- **19.** Why are olfactory sensations long-lasting and an important part of our memories and emotions?
- **20.** What is the usual result if a sebaceous gland of an eyelash or a tarsal gland becomes infected?
- Displacement of stereocilia toward the kinocilium of a hair cell

 (a) produces a depolarization of the membrane,
 (b) produces a hyperpolarization of the membrane,
 (c) decreases the membrane permeability to sodium ions,
 (d) increases the membrane permeability to potassium ions,
 (e) does not affect the membrane potential of the cell.

- **22.** Damage to the cupula of the lateral semicircular duct would interfere with the perception of **(a)** the direction of gravitational pull, **(b)** linear acceleration, **(c)** horizontal rotation of the head, **(d)** vertical rotation of the head, **(e)** angular rotation of the head.
- When viewing an object *close* to you, your lens should be more ______. (a) rounded, (b) flattened, (c) concave, (d) lateral, (e) medial.

LEVEL 3 Critical Thinking and Clinical Applications

- 24. You are at a park watching some deer 35 feet away from you. A friend taps you on the shoulder to ask a question. As you turn to look at your friend, who is standing just 2 feet away, what changes would your eyes undergo?
- 25. Your friend Shelly suffers from myopia (nearsightedness). You remember from your physics class that concave lenses cause light waves to spread or diverge and that convex lenses cause light waves to converge. What type of corrective lenses would you suggest to your friend?(a) concave lenses, (b) convex lenses.
- **26.** Tom has surgery to remove polyps (growths) from his sinuses. After he heals from the surgery, he notices that his sense of smell is not as keen as it was before the surgery. Can you suggest a reason for this?
- **27.** For a few seconds after you ride the express elevator from the 20th floor to the ground floor, you still feel as if you are descending, even though you have come to a stop. Why?
- **28.** Juan tells his physician that he has been feeling dizzy, especially when he closes his eyes. He is asked to stand with his feet together and arms extended forward. As long as he keeps his eyes open, he exhibits very little movement. But when he closes his eyes, his body begins to sway a great deal, and his arms tend to drift together toward the left side of his body. Why does this occur?

CLINICAL CASE V

A Chance to See

Makena suffers from *myopia*, or nearsightedness. Due to the elongated shape of Makena's eyeballs, distant images are projected in front of her retina and appear blurry and out of focus to her. Glasses can correct this easily, but nobody in Makena's village has ever met an eye doctor of any kind The closest optical shop is far out of this family's reach, both

kind. The closest optical shop is far out of this family's reach, both in distance and cost. Makena's teacher sets up a makeshift eye clinic with the help of volunteers from the Centre for Vision in the Developing World,

a group dedicated to correcting vision for poor children. To test her vision, Makena attempts to read from an eye chart taped to the wall of the school building 20 feet away. Makena's visual acuity tests at 20/200.

Next, Makena puts on a simple pair of universal glasses, made with a clear membrane filled with silicone oil, held between two

Wrap-Up

plastic discs on each side. A removable syringe filled with silicone oil is attached to each side. With her right eye covered, Makena uses the syringe to inject more silicone into the left lens until her left eye can

read the eye chart perfectly. Then she repeats the process for her right eye. The final step is to remove the syringes. Now she can see things she never knew she had been missing—and she gets to keep the glasses.

- 1. What does Makena's initial eye test finding of 20/200 mean?
- **2.** If Makena's vision is corrected to a state of emmetropia, what does this mean?

CLINICAL CASE

Stones, Bones, and Groans

Monica is back in her doctor's office, following up on her lab results. She feels a little crazy, seeing a

new family practitioner with so many vague complaints. She has a history of high blood pressure (hypertension) and heart palpitations (irregular heartbeats). She has had several kidney stones. She has osteopenia and suffers from nagging bone pain. Recently she has experienced vague abdominal pain with loss of appetite and constipation. Furthermore, she has been feeling chronic fatigue, some of which she attributes to having trouble falling asleep and regularly awakening in the middle of the night. Monica has also noticed that her memory is getting worse and that she feels increasingly depressed. Worst of all, her husband of 40 years has complained that she is getting more irritable and cranky.

"Monica," says her doctor, "I think I know what is causing your symptoms. The answer is right here in your lab

results." What could be causing Monica's many complaints? To find out, turn to the Clinical Case Wrap-Up on p. 651.

18

An Introduction to the Endocrine System

The human body contains about 30 chemical messengers known as hormones, which regulate activities such as sleep, body temperature, hunger, and stress management. These hormones are products of the endocrine system, which along with the nervous system, controls and coordinates our body processes.

In this chapter we examine the structural and functional organization of the endocrine system and compare it to the nervous system. After an overview of the endocrine system and the characteristics of the hormones it produces, we consider the structure and function of the body's various endocrine glands. Finally, we look at the ways in which hormones modify metabolic operations, and the interactions between the endocrine system and other body systems. Let's begin by considering the role of intercellular communication in maintaining homeostasis.

18–1 Homeostasis is preserved through intercellular communication

Learning Outcome Explain the importance of intercellular communication, describe the mechanisms involved, and compare the modes of intercellular communication that occur in the endocrine and nervous systems.

To preserve homeostasis, cellular activities must be coordinated throughout the body. Neurons monitor or control specific cells or groups of cells. Only a small fraction of all the cells in the body are innervated, however, and the commands from the nervous system are very specific and relatively short-lived. Yet many life processes are not short-lived. For example, your body takes decades to reach adult height. The body continually controls and maintains its reproductive capabilities for at least 30 years in a typical female, and even longer in males. Longterm processes, such as growth, development, or reproduction, involve or affect metabolic activities in virtually every cell and tissue. There is no way that the nervous system can regulate such processes. Instead, the endocrine system provides this type of regulation. It uses chemical messengers to relay information and instructions between cells. To understand how these messages are generated and interpreted, let's take a closer look at how cells communicate with one another.

In a few specialized cases, adjacent cells coordinate cellular activities by exchanging ions and molecules across gap junctions. This **direct communication** occurs between two cells of the same type, and the cells must be in extensive physical contact. The two cells communicate so closely that they function as a single entity. Gap junctions (1) coordinate ciliary movement among epithelial cells, (2) coordinate the contractions of cardiac muscle cells, and (3) facilitate the propagation of action potentials from one neuron to the next at electrical synapses.

Most communication between cells involves the release and receipt of chemical messages. Each cell continuously "talks" to its neighbors by releasing chemicals into the extracellular fluid. These chemicals tell cells what their neighbors are doing at any moment. The result is the coordination of tissue function at the local level. The use of chemical messengers to transfer information from cell to cell within a single tissue is called **paracrine communication**. The chemicals involved are called *paracrine factors*, also known as *local hormones*. Examples of paracrine factors include the prostaglandins, introduced in Chapter 2, and the various growth factors, discussed in Chapter 3. ⊃ pp. 47, 103

Paracrine factors enter the bloodstream, but their concentrations are usually so low that distant cells and tissues are not affected. However, some paracrine factors, including several of the prostaglandins and related chemicals, have primary effects in their tissues of origin and secondary effects in other tissues and organs. When these secondary effects occur, the paracrine factors are also acting as **hormones**—chemical messengers that are released in one tissue and transported in the bloodstream to alter the activities of specific cells in other tissues. Most cells release paracrine factors, but only specialized cells produce typical hormones.

Nevertheless, the difference between paracrine factors and hormones is mostly a matter of degree. Paracrine factors can diffuse out of their tissue of origin and have widespread effects, and hormones can affect their tissues of origin as well as distant cells. By convention, a substance with effects outside its tissue of origin is called a *hormone* if its chemical structure is known, and a *factor* if that structure remains to be determined.

In intercellular communication, hormones are like messages and the cardiovascular system is e-mail. A hormone released into the bloodstream is distributed throughout the body. Each hormone has **target cells**, specific cells that have the receptors needed to bind and "read" the hormonal message when it arrives. But hormones are really like e-mail spam—cells throughout the body are exposed to them whether or not they have the necessary receptors. At any moment, each individual cell can respond to only a few of the hormones present. The cell ignores other hormones, because it lacks the receptors to read the messages they contain. The activity of hormones in coordinating cellular activities in tissues in distant portions of the body is called **endocrine communication**.

How do hormones work? They alter the operations of target cells by changing the types, quantities, or activities of important enzymes and structural proteins. A hormone may

- stimulate the synthesis of an enzyme or a structural protein not already present in the cytoplasm by activating appropriate genes in the cell nucleus;
- increase or decrease the rate of synthesis of a particular enzyme or other protein by changing the rate of transcription or translation; or
- turn an existing enzyme or membrane channel "on" or "off" by changing its shape or structure.

Through one or more of these mechanisms, a hormone can modify the physical structure or biochemical properties of its target cells. Because the target cells can be anywhere in the body, a single hormone can alter the metabolic activities of multiple tissues and organs at the same time. These effects may be slow to appear, but they typically last for days. Consequently, hormones are effective in coordinating cell, tissue, and organ activities on a sustained, long-term basis. For example, circulating hormones keep body water content and levels of electrolytes and organic nutrients within normal limits 24 hours a day throughout our entire lives.

Cells can respond to several different hormones simultaneously. Gradual changes in the quantities and identities of circulating hormones can produce complex changes in the body's physical structure and physiological capabilities. Examples include the processes of embryonic and fetal development, growth, and puberty. Hormonal regulation is quite suitable for

Table 18–1	Mechanisms	of Intercellular Communicat	ion	
Mechanism		Transmission	Chemical Mediators	Distribution of Effects
Direct communication	ation	Through gap junctions	lons, small solutes, lipid-soluble materials	Usually limited to adjacent cells of the same type that are interconnected by connexons
Paracrine commu	unication	Through extracellular fluid	Paracrine factors	Primarily limited to a local area, where paracrine factor concentrations are relatively high Target cells must have appropriate receptors
Endocrine comm	unication	Through the bloodstream	Hormones	Target cells are primarily in other tissues and organs and must have appropriate receptors
Synaptic commun	nication	Across synapses	Neurotransmitters	Limited to very specific area; target cells must have appropriate receptors

directing gradual, coordinated processes, but it is totally unable to handle situations requiring split-second responses. That kind of crisis management is the job of the nervous system.

The nervous system, too, relies primarily on chemical communication, but it does not send messages through the bloodstream. Instead, as we have seen, neurons release a neurotransmitter at a synapse very close to target cells that have the appropriate receptors. The command to release the neurotransmitter rapidly travels from one location to another in the form of action potentials propagated along axons. The nervous system thus acts like a telecommunications company, with a cable network carrying highspeed "messages" to specific destinations throughout the body. The effects of neural stimulation are generally short-lived, and they tend to be restricted to specific target cells-primarily because the neurotransmitter is rapidly broken down or recycled. This synaptic communication is ideal for crisis management: If you are in danger of being hit by a speeding bus, the nervous system can coordinate and direct your leap to safety. Once the crisis is over and the neural circuits quiet down, things soon return to normal.

Table 18–1 summarizes the four ways cells and tissues communicate with one another. Viewed from a general perspective, the differences between the nervous system and endocrine system seem relatively clear. In fact, these broad organizational and functional distinctions are the basis for treating them as two separate systems. Yet when we consider them in detail, we see that the two systems are similarly organized:

- Both systems rely on the release of chemicals that bind to specific receptors on their target cells.
- The two systems share many chemical messengers. For example, norepinephrine and epinephrine are called *hormones* when released into the bloodstream, but *neurotransmitters* when released across synapses.
- Both systems are regulated mainly by negative feedback control mechanisms.
- The two systems share a common goal: to preserve homeostasis by coordinating and regulating the activities of other cells, tissues, organs, and systems.

Next we introduce the components and functions of the endocrine system and further explore the interactions between the nervous and endocrine systems. We consider specific endocrine organs, hormones, and functions in detail in later sections.

CHECKPOINT

- 1. Define hormone.
- 2. Describe paracrine communication.
- 3. Identify four mechanisms of intercellular communication.

See the blue Answers tab at the back of the book.

18-2 The endocrine system regulates physiological processes through the binding of hormones to receptors

Learning Outcome Compare the cellular components of the endocrine system with those of other systems, contrast the major structural classes of hormones, and explain the general mechanisms of hormonal action on target organs.

The **endocrine system** includes all the endocrine cells and tissues of the body that produce hormones or paracrine factors with effects beyond their tissues of origin. As noted in Chapter 4, *endocrine cells* are glandular secretory cells that release their secretions into the extracellular fluid. This characteristic distinguishes them from *exocrine cells*, which secrete their products onto epithelial surfaces, generally by way of ducts. \bigcirc **p. 123** The chemicals released by endocrine cells may affect only nearby cells, as in the case of most paracrine factors, or they may affect cells throughout the body.

Figure 18–1 introduces the tissues, organs, and hormones of the endocrine system. Some of these organs, such as the pituitary gland, have endocrine secretion as a primary function. Others, such as the pancreas, have many other functions in addition to endocrine secretion. We consider such endocrine organs in more detail in chapters on other systems.

Classes of Hormones

We can divide hormones into three groups on the basis of their chemical structure: (1) *amino acid derivatives*, (2) *peptide hormones*, and (3) *lipid derivatives*.

Amino acid derivatives, sometimes known as *biogenic amines*, are relatively small molecules that are structurally related to amino acids, the building blocks of proteins. $\supset p$. 51 These hormones are synthesized from the amino acids *tyrosine* (TĪ-rō-sēn) and *tryptophan* (TRIP-tō-fan). Those made from tyrosine include (1) thyroid hormones, produced by the thyroid gland, and (2) the compounds epinephrine (E), norepinephrine (NE), and dopamine, which are sometimes called *catecholamines* (kat-e-KŌ-la-mēnz). The primary hormone made from tryptophan is melatonin (mel-a-TŌ-nin), produced by the pineal gland.

We can divide peptide hormones into two groups. One group consists of glycoproteins, and the other group is made up of short polypeptides and small proteins.

There are two classes of lipid derivatives: (1) *eicosanoids* and (2) *steroid hormones*. Eicosanoids are signaling molecules and include leukotrienes, prostaglandins, thromboxanes, and

prostacyclins. Steroid hormones are lipids structurally similar to cholesterol (Figure 2–17a, p. 49). The individual hormones differ in the side chains attached to the basic ring structure. Over time, the liver gradually absorbs these steroids and converts them to a soluble form that can be excreted in the bile or urine (Spotlight Figure 18–2).

In this chapter we focus on circulating hormones that function primarily to coordinate activities in many tissues and organs. We consider eicosanoids in chapters that discuss individual tissues and organs, including Chapters 19 (the blood), 22 (the lymphatic system), and 28 (the reproductive system).

Secretion and Distribution of Hormones

Hormones are typically released where capillaries are abundant, and the hormones quickly enter the bloodstream for distribution throughout the body. Within the blood, hormones may circulate freely or travel bound to special carrier proteins. A freely circulating hormone remains functional for less than one hour, and sometimes for as little as two minutes. It is inactivated when (1) it diffuses out of the bloodstream and binds to receptors on target cells, (2) it is absorbed and broken down by cells of the liver or kidneys, or (3) it is broken down by enzymes in the blood or interstitial fluids.

