, is an air-filled chamber separated from the external acoustic meatus by the tympanic membrane. The middle ear communicates both with the nasopharynx (the superior portion of the pharynx), through the auditory tube, and with the mastoid air cells, through a number of small connections (Figures 17-21 and 17-22). The auditory tube is also called the pharyngotympanic tube or the Eustachian tube. About 4 cm (1.6 in.) long, it consists of two portions. The portion near the connection to the middle ear is narrow and is supported by elastic cartilage. The portion near the opening into the nasopharynx is broad and funnel shaped. The auditory tube equalizes pressure on either side of the tympanic membrane. Unfortunately, the auditory tube can also allow microorganisms to travel from the nasopharynx into the middle ear. Invasion by microorganisms can lead to an unpleasant middle ear infection known as otitis media.

The Auditory Ossicles. The middle ear contains three tiny ear bones, collectively called **auditory ossicles**. These ear bones connect the tympanic membrane with one of the receptor complexes of the internal ear (Figures 17–21 and 17–22). The three auditory ossicles are the malleus, the incus, and the stapes. The **malleus** (*malleus*, hammer) attaches at three points to the interior surface of the tympanic membrane. The **incus** (*incus*, anvil), the middle ossicle, attaches the malleus to the **stapes** (*stapes*, stirrup), the inner ossicle. The edges of the base of the

stapes are bound to the edges of the *oval window*, an opening in the temporal bone that surrounds the internal ear.

The articulations between the auditory ossicles are the smallest synovial joints in the body. Each has a tiny joint capsule and supporting extracapsular ligaments.

Vibration of the tympanic membrane converts arriving sound waves into mechanical movements. The auditory ossicles act as levers that conduct those vibrations to the internal ear. The ossicles are connected in such a way that an in–out movement of the tympanic membrane produces a rocking motion of the stapes. In this way, the ossicles function as a lever system that collects the force applied to the tympanic membrane and focuses it on the oval window. Considerable amplification occurs, so we can hear very faint sounds, because the tympanic membrane is 22 times larger and heavier than the oval window.

That degree of amplification can be a problem when we are exposed to very loud noises. In the middle ear, two small muscles protect the tympanic membrane and ossicles from violent movements under very noisy conditions:

- The tensor tympani (TEN-sor tim-PAN-ē) muscle is a short ribbon of muscle originating on the petrous part of the temporal bone and the auditory tube, and inserting on the "handle" of the malleus. When the tensor tympani contracts, it pulls the malleus medially, stiffening the tympanic membrane. This increased stiffness reduces the amount of movement possible. The tensor tympani muscle is innervated by motor fibers of the mandibular branch of the trigeminal nerve (V).
- The stapedius (sta-PĒ-dē-us) muscle, innervated by the facial nerve (VII), originates from the posterior wall of the middle ear and inserts on the stapes. Contraction of the stapedius pulls the stapes, reducing movement of the stapes at the oval window.

The Internal Ear

Receptors in the **internal ear** provide us with the senses of equilibrium and hearing (Figures 17–21 and 17–23).

The superficial contours of the internal ear are formed by a layer of dense bone known as the **bony labyrinth** (*labyrinthos,* network of canals). The walls of the bony labyrinth are continuous with the surrounding temporal bone. The inner contours of the bony labyrinth closely follow the contours of the **membranous labyrinth**, a delicate, interconnected network of fluid-filled tubes. The receptors of the internal ear are found within those tubes.

Between the bony and membranous labyrinths flows **perilymph** (PER-i-limf), a liquid that closely resembles cerebrospinal fluid. The membranous labyrinth contains **endolymph** (EN-dō-limf), a fluid with electrolyte concentrations that differ from those of typical body fluids. The physical relationships

are shown in **Figure 17–23a**. (See the Appendix for a chemical analysis of perilymph, endolymph, and other body fluids.)

We can subdivide the bony labyrinth into the *vestibule*, three *semicircular canals*, and the *cochlea* (Figure 17–23b). The **vestibule** (VES-ti-būl) consists of a pair of membranous sacs: the **saccule** (SAK-ūl) and the **utricle** (\overline{U} -tri-kul). Receptors in these sacs provide sensations of gravity and linear acceleration.

The **semicircular canals** enclose slender *semicircular ducts*. Receptors in the semicircular ducts are stimulated by rotation of the head. The combination of vestibule and semicircular canals is called the **vestibular complex**. The fluid-filled chambers within the vestibule are continuous with those of the semicircular canals.

The **cochlea** (KOK-lē-uh; *cochlea*, a snail shell) is a spiralshaped, bony chamber that contains the **cochlear duct** of the membranous labyrinth. Receptors within the cochlear duct provide the sense of hearing. The duct is sandwiched between a pair of perilymph-filled chambers. The entire complex spirals around a central bony hub, much like a snail shell.