SPOTLIGHT Figure 18–2 Structural Classification of Hormones

HORMONES

The hormones of the body can be divided into three groups on the basis of their chemical structure.

Amino Acid Derivatives

Amino acid derivatives are small molecules that are structurally related to amino acids, the building blocks of proteins.

Derivative of Tryptophan

Peptide Hormones

Peptide hormones are chains of amino acids. Most peptide hormones are synthesized as prohormones—inactive molecules that are converted to active hormones before or after they are secreted.

Glycoproteins

These proteins are more than 200 amino acids long and have carbohydrate side chains. The glycoproteins include thyroid-stimulating hormone (TSH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) from the anterior lobe of the pituitary gland, as well as several hormones produced in other organs.

Short Polypeptides/ Small Proteins

This group of peptide hormones is large and diverse. It includes hormones that range from **short** chain polypeptides, such as antidiuretic hormone (ADH) and oxytocin (OXT) (each 9 amino acids long), to small proteins, such as insulin (51 amino acids), growth hormone (GH; 191 amino acids), and prolactin (PRL: 198 amino acids). This group includes all the hormones secreted by the hypothalamus, heart, thymus, digestive tract, pancreas, and posterior lobe of the pituitary gland, as well as several hormones produced in other organs.

Lipid Derivatives

There are two classes of lipid derivatives: eicosanoids, derived from arachidonic acid, a 20-carbon fatty acid; and steroid hormones, derived from cholesterol.

Eicosanoids

Eicosanoids (Ī-kō-sa-noydz) are important paracrine fac-

tors that coor-

Prostaglandin E

dinate cellular activities and affect enzymatic processes (such as blood clotting) in extracellular fluids. Some eicosanoids, such as leukotrienes (lū-kō-TRĪ-ēns), have secondary roles as hormones. A second group of eicosanoids—prostaglandins—are involved primarily in coordinating local cellular activities. In some tissues, prostaglandins are converted to

thromboxanes (throm-BOX-ānz) and prostacyclins (pros-ta-SĪklinz), which also have strong paracrine effects.

Aspirin suppresses the production of prostaglandins.

Steroid Hormones

Steroid hormones

are released by the reproductive organs (androgens by the testes in males, estrogens and

Estrogen

progesterone by the ovaries in females), by the cortex of the adrenal glands (corticosteroids), and by the kidneys (calcitriol). Because circulating steroid hormones are bound to specific transport proteins in the plasma, they remain in circulation longer than do secreted peptide hormones.

Thyroid hormones and steroid hormones remain in circulation much longer, because when these hormones enter the bloodstream, more than 99 percent of them become attached to special transport proteins. For each hormone an equilibrium state exists between its free and bound forms. As the free hormones are removed and inactivated, bound hormones are released to replace them. At any given time, the bloodstream contains a substantial reserve (several weeks' supply) of bound hormones.

Mechanisms of Hormone Action

Hormones coordinate cell, tissue, and organ activities on a sustained basis. They circulate in the extracellular fluid and bind to specific receptors on plasma membranes or within target cells. Binding modifies cellular activities by altering membrane permeability, activating or inactivating key enzymes, or changing genetic activity.

To affect a target cell, a hormone must first interact with an appropriate receptor. A hormone receptor, like a neurotransmitter receptor, is a protein molecule to which a particular molecule binds strongly. Each cell has receptors for several different hormones, but cells in different tissues have different combinations of receptors. This arrangement is one reason hormones have different effects on different tissues. For every cell, the presence or absence of a specific receptor determines the cell's hormonal sensitivities. If a cell has a receptor that can bind a particular hormone, that cell responds to the hormone. If a cell lacks that receptor, the hormone has no effect on that cell.

Hormone receptors are located either on the plasma membrane or inside the cell. Using a few specific examples, let's consider the basic mechanisms involved.

Hormones and Plasma Membrane Receptors

The receptors for catecholamines (E, NE, and dopamine), peptide hormones, and eicosanoids are in the plasma membranes of their target cells. Catecholamines and peptide hormones cannot penetrate a plasma membrane because they are not lipid soluble. Instead, these hormones bind to receptor proteins at the *outer* surface of the plasma membrane (extracellular receptors). Eicosanoids *are* lipid soluble. They diffuse across the plasma membrane to reach receptor proteins on the *inner* surface of the membrane (intracellular receptors).

First and Second Messengers

Communication between the hormone and the cell uses first and second messengers. A *first messenger* is a hormone that binds to a receptor on the plasma membrane surface. A second messenger is an intermediary molecule that appears due to a hormone-receptor interaction. Important second messengers are (1) *cyclic AMP (cAMP)*, a derivative of ATP; (2) *cyclic GMP* (*cGMP*), a derivative of GTP, another high-energy compound; and (3) calcium ions (Ca^{2+}). Spotlight Figure 18–3 focuses on cAMP and Ca^{2+} .

When a small number of hormone molecules binds to membrane receptors, thousands of second messengers may appear in a cell. This process, called *amplification*, magnifies the effect of a hormone on the target cell. Moreover, the arrival of a single hormone may promote the release of more than one type of second messenger, or the production of a linked sequence of enzymatic reactions known as a *receptor cascade*. Through such mechanisms, the hormone can alter many aspects of cell function at the same time.

The presence or absence of a hormone can also affect the nature and number of hormone receptor proteins in the plasma membrane. **Down-regulation** is a process in which the presence of a hormone triggers a decrease in the number of hormone receptors. In down-regulation, cells become *less* sensitive to high levels of a particular hormone. In contrast, **up-regulation** is a process in which the absence of a hormone triggers an increase in the number of hormone receptors. In up-regulation, cells become *more* sensitive to low levels of a particular hormone.

The link between the first messenger and the second messenger generally involves a **G protein**, an enzyme complex coupled to a membrane receptor. The name *G protein* refers to the fact that these proteins bind GTP. \bigcirc **p**. 420 A G protein is activated when a hormone binds to its receptor at the membrane surface. What happens next depends on the nature of the G protein and its effects on second messengers in the cytoplasm. **Spotlight Figure 18–3** diagrams three major patterns of response to G protein activation. Roughly 80 percent of prescription drugs target receptors coupled to G proteins.

G Proteins and cAMP. Spotlight Figure 18–3 shows the steps involved in *increasing* cAMP levels:

- The activated G protein activates the enzyme **adenylate cyclase**.
- Adenylate cyclase converts ATP to the ring-shaped molecule *cyclic AMP*.
- Cyclic AMP then functions as a second messenger, typically by activating a *kinase* ($K\bar{I}$ -n $\bar{a}s$). A kinase is an enzyme that attaches a high-energy phosphate group (-PO₄³⁻) to another molecule in a process called *phosphorylation*.
- Generally, cyclic AMP activates kinases that phosphorylate proteins. The effect on the target cell depends on the nature of these proteins. The phosphorylation of plasma membrane proteins, for example, can open ion channels. In the cytoplasm, many important enzymes can be activated only by phosphorylation. One important example is the enzyme that releases glucose from glycogen reserves in skeletal muscles and the liver.

Many hormones, including calcitonin, parathyroid hormone, ADH, ACTH, epinephrine, FSH, LH, TSH, and glucagon,

SPOTLIGHT Figure 18–3 G Proteins and Second Messengers

The first messenger

(a peptide hormone,

catecholamine, or

MECHANISM OF HORMONE ACTION First and Second Messengers

A hormone that binds to receptors in the plasma membrane cannot directly affect the activities inside the target cell. For example, it cannot begin building a protein or catalyzing a specific reaction. Instead, the hormone uses an intracellular intermediary to bring about its effects. The hormone, or **first messenger**, does something that leads to the appearance of a **second messenger** in the cytoplasm. The second messenger may act as an enzyme activator, inhibitor, or cofactor. The net result is a change in the rates of various metabolic reactions. The two most important second messengers are cyclic AMP (cAMP), a derivative of ATP, and calcium ions (Ca²⁺).

Effects on Ca²⁺ Levels

produce their effects by this mechanism. The increase in cAMP levels is usually short-lived, because the cytoplasm contains another enzyme, **phosphodiesterase (PDE)**, which inactivates cyclic AMP by converting it to AMP (adenosine monophosphate).

Spotlight Figure 18–3 (center) depicts one way the activation of a G protein can *lower* the concentration of cAMP within the cell. In this case, the activated G protein stimulates PDE activity and inhibits adenylate cyclase activity. Levels of cAMP then decline, because cAMP breakdown accelerates while cAMP synthesis is prevented. The decline has an inhibitory effect on the cell, because without phosphorylation, key enzymes remain inactive. This mechanism is responsible for the inhibitory effects that follow when epinephrine and norepinephrine stimulate α_2 adrenergic receptors, as discussed in Chapter 16. \bigcirc p. 541

G Proteins and Calcium lons. An activated G protein can trigger either the opening of calcium ion channels in the plasma membrane or the release of calcium ions from intracellular compartments. **Spotlight Figure 18–3** (right panel) diagrams the steps involved. The G protein first activates the enzyme *phospholipase C (PLC)*. This enzyme triggers a receptor cascade that begins with the production of **diacylglycerol (DAG)** and **inositol triphosphate (IP₃)** from membrane phospholipids. The cascade then proceeds as follows:

- IP₃ diffuses into the cytoplasm and triggers the release of Ca²⁺ from intracellular reserves, such as those in the smooth endoplasmic reticulum of many cells.
- The combination of DAG and intracellular calcium ions activates another membrane protein: protein kinase C (PKC). The activation of PKC leads to the phosphorylation of calcium channel proteins, a process that opens the channels and permits extracellular Ca²⁺ to enter the cell. This sets up a positive feedback loop that rapidly elevates intracellular calcium ion concentrations.
- The calcium ions themselves serve as messengers, generally in combination with an intracellular protein called calmodulin. Once it has bound calcium ions, calmodulin can activate specific cytoplasmic enzymes. This chain of events is responsible for the stimulatory effects that follow when epinephrine or norepinephrine activates α₁ receptors. D p. 541 Calmodulin activation is also involved in the responses to oxytocin and to several regulatory hormones secreted by the hypothalamus.

Hormones and Intracellular Receptors

Steroid hormones diffuse across the lipid part of the plasma membrane and bind to receptors in the cytoplasm or nucleus. The hormone–receptor complexes then activate or deactivate specific genes (Figure 18–4a). By this mechanism, steroid hormones can alter the rate of DNA transcription in the nucleus.

In this way, they change the pattern of protein synthesis. Alterations in the synthesis of enzymes or structural proteins directly affect both the metabolic activity and the structure of the target cell. For example, the sex hormone *testosterone* stimulates the production of enzymes and structural proteins in skeletal muscle fibers, causing muscle size and strength to increase.

Thyroid hormones cross the plasma membrane primarily by a transport mechanism. Once in the cytoplasm, these hormones bind to receptors within the nucleus and on mitochondria (Figure 18–4b). The hormone–receptor complexes in the nucleus activate specific genes or change the rate of transcription. The change in transcription rate affects the metabolic activities of the cell by increasing or decreasing the concentration of specific enzymes. Thyroid hormones bound to mitochondria increase the mitochondrial rates of ATP production.

Control of Endocrine Activity by Endocrine Reflexes

As noted earlier, the functional organization of the nervous system parallels that of the endocrine system in many ways. In Chapter 13, we considered the basic operation of neural reflex arcs, the simplest organizational units in the nervous system. **D p**. 449 The most direct arrangement was a monosynaptic reflex, such as the stretch reflex. Polysynaptic reflexes provide more complex and variable responses to stimuli. Higher centers, which integrate multiple inputs, can facilitate or inhibit these reflexes as needed.

Endocrine reflexes are the functional counterparts of neural reflexes. Endocrine reflexes can be triggered by (1) *humoral stimuli* (changes in the composition of the extracellular fluid), (2) *hormonal stimuli* (the arrival or removal of a specific hormone), or (3) *neural stimuli* (the arrival of neurotransmitters at neuroglandular junctions). In most cases, negative feedback controls endocrine reflexes: A stimulus triggers the production of a hormone, and the direct or indirect effects of the hormone reduce the intensity of the stimulus.

A simple endocrine reflex involves only one hormone. The endocrine cells involved respond directly to changes in the composition of the extracellular fluid. The secreted hormone adjusts the activities of target cells and restores homeostasis. Simple endocrine reflexes control hormone secretion by the heart, pancreas, parathyroid glands, and digestive tract.

More complex endocrine reflexes involve one or more intermediary steps and two or more hormones.

The hypothalamus provides the highest level of endocrine control. It integrates the activities of the nervous and endocrine systems in three ways (Figure 18–5):

1. The hypothalamus itself acts as an endocrine organ. Hypothalamic neurons synthesize hormones and transport them along axons to the posterior lobe of the

Figure 18–4 Effects of Intracellular Hormone Binding.

a Steroid hormones diffuse through the plasma membrane and bind to receptors in the cytoplasm or nucleus. The complex then binds to DNA in the nucleus, activating specific genes.

b Thyroid hormones enter the cytoplasm and bind to receptors in the nucleus to activate specific genes. They also bind to receptors on mitochondria and accelerate ATP production.

pituitary gland, where they are released into the circulation. We introduced two of these hormones, antidiuretic hormone (ADH) and oxytocin (OXT), in Chapter 14. **D** p. 478

2. The hypothalamus secretes **regulatory hormones**, special hormones that control endocrine cells in the pituitary gland. The hypothalamic regulatory hormones control the secretory activities of endocrine cells in the anterior lobe of the pituitary gland. In turn, the hormones from the anterior lobe control the activities of endocrine cells in the thyroid, adrenal cortex, and reproductive organs.

3. The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medullae. When the sympathetic division is activated, the adrenal medullae release the hormones epinephrine (E) and norepinephrine (NE) into the bloodstream.

The hypothalamus secretes regulatory hormones and ADH in response to changes in the composition of the circulating

blood. The secretion of oxytocin OXT, E, and NE involves both neural and hormonal mechanisms. For example, the adrenal medullae secrete E and NE in response to action potentials rather than to circulating hormones. Such pathways are called *neuroendocrine reflexes*, because they include both neural and endocrine components. We will consider these reflex patterns in more detail as we examine specific endocrine tissues and organs.

In Chapter 15, we noted that sensory receptors provide complex information by varying the frequency and pattern of action potentials in a sensory neuron. In a similar way, the endocrine system sends complex commands by changing the amount of hormone secreted and the pattern of hormone release. In a simple endocrine reflex, hormones are released continuously, but the rate of secretion rises and falls in response to humoral stimuli. For example, when blood glucose levels climb, the pancreas increases its secretion of *insulin*, a hormone that stimulates glucose uptake and utilization. As insulin levels rise, glucose levels decline, reducing the stimulation of the insulin-secreting cells. As glucose levels return to normal, the rate of insulin secretion returns to resting levels. (We introduced this regulatory pattern, called *negative feedback*, in Chapter 1 when we considered the control of body temperature. \bigcirc **p**. 10)

In this example, the responses of the target cells change over time, because the effect of insulin is proportional to its concentration. However, the relationship between hormone concentration and target cell response is not always predictable. For instance, a hormone can have one effect at low concentrations and more exaggerated effects—or even different effects at high concentrations. (We consider specific examples later in the chapter.)

Several hypothalamic and pituitary hormones are released in sudden bursts called *pulses*, rather than continuously. When hormones arrive in pulses, target cells may vary their response with the frequency of the pulses. For example, the target cell response to one pulse every three hours can differ from the response when pulses arrive every 30 minutes. The most complicated hormonal instructions from the hypothalamus involve changes in the frequency of pulses *and* in the amount secreted in each pulse.

CHECKPOINT

- 4. How could you distinguish between a neural response and an endocrine response on the basis of response time and duration?
- 5. How would the presence of a substance that inhibits the enzyme adenylate cyclase affect the activity of a hormone that produces its cellular effects by way of the second messenger cAMP?
- 6. What primary factor determines each cell's hormonal sensitivities?

See the blue Answers tab at the back of the book.

18-3 The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones

Learning Outcome Describe the location, hormones, and functions of the pituitary gland, and discuss the effects of abnormal pituitary hormone production.

Figure 18–6 shows the anatomy of the **pituitary gland**, or **hypophysis** (hī-POF-i-sis). This small, oval gland lies nestled within the *sella turcica*, a depression in the sphenoid bone (**Figure 7–8**, p. 217). The pituitary gland is inferior to the hypothalamus. It is connected by the slender, funnel-shaped

structure called the **infundibulum** (in-fun-DIB-ū-lum; funnel). The base of the infundibulum lies between the optic chiasm and the mammillary bodies. Cradled by the sella turcica, the pituitary gland is held in position by the *sellar diaphragm*, a dural sheet that encircles the infundibulum. The sellar diaphragm locks the pituitary gland in position and isolates it from the cranial cavity.

The pituitary gland has anterior and posterior lobes that differ in function and developmental anatomy. It releases nine important peptide hormones. Seven come from the anterior lobe and two from the posterior lobe. All nine hormones bind to membrane receptors, and all nine use cAMP as a second messenger. ATLAS: Embryology Summary 14: The Development of the Endocrine System

The Anterior Lobe of the Pituitary Gland

The **anterior lobe** of the pituitary gland, also called the **adeno-hypophysis** (ad-e-no-hī-POF-i-sis), contains a variety of endocrine cells. The anterior lobe has three regions: (1) the **pars distalis** (dis-TAL-is; distal part), the largest and most anterior portion of the pituitary gland; (2) an extension called the **pars tuberalis**, which wraps around the adjacent portion of the infundibulum; and (3) the slender **pars intermedia**, a narrow band bordering the posterior lobe (Figure 18–6). An extensive

Figure 18–6 The Anatomy and Orientation of the Pituitary Gland.
capillary network radiates through these regions, giving every endocrine cell immediate access to the bloodstream.

The Hypophyseal Portal System

The hypothalamus controls the production of hormones in the anterior lobe of the pituitary gland by secreting specific regulatory hormones. At the *median eminence*, a swelling near the attachment of the infundibulum, hypothalamic neurons release regulatory factors into the surrounding interstitial fluids. Their secretions enter the bloodstream quite easily, because the endothelial cells lining the capillaries in this region are unusually permeable. These **fenestrated** (FEN-es-trā-ted; *fenestra*, window) **capillaries** allow relatively large molecules to enter or leave the bloodstream. \supset p. 469

The capillary networks in the median eminence are supplied by the *superior hypophyseal artery* (Figure 18–7). Before leaving the hypothalamus, the capillary networks unite to form a series of larger vessels that spiral around the infundibulum to reach the anterior lobe. In the anterior lobe, these vessels form a second capillary network that branches among the endocrine cells.

This vascular arrangement is unusual because it carries blood from one capillary network to another. In contrast, a

typical artery conducts blood from the heart to a capillary network, and a typical vein carries blood from a capillary network back to the heart. Blood vessels that link two capillary networks are called **portal vessels**. In this case, they have the histological structure of veins, so they are also called portal veins. The entire complex is a **portal system**. Portal systems are named for their destinations. This particular network is the **hypophyseal** (hī-po-FI-sē-al) portal system.

Portal systems are an efficient means of chemical communication. This one ensures that all the hypothalamic hormones entering the portal vessels reach the target cells in the anterior lobe before being diluted through mixing with the general circulation. The communication is strictly one way, however. Any chemicals released by the cells "downstream" must do a complete circuit of the cardiovascular system before they reach the capillaries of the portal system.

Hypothalamic Control of the Anterior Lobe

Two classes of hypothalamic regulatory hormones exist: releasing hormones and inhibiting hormones. A **releasing hormone (RH)** stimulates the synthesis and secretion of one or more hormones at the anterior lobe. In contrast, an **inhibiting**

Figure 18–7 The Hypophyseal Portal System and the Blood Supply to the Pituitary Gland.

Releasing hormone (RH)	Hormone 1 (from pituitary)	Endocrine target organ	Hormone 2 (from target organ)

	LH	Testes Ovaries	Androgens Progesterone Estrogens

d Table showing the hypothalamic releasing hormones that follow the typical pattern of regulation shown in **a** above.

hormone (IH) prevents the synthesis and secretion of hormones from the anterior lobe. Releasing hormones, inhibiting hormones, or some combination of the two may control an endocrine cell in the anterior lobe. The regulatory hormones released at the hypothalamus travel directly to the anterior lobe by the hypophyseal portal system.

Negative feedback controls the rate at which the hypothalamus secretes regulatory hormones. The primary regulatory patterns are diagrammed in **Figure 18–8**, and we will refer to them as we examine specific pituitary hormones.

Hormones of the Anterior Lobe

The functions and control mechanisms of seven hormones from the anterior lobe are reasonably well understood:

thyroid-stimulating hormone; adrenocorticotropic hormone; two gonadotropins called *follicle-stimulating hormone* and *luteinizing hormone; prolactin; growth hormone;* and *melanocytestimulating hormone.* Of the six hormones produced by the pars distalis, four regulate the production of hormones by other endocrine glands. The names of these hormones indicate their activities, but many of the phrases are so long that we often use abbreviations instead.

The hormones of the anterior lobe are also called *tropic hormones* (*trope*, a turning). They "turn on" endocrine glands or support the functions of other organs. (Some sources call them *trophic hormones* [*trophe*, nourishment] instead.)

Thyroid-Stimulating Hormone. Thyroid-stimulating hor-mone (TSH), or *thyrotropin*, targets the thyroid gland and triggers the release of thyroid hormones. TSH is released in response to *thyrotropin-releasing hormone (TRH)* from the hypothalamus. Then as circulating concentrations of thyroid hormones rise, the rates of TRH and TSH production decline (Figure 18–8a).

Adrenocorticotropic Hormone. Adrenocorticotropic hormone (ACTH), also known as *corticotropin*, stimulates the release of steroid hormones by the *adrenal cortex*, the outer portion of the adrenal gland. ACTH specifically targets cells that produce *glucocorticoids* (gloo-kō-KOR-ti-koydz), hormones that affect glucose metabolism. ACTH release occurs under the stimulation of **corticotropin-releasing hormone (CRH)** from the hypothalamus. As glucocorticoid levels increase, the rates of CRH release and ACTH release decline (Figure 18–8a).

Gonadotropins. The hormones called **gonadotropins** (gō-nad-ō-TRŌ-pinz) regulate the activities of the *gonads*. (These organs—the testes in males and the ovaries in females—produce reproductive cells as well as hormones.) Gonadotropin-releasing hormone (GnRH) from the hypothalamus stimulates production of gonadotropins. An abnormally low production of gonadotropins results in **hypogonadism**. Children with this condition do not mature sexually, and adults with hypogonadism cannot produce functional sperm (males) or oocytes (females). The two gonadotropins are follicle-stimulating hormone and luteinizing hormone.

Follicle-stimulating hormone (FSH), or *follitropin*, promotes follicle development in females and, in combination with luteinizing hormone, stimulates the secretion of *estrogens* (ES-trō-jenz) by ovarian cells. *Estradiol* is the most important estrogen. In males, FSH stimulates *nurse cells*, specialized cells in the seminiferous tubules where sperm differentiate. In response, the nurse cells promote the physical maturation of developing sperm. FSH production is inhibited by *inhibin*, a peptide hormone released by cells in the testes and ovaries (Figure 18–8a). (The role of inhibin in suppressing the release of GnRH as well as FSH is under debate.)

Luteinizing (LOO-tē-in-ī-zing) hormone (LH), or *lutro-pin*, induces *ovulation*, the production of reproductive cells in females. It also promotes ovarian secretion of estrogens and *progesterone*, which prepare the body for possible pregnancy. In males, this gonadotropin is sometimes called *interstitial cell-stimulating hormone (ICSH)*, because it stimulates the production of sex hormones by the *interstitial cells* of the testes. These male sex hormones are called **androgens** (AN-drō-jenz; *andros*, man). The most important one is *testosterone*. LH production, like FSH production, is stimulated by GnRH from the hypothalamus. Estrogens, progesterone, and androgens inhibit GnRH production (Figure 18–8a).

Prolactin. Prolactin (*pro-*, before + *lac*, milk) (**PRL**) works with other hormones to stimulate mammary gland development. In pregnancy and during the nursing period that follows delivery, PRL also stimulates milk production by the mammary glands. The functions of PRL in males are poorly understood, but evidence indicates that PRL helps regulate androgen production by making interstitial cells more sensitive to LH.

Prolactin production is inhibited by the neurotransmitter dopamine, also known as **prolactin-inhibiting hormone (PIH)**. The hypothalamus also secretes several *prolactin-releasing factors (PRF)*. Few of these have been identified. Circulating PRL stimulates PIH release and inhibits the secretion of PRF **(Figure 18–8b)**.

Although PRL exerts the dominant effect on the glandular cells, normal development of the mammary glands is regulated by the interaction of several hormones. Prolactin, estrogens, progesterone, glucocorticoids, pancreatic hormones, and hormones produced by the placenta cooperate in preparing the mammary glands for secretion. Milk ejection occurs only in response to oxytocin release at the posterior lobe of the pituitary gland. We describe the functional development of the mammary glands in Chapter 28.

Growth Hormone. Growth hormone (GH), or **somatotropin**, stimulates cell growth and replication by accelerating the rate of protein synthesis. Skeletal muscle cells and chondrocytes (cartilage cells) are particularly sensitive to GH, although virtually every tissue responds to some degree.

The stimulation of growth by GH involves two mechanisms. The primary mechanism, which is indirect, is best understood. Liver cells respond to GH by synthesizing and releasing **somatomedins** (compounds that stimulate tissue growth), or **insulin-like growth factors (IGFs)**. These peptide hormones bind to receptors on a variety of plasma membranes (Figure 18–8b). In skeletal muscle fibers, cartilage cells, and other target cells, somatomedins increase the uptake of amino acids and their incorporation into new proteins. These effects develop almost immediately after GH is released. They are particularly important after a meal, when the blood contains high concentrations of glucose and amino acids. In functional terms, cells can now obtain ATP easily through the aerobic metabolism of glucose, and amino acids are readily available for protein synthesis. Under these conditions, GH, acting through the somatomedins, stimulates protein synthesis and cell growth.

The direct actions of GH are more selective. They tend to appear after blood glucose and amino acid concentrations have returned to normal levels:

- In epithelia and connective tissues, GH stimulates stem cell divisions and the differentiation of daughter cells. (Somatomedins then stimulate the growth of these daughter cells.)
- In adipose tissue, GH stimulates the breakdown of stored triglycerides by adipocytes (fat cells), which then release fatty acids into the blood. As circulating fatty acid levels rise, many tissues stop breaking down glucose to generate ATP and instead start breaking down fatty acids. This process is termed a **glucose-sparing effect**.
- In the liver, GH stimulates the breakdown of glycogen reserves by liver cells, which then release glucose into the bloodstream. Because most other tissues are now metabolizing fatty acids rather than glucose, blood glucose concentrations begin to climb to levels significantly higher than normal. The elevation of blood glucose levels by GH has been called a **diabetogenic effect**, because *diabetes mellitus*, an endocrine disorder we consider later in the chapter, is characterized by abnormally high blood glucose concentrations.

The production of GH is regulated by **growth hormonereleasing hormone (GH–RH**, or *somatocrinin*) and **growth hormone–inhibiting hormone (GH–IH**, or *somatostatin*) from the hypothalamus. Somatomedins inhibit GH–RH and stimulate GH–IH (Figure 18–8b).

Melanocyte-Stimulating Hormone. The pars intermedia may secrete two forms of melanocyte-stimulating hormone (MSH), or *melanotropin*. As the name indicates, MSH stimulates the melanocytes of the skin, increasing their production of melanin, a brown, black, or yellow-brown pigment. ^{\(\box)} p. 156 Dopamine inhibits the release of MSH.

Melanocyte-stimulating hormone from the pituitary gland is important in the control of skin pigmentation in fishes, amphibians, reptiles, and many mammals other than primates. In humans, MSH is produced locally, within sun-exposed skin. The pars intermedia in adult humans is virtually nonfunctional, and the circulating blood usually does not contain MSH. However, the human pars intermedia secretes MSH (1) during fetal development, (2) in very young children, (3) in pregnant women, and (4) in the course of some diseases. The functional significance of MSH secretion under these circumstances is not known. The administration of a synthetic form of MSH causes the skin to darken, so MSH has been suggested as a means of obtaining a "sunless tan."

The Posterior Lobe of the Pituitary Gland

The **posterior lobe** of the pituitary gland, also called the **neurohypophysis** (noo-rō-hī-POF-i-sis), contains the axons of hypothalamic neurons. Neurons of the **supraoptic** and **paraventricular nuclei** manufacture antidiuretic hormone (ADH) and oxytocin (OXT), respectively. These hormones move along axons in the infundibulum to axon terminals, which end on the basement membranes of capillaries in the posterior lobe. They travel by means of axoplasmic transport. \bigcirc **p**. 390

Antidiuretic Hormone

Antidiuretic hormone (ADH), also known as *vasopressin (VP)*, is released in response to a variety of stimuli, most notably a rise in the solute concentration in the blood or a fall in blood volume or blood pressure. A rise in the solute concentration stimulates specialized neurons in the hypothalamus. These neurons are called *osmoreceptors* because they respond to a change in the osmotic concentration of body fluids. The osmoreceptors then stimulate the neurosecretory neurons that release ADH.

Clinical Note

Diabetes Insipidus *Diabetes* occurs in several forms. All are characterized by excessive urine production (polyuria). Most forms result from endocrine abnormalities, but physical damage to the kidneys can also cause diabetes. The two most prevalent forms are diabetes insipidus and diabetes mellitus. (We describe diabetes mellitus in the Spotlight on page 638.) **Diabetes insipidus** generally develops because the posterior lobe of the pituitary gland no longer releases adequate amounts of ADH. Water conservation by the kidneys is impaired, and excessive amounts of water are lost in the urine. As a result, the person is constantly thirsty, but the body does not retain the fluids consumed.