The walls of the bony labyrinth consist of dense bone everywhere except at two small areas near the base of the cochlear spiral (Figure 17–21). The **round window** is a thin,

linical Note

Motion Sickness The signs and symptoms of motion sickness are exceedingly unpleasant. They include headache, sweating, facial flushing, nausea, vomiting, and various changes in mental perspective. Motion sickness may result when central processing stations, such as the tectum of the midbrain, receive conflicting sensory information. Why and how these conflicting reports result in nausea, vomiting, and other signs and symptoms are not known. Sitting belowdecks on a moving boat or reading in a car or airplane tends to provide the necessary conditions. Your eyes (which are tracking lines on a page) report that your position in space is not changing, but your semicircular ducts report that your body is lurching and turning. To counter this effect, seasick sailors watch the horizon rather than their immediate surroundings, so that their eyes will provide visual confirmation of the movements detected by their internal ears. It is not known why some individuals are almost immune to motion sickness, but others find travel by boat or plane almost impossible.

Drugs commonly used to prevent motion sickness include dimenhydrinate (*Dramamine*), scopolamine (*Transderm Scop*), and promethazine. These drugs appear to depress activity at the vestibular nuclei. Sedatives, such as prochlorperazine (*Compazine*), may also be effective. membranous partition that separates the perilymph of the cochlear chambers from the air-filled middle ear. Collagen fibers connect the bony margins of the opening known as the **oval window** to the base of the stapes.

Equilibrium

As just noted, receptors of the vestibular complex provide you with equilibrium sensations. The semicircular ducts convey information about rotational movements of the head. For example, when you turn your head to the left, receptors stimulated in the semicircular ducts tell you how rapid the movement is, and in which direction. The saccule and the utricle convey information about your position with respect to gravity. If you stand with your head tilted to one side, these receptors report the angle involved and whether your head tilts forward or backward. The saccule and the utricle are also stimulated by sudden acceleration. When your car accelerates from a stop, the saccular and utricular receptors give you the sensation of increasing speed.

The Semicircular Ducts

Sensory receptors in the semicircular ducts respond to rotational movements of the head. These **hair cells** are active during a movement, but are quiet when the body is motionless. The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle (**Figure 17–24a**). Each semicircular 17

Figure 17–24 The Semicircular Ducts.

duct contains an **ampulla**, an expanded region that contains the receptors. The region in the wall of the ampulla that contains the receptors is known as a **crista ampullaris** or *crista* (**Figure 17–24b**). Each crista ampullaris is bound to a **cupula** (KŪ-pū-luh), a gelatinous structure that extends the full width of the ampulla. The receptors in the cristae ampullares are hair cells (**Figure 17–24b**,d).

Hair cells are the receptors in other portions of the membranous labyrinth as well. Regardless of location, they are always surrounded by supporting cells and monitored by the dendrites of sensory neurons. The free surface of each hair cell supports 80–100 long **stereocilia**, which resemble very long microvilli (Figure 17–24d). Each hair cell in the vestibule also contains a single large cilium called a **kinocilium** (kī-nō-SILē-um). Hair cells do not actively move their kinocilia or stereocilia. However, when an external force pushes against these processes, the distortion of the plasma membrane alters the rate at which the hair cell releases chemical transmitters.

Hair cells provide information about the direction and strength of mechanical stimuli. The stimuli involved, however, depend on the hair cell's location: gravity or acceleration in the vestibule, rotation in the semicircular canals, and sound in the cochlea. The sensitivities of the hair cells differ, because each of these regions has different accessory structures that determine which stimulus will provide the force to deflect the kinocilia and stereocilia.

At a crista, the kinocilia and stereocilia of the hair cells are embedded in the cupula (Figure 17–24b). Because the cupula has a density very close to that of the surrounding endolymph, it essentially floats above the receptor surface. When your head rotates in the plane of the duct, the movement of endolymph along the length of the semicircular duct pushes the cupula to the side and distorts the receptor processes (Figure 17–24c). Movement of fluid in one direction stimulates the hair cells, and movement in the opposite direction inhibits them. When the endolymph stops moving, the elastic nature of the cupula makes it return to its normal position.

Even the most complex movement can be analyzed in terms of motion in three rotational planes. Each semicircular duct responds to one of these rotational movements. A horizontal rotation, as in shaking your head "no," stimulates the hair cells of the lateral semicircular duct. Nodding "yes" excites the anterior duct, and tilting your head from side to side activates receptors in the posterior duct.

The Utricle and Saccule

The utricle and saccule provide equilibrium sensations, whether the body is moving or is stationary. A slender passageway that is continuous with the narrow endolymphatic duct connects the two chambers. The **endolymphatic duct** ends in a closed cavity called the **endolymphatic sac** (Figure 17–24a). This sac projects through the dura mater that lines the temporal bone and into the subarachnoid space, where a capillary network surrounds it. Portions of the cochlear duct secrete endolymph continuously, and excess fluid returns to the general circulation at the endolymphatic sac. There the capillaries absorb endolymph removed by a combination of active transport and vesicular transport.

The hair cells of the utricle and saccule are clustered in oval structures called **maculae** (MAK-ū-lē; *macula*, spot) (Figure 17–25a). The macula in the utricle is sensitive to changes in horizontal movement. The macula in the saccule is sensitive to changes in vertical movement. As in the ampullae, the hair cell processes are embedded in a gelatinous otolithic membrane whose surface contains densely packed calcium carbonate crystals. These crystals are called **otoliths** ("ear stones").