Mild cases of diabetes insipidus may not require treatment if fluid and electrolyte intake keep pace with urinary losses. In severe cases, the fluid losses can reach 10 liters per day, and dehydration and electrolyte imbalances are fatal without treatment. This condition can be effectively treated with desmopressin, a synthetic form of ADH. The primary function of ADH is to act on the kidneys to retain water and decrease urination. With losses minimized, any water absorbed from the digestive tract will be retained, reducing the concentrations of electrolytes in the extracellular fluid. In high concentrations, ADH also causes *vasoconstriction*, a narrowing of peripheral blood vessels that helps elevate blood pressure. Alcohol inhibits ADH release, which explains why people find themselves making frequent trips to the bathroom after consuming alcoholic beverages.

Oxytocin

In women, **oxytocin** (oxy-, quick + tokos, childbirth) **(OXT)** stimulates smooth muscle contraction in the wall of the uterus, promoting labor and delivery. After delivery, oxytocin promotes the ejection of milk by stimulating the contraction of myoepithelial cells around the secretory alveoli and the ducts of the mammary glands.

Until the last stages of pregnancy, the uterine smooth muscles are relatively insensitive to oxytocin, but they become more sensitive as the time of delivery approaches. The trigger for normal labor and delivery is probably a sudden rise in oxytocin levels at the uterus. There is good evidence, however, that the uterus and fetus secrete most of the oxytocin involved. Oxytocin from the posterior lobe plays only a supporting role.

Oxytocin secretion and milk ejection are part of a neuroendocrine reflex called the *milk let-down reflex*. The normal stimulus is an infant suckling at the breast, and sensory nerves innervating the nipples relay the information to the hypothalamus. Oxytocin is then released into the circulation at the posterior lobe, and the myoepithelial cells respond by squeezing milk from the secretory alveoli into large collecting ducts. Any factor that affects the hypothalamus can modify this reflex. For example, anxiety, stress, and other factors can

Figure 18–9 Pituitary Hormones and Their Targets.

Table 18–2	The Pituitary Hormones				
	Hormone	Target	Hormonal Effect	Hypothalamic Regulatory Hormone	
ANTERIOR LOBE					
Pars distalis	Thyroid-stimulating hormone (TSH)	Thyroid gland	Secretion of thyroid hormones	Thyrotropin-releasing hormone (TRH)	
	Adrenocorticotropic hormone (ACTH)	Adrenal cortex (zona fasciculata)	Secretion of glucocorticoids (cortisol, corticosterone)	Corticotropin-releasing hormone (CRH)	
	Gonadotropins:				
	Follicle-stimulating hormone (FSH)	Follicle cells of ovaries	Secretion of estrogen, follicle development	Gonadotropin-releasing hormone (GnRH)	
		Nurse cells of testes	Stimulation of sperm maturation	Gonadotropin-releasing hormone (GnRH)	
	Luteinizing hormone (LH)	Follicle cells of ovaries	Ovulation, formation of corpus luteum, secretion of progesterone	Gonadotropin-releasing hormone (GnRH)	
		Interstitial cells of testes	Secretion of testosterone	Gonadotropin-releasing hormone (GnRH)	
	Prolactin (PRL)	Mammary glands	Production of milk	Prolactin-releasing factor (PRF)	
				Prolactin-inhibiting hormone (PIH)	
	Growth hormone (GH)	All cells	Growth, protein synthesis, lipid mobilization and catabolism	Growth hormone–releasing hormone (GH–RH)	
				Growth hormone–inhibiting hormone (GH–IH)	
Pars intermedia (not active in normal adults)	Melanocyte-stimulating hormone (MSH)	Melanocytes	Increased melanin synthesis in epidermis	Melanocyte-stimulating hormone– inhibiting hormone (MSH–IH)	
POSTERIOR LOBE					
	Antidiuretic hormone (ADH)	Kidneys	Reabsorption of water, elevation of blood volume and pressure	None: Transported along axons from supraoptic nucleus to the posterior lobe of the pituitary gland	
	Oxytocin (OXT)	Uterus, mammary glands (females)	Labor contractions, milk ejection	None: Transported along axons from paraventricular nucleus to the	
		Ductus deferens and prostate gland (males)	Contractions of ductus deferens and prostate gland	posterior lobe of the pituitary gland	

prevent the flow of milk, even when the mammary glands are fully functional. In contrast, nursing mothers can become conditioned to associate a baby's crying with suckling. In these women, milk let-down may begin as soon as they hear a baby cry.

The functions of oxytocin in sexual activity remain uncertain, but it is known that circulating concentrations of oxytocin rise during sexual arousal and peak at orgasm in both sexes. Evidence indicates that in men, oxytocin stimulates smooth muscle contractions in the walls of the *ductus deferens* (sperm duct) and prostate gland. These actions may be important in *emission*—the ejection of sperm, secretions of the prostate gland, and the secretions of other glands into the male reproductive tract before ejaculation. Studies suggest that the oxytocin released in females during intercourse may stimulate smooth muscle contractions in the uterus and vagina that promote the transport of sperm toward the uterine tubes.

Summary: The Hormones of the Pituitary Gland

Figure 18–9 and **Table 18–2** summarize important information about the hormones of the pituitary gland. Review them carefully before considering the structure and function of other endocrine organs.

CHECKPOINT

- 7. Identify the two lobes of the pituitary gland.
- 8. If a person were dehydrated, how would the amount of ADH released by the posterior pituitary lobe change?
- 9. A blood sample contains elevated levels of somatomedins. Which pituitary hormone would you also expect to be elevated?
- **10**. What effect would elevated circulating levels of cortisol, a steroid hormone from the adrenal cortex, have on the pituitary secretion of ACTH?

See the blue Answers tab at the back of the book.

18-4 I The thyroid gland lies inferior to the larynx and requires iodine for hormone synthesis

Learning Outcome Describe the location, hormones, and functions of the thyroid gland, and discuss the effects of abnormal thyroid hormone production.

The thyroid gland curves across the anterior surface of the trachea just inferior to the thyroid ("shield-shaped") cartilage, which forms most of the anterior surface of the larynx (Figure 18–10a). The two lobes of the thyroid gland are united by a slender connection, the **isthmus** (IS-mus). You can feel the gland with your fingers. When something goes wrong with this gland, it typically becomes visible as it enlarges and distorts the surface of the neck. The size of the gland varies, depending on heredity and environmental and nutritional factors, but its average weight is about 34 g (1.2 oz). An extensive blood supply gives the thyroid gland a deep red color.

Thyroid Follicles and Thyroid Hormones

The thyroid gland contains large numbers of thyroid follicles, hollow spheres lined by a simple cuboidal epithelium (Figure 18–10b,c). The follicle cells surround a follicle cavity that holds a viscous *colloid*, a fluid containing large quantities of dissolved proteins. A network of capillaries surrounds each follicle, delivering nutrients and regulatory hormones to the glandular cells and accepting their secretory products and metabolic wastes.

TIPS

The structure of a thyroid follicle is similar to that of a gel capsule: The simple cuboidal epithelium is comparable to the capsule itself, and the colloid to the capsule's viscous contents.

Follicle cells synthesize a globular protein called thyroglobulin (thī-rō-GLOB-ū-lin) and secrete it into the colloid of the thyroid follicles (Figure 18–10c). Thyroglobulin molecules contain the amino acid tyrosine, the building block of thyroid hormones. The formation of thyroid hormones involves the following basic steps (Figure 18–11a, p. 628):

1 Iodide ions are absorbed from the diet by the digestive tract, and the bloodstream delivers them to the thyroid gland. TSH-sensitive carrier proteins in the basement membrane of the follicle cells actively transport iodide ions (I⁻) into the cytoplasm. Normally, the follicle cells maintain intracellular concentrations of iodide that are many times higher than those in the extracellular fluid.

2 The iodide ions diffuse to the apical surface of each follicle cell, where they lose an electron and are converted to an atom

of iodine (I⁰) by the enzyme *thyroid peroxidase*. This reaction sequence, which occurs at the apical membrane surface, also attaches one or two iodine atoms (I^0) to the tyrosine portions of a thyroglobulin molecule within the follicle cavity.

3 Tyrosine molecules with attached iodine atoms (I^0) become linked by covalent bonds, forming molecules of thyroid hormones that remain incorporated into thyroglobulin. Thyroid peroxidase probably carries out the pairing process. The hormone thyroxine (thi-ROKS-en), also known as tetraiodothyronine or T_{4} , contains four iodine atoms. A related molecule called **triiodothyronine**, or T_{3} , contains three iodine atoms. Eventually, each molecule of thyroglobulin contains four to eight molecules of T_3 or T_4 hormones or both.

The major factor controlling the rate of thyroid hormone release is the concentration of TSH in the circulating blood (Figure 18–11b). TSH stimulates iodide transport into the follicle cells and stimulates the production of thyroglobulin and thyroid peroxidase. TSH also stimulates the release of thyroid hormones. Under the influence of TSH, the following steps occur (Figure 18–11a):

4 Follicle cells remove thyroglobulin from the follicles by endocvtosis.

5 Lysosomal enzymes break down the thyroglobulin, and the amino acids and thyroid hormones enter the cytoplasm. The amino acids are then recycled and used to synthesize more thyroglobulin.

6 The released molecules of T_3 and T_4 diffuse across the basement membrane and enter the bloodstream. About 90 percent of all thyroid secretions is T₄, and T₃ is secreted in comparatively small amounts.

7 About 75 percent of the T_4 molecules and 70 percent of the T₃ molecules entering the bloodstream become attached to transport proteins called thyroid-binding globulins **(TBGs)**. Most of the rest of the T_4 and T_3 in the circulation is attached to **transthyretin**, also known as *thyroid-binding* prealbumin (TBPA), or to albumin, one of the plasma proteins. Only the relatively small quantities of thyroid hormones that remain unbound—roughly 0.3 percent of the circulating T₃ and 0.03 percent of the circulating T₄—are free to diffuse into peripheral tissues.

Equilibrium exists between the amount of bound and unbound thyroid hormones. At any moment, free thyroid hormones are being bound to carriers at the same rate at which bound hormones are being released. When unbound thyroid hormones diffuse out of the bloodstream and into other tissues, the equilibrium is disturbed. The carrier proteins then release additional thyroid hormones until a new equilibrium is reached. The bound thyroid hormones make up a substantial reserve: The bloodstream normally has more than a week's supply of thyroid hormones.

18

follicular epithelium ATLAS: Plate 18c

The numbered events are explained in the text.

TSH plays a key role in both the synthesis and the release of thyroid hormones. In the absence of TSH, the thyroid follicles become inactive, and neither synthesis nor secretion occurs. TSH binds to plasma membrane receptors and, by stimulating adenylate cyclase, it activates key enzymes involved in thyroid hormone production (Spotlight Figure 18–3).

Functions of Thyroid Hormones

Thyroid hormones affect almost every cell in the body. They enter target cells by means of an energy-dependent transport system. Inside a target cell, they bind to receptors (1) in the cytoplasm, (2) on the surfaces of mitochondria, and (3) in the nucleus.

Thyroid hormones bound to cytoplasmic receptors are essentially held in storage. If intracellular levels of thyroid hormones decline, the bound thyroid hormones are released into the cytoplasm.

- The thyroid hormones binding to mitochondria increase the rates of mitochondrial ATP production.
- The binding to receptors in the nucleus activates genes that control the synthesis of enzymes involved in energy transformation and utilization. One specific effect is the accelerated production of sodium–potassium ATPase. Recall that this membrane protein ejects intracellular sodium and recovers extracellular potassium. As noted in Chapter 3, this exchange pump uses large amounts of ATP. ⊃ p. 96

Thyroid hormones also activate genes that code for enzymes involved in glycolysis and ATP production. Coupled with the direct effect of thyroid hormones on mitochondria, this effect increases the metabolic rate of the cell. The effect is called the **calorigenic effect** (*calor*, heat) of thyroid hormones because the cell consumes more energy and generates more heat. In young children, TSH production increases in cold weather, and the calorigenic effect may help them adapt to cold climates. (This response does not occur in adults.) In growing children, thyroid hormones are also essential to normal development of the skeletal, muscular, and nervous systems.

The thyroid gland produces large amounts of T_4 , but T_3 is primarily responsible for the observed effects of thyroid hormones: a strong, immediate, and short-lived increase in the rate of cellular metabolism. At any moment, T_3 released from the thyroid gland accounts for only 10–15 percent of the T_3 in peripheral tissues. However, enzymes in the liver, kidneys, and other tissues convert T_4 to T_3 . Roughly 85–90 percent of the T_3 that reaches the target cells comes from the conversion of T_4 within peripheral tissues. **Table 18–3** summarizes the effects of thyroid hormones on major organs and systems.

Iodine and Thyroid Hormones

We obtain iodine from the food we eat. Each day the follicle cells in the thyroid gland absorb 120–150 μ g of I⁻, the minimum dietary amount needed to maintain normal thyroid function. The iodine ions are actively transported into the thyroid follicle cells. As a result, the concentration of I⁻ inside thyroid follicle cells is generally about 30 times higher than that in the blood. If blood I⁻ levels rise, so do levels inside the follicle cells.

The thyroid follicles contain most of the iodide reserves in the body. TSH stimulates the active transport of iodide. The resulting increase in the rate of iodide movement into the cytoplasm accelerates the formation of thyroid hormones.

The typical diet in the United States provides approximately 500 μ g of iodide per day, about three times the minimum daily requirement. Much of the excess is due to the I⁻ added to table salt (iodized salt), which is consumed in large quantities in processed foods. For this reason, iodide deficiency is seldom responsible for limiting the rate of thyroid hormone production. (This is not necessarily the case in other countries.) The kidneys remove excess I⁻ from the blood, and each day the liver excretes a small amount of I⁻ (about 20 μ g) into the *bile*, an exocrine product stored in the gallbladder. Iodide excreted by the kidneys is eliminated in urine. The I⁻ excreted in bile is eliminated in feces. The losses in the bile continue even if the diet contains less than the minimum iodide requirement and

Table 18–3 Effects of Thyroid Hormones on Peripheral Tissues

- 1. Elevates rates of oxygen consumption and energy consumption; in children, may cause a rise in body temperature
- 2. Increases heart rate and force of contraction; generally results in a rise in blood pressure
- 3. Increases sensitivity to sympathetic stimulation
- 4. Maintains normal sensitivity of respiratory centers to changes in oxygen and carbon dioxide concentrations
- 5. Stimulates red blood cell formation and thus enhances oxygen delivery
- 6. Stimulates activity in other endocrine tissues
- 7. Accelerates turnover of minerals in bone

can gradually deplete the iodide reserves in the thyroid. Thyroid hormone production then declines, regardless of the circulating levels of TSH.