The macula of the saccule is diagrammed in Figure 17–25b. The function of the macula in the utricle is shown in Figure 17–25c. When your head is in the normal, upright position, the otoliths sit atop the otolithic membrane of the utricular macula (1). Their weight presses on the macular surface, pushing the hair cell processes down rather than to one side or another. When your head is tilted, the pull of gravity on the otoliths shifts them to the side, distorting the hair cell processes and stimulating the macular receptors (2). The change in receptor activity tells the CNS that your head is no longer level.

A similar mechanism accounts for your perception of linear acceleration when you are in a car that speeds up suddenly. The otoliths lag behind, and the effect on the hair cells is comparable to tilting your head back. Under normal circumstances, your nervous system distinguishes between the sensations of tilting and linear acceleration by integrating vestibular sensations with visual information. Many amusement park rides confuse your sense of equilibrium by combining rapid rotation with changes in position and acceleration while providing restricted or misleading visual information.

Pathways for Equilibrium Sensations

Hair cells of the vestibule and semicircular ducts are monitored by sensory neurons located in adjacent **vestibular ganglia**. Sensory fibers from these ganglia form the **vestibular branch** of the vestibulocochlear nerve (VIII). \bigcirc **p.** 498 These fibers innervate neurons within the pair of **vestibular nuclei** at the boundary between the pons and the medulla oblongata.

The two vestibular nuclei have four functions:

- 1. Integrating sensory information about balance and equilibrium that arrives from both sides of the head.
- 2. Relaying information from the vestibular complex to the cerebellum.

- **3.** Relaying information from the vestibular complex to the cerebral cortex, providing a conscious sense of head position and movement.
- 4. Sending commands to motor nuclei in the brain stem and spinal cord.

The reflexive motor commands issued by the vestibular nuclei are distributed to the motor nuclei for cranial nerves involved with eye, head, and neck movements (N III, N IV, N VI, and N XI). Instructions descending in the *vestibulospinal tracts* of the spinal cord adjust peripheral muscle tone and complement the reflexive movements of the head or neck. ⊃ p. 526 These pathways are indicated in Figure 17–26.

The automatic movements of the eyes in response to sensations of motion are directed by the *superior colliculi* of the midbrain. **D p**. 475 These movements attempt to keep your gaze focused on a specific point in space, despite changes in body position and orientation. If your body is turning or spinning rapidly, your eyes will fix on one point for a moment and then jump ahead to another in a series of short, jerky movements.

If either the brain stem or the internal ear is damaged, this type of eye movement can occur even when the body is stationary. Individuals with this condition, which is called **nystagmus** (nis-TAG-mus), have trouble controlling their eye movements. Physicians commonly check for nystagmus by asking patients to watch a small penlight as it is moved across the field of vision.

Hearing

The receptors of the cochlear duct provide a sense of hearing that enables us to detect the quietest whisper, yet remain functional in a noisy room. The receptors responsible for auditory sensations are hair cells similar to those of the vestibular complex. However, their placement within the cochlear duct and the organization of the surrounding accessory structures shield them from stimuli other than sound.

In conveying vibrations from the tympanic membrane to the oval window, the auditory ossicles convert pressure fluctuations in air into much greater pressure fluctuations in the perilymph of the cochlea. These fluctuations stimulate hair cells along the cochlear spiral. The *frequency* of the perceived sound is determined by *which part* of the cochlear duct is stimulated. The *intensity* (volume) of the perceived sound is determined by *how many* of the hair cells at that location are stimulated. Let's take a closer look at the mechanics of this remarkably elegant process.

The Cochlear Duct

In sectional view (Figures 17–27 and 17–28), the cochlear duct lies between a pair of perilymphatic chambers or *scalae*: the **scala vestibule** (SKĀ-luh ves-TIB-yū-lē), or *vestibular duct*, and the **scala tympani** (SKĀ-luh TIM-pa-nē), or *tympanic duct*. The outer surfaces of these ducts are encased by the bony labyrinth everywhere except at the oval window (the base of the scala vestibuli) and the round window (the base of the scala tympani). These scalae really form one long and continuous perilymphatic chamber because they are interconnected at the tip of the cochlear spiral. This chamber begins at the oval window; extends through the scala vestibuli, around the top of the cochlea, and along the scala tympani; and ends at the round window.

The cochlear duct is an elongated tubelike structure suspended between the vestibular duct and the tympanic duct. The hair cells of the cochlear duct are located in a structure called the spiral organ (organ of Corti) (Figures 17-27b and 17-28a,b). This sensory structure sits on the basilar mem**brane**, a membrane that separates the cochlear duct from the scala tympani. The hair cells are arranged in a series of longitudinal rows. They lack kinocilia, and their stereocilia are in contact with the overlying tectorial (tek-TOR-ē-al; tectum, roof) membrane. This membrane is firmly attached to the inner wall of the cochlear duct. When a portion of the basilar membrane bounces up and down, the stereocilia of the hair cells are pressed against the tectorial membrane and become distorted. The basilar membrane moves in response to pressure fluctuations within the perilymph. These pressure changes are triggered by sound waves arriving at the tympanic membrane. The basic properties of sound are key to understanding this process.

An Introduction to Sound

Hearing is the perception of sound, but what is sound? It consists of waves of pressure conducted through a medium such as air or water. In air, each *pressure wave* consists of a region where the air molecules are crowded together and an adjacent zone

b Diagrammatic and sectional views of the cochlear spiral

where they are farther apart (Figure 17–29a). These waves are sine waves—that is, S-shaped curves that repeat in a regular pattern. They travel through the air at about 1235 km/h (768 mph).

The *wavelength* of sound is the distance between two adjacent wave crests (peaks), or the distance between two adjacent wave troughs (Figure 17–29b). The **frequency** of a sound is the number of waves that pass a fixed reference point in a given time. Physicists use the term **cycles** rather than *waves*. We measure the frequency of a sound in terms of the number of cycles

per second (cps), a unit called **hertz (Hz)**. Wavelength and frequency are inversely related.

What we perceive as the **pitch** of a sound is our sensory response to its frequency. A *high-frequency* sound (high pitch, short wavelength) might have a frequency of 15,000 Hz or more. A very *low-frequency* sound (low pitch, long wavelength) could have a frequency of 100 Hz or less.

It takes energy to produce sound waves. When you strike a tuning fork, it vibrates, pushing against the surrounding air.

b Diagrammatic and sectional views of the receptor hair cell complex of the spiral organ

It produces sound waves whose frequency depends on the instrument's frequency of vibration.

The harder you strike the tuning fork, the more energy you provide. The energy increases the **amplitude**, or height, of the sound wave (Figure 17–29b). The amount of energy in a sound wave, or *intensity*, determines how loud it seems. The greater the energy content, the larger the amplitude, and the louder the sound. We report sound energy in **decibels** (DES-i-belz, dB). Table 17–1 shows the decibel levels of familiar sounds.

When sound waves strike an object, their energy is a physical pressure. You may have seen windows move in a room where

a stereo is blasting. The more flexible the object, the more easily it will respond to the pressure of sound waves. Even soft stereo music will vibrate a sheet of paper held in front of the speaker. Given the right combination of frequencies and amplitudes, an object will begin to vibrate at the same frequency as the sound, a phenomenon called *resonance*. For you to be able to hear any sound, your thin, flexible tympanic membrane must vibrate in resonance with the sound waves.

Probably more than 6 million people in the United States have at least a partial hearing deficit. It is due to problems with either the transfer of vibrations by the auditory ossicles or damage to the receptors or the auditory pathways.

Figure 17–29 The Nature of Sound.

A graph showing the sound energy arriving at the tympanic membrane. The distance between wave peaks is the wavelength. The number of waves arriving each second is the frequency, which we perceive as pitch. Frequencies are reported in cycles per second (cps), or hertz (Hz). The amount of energy carried by the wave is its amplitude. The greater the amplitude, the louder the sound.

The Hearing Process

We divide the process of hearing into six basic steps (Figure 17–30):

Sound waves arrive at the tympanic membrane. Sound waves enter the external acoustic meatus and travel toward the tympanic membrane. The orientation of the auditory canal provides some directional sensitivity. Sound waves approaching a particular side of the head have direct access to the tympanic membrane on that side. Sounds arriving from another direction must bend around corners or pass through the auricle or other body tissues.

2 Movement of the tympanic membrane causes displacement of the auditory ossicles. The tympanic membrane provides a

Table 17	-1 Intensity of R	epresentative	ntative Sounds	
Typical Decibel Level	Example		Dangerous Time Exposure	
0	Lowest audible sound			
30	Quiet library; soft whis	per		
40	Quiet office; living roor away from traffic	n; bedroom		
50	Light traffic at a distand refrigerator; gentle bre	ce; eze		
60	Air conditioner at 20 fe conversation; sewing n in operation	et; nachine		
70	Busy traffic; noisy resta	urant	Some damage if continuous	
80	Subway; heavy city traf clock at 2 feet; factory i	fic; alarm noise	More than 8 hours	
90	Truck traffic; noisy hom shop tools; gas lawn m	ie appliances; ower	Less than 8 hours	
100	Chain saw; boiler shop drill	pneumatic	2 hours	
120	"Heavy metal" rock con sandblasting; thunder	cert; lap nearby	Immediate danger	
140	Gunshot; jet plane		Immediate danger	
160	Rocket launching pad		Hearing loss inevitable	

surface for the collection of sound. The membrane vibrates in resonance to sound waves with frequencies between approximately 20 and 20,000 Hz. When the tympanic membrane vibrates, so do the malleus, incus, and stapes. In this way, the sound is amplified.

3 Movement of the stapes at the oval window establishes pressure waves in the perilymph of the scala vestibuli. Liquids are not compressible: If you push down on one part of a waterbed, the bed bulges somewhere else. Because the rest of the cochlea is sheathed in bone, pressure applied at the oval window can be relieved only at the round window. The stapes actually has a rocking movement, but the in–out component is easiest to visualize and describe. Basically, when the stapes moves inward, the round window bulges outward, into the middle ear cavity. As the stapes moves in and out, vibrating at the frequency of the sound arriving at the tympanic membrane, it creates pressure waves within the perilymph.