The C Cells of the Thyroid Gland and Calcitonin

The thyroid also contains a second population of endocrine cells. These cells are the **C** (clear) cells, or *parafollicular cells* (Figure 18–10c). They lie sandwiched between the cuboidal follicle cells and their basement membrane. They are larger than the cells of the follicular epithelium and do not stain as clearly.

C cells produce the hormone **calcitonin (CT)**, which helps to regulate Ca^{2+} concentrations in body fluids. We introduced the functions of this hormone in Chapter 6. \bigcirc **p**. 197 The net effect of calcitonin release is a drop in the Ca^{2+} concentration in body fluids. Calcitonin (1) inhibits osteoclasts, which slows the rate of Ca^{2+} release from bone, and (2) stimulates Ca^{2+} excretion by the kidneys.

The control of calcitonin secretion is an example of direct endocrine regulation: Neither the hypothalamus nor the pituitary gland is involved. The C cells respond directly to an elevation in the Ca^{2+} concentration of blood. When the concentration rises, calcitonin secretion increases. The Ca^{2+} concentration then drops, eliminating the stimulus and "turning off" the C cells.

Calcitonin is probably most important during childhood, when it stimulates bone growth and mineral deposition in the skeleton. It also appears to be important in reducing the loss of bone mass (1) during prolonged starvation and (2) in the late stages of pregnancy. At that time the maternal skeleton competes with the developing fetus for calcium ions from the diet. The role of calcitonin in the healthy nonpregnant adult is unclear.

In several chapters, you have seen the importance of Ca²⁺ in controlling muscle cell and neuron activities. Calcium ion concentrations also affect the sodium permeabilities of excitable membranes. At high Ca²⁺ concentrations, sodium permeability decreases and membranes become less responsive. Such problems are relatively rare.

Problems caused by lower-than-normal Ca²⁺ concentrations are equally dangerous and much more common. When calcium ion concentrations decline, sodium permeabilities increase. As a result, cells become extremely excitable. If calcium levels fall too far, convulsions or muscular spasms can result. The *parathyroid glands* and *parathyroid hormone* are largely responsible for maintaining adequate calcium levels.

- CHECKPOINT

- 11. Identify the hormones of the thyroid gland.
- 12. What signs and symptoms would you expect to see in an individual whose diet lacks iodine?
- 13. When a person's thyroid gland is removed, signs of decreased thyroid hormone concentration do not appear until about one week later. Why?
- See the blue Answers tab at the back of the book.

18

18–5 The four parathyroid glands, embedded in the posterior surface of the thyroid gland, secrete parathyroid hormone to elevate blood Ca²⁺

Learning Outcome Describe the location, hormone, and functions of the parathyroid glands, and discuss the effects of abnormal parathyroid hormone production.

There are normally two pairs of **parathyroid glands** embedded in the posterior surfaces of the thyroid gland (Figure 18–12a). A dense capsule surrounding each parathyroid gland separates it from the cells of the thyroid gland. All together, the four parathyroid glands weigh a mere 1.6 g (0.06 oz). The histological appearance of a single parathyroid gland is shown in Figure 18–12b,c. The parathyroid glands have at least two cell populations. The **parathyroid (chief) cells** produce parathyroid hormone. The functions of the other cells, called *oxyphils*, are unknown.

Like the C cells of the thyroid gland, the parathyroid cells monitor the circulating concentration of calcium ions. When the Ca²⁺ concentration of the blood falls below normal, the parathyroid cells secrete **parathyroid hormone (PTH)**, or *parathormone*. The net result of PTH secretion is an increase in Ca²⁺ concentration in body fluids. Parathyroid hormone has three major effects:

- 1. It mobilizes calcium from bone by affecting osteoblast and osteoclast activity. PTH stimulates osteoblasts to secrete a growth factor known as RANKL. Osteoclasts have no PTH receptors, but both precursor and mature osteoclasts have RANKL receptors. This growth factor results in an increase in osteoclasts and osteoclast activity. With more active osteoclasts, the rates of mineral turnover and Ca^{2+} release accelerate. As bone matrix erodes, blood Ca^{2+} rises.
- 2. It enhances the resorption of Ca²⁺ by the kidneys, reducing urinary losses.

Figure 18–13 The Homeostatic Regulation of Calcium Ion Concentrations.

3. It stimulates the formation and secretion of *calcitriol* by the kidneys. In general, the effects of calcitriol complement or enhance those of PTH, but calcitriol also enhances Ca^{2+} and PO_4^{3-} absorption by the digestive tract. \supset p. 195

Figure 18–13 illustrates the roles of calcitonin and PTH in regulating Ca²⁺ concentrations. It is likely that PTH, aided by calcitriol, is the primary regulator of circulating calcium ion concentrations in healthy adults. Information about the hormones of the thyroid gland and parathyroid glands is summarized in Table 18–4.

CHECKPOINT

- 14. Describe the location of the parathyroid glands.
- **15**. Identify the hormone secreted by the parathyroid glands.
- **16**. The removal of the parathyroid glands would result in a decrease in the blood concentration of which important mineral?
- See the blue Answers tab at the back of the book.

18-6 The adrenal glands, consisting of a cortex and medulla, cap the kidneys and secrete several hormones

Learning Outcome Describe the location, structure, hormones, and general functions of the adrenal glands, and discuss the effects of abnormal adrenal hormone production.

A yellow, pyramid-shaped **adrenal** (ad-RĒ-nal) **gland** (*ad-*, *near* + *renes*, kidneys), or *suprarenal gland*, sits on the superior border of each kidney (Figure 18–14). Each adrenal gland lies near the level of the 12th rib. A dense fibrous capsule firmly attaches each adrenal gland to the superior portion of each kidney. The adrenal gland on each side nestles among the kidney, the diaphragm, and the major arteries and veins that run along the posterior wall of the abdominopelvic cavity. The adrenal glands project into the peritoneal cavity, and their anterior surfaces are covered by a layer of parietal peritoneum. Like other endocrine glands, the adrenal glands are highly vascularized.

A typical adrenal gland weighs about 5.0 g (0.18 oz), but its size can vary greatly as secretory demands change. The adrenal gland has two parts with separate endocrine functions: a superficial **adrenal cortex** and an inner **adrenal medulla** (Figure 18–14b).

The Adrenal Cortex

The yellowish color of the adrenal cortex is due to stored lipids, especially cholesterol and various fatty acids. The adrenal cortex produces more than two dozen steroid hormones. They are collectively called **corticosteroids**. In the bloodstream, these hormones are bound to transport proteins called *transcortins*.

Corticosteroids are vital. If the adrenal glands are destroyed or removed, the person will die unless corticosteroids are administered. Like other steroid hormones, corticosteroids exert their effects by turning on transcription of certain genes in the nuclei of their target cells and determining their transcription rates. The resulting changes in the nature and concentration of enzymes in the cytoplasm affect cellular metabolism.

Deep to the adrenal capsule are three distinct zones in the adrenal cortex (Figure 18–14c): (1) an outer *zona glomerulosa;* (2) a middle *zona fasciculata;* and (3) an inner *zona reticularis.* Each zone synthesizes specific steroid hormones.

Table 18–4	Hormones of the Thyroid Gland and Parathyroid Glands				
Gland/Cells	Hormone	Target	Hormonal Effect	Regulatory Control	
THYROID GLAND					
Follicular epitheli	um Thyroxine (T ₄) Triiodothyronine (T ₃)	Most cells	Increases energy utilization, oxygen consumption, growth, and development	Stimulated by TSH from the anterior lobe of the pituitary gland	
C cells	Calcitonin (CT)	Bone, kidneys	Decreases Ca ²⁺ concentrations in body fluids	Stimulated by elevated blood Ca ²⁺ levels; actions opposed by PTH	
PARATHYROID GLANDS					
Parathyroid (chief	i) cells Parathyroid hormone (PTH)	Bone, kidneys	Increases Ca ²⁺ concentrations in body fluids	Stimulated by low blood Ca ²⁺ levels; PTH effects enhanced by calcitriol and opposed by calcitonin	

The Zona Glomerulosa

The **zona glomerulosa** (glō-mer-ū-LŌ-suh) is the outer region of the adrenal cortex. It produces **mineralocorticoids**, steroid hormones that affect the electrolyte composition of body fluids. **Aldosterone** is the main mineralocorticoid of the zona glomerulosa.

The zona glomerulosa accounts for about 15 percent of the volume of the adrenal cortex (Figure 18–14c). A *glomerulus* is a little ball, and as the term *zona glomerulosa* implies, the endocrine cells in this region form small, dense knots or clusters. This zone extends from the capsule to the radiating cords of the deeper zona fasciculata.

Aldosterone. Aldosterone stimulates the conservation of sodium ions and the elimination of potassium ions. This hormone targets cells that regulate the ionic composition of excreted fluids. It causes the retention of sodium ions by the kidneys, sweat glands, salivary glands, and pancreas, preventing Na⁺ loss in urine, sweat, saliva, and digestive secretions. A loss of K⁺ accompanies this retention of Na⁺. As a secondary effect, the retention of Na⁺ enhances the osmotic reabsorption of water by the kidneys, sweat glands, salivary glands, and pancreas. The effect at the kidneys is most dramatic when normal levels of ADH are present. In addition, aldosterone increases the sensitivity of salt receptors in the taste buds of the tongue. As a result, a person's interest in (and consumption of) salty food increases.

Aldosterone secretion occurs in response to a drop in blood Na⁺ content, blood volume, or blood pressure, or to a rise in blood K⁺ concentration. Changes in either Na⁺ or K⁺ concentration have a direct effect on the zona glomerulosa, but the secretory cells are most sensitive to changes in potassium levels. A rise in potassium levels is very effective in stimulating the release of aldosterone. Aldosterone release also occurs in response to *angiotensin II*. We discuss this hormone, part of the *renin-angiotensin-aldosterone system*, later in this chapter.

The Zona Fasciculata

The **zona fasciculata** (fa-sik-ū-LA-tuh; *fasciculus*, little bundle) produces steroid hormones collectively known as **glucocorti-coids**, due to their effects on glucose metabolism. This zone begins at the inner border of the zona glomerulosa and extends toward the adrenal medulla (**Figure 18–14c**). It contributes about 78 percent of the cortical volume. The endocrine cells are larger and contain more lipids than those of the zona glomerulosa, and the lipid droplets give the cytoplasm a pale, foamy appearance. The cells of the zona fasciculata form individual cords composed of stacks of cells. Adjacent cords are separated by flattened blood vessels (sinusoids) with fenestrated walls.

The Glucocorticoids. When stimulated by ACTH from the anterior lobe of the pituitary gland, the zona fasciculata secretes primarily **cortisol** (KOR-ti-sol), also called *hydrocortisone*, along with smaller amounts of the related steroid **corticosterone** (kor-ti-KOS-te-rōn). The liver converts some of the circulating cortisol to **cortisone**, another active glucocorticoid. Negative feedback regulates glucocorticoid secretion: The glucocorticoid secretion of corticotropin-releasing hormone (CRH) in the hypothalamus, and on ACTH in the anterior pituitary lobe (**Figure 18–8a**).

Effects of Glucocorticoids. Glucocorticoids speed up the rates of glucose synthesis and glycogen formation, especially in the liver. Adipose tissue responds by releasing fatty acids into the blood, and other tissues begin to break down fatty acids and proteins instead of glucose. This process is another example of a glucose-sparing effect (p. 623).

Glucocorticoids also show **anti-inflammatory** effects. That is, they inhibit the activities of white blood cells and other components of the immune system. "Steroid creams" are commonly used to control irritating allergic rashes, such as poison ivy rash, and injections of glucocorticoids may be used

to control more severe allergic reactions. How do these treatments work? Glucocorticoids slow the migration of phagocytic cells into an injury site and cause phagocytic cells already in the area to become less active. In addition, mast cells exposed to these steroids are less likely to release histamine and other chemicals that promote inflammation. \bigcirc pp. 144–145 As a result, swelling and further irritation are dramatically reduced. On the negative side, the rate of wound healing decreases, and the weakening of the region's defenses makes it more susceptible to infectious organisms. For that reason, the topical steroids used to treat superficial rashes should never be applied to open wounds.

The Zona Reticularis

The **zona reticularis** (re-tik-ū-LAR-is; *reticulum*, network) forms a narrow band bordering each adrenal medulla (Figure 18–14c). This zone accounts for only about 7 percent of the total volume of the adrenal cortex. The endocrine cells of the zona reticularis form a folded, branching network, and fenestrated blood vessels wind among the cells.

Under stimulation by ACTH, the zona reticularis normally produces small quantities of androgens, the sex hormones produced in large quantities by the testes in males. Once in the bloodstream, some of the androgens from the zona reticularis are converted to estrogens, the dominant sex hormones in females. Adrenal androgens stimulate the development of pubic hair in boys and girls before puberty. Adrenal androgens are not important in adult men, but in adult women they promote muscle mass and blood cell formation, and support the sex drive.

The Adrenal Medulla

The boundary between the adrenal cortex and the adrenal medulla is irregular, and the supporting connective tissues and blood vessels are extensively interconnected. The adrenal medulla is pale gray or pink, due in part to the many blood vessels in the area. It contains large, rounded cells—similar to cells in sympathetic ganglia that are innervated by preganglionic sympathetic fibers. The sympathetic division of the autonomic nervous system controls secretory activities of the adrenal medullae. \bigcirc p. 536

The adrenal medulla contains two populations of secretory cells: One produces epinephrine (adrenaline), the other norepinephrine (noradrenaline). Evidence suggests that the two types of cells are distributed in different areas and that their secretory activities can be independently controlled. The secretions are packaged in vesicles that form dense clusters just inside plasma membranes. The hormones in these vesicles are continuously released at low levels by exocytosis. Sympathetic stimulation dramatically accelerates the rate of exocytosis and hormone release.

Epinephrine and Norepinephrine

Epinephrine makes up 75–80 percent of the secretions from the adrenal medullae. The rest is norepinephrine. These hormones interact with alpha and beta receptors on plasma membranes, as we described in Chapter 16. \bigcirc **p**. 541 Stimulation of α_1 and β_1 receptors, the most common types, speeds up the use of cellular energy and the mobilization of energy reserves.

Activation of the adrenal medullae has the following effects:

- In skeletal muscles, epinephrine and norepinephrine trigger mobilization of glycogen reserves and accelerate the breakdown of glucose to provide ATP. This combination increases both muscular strength and endurance.
- In adipose tissue, stored fats are broken down into fatty acids, which are released into the bloodstream for other tissues to use for ATP production.
- In the liver, glycogen molecules are broken down. The resulting glucose molecules are released into the bloodstream, primarily for use by neural tissue, which cannot shift to fatty acid metabolism.
- In the heart, the stimulation of β₁ receptors triggers an increase in the rate and force of cardiac muscle contraction.

The metabolic changes that follow the release of catecholamines such as E and NE reach their peak about 30 seconds after adrenal stimulation, and they persist for several minutes. As a result, the effects of stimulating the adrenal medullae outlast the other signs of sympathetic activation.

CHECKPOINT

- 17. Identify the two regions of the adrenal gland, and cite the hormones secreted by each.
- 18. List the three zones of the adrenal cortex.
- 19. What effect would elevated cortisol levels have on blood glucose levels?
- See the blue Answers tab at the back of the book.

18–7 The pineal gland, attached to the roof of the third ventricle, secretes melatonin

Learning Outcome Describe the location of the pineal gland, and discuss the functions of the hormone it produces.

The **pineal gland**, part of the epithalamus, lies in the posterior portion of the roof of the third ventricle. The pineal gland contains neurons, neuroglia, and special secretory cells called **pinealocytes** (pin-Ē-al-ō-sīts). These cells synthesize the hormone **melatonin** from molecules of the neurotransmitter *serotonin* (Figure 18–15). Collaterals from the visual pathways enter the pineal gland and affect the rate of melatonin production. This rate is lowest during daylight hours and highest at night.

Figure 18–15 The Pineal Gland.

Among the functions suggested for melatonin in humans are the following:

- Inhibiting Reproductive Functions. In some mammals, melatonin slows the maturation of sperm, oocytes, and reproductive organs by reducing the rate of GnRH secretion. The significance of this effect in humans remains unclear. Circumstantial evidence suggests that melatonin may play a role in the timing of human sexual maturation. Melatonin levels in the blood decline at puberty, and pineal tumors that eliminate melatonin production cause premature puberty in young children.
- Protecting against Damage by Free Radicals. Melatonin is a very effective antioxidant. It may protect CNS neurons from free radicals, such as nitric oxide (NO) or hydrogen peroxide (H₂O₂), that may form in active neural tissue.

Influencing Circadian Rhythms. Because its activity is cyclical, the pineal gland may also be involved in maintaining basic circadian thythms—daily changes in physiological processes that follow a regular day–night pattern. ⊃ p. 480 Increased melatonin secretion in darkness has been suggested as a primary cause of seasonal affective disorder (SAD). This condition can develop during the winter in people who live at high latitudes, where sunlight is scarce or lacking. It is characterized by changes in mood, eating habits, and sleeping patterns.

CHECKPOINT

- **20**. Identify the hormone-secreting cells of the pineal gland.
- 21. Increased amounts of light would inhibit the production of which hormone?
- 22. List three possible functions of melatonin.
- See the blue Answers tab at the back of the book.

18-8 The pancreas is both an exocrine organ and endocrine gland

Learning Outcome Describe the location, structure, hormones, and functions of the pancreas, and discuss the effects of abnormal pancreatic hormone production.

The **pancreas** is mostly retroperitoneal and lies in the loop between the inferior border of the stomach and the proximal portion of the small intestine (Figure 18–1). It is a slender, pale organ with a nodular (lumpy) texture (Figure 18–16a). The pancreas is 20–25 cm (8–10 in.) long and weighs about 80 g (2.8 oz) in adults. We will consider its anatomy further in Chapter 24, because it is primarily an exocrine organ that makes digestive enzymes.

Figure 18–16 The Pancreas. ATLAS: Plate 49e

The **exocrine pancreas** consists of clusters of gland cells, called *pancreatic acini*, and their attached ducts. The exocrine pancreas takes up roughly 99 percent of the pancreatic volume. Together the gland and duct cells secrete large quantities of an alkaline, enzyme-rich fluid that reaches the lumen of the digestive tract through a network of secretory ducts.

The **endocrine pancreas** consists of small groups of cells scattered among the exocrine cells. The endocrine clusters are known as **pancreatic islets**, or the *islets of Langerhans* (LAN-ger-hanz) (Figure 18–16b). Pancreatic islets account for only about 1 percent of all cells in the pancreas. Nevertheless, a typical pancreas contains approximately 2 million pancreatic islets and their secretions are vital to our survival.

The Pancreatic Islets

The pancreatic islets are surrounded by an extensive, fenestrated capillary network that carries pancreatic hormones into the bloodstream. Each islet contains four types of cells:

- 1. **Alpha cells** produce the hormone glucagon (GLŪ-ka-gon). Glucagon raises blood glucose levels by increasing the rates of glycogen breakdown and glucose release by the liver.
- 2. Beta cells produce the hormone insulin (IN-suh-lin). Insulin lowers blood glucose levels by increasing the rate of glucose uptake and utilization by most body cells, and by increasing glycogen synthesis in skeletal muscles and the liver. Beta cells also secrete *amylin*, a peptide hormone whose level rises after a meal.
- 3. **Delta cells** produce a peptide hormone identical to growth hormone–inhibiting hormone (GH–IH), a hypothalamic regulatory hormone. GH–IH suppresses the release of glucagon and insulin by other islet cells and slows the rates of food absorption and enzyme secretion along the digestive tract.
- 4. F cells produce the hormone pancreatic polypeptide (PP). PP inhibits gallbladder contractions and regulates the production of some pancreatic enzymes. It may also help control the rate of nutrient absorption by the digestive tract.

We will focus on insulin and glucagon, the hormones that regulate blood glucose levels (Figure 18–17). When blood glucose levels increase, beta cells secrete insulin, which then stimulates the transport of glucose across plasma membranes and into target cells. When blood glucose levels decrease, alpha cells secrete glucagon, which stimulates glycogen breakdown and glucose release by the liver.

Figure 18–17 The Regulation of Blood Glucose Concentrations.

TIPS&TRICKS

To help in differentiating between the polysaccharide storage molecule "glycogen" and the pancreatic hormone "glucagon," remember that glyco**gen** literally means **gen**erates sugar; and associate gluca**gon** with the Penta**gon**, both of which "issue orders."

Insulin

Insulin is a peptide hormone released by beta cells when blood glucose concentrations exceed normal levels (70–110 mg/dL). Elevated levels of some amino acids, including arginine and leucine, also stimulate secretion of insulin. This hormone affects cellular metabolism in a series of steps that begins when insulin binds to receptor proteins on the plasma membrane of a target cell. Binding activates the receptor, which functions as a kinase, attaching phosphate groups to intracellular enzymes. These enzymes then produce primary and secondary effects in the cell. The biochemical details of these effects remain unresolved.

One of the most important effects is the enhancement of glucose absorption and utilization. Insulin receptors are present in most plasma membranes, and cells that have them are called *insulin dependent*. However, cells in the brain and kidneys, cells in the lining of the digestive tract, and red blood cells lack insulin receptors. These cells are called *insulin independent*, because they can absorb and utilize glucose without insulin stimulation.

The effects of insulin on its target cells include the following:

- Accelerating Glucose Uptake (All Target Cells). This effect results from an increase in the number of glucose transport proteins in the plasma membrane. These proteins move glucose into the cell by facilitated diffusion, which follows the concentration gradient for glucose and does not require ATP.
- Accelerating Glucose Utilization (All Target Cells) and Enhanced ATP Production. This effect occurs for two reasons:

 The rate of glucose use is proportional to its availability, so when more glucose enters the cell, more is used.
 Second messengers activate a key enzyme involved in the initial steps of glycolysis.
- Stimulating Glycogen Formation (Skeletal Muscles and Liver Cells). When excess glucose enters these cells, it is stored as glycogen.
- Stimulating Amino Acid Absorption and Protein Synthesis. This helps to maintain glucose levels by preventing the conversion of amino acids to glucose.
- *Stimulating Triglyceride Formation in Adipose Tissue.* Insulin stimulates the absorption of fatty acids and glycerol by adipocytes, which store these components as triglycerides. Adipocytes also increase their absorption of glucose, and excess glucose is used in the synthesis of additional triglycerides.

To summarize, the pancreas secretes insulin when glucose is abundant. The hormone stimulates glucose utilization to support growth and to build carbohydrate (glycogen) and lipid (triglyceride) reserves. The accelerated use of glucose soon brings circulating glucose levels within normal limits.

TIPS&TRICKS

The function of *in*sulin is to get glucose *in*to cells.

Glucagon

When glucose concentrations decrease below normal, alpha cells release glucagon to mobilize energy reserves. When glucagon binds to a receptor in the target cell's plasma membrane, the hormone activates adenylate cyclase. As we have seen, cAMP acts as a second messenger that activates cytoplasmic enzymes (p. 614). The primary effects of glucagon are as follows:

- Stimulating the Breakdown of Glycogen in Skeletal Muscle and Liver Cells. The glucose molecules released are either metabolized for energy (in skeletal muscle fibers) or released into the bloodstream (by liver cells).
- Stimulating the Breakdown of Triglycerides in Adipose Tissue. The adipocytes then release the fatty acids into the bloodstream for use by other tissues.
- Stimulating the Production and Release of Glucose by the Liver. Liver cells absorb amino acids from the bloodstream, convert them to glucose, and release the glucose into the circulation. This process of glucose synthesis in the liver is called gluconeogenesis (gloo-kō-nē-ō-JEN-e-sis).

The results are a reduction in glucose use and the release of more glucose into the bloodstream. Blood glucose concentrations soon increase toward normal levels.

Pancreatic alpha cells and beta cells monitor blood glucose concentrations, and they secrete glucagon and insulin without endocrine or nervous instructions. Yet because the alpha cells and beta cells are highly sensitive to changes in blood glucose levels, any hormone that affects blood glucose concentrations indirectly affects the production of both insulin and glucagon. Autonomic activity also influences insulin production: Parasympathetic stimulation enhances insulin release, and sympathetic stimulation inhibits it. Information about insulin, glucagon, and other pancreatic hormones is summarized in Table 18–5.

Diabetes Mellitus

Whether glucose is absorbed by the digestive tract or manufactured and released by the liver, very little glucose leaves the body once it has entered the bloodstream. The kidneys reabsorb virtually all glucose, so glucose does not appear in the urine. However, in diabetes mellitus, glucose accumulates in the blood and urine as a result of faulty glucose metabolism.

Diabetes mellitus can be caused by genetic abnormalities, and some of the genes responsible have been identified. Mutations that result in inadequate insulin production, the synthesis of abnormal insulin molecules, or the production of defective receptor proteins produce comparable symptoms. Under these

SPOTLIGHT Figure 18–18 Diabetes Mellitus

Untreated diabetes mellitus disrupts metabolic activities throughout the body. Clinical problems arise because the tissues involved are experiencing an energy crisis—in essence, most of the tissues are responding as they would during chronic starvation, breaking down lipids and even proteins because they are unable to absorb glucose from their surroundings. Problems involving abnormal changes in blood vessel structure are particularly dangerous. An estimated 25.8 million people in the United States have some form of diabetes.

Kidney Degeneration

Degenerative changes in the kidneys, a condition called diabetic nephropathy, can lead to kidney failure.

Diabetes Mellitus

Diabetes mellitus (mel-Ī-tus; mellitum, honey), is characterized by glucose concentrations that are high enough to overwhelm the reabsorption capabilities of the kidneys. (The presence of abnormally high glucose levels in the blood in general is called hyperglycemia [hī-per-glī-SĒ-mē-ah].) Glucose appears in the urine (glycosuria; glī-kō-SYŪ-rē-a), and urine volume generally becomes excessive (polyuria).

subdivided into

Type 1 Diabetes

Type 1 is characterized by inadequate insulin production by the pancreatic beta cells. Persons with Type 1 diabetes require insulin to live and usually require multiple injections daily, or continuous infusion through an insulin pump or other device. This form of diabetes accounts for approximately 5% of cases. It usually develops in children and young adults.

Type 2 Diabetes

Type 2 is the most common form of diabetes mellitus. Most people with this form of diabetes produce normal amounts of insulin, at least initially, but their tissues do not respond properly, a condition known as insulin resistance. Type 2 diabetes is associated with obesity, and weight loss through diet and exercise can be an effective treatment, especially when coupled with oral medicines.

The proliferation of capillaries and hemorrhaging at the retina may cause partial or complete blindness. This condition is called diabetic retinopathy.

Early Heart Attacks

Degenerative blockages in cardiac circulation can lead to early heart attacks. For a given age group, heart attacks are three to five times more likely in people with diabetes than in nondiabetic people.

Peripheral Nerve Problems

Abnormal blood flow to neural tissues is probably responsible for a variety of neural problems with peripheral nerves, including abnormal autonomic function. These disorders are collectively termed diabetic neuropathies.

Blood flow to the distal portions of the limbs is reduced, and peripheral tissues may suffer as a result. For example, a reduction in blood flow to the feet can lead to tissue death, ulceration, infection, and loss of toes or a major portion of one or both feet.

Table 18–5	Hormones Produced by the Pancreatic Islets			
Structure/Cells	Hormone	Primary Targets	Hormonal Effect	Regulatory Control
PANCREATIC ISLE	TS			
Alpha cells	Glucagon	Liver, adipose tissue	Mobilizes lipid reserves; promotes glucose synthesis and glycogen breakdown in liver; elevates blood glucose concentrations	Stimulated by low blood glucose concentrations; inhibited by GH–IH from delta cells
Beta cells	Insulin	Most cells	Facilitates uptake of glucose by target cells; stimulates formation and storage of lipids and glycogen	Stimulated by high blood glucose concentrations, parasympathetic stimulation, and high levels of some amino acids; inhibited by GH–IH from delta cells and by sympathetic activation
Delta cells	GH–IH (somatostatin)	Other islet cells, digestive epithelium	Inhibits insulin and glucagon secretion; slows rates of nutrient absorption and enzyme secretion along digestive tract	Stimulated by protein-rich meal; mechanism unclear
F cells	Pancreatic polypeptide (PP)	Digestive organs	Inhibits gallbladder contraction; regulates production of pancreatic enzymes; influences rate of nutrient absorption by digestive tract	Stimulated by protein-rich meal and by parasympathetic stimulation

conditions, obesity accelerates the onset and severity of the disease. Diabetes mellitus can also result from other pathological conditions, injuries, immune disorders, or hormonal imbalances.

The two major types of diabetes mellitus are Type 1 diabetes (previously known as juvenile diabetes) and Type 2 diabetes. This disorder is described in **Spotlight Figure 18–18**.

CHECKPOINT

- **23**. Identify the types of cells in the pancreatic islets and the hormones produced by each.
- 24. Why does a person with Type 1 or Type 2 diabetes urinate frequently and have increased thirst?
- **25**. What effect would increased levels of glucagon have on the amount of glycogen stored in the liver?

See the blue Answers tab at the back of the book.

18-9 Many organs have secondary endocrine functions

Learning Outcome Describe the functions of the hormones produced by the kidneys, heart, thymus, testes, ovaries, and adipose tissue.

As we noted earlier, many organs of other body systems have secondary endocrine functions. Examples are the intestines (digestive system), the kidneys (urinary system), the heart (cardiovascular system), the thymus (lymphatic system), and the *gonads*—the testes in males and the ovaries in females (reproductive system).