4 The pressure waves distort the basilar membrane on their way to the round window of the scala tympani. The stapes create pressure waves that travel through the perilymph of the scala vestibuli and scala tympani to reach the round window. In doing so, the waves distort the basilar membrane. The location of maximum distortion varies with the frequency of the sound, due to regional differences in the width and

Figure 17–30 Sound and Hearing. Steps in the reception and transduction of sound energy.

flexibility of the basilar membrane along its length. High-frequency sounds, which have a very short wavelength, vibrate the basilar membrane near the oval window. The lower the frequency of the sound, the longer the wavelength, and the farther from the oval window is the area of maximum distortion (Figure 17–31). In this way, information about frequency is translated into information about *position* along the basilar membrane.

The *amount* of movement at a given location depends on the amount of force applied by the stapes, which in turn depends on the energy content of the sound. The louder the sound, the more the basilar membrane moves.

S Vibration of the basilar membrane causes hair cells to vibrate against the tectorial membrane. Vibration of the affected region of the basilar membrane moves hair cells against the tectorial membrane. This movement leads to the displacement of the stereocilia, which in turn opens ion channels in the plasma membranes of the hair cells. The resulting inrush of ions depolarizes

the hair cells, leading to the release of neurotransmitters that stimulate sensory neurons.

The hair cells of the spiral organ are arranged in several rows. A very soft sound may stimulate only a few hair cells in a portion of one row. As the intensity of a sound increases, not only do these hair cells become more active, but additional hair cells—first in the same row and then in adjacent rows—are stimulated as well. The number of hair cells responding in a given region of the spiral organ provides information on the intensity of the sound.

6 Information about the region and the intensity of stimulation is relayed to the CNS over the cochlear branch of cranial nerve VIII. The cell bodies of the bipolar sensory neurons that monitor the cochlear hair cells are located at the center of the bony cochlea, in the **spiral ganglion** (Figure 17–28a). From there, the information is carried by the cochlear branch of cranial nerve VIII to the cochlear nuclei of the medulla oblongata for distribution to other centers in the brain.

Figure 17–31 Frequency Discrimination.

Auditory Pathways

Stimulation of hair cells activates sensory neurons whose cell bodies are in the adjacent spiral ganglion (Figure 17–32 1). The afferent fibers of those neurons form the cochlear branch of the vestibulocochlear nerve (VIII). These axons enter the medulla oblongata, where they synapse at the cochlear nucleus on that side 2. From there, information ascends to the superior olivary nucleus of the pons and both inferior colliculi of the midbrain 3. This midbrain processing center coordinates a number of responses to acoustic stimuli, including auditory reflexes that involve skeletal muscles of the head, face, and trunk 4. These reflexes automatically change the position of your head in response to a sudden loud noise. You usually turn your head and your eyes toward the source of the sound.

Before reaching the cerebral cortex and your awareness, ascending auditory sensations synapse in the medial geniculate nucleus of the thalamus (5). Projection fibers then deliver the information to the auditory cortex of the temporal lobe (6). Information travels to the cortex over labeled lines: Highfrequency sounds activate one portion of the cortex, lowfrequency sounds another. In effect, the auditory cortex contains a map of the spiral organ. So, information about *frequency*, translated into information about *position* on the basilar membrane, is projected in that form onto the auditory cortex. There it is interpreted to produce your subjective sensation of pitch.

Most of the auditory information from one cochlea is projected to the auditory complex of the cerebral hemisphere on the opposite side of the brain. However, each auditory cortex also receives information from the cochlea on that side. These interconnections play a role in localizing left/right sounds. They can also reduce the functional impact of damage to a cochlea or ascending pathway.

An individual whose auditory cortex is damaged will respond to sounds and have normal acoustic reflexes, but will find it difficult or impossible to interpret the sounds and recognize a pattern in them. Damage to the adjacent association area leaves the ability to detect the tones and patterns intact, but produces an inability to comprehend their meaning.

Auditory Sensitivity

Our hearing abilities are remarkable, but it is difficult to assess the absolute sensitivity of the system. The range from the softest audible sound to the loudest tolerable blast represents a trillionfold increase in power. The receptor mechanism is

so sensitive that, if we were to remove the stapes, we could, in theory, hear air molecules bouncing off the oval window. We never use the full potential of this system, because body movements and our internal organs produce squeaks, groans, thumps, and other sounds that are tuned out by central and peripheral adaptation. When other environmental noises fade away, the level of adaptation drops and the system becomes increasingly sensitive. For example, when you relax in a quiet room, your heartbeat seems to get louder and louder as the auditory system adjusts to the level of background noise.

Young children have the greatest hearing range: They can detect sounds ranging from a 20-Hz buzz to a 20,000-Hz whine. With age, damage due to loud noises or other injuries

accumulates. The tympanic membrane gets less flexible, the articulations between the ossicles stiffen, and the round window may begin to ossify. As a result, older individuals show some degree of hearing loss.

CHECKPOINT

- 14. If the round window were not able to bulge out with increased pressure in the perilymph, how would the perception of sound be affected?
- **15**. How would the loss of stereocilia from hair cells of the spiral organ affect hearing?
- 16. Why would blockage of the auditory tube produce an earache?

See the blue Answers tab at the back of the book.