Several new hormones from these endocrine tissues have been identified. In many cases, their structures and modes of action remain uncertain, and we have not described them in this chapter. However, in one instance, researchers traced a significant new hormone to an unexpected site of origin, leading to the realization that the body's adipose tissue has important endocrine functions. We include the endocrine functions of adipose tissue in this section, although all the details have yet to be worked out. Table 18–6 provides an overview of some of the hormones those organs of other systems produce.

The Intestines

The intestines process and absorb nutrients. They release a variety of hormones that coordinate the activities of the digestive system. Most digestive processes are hormonally controlled locally, although the autonomic nervous system can affect the pace of digestive activities. We describe these hormones in Chapter 24.

The Kidneys

The kidneys release the steroid hormone *calcitriol*, the peptide hormone *erythropoietin*, and the enzyme *renin*. Calcitriol is important for calcium ion homeostasis. Erythropoietin and renin are involved in the regulation of blood volume and blood pressure.

Calcitriol

Calcitriol is a steroid hormone secreted by the kidneys in response to parathyroid hormone (PTH) (Figure 18–19a). *Cholecalciferol* (vitamin D_3) is a related steroid that is synthesized in the skin or absorbed from the diet. Cholecalciferol is converted to calcitriol, although not directly. The term *vitamin* D applies to the entire group of related steroids, including calcitriol, cholecalciferol, and various intermediate products.

The best-known function of calcitriol is to stimulate calcium and phosphate ion absorption along the digestive tract. The effects of PTH on Ca^{2+} absorption result primarily from stimulation of calcitriol release. Calcitriol's other effects on calcium metabolism include (1) stimulating the formation and

Table 18–6	Representative Hormones Produced by Organs of Other Systems			
Organ	Hormone	Primary Target	Hormonal Effect	
Intestines	Many (secretin, gastrin, cholecystokinin, etc.)	Other regions and organs of the digestive system	Coordinate digestive activities	
Kidneys	Erythropoietin (EPO) Calcitriol	Red bone marrow Intestinal lining, bone, kidneys	Stimulates red blood cell production Stimulates calcium and phosphate absorption; stimulates Ca ²⁺ release from bone; inhibits PTH secretion	
Heart	Natriuretic peptides (ANP and BNP)	Kidneys, hypothalamus, adrenal gland	Increase water and salt loss at kidneys; decrease thirst; suppress secretion of ADH and aldosterone	
Thymus	Thymosins (many)	Lymphocytes and other cells of the immune response	Coordinate and regulate immune response	
Gonads	See Table 18–7			
Adipose tissues	Leptin	Hypothalamus	Suppression of appetite; permissive effects on GnRH and gonadotropin synthesis	

differentiation of osteogenic cells and osteoclasts, (2) stimulating bone resorption by osteoclasts, (3) stimulating Ca^{2+} reabsorption by the kidneys, and (4) suppressing PTH production. Evidence indicates that calcitriol also affects lymphocytes and keratinocytes in the skin, but these effects have nothing to do with regulating calcium levels.

Erythropoietin

Erythropoietin (e-rith-rō-POY-e-tin; *erythros*, red + *poiesis*, making), or **EPO**, is a peptide hormone released by the kidneys in response to low oxygen levels in kidney tissues. EPO stimulates the red bone marrow to produce red blood cells. The increase in the number of red blood cells elevates blood volume. Because these cells transport oxygen, this increase also improves oxygen delivery to peripheral tissues. We will consider EPO again in Chapter 19.

Renin

Specialized kidney cells called juxtaglomerular cells release renin (RĒ-nin) in response to (1) sympathetic stimulation or (2) a decline in renal blood flow. Once in the bloodstream, renin functions as an enzyme that starts an enzymatic cascade known as the renin-angiotensin-aldosterone system (RAAS) (Figure 18–19b). RAAS is involved with blood pressure regulation and electrolyte metabolism. First, renin converts angiotensinogen, a plasma protein produced by the liver, to angiotensin I. In the capillaries of the lungs, angiotensin-converting enzyme (ACE) modifies angiotensin I to the hormone angiotensin II. This hormone, in turn, stimulates the secretion of aldosterone by the adrenal cortex and ADH by the posterior lobe of the pituitary gland. The combination of aldosterone and ADH retains salt and water by restricting their loss by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. For these reasons, drugs known as ACE inhibitors are used to treat hypertension.

Because renin plays such a key role in the renin-angiotensinaldosterone system, many physiological and endocrinological references consider renin to be a hormone. We will take a closer look at the renin-angiotensin-aldosterone system when we examine the control of blood pressure and blood volume in Chapter 21.

The Heart

The endocrine cells in the heart are cardiac muscle cells in the walls of the atria (chambers that receive blood from the veins) and the ventricles (chambers that pump blood to the rest of the body). If blood volume becomes too great, these cells are stretched excessively, to the point at which they begin to secrete natriuretic peptides (nā-trē-ū-RET-ik; natrium, sodium + ouresis, urination). In general, the effects of natriuretic peptides oppose those of angiotensin II: Natriuretic peptides promote the loss of Na⁺ and water by the kidneys, and inhibit renin release and the secretion of ADH and aldosterone. They also suppress thirst and prevent angiotensin II and norepinephrine from elevating blood pressure. The net result is a reduction in both blood volume and blood pressure, thereby reducing the stretching of the cardiac muscle cells in the heart walls. We discuss two natriuretic peptides—ANP (atrial natriuretic peptide) and BNP (brain natriuretic peptide)-when we consider the control of blood pressure and volume in Chapters 21 and 26.

The Thymus

The **thymus** is located in the mediastinum, generally just deep to the sternum. This gland produces several hormones that are important in developing and maintaining immune defenses. **Thymosin** (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of *lymphocytes*, the white blood cells responsible for immunity. The extract actually contains a blend of several complementary hormones. The term *thymosins* is sometimes used to refer to all thymic hormones. We consider the histological organization of the thymus and the functions of the thymosins in Chapter 22.

Figure 18–19 Endocrine Functions of the Kidneys.

The Gonads

Information about the reproductive hormones of the testes and ovaries is presented in Table 18–7. In males, the **inter-stitial cells** of the testes produce the male hormones known as androgens. **Testosterone** (tes-TOS-ter-ōn) is the most important androgen. During embryonic development, the production of testosterone affects the development of CNS structures, including hypothalamic nuclei, which will later

b The release of renin and erythropoietin, and an overview of the reninangiotensin-aldosterone system beginning with the activation of angiotensinogen by renin

Table 18–7	Hormones of the Reproductive System			
Structure/Cells	Hormone	Primary Target	Hormonal Effect	Regulatory Control
TESTES				
Interstitial cells	Androgens	Most cells	Support functional maturation of sperm, protein synthesis in skeletal muscles, male secondary sex characteristics, and associated behaviors	Stimulated by LH from the anterior lobe of the pituitary gland
Nurse cells	Inhibin	Pituitary gland	Inhibits secretion of FSH	Stimulated by FSH from the anterior lobe
OVARIES				
Follicular cells	Estrogens Inhibin	Most cells Pituitary gland	Support follicle maturation, female secondary sex characteristics, and associated behaviors Inhibits secretion of FSH	Stimulated by FSH and LH from the anterior lobe of the pituitary gland Stimulated by FSH from anterior lobe
Corpus luteum	Progesterone	Uterus, mammary glands	Prepares uterus for implantation; prepares mammary glands for secretory activity	Stimulated by LH from the anterior lobe of the pituitary gland

Clinical Note

Endocrine Disorders Regulation of hormone levels often involves negative feedback control mechanisms. These mechanisms involve the endocrine organ, neural regulatory factors, and the target tissues. Hormone overproduction (hypersecretion) or underproduction (hyposecretion) may cause problems. Abnormal cellular sensitivity to the hormone can also lead to problems.

Primary disorders arise from problems within the endocrine organ. The underlying cause may be a metabolic factor. Hypothyroidism due to a lack of dietary iodine is an example. An endocrine organ may also malfunction due to physical damage that destroys cells or disrupts the normal blood supply. Congenital problems may also affect the regulation, production, or release of hormones by endocrine cells. Secondary disorders are due to problems in other organs or target tissues. Such disorders often involve the hypothalamus or pituitary gland. For example, secondary hypothyroidism occurs when the hypothalamus or pituitary gland doesn't produce enough TRH and/or TSH.

Abnormalities in target cells can affect their sensitivity or responsiveness to a particular hormone. For example, Type 2 diabetes is due to the target cells' decreased sensitivity to insulin.

Endocrine disorders often reflect either abnormal hormone production or abnormal cellular sensitivity to hormones. The signs and symptoms highlight the significance of normally "silent" hormonal contributions. The characteristics of these disorders are summarized in Table 18–8.

Table 18–8	Clinic	Clinical Implications of Endocrine Malfunctions			
Hormone		Underproduction or Tissue Insensitivity	Principal Signs and Symptoms	Overproduction or Tissue Hypersensitivity	Principal Signs and Symptoms
Growth hormone	(GH)	Pituitary growth failure	Retarded growth, abnormal fat distribution, low blood glucose hours after a meal	Gigantism, acromegaly	Excessive growth
Antidiuretic hormone (ADH) or vasopressin (V	'P)	Diabetes insipidus	Polyuria, dehydration, thirst	SIADH (syndrome of inappropriate ADH secretion)	Increased body weight and water content
Thyroxine (T ₄), triiodothyronine	(T ₃)	Hypothyroidism, infantile hypothyroidism, myxedema	Low metabolic rate; low body temperature; impaired physical and mental development	Hyperthyroidism, Graves disease	High metabolic rate and body temperature
Parathyroid horm (PTH)	none	Hypoparathyroidism	Muscular weakness, neurological problems, formation of dense bones, tetany due to low blood Ca2 ⁺ concentrations	Hyperparathyroidism	Neurological, mental, muscular problems due to high blood Ca ²⁺ concentrations; weak and brittle bones
Insulin		Diabetes mellitus (Type 1)	High blood glucose, impaired glucose utilization, dependence on lipids for energy; glycosuria	Excess insulin production or administration	Low blood glucose levels, possibly causing coma
Mineralocorticoio (MCs)	ds	Hypoaldosteronism	Polyuria, low blood volume, high blood K ⁺ , low blood Na ⁺ concentrations	Aldosteronism	Increased body weight due to Na^+ and water retention; low blood K^+ concentration
Glucocorticoids (GCs)	Addison's disease	Inability to tolerate stress, mobilize energy reserves, or maintain normal blood glucose concentrations	Cushing's disease	Excessive breakdown of tissue proteins and lipid reserves; impaired glucose metabolism
Epinephrine (E), norepinephrine (NE)	None identified		Pheochromocytoma	High metabolic rate, body temperature, and heart rate; elevated blood glucose levels
Estrogens (female	es)	Hypogonadism	Sterility, lack of secondary sex characteristics	Adrenogenital syndrome	Overproduction of androgens by zona reticularis of adrenal cortex leads to masculinization
				Precocious puberty	Premature sexual maturation and related behavioral changes
Androgens (male	s)	Hypogonadism	Sterility, lack of secondary sex characteristics	Adrenogenital syndrome (gynecomastia)	Abnormal production of estrogen, sometimes due to adrenal or interstitial cell tumors; leads to breast enlargement
				Precocious puberty	Premature sexual maturation and related behavioral changes

influence sexual behaviors. **Nurse cells** in the testes support the differentiation and physical maturation of sperm. Under FSH stimulation, these cells secrete the hormone **inhibin**. It inhibits the secretion of FSH at the anterior lobe of the pituitary gland and perhaps suppresses GnRH release at the hypothalamus.

In females, steroid hormones called **estrogens** are produced in the ovaries under FSH and LH stimulation. **Estradiol** is the main estrogen. Circulating FSH stimulates the secretion of inhibin by ovarian cells, and inhibin suppresses FSH release through a feedback mechanism comparable to that in males.

At ovulation, follicles in the ovary release an immature gamete, or oocyte. The remaining follicle cells then reorganize into a *corpus luteum* (LOO-tē-um; "yellow body") that releases a mixture of estrogens and **progesterone** (prō-JES-ter-ōn). During pregnancy, the placenta and uterus produce additional hormones that interact with those produced by the ovaries and the pituitary gland to promote normal fetal development and delivery. We consider the hormonal aspects of pregnancy in Chapter 29.

Adipose Tissue

Recall from Chapter 4 that adipose tissue is a type of loose connective tissue. \bigcirc p. 129 Adipose tissue produces a peptide hormone called **leptin**, which has several functions. Its best known function is feedback control of appetite. When we eat, adipose tissue absorbs glucose and lipids and synthesizes triglycerides for storage. At the same time, it releases leptin into the bloodstream. Leptin binds to hypothalamic neurons involved with emotion and appetite control. The result is a sense of fullness (satiation) and the suppression of appetite.

Leptin was first discovered in a strain of obese mice that had a defective leptin gene. When treated with leptin, these overweight mice quickly turned into slim, athletic animals. The initial hope that leptin could be used to treat human obesity was soon dashed, however. Most obese people appear to have defective leptin receptors (or leptin pathways) in the appetite centers of the CNS. Their circulating leptin levels are already several times higher than those in individuals of normal body weight. Additional leptin would have no effect. Researchers are now investigating the structure of the receptor protein and the biochemistry of the pathway triggered by leptin binding.

Leptin must be present for normal levels of GnRH and gonadotropin synthesis to take place. This explains why (1) thin girls commonly enter puberty relatively late, (2) an increase in body fat can improve fertility, and (3) women stop menstruating when their body fat content becomes very low.

CHECKPOINT

- 26. Identify two hormones secreted by the kidneys.
- 27. Identify a hormone released by adipose tissue.
- **28**. Describe the action of renin in the bloodstream.
- See the blue Answers tab at the back of the book.

18–10 Hormones interact to produce coordinated physiological responses

Learning Outcome Explain how hormones interact to produce coordinated physiological responses and influence behavior, describe the role of hormones in the general adaptation syndrome, and discuss how aging affects hormone production and give examples of interactions between the endocrine system and other organ systems.

We usually study hormones individually, but the extracellular fluids contain a mixture of hormones whose concentrations change daily or even hourly. As a result, cells never respond to only one hormone. Instead, they respond to multiple hormones. When a cell receives instructions from two hormones at the same time, four outcomes are possible:

- 1. The two hormones may have opposing or **antagonistic effects**, as in the case of PTH and calcitonin, or insulin and glucagon. The net result depends on the balance between the two hormones. In general, when two antagonistic hormones are present, the observed effects are weaker than those produced by either hormone acting unopposed.
- 2. The two hormones may have additive effects, so that the net result is greater than the effect that each would produce acting alone. In some cases, the net result is greater than the *sum* of the hormones' individual effects. This interaction is a **synergistic effect** (sin-er-JIS-tik; *synairesis*, a drawing together). An example is the glucose-sparing action of GH and glucocorticoids.
- **3.** One hormone can have a **permissive effect** on another. In such cases, the first hormone is needed for the second to produce its effect. For example, epinephrine does not change energy consumption unless thyroid hormones are also present in normal concentrations.
- 4. Finally, hormones may produce different, but complementary, results in specific tissues and organs. These **integrative effects** are important in coordinating the activities of diverse physiological systems. The differing effects of calcitriol and parathyroid hormone on tissues involved in calcium metabolism are an example.