Related Clinical Terms

age-related macular degeneration: A disease associated with aging that gradually destroys sharp, central vision by affecting the macula, the part of the eye that allows a person to see fine detail. It is painless and in some cases can slowly worsen over time, causing little concern to the person, or it can rapidly progress and may cause blindness in both eyes. It is the leading cause of blindness in persons over the age of 60. It has two forms, wet and dry.

- **ageusia:** A rare inability to taste. More common is hypogeusia, a disorder in which the person affected has trouble distinguishing between tastes.
- **anosmia:** The complete loss of smell, which can be temporary (caused by an obstruction such as a polyp) or permanent (perhaps due to aging or a brain tumor).
- **blepharitis:** Common and persistent inflammation of the eyelid caused by poor hygiene, excessive oil production by the glands of the eyelid, or a bacterial infection. Signs and symptoms include itching, flakes on the eyelashes, and a gritty, sandy feeling.
- **conductive deafness:** Deafness resulting from conditions in the external or middle ear that block the transfer of vibrations from the tympanic membrane to the oval window.

hyposmia: A lessened sensitivity to odors.

- **mydriasis:** Dilation of the pupils of the eye induced by medical eye drops or caused by disease.
- **nerve deafness:** Deafness resulting from problems within the cochlea or along the auditory nerve pathway.

ophthalmologist: A physician who specializes in ophthalmology, which is the branch of medicine dealing with the diseases and surgery of the visual pathways, including the eye, brain, and areas surrounding the eye.

optometrist: A primary eye care doctor who diagnoses, manages, and treats disorders of the visual system and eye diseases and who also measures vision for the purpose of correcting one's vision problems with specifically prescribed lenses.

otalgia: Pain in the ear; an earache.

- **photophobia:** An oversensitivity to light possibly leading to tearing, discomfort, or pain. Causes include abrasions to the corneal area, inflammation, disease, and some medications.
- **Snellen chart:** A printed chart of block letters in graduated type sizes used to measure visual acuity.
- **strabismus:** The abnormal alignment of one or both eyes that prevents the person from gazing on the same point with both eyes.
- **synesthesia:** Abnormal condition in which sensory nerve messages connect to the wrong centers of the brain. For example, touching an object may produce the perception of a sound, while hearing a tone may produce the visualization of a color.
- **tinnitus:** A buzzing, whistling, or ringing sound heard in the absence of an external stimulus. Causes include injury, disease, inflammation, or some drugs.
- **vertigo:** A feeling that you are dizzily spinning or that things are dizzily turning about you. Vertigo is usually caused by a problem with the internal ear, but can also be due to vision problems.

- 17-1 Olfaction, the sense of smell, involves olfactory receptors responding to chemical stimuli p. 564
- 1. The **olfactory organs** contain the **olfactory epithelium** with **olfactory receptors**, supporting cells, and **basal (stem) cells**. The surfaces of the olfactory organs are coated with the secretions of the **olfactory glands**. (*Figure 17–1*)
- 2. The olfactory receptors are highly modified neurons.
- 3. In olfaction, the arriving information reaches the information centers without first synapsing in the thalamus. (*Figure 17–1*)

- 4. Olfactory reception involves detecting dissolved chemicals as they interact with odorant-binding proteins. (*Spotlight Figure 17–2*)
- **5.** The olfactory system can distinguish thousands of chemical stimuli. The CNS interprets smells by the pattern of receptor activity.
- **6.** The olfactory receptor population shows considerable turnover. The number of olfactory receptors declines with age.
- **17-2** Gustation, the sense of taste, involves taste receptors responding to chemical stimuli p. 568
- 7. Taste (gustatory) receptors are clustered in taste buds.
- 8. Taste buds are associated with epithelial projections (*lingual papillae*) on the tongue. (*Figure 17–3*)
- Each taste bud contains basal cells (stem cells) and gustatory cells, which extend *taste hairs* through a narrow taste pore. (*Figure 17–3*)
- **10.** The taste buds are monitored by cranial nerves that synapse within the solitary nucleus of the medulla oblongata. Post-synaptic neurons carry the nerve impulses on to the thalamus, where third-order neurons project to the primary sensory cortex.

- **11.** The **primary taste sensations** are sweet, salty, sour, and bitter. Receptors also exist for **umami** and **water**. (*Spotlight Figure 17–2*)
- **12.** Taste sensitivity exhibits significant individual differences, some of which are inherited.
- 13. The number of taste buds declines with age.
- 17-3 Internal eye structures contribute to vision, while accessory eye structures provide protection p. 570
- 14. The **accessory structures** of the eye include the **palpebrae** (eyelids), separated by the **palpebral fissure**, the **eyelashes**, and the **tarsal glands**. (*Figures* 17–4, 17–5)
- **15.** An epithelium called the **conjunctiva** covers most of the exposed surface of the eye. The **cornea** is transparent. *(Figures 17–4, 17–5)*
- 16. The secretions of the lacrimal gland contain lysozyme. Tears collect in the *lacrimal lake* and reach the inferior meatus of the nose after they pass through the lacrimal puncta, the lacrimal canaliculi, the lacrimal sac, and the nasolacrimal duct. (*Figure 17–4*)
- The eye has three layers, formerly called tunics: an outer fibrous layer, a middle vascular layer (uvea), and a deeper, inner layer (retina). (*Figure 17–5*)
- **18.** The fibrous layer consists of the **sclera**, the cornea, and the **corneal limbus**. (*Figure 17–5*)
- 19. The vascular layer, or uvea, includes the iris, the ciliary body, and the choroid. The iris contains muscle fibers that change the diameter of the pupil. The ciliary body contains the ciliary muscle and the ciliary processes, which attach to the ciliary zonule (*suspensory ligament*) of the lens. (*Figures* 17–5, 17–6)
- **20.** The **inner layer**, or **retina**, consists of an outer *pigmented part* and an inner *neural part* which contains visual receptors and associated neurons. (*Figures 17–5, 17–7*)
- 21. The retina contains two types of **photoreceptors: rods** and **cones**.
- **22.** Cones are densely clustered in the **fovea (fovea centralis)**, at the center of the **macula**. (*Figure 17–7*)
- 23. The direct line to the CNS proceeds from the photoreceptors to **bipolar cells**, then to **ganglion cells**, and, finally, to the brain by the optic nerve. The axons of ganglion cells converge at the **optic disc**, or **blind spot**. **Horizontal cells** and **amacrine cells** modify the signals passed among other components of the retina. (*Figures 17–7, 17–8*)
- 24. The ciliary body and lens divide the interior of the eye into a large **posterior cavity**, or *vitreous chamber*, and a smaller **anterior cavity**. The anterior cavity is subdivided into the **anterior chamber**, which extends from the cornea to the iris, and a **posterior chamber**, between the iris and the ciliary body and lens. (*Figure 17–9*)
- **25.** The fluid **aqueous humor** circulates within the eye and reenters the circulation after diffusing through the walls of the anterior chamber and into the **scleral venous sinus** (*canal of Schlemm*). (*Figure 17–9*)
- **26.** The **lens** lies posterior to the cornea and forms the anterior boundary of the posterior cavity. This cavity contains the **vitreous body**, a clear, gelatinous mass that helps stabilize the shape of the eye and support the retina. (*Figure 17–9*)
- **27.** The lens focuses a visual image on the photoreceptors. A **cata***ract* is the condition in which a lens has lost its transparency.
- 28. Light is **refracted** (bent) when it passes through the cornea and lens. During **accommodation**, the shape of the lens changes to focus an image on the retina. "Normal" **visual acuity** is rated 20/20. (*Figures 17–10 to Spotlight Figure 17–13*)

- 17-4 Photoreceptors respond to light and change it into electrical signals essential to visual physiology p. 581
- **29.** The two types of photoreceptors are rods, which respond to almost any photon, regardless of its energy content, and cones, which have characteristic ranges of sensitivity. *(Figure 17–14)*
- **30.** Each photoreceptor contains an **outer segment** with membranous **discs**. A narrow stalk connects the outer segment to the **inner segment**. Light absorption occurs in the **visual pigments**, which are derivatives of **rhodopsin** (opsin plus the pigment retinal, which is synthesized from vitamin A). (*Figure 17–14*)
- **31.** Color sensitivity depends on the integration of information from **red**, **green**, and **blue** cones. **Color blindness** is the inability to detect certain colors. (*Figures* 17–15, 17–18)
- **32.** In the absence of photons, a photoreceptor produces a dark current and constantly releases neurotransmitter. Photon absorption reduces the dark current and decreases the release of neurotransmitter to the bipolar cell. (*Spotlight Figure 17–16*)
- **33.** During the process of **bleaching**, rhodopsin molecules are broken down to regenerate retinal back to its photon-absorbing 11-*cis* form. (*Spotlight Figure 17–16*, *Figure 17–17*)
- 34. In the **dark-adapted state**, most visual pigments are fully receptive to stimulation. In the **light-adapted state**, the pupil constricts and bleaching of the visual pigments takes place.
- 35. The ganglion cells that monitor rods, called **M cells** (*magnocells*), are relatively large. The ganglion cells that monitor cones, called **P cells** (*parvo cells*), are smaller and more numerous. (*Figure 17–19*)
- **36.** Visual data from the left half of the combined field of vision arrive at the visual cortex of the right occipital lobe. Data from the right half of the combined field of vision arrive at the visual cortex of the left occipital lobe. (*Figure 17–20*)
- **37. Depth perception** is obtained by comparing relative positions of objects between the left- and right-eye images. (*Figure 17–20*)
- **38.** Visual inputs to the suprachiasmatic nucleus of the hypothalamus affect the function of other brain stem nuclei. This nucleus establishes a visceral **circadian rhythm**, which is tied to the day–night cycle and affects other metabolic processes.
- 17-5 Equilibrium sensations originate within the internal ear, while hearing involves the detection and interpretation of sound waves p. 590
- **39.** The receptors of the internal ear provide the senses of equilibrium and hearing.
- **40.** The ear is divided into the **external ear**, the **middle ear**, and the **internal ear**. (*Figure 17–21*)
- **41.** The external ear includes the **auricle**, or *pinna*, which surrounds the entrance to the **external acoustic meatus**, which ends at the **tympanic membrane** (*eardrum*). (*Figure 17–21*)
- **42.** The middle ear communicates with the nasopharynx by the **auditory** (*pharyngotympanic*) **tube**. The middle ear encloses and protects the **auditory ossicles**. (*Figures* 17–21, 17–22)
- 43. The **membranous labyrinth** (the chambers and tubes) of the internal ear contains the fluid **endolymph**. The **bony labyrinth** surrounds and protects the membranous labyrinth and can be subdivided into the **vestibule**, the **semicircular canals**, and the **cochlea**. (*Figures 17–21, 17–23*)
- 44. The vestibule of the internal ear encloses the saccule and utricle. The semicircular canals contain the semicircular ducts. The cochlea contains the cochlear duct, an elongated portion of the membranous labyrinth. (*Figure 17–23*)

- **45.** The **round window** separates the **perilymph** from the air spaces of the middle ear. The **oval window** is connected to the base of the stapes. (*Figure 17–21*)
- **46.** The basic receptors of the internal ear are **hair cells**, which provide information about the direction and strength of mechanical stimuli. (*Figure 17–24*)
- **47.** The **anterior**, **posterior**, and **lateral semicircular ducts** are continuous with the utricle. Each duct contains an **ampulla** with a gelatinous **cupula** and associated sensory receptors. (*Figures 17–23, 17–24*)
- 48. The saccule and utricle are connected by a passageway that is continuous with the **endolymphatic duct**. This duct terminates in the **endolymphatic sac**. In the saccule and utricle, hair cells cluster within **maculae**, where their hair cells contact the gelatinous otolithic membrane. The surface of the membrane contains calcium carbonate crystals called **otoliths**. (*Figures* 17–24, 17–25)
- **49.** The vestibular receptors activate sensory neurons of the **vestibular ganglia**. The axons form the **vestibular branch** of the vestibulocochlear nerve (VIII), synapsing within the **vestibular nuclei**. (*Figure 17–26*)

- 50. The cochlear duct lies between the scala vestibuli (vestibular duct) and the scala tympani (tympanic duct). The hair cells of the cochlear duct lie within the spiral organ (organ of Corti). (Figures 17–27, 17–28)
- **51.** The energy content of a sound determines its *intensity*, or loudness, measured in **decibels**. Sound waves travel toward the tympanic membrane, which vibrates, and the auditory ossicles then conduct these vibrations to the internal ear. Movement at the oval window applies pressure to the perilymph of the scala vestibuli. (*Figures* 17–29, 17–30; *Table* 17–1)
- 52. Pressure waves distort the basilar membrane and push the hair cells of the spiral organ against the tectorial membrane. The tensor tympani and stapedius muscles contract to reduce the amount of motion when very loud sounds arrive. (*Figures 17–30, 17–31*)
- 53. The sensory neurons are located in the **spiral ganglion** of the cochlea. The afferent fibers of these neurons form the **cochlear branch** of the vestibulocochlear nerve (VIII), synapsing at their respective left or right **cochlear nucleus**. (*Figure 17–32*)

Review Questions

(a)

(c)

(e)

(g)

(i)

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures in the following horizontal section of the eye.

- A reduction in sensitivity in the presence of a constant stimulus is
 (a) transduction, (b) sensory coding, (c) line labeling, (d) adaptation.
- 3. A blind spot occurs in the retina where (a) the fovea is located,
 (b) ganglion cells synapse with bipolar cells, (c) the optic nerve attaches to the retina, (d) rod cells are clustered to form the macula,
 (e) amacrine cells are located.
- Sound waves are converted into mechanical movements by the

 (a) auditory ossicles,
 (b) cochlea,
 (c) oval window,
 (d) round window,
 (e) tympanic membrane.
- 5. The basic receptors in the internal ear are the (a) utricles, (b) saccules, (c) hair cells, (d) supporting cells, (e) ampullae.

See the blue Answers tab at the back of the book.

- The retina is also called (a) the vascular layer, (b) the fibrous layer, (c) the inner layer, (d) all of these.
- 7. At sunset, your visual system adapts to (a) fovea vision, (b) rod-based vision, (c) macular vision, (d) cone-based vision.
- A better-than-average visual acuity rating is (a) 20/20, (b) 20/30, (c) 15/20, (d) 20/15.
- 9. The malleus, incus, and stapes are the tiny bones located in the (a) external ear, (b) middle ear, (c) internal ear, (d) membranous labyrinth.
- **10.** Identify the structures of the external, middle, and internal ear in the following figure.

- Receptors in the saccule and utricle provide sensations of

 (a) angular acceleration,
 (b) hearing,
 (c) vibration,
 (d) gravity and linear acceleration.
- 12. The spiral organ is located in the ______ of the internal ear.(a) utricle, (b) bony labyrinth, (c) vestibule, (d) cochlea.
- Auditory information about the frequency and intensity of stimulation is relayed to the CNS over the cochlear branch of cranial nerve (a) IV, (b) VI, (c) VIII, (d) X.
- 14. What are the four types of papillae on the human tongue?
- **15.** (a) What structures make up the fibrous layer of the eye? (b) What are the functions of the fibrous layer?
- 16. What structures make up the vascular layer of the eye?
- **17.** What are the three auditory ossicles in the middle ear, and what are their functions?

LEVEL 2 Reviewing Concepts

- **18.** Trace the olfactory pathway from the time an odor reaches the olfactory epithelium until nerve impulses reach their final destination in the brain.