When multiple hormones regulate a complex process, it is very difficult to determine whether a hormone has synergistic, permissive, or integrative effects. Next we consider three examples of processes regulated by complex hormonal interactions: growth, the response to stress, and behavior.

Role of Hormones in Growth

Several endocrine organs work together to bring about normal growth. Several hormones—GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones—are especially important. Many others have secondary effects on growth. The circulating concentrations of these hormones are regulated independently. Every time the hormonal mixture changes, metabolic operations are modified to some degree. The modifications vary in duration and intensity, producing unique individual growth patterns.

- Growth Hormone (GH). The effects of GH on protein synthesis and cellular growth are most apparent in children. GH supports their muscular and skeletal development. In adults, growth hormone helps to maintain normal blood glucose concentrations and to mobilize lipid reserves in adipose tissue. GH is not the primary hormone involved, however. An adult with a GH deficiency but normal levels of thyroxine (T₄), insulin, and glucocorticoids will have no physiological problems.
- *Thyroid Hormones.* Normal growth also requires appropriate levels of thyroid hormones. If these hormones are absent during fetal development or for the first year after birth, the nervous system fails to develop normally, and developmental delay results. If T₄ concentrations decline later in life but before puberty, normal skeletal development does not continue.
- Insulin. Growing cells need adequate supplies of energy and nutrients. Without insulin, the passage of glucose and amino acids across plasma membranes stops or is drastically reduced.
- Parathyroid Hormone (PTH) and Calcitriol. Parathyroid hormone and calcitriol promote the absorption of calcium salts from the bloodstream for deposition in bone. Without adequate levels of both hormones, bones can still enlarge, but are poorly mineralized, weak, and flexible. For example, *rickets* is a condition typically caused by inadequate calcitriol production due to vitamin D deficiency in growing children. As a result, the lower limb bones are so weak that they bend under the body's weight. ⁵ p. 159
- Reproductive Hormones. The presence or absence of reproductive hormones (androgens in males, estrogens in females) affects the activity of osteoblasts in key locations and the growth of specific cell populations. Androgens and estrogens stimulate cell growth and differentiation in their target tissues, but their targets differ. The differential growth induced by each accounts for gender-related differences in skeletal proportions and secondary sex characteristics.

The Hormonal Responses to Stress

Any condition—physical or emotional—that threatens homeostasis is a form of **stress**. Specific homeostatic adjustments oppose many stresses. For example, a decrease in body temperature leads to shivering or changes in the pattern of blood flow, which can restore normal body temperature.

In addition, the body has a *general* response to stress that can occur while other, more specific responses are under way. A wide variety of stress-causing factors produce the same general pattern of hormonal and physiological adjustments. These responses are part of the **general adaptation syndrome (GAS)**, also known as the **stress response**. Hans Selye first described GAS in 1936. It has three phases: the *alarm phase*, the *resistance phase*, and the *exhaustion phase* (Spotlight Figure 18–20).

The Effects of Hormones on Behavior

As we have seen, the hypothalamus regulates many endocrine functions, and hypothalamic neurons monitor the levels of many circulating hormones. Other portions of the CNS are also quite sensitive to hormonal stimulation.

We can see the behavioral effects of specific hormones most clearly in individuals whose endocrine glands are oversecreting or undersecreting. But even normal changes in circulating hormone levels can cause behavioral changes. For example, in *precocious* (premature) *puberty*, sex hormones are produced at an inappropriate time, perhaps as early as age 5 or 6. Not only does an affected child begin to develop adult secondary sex characteristics, but the child's behavior also changes. The "nice little kid" disappears, and the child becomes aggressive and assertive due to the effects of sex hormones on CNS function. In normal teenagers, these behaviors are usually attributed to environmental stimuli, such as peer pressure, but here we can see that they have a physiological basis as well. In adults, changes in the mixture of hormones reaching the CNS can affect intellectual capabilities, memory, learning, and emotional states.

We now briefly turn to the effects of aging on hormone production.

Aging and Hormone Production

The endocrine system undergoes relatively few functional changes with age. The most dramatic exception is the decline in the concentrations of reproductive hormones. We noted the effects of these hormonal changes on the skeletal system in Chapter 6 \bigcirc p. 202, and we will continue the discussion in Chapter 29.

Blood and tissue concentrations of many other hormones, including TSH, thyroid hormones, ADH, PTH, prolactin, and glucocorticoids, do not change with advancing age. Circulating hormone levels may remain within normal limits, but some endocrine tissues become less responsive to stimulation. For example, in elderly individuals, smaller amounts of GH and insulin are secreted after a carbohydrate-rich meal. The

SPOTLIGHT Figure 18–20 The General Adaptation Syndrome

Alarm Phase ("Fight or Flight")

ALARM

Pancreas

Resistance Phase

If a stress lasts longer than a few hours, the person enters the **resistance** phase of GAS. Glucocorticoids are the dominant hormones of the resistance phase. Epinephrine, GH, and thyroid

hormones are also involved. Energy demands in the resistance

phase remain higher than normal, due to the combined effects of these hormones. Neural tissue has a high demand for energy, and requires a reliable supply of glucose. If blood glucose levels fall too low, neural function deteriorates. Glycogen reserves can meet neural demand during the alarm phase, but become depleted after several hours. Hormones of the resistance phase mobilize lipids and amino acids as energy sources to conserve glucose for use by neural tissue.

Growth hormone

Glucagon 📄

Long-Term Metabolic Adjustments

ESISTANO

- Mobilization of remaining energy reserves: Lipids are released by adipose tissue; amino acids are released by skeletal muscle
- Conservation of glucose: Peripheral tissues (except neural) break down lipids to obtain energy
- Elevation of blood alucose concentrations: Liver synthesizes glucose from other carbohydrates, amino acids, and lipids
- Conservation of salts and water, loss of K^+ and H^+

Exhaustion Phase

The body's lipid reserves are sufficient to maintain the resistance phase for weeks or even months. But when the resistance phase ends, homeostatic regulation breaks down and the exhaustion phase begins. Unless corrective actions are taken almost immediately, the failure of one or more organ systems will prove fatal. The production of aldosterone throughout the resistance phase

Collapse of Vital Systems

EXHAUSTION

- · Exhaustion of lipid reserves
- Cumulative structural or functional damage to vital organs
- · Inability to produce glucocorticoids
- · Failure of electrolyte balance

Clinical Note

Hormones and Athletic Performance The use of hormones to improve athletic performance is widely banned. The International Olympic Committee, the U.S. Olympic Committee, the National Collegiate Athletic Association, Major League Baseball, and the National Football League all ban it. The American Medical Association and the American College of Sports Medicine condemn the practice. Yet a significant number of amateur and professional athletes persist in this dangerous practice. Athletes most often use synthetic forms of testosterone. They might also use any combination of testosterone, GH, EPO, and a variety of synthetic hormones.

Androgen Abuse

The use of anabolic steroids, or androgens, has become popular with many amateur and professional athletes. The goal of steroid use is to increase muscle mass, endurance, and "competitive spirit." A steroid, such as androstenedione, is converted to testosterone in the body. One supposed justification for this steroid use is the unfounded opinion that compounds made in the body are not only safe, but good for you. In reality, the administration of natural or synthetic androgens in abnormal amounts carries unacceptable health risks. Androgens are known to produce several complications. These problems include (1) premature closure of epiphyseal cartilages, (2) various liver dysfunctions (such as jaundice and liver tumors), (3) prostate gland enlargement and urinary tract obstruction, and (4) testicular atrophy and infertility. Links to heart attacks, impaired cardiac function, and strokes have also been suggested.

The normal regulation of androgen production involves a feedback mechanism comparable to that described for adrenal steroids earlier in this chapter. GnRH stimulates the production of LH, and LH stimulates the secretion of testosterone and other androgens by the interstitial cells of the testes. Circulating androgens, in turn, inhibit the production of both GnRH and LH. For this reason, high doses of synthetic androgens can suppress the normal production of testosterone and depress the manufacture of GnRH by the hypothalamus. *This suppression of GnRH release can be permanent*. The use of androgens as "bulking agents" by female bodybuilders may add muscle mass, but it can also alter muscular proportions and secondary sex characteristics. For example, women taking steroids can develop irregular menstrual periods and changes in body hair distribution (such as baldness). Finally, androgen abuse can depress the immune system.

Erythropoietin Abuse

Erythropoietin (EPO) is readily available because it is now synthesized by recombinant DNA techniques. Endurance athletes, such as cyclists and marathon runners, sometimes use it to boost the number of oxygen-carrying red blood cells in the bloodstream. This effect increases the oxygen content of blood, but it also makes blood more viscous. For this reason, the heart must work harder to push the "thick" blood through the blood vessels. This effort can result in death due to heart failure or stroke in young and otherwise healthy individuals. The Tour de France bicycle races have been tainted by competitors testing positive for banned substances. These include testosterone, erythropoietin, and an illegal blood transfusion.

Androgens and EPO are hormones with reasonably well-understood effects. Drug testing is now widespread in amateur and professional sports, but athletes interested in "getting an edge" are experimenting with drugs not easily detected by standard tests. The long-term and short-term effects of these drugs are difficult to predict.

Gamma-hydroxybutyrate Use

Another drug used by amateur athletes is **gamma-hydroxybutyrate (GHB)**. It was tested for use as an anesthetic in the 1960s but rejected, in part because it was linked to seizures. In 1990, the drug appeared in health-food stores. It was sold as an anabolic agent and diet aid. It has also been used as a "date rape" drug. According to the FDA, GHB and related compounds—sold or distributed under the names Renewtrient, Revivarant, Blue Nitro, Firewater, and Serenity—have recently been responsible for serious illnesses and even deaths. Signs and symptoms include reduced heart rate, lowered body temperature, confusion, hallucinations, seizures, and coma at doses from 0.25 teaspoon to 4 tablespoons.

reduced levels of GH and other tropic hormones affect tissues throughout the body. These hormonal effects involve the reductions in bone density and muscle mass noted in earlier chapters.

Finally, age-related changes in peripheral tissues may make them less responsive to some hormones. This loss of sensitivity has been documented in the case of glucocorticoids and ADH.

Extensive integration occurs between the endocrine system and other body systems. For all systems, the endocrine system adjusts metabolic rates and substrate utilization. It also regulates growth and development. Figure 18–21 shows the functional relationships between the endocrine system and other systems studied so far.

CHECKPOINT

- 29. Insulin decreases blood glucose levels and glucagon increases blood glucose levels. This is an example of which type of hormonal interaction?
- **30**. The lack of which hormones would inhibit skeletal formation?
- **31**. Why do levels of GH–RH and CRH rise during the resistance phase of the general adaptation syndrome?
- **32**. Discuss the general role of the endocrine system in the functioning of other body systems.
- **33**. Discuss the functional relationship between the endocrine system and the muscular system.

See the blue Answers tab at the back of the book.

Several hormones affect neural metabolism and brain development; hormones help regulate fluid and electrolyte balance; reproductive hormones influence CNS development and behaviors

Gonads—ovaries in females and testes in males—are organs that produce gametes (sex cells). LH and FSH, hormones secreted by the anterior lobe of the pituitary gland, affect these organs. The ovaries and testes are discussed further in Chapter 28.

Related Clinical Terms

adrenalectomy: Surgical removal of an adrenal gland.empty sella syndrome: Condition in which the pituitary gland becomes shrunken or flattened.

- **exophthalmos:** Abnormal protrusion of the eyeballs.
- **galactorrhea:** A milky discharge from the nipple unrelated to normal breast feeding.
- **Hashimoto's disease:** Disorder that affects the thyroid gland, also known as chronic lymphocytic thyroiditis, causing the immune system to attack the thyroid gland. It is the most common cause of hypothyroidism in the United States.
- **hirsutism:** Excessive growth of facial or body hair in a woman. Hirsutism is a sign of hyperandrogenism, or the presence of abnormally high levels of androgens. It may be a sign of polycystic ovarian syndrome, congenital adrenal hyperplasia (CAH), or androgen-secreting tumors, all of which may cause infertility in women.
- **hypocalcemic tetany:** Muscle spasms affecting the face and upper extremities; caused by low Ca²⁺ concentrations in body fluids.

hypophysectomy: Surgical removal of the pituitary gland.

- **posttraumatic stress disorder (PTSD):** A common anxiety disorder that develops after being exposed to a life-threatening situation or terrifying event.
- **prolactinoma:** Noncancerous pituitary tumor that produces prolactin, resulting in too much prolactin in the blood.
- **psychosocial dwarfism:** Growth disorder occurring between the ages of 2 and 15, caused by extreme emotional deprivation or stress; also called deprivation dwarfism.
- thyroidectomy: Surgical removal of all or part of the thyroid gland.

thyroid function tests: Blood and radionuclide tests to determine thyroid gland activity.

- **thyrotoxicosis:** A condition caused by the oversecretion of thyroid hormones (hyperthyroidism). Signs and symptoms include increases in metabolic rate, blood pressure, and heart rate; excitability and emotional instability; and lowered energy reserves.
- **virilism:** A disorder of females in which there is development of secondary male sexual characteristics such as hirsutism and lowered voice caused by a number of conditions that affect hormone regulation.

18-1 Homeostasis is preserved through intercellular communication p. 609

- 1. In general, the nervous system performs short-term "crisis management," whereas the endocrine system regulates longer-term, ongoing metabolic processes.
- 2. **Paracrine communication** involves the use of chemical signals to transfer information from cell to cell within a single tissue.
- **3. Endocrine communication** results when chemicals, called hormones, are released into the circulation by *endocrine cells*. The hormones alter the metabolic activities of many tissues and organs simultaneously by modifying the activities of **target cells**. (*Table 18–1*)
- **18-2** The endocrine system regulates physiological processes through the binding of hormones to receptors p. 611
- The endocrine system includes all the cells and endocrine tissues of the body that produce hormones or paracrine factors. (*Figure 18–1*)

- Hormones can be divided into three groups according to their chemical structure: *amino acid derivatives; peptide hormones;* and *lipid derivatives,* including **steroid hormones** and **eicosanoids**. (*Spotlight Figure 18–2*)
- **6.** Hormones may circulate freely or bound to transport proteins. Free hormones are rapidly removed from the bloodstream.
- Receptors for *catecholamines*, peptide hormones, and eicosanoids are in the plasma membranes of target cells. Thyroid and steroid hormones cross the plasma membrane and bind to receptors in the cytoplasm or nucleus, activating or inactivating specific genes. (*Spotlight Figure 18–3*, *Figure 18–4*)
- 8. **Endocrine reflexes** are the functional counterparts of neural reflexes.
- 9. The hypothalamus regulates the activities of the nervous and endocrine systems by (1) secreting **regulatory hormones**, which control the activities of endocrine cells in the anterior lobe of the pituitary gland; (2) acting as an endocrine organ by releasing hormones into the bloodstream at the posterior lobe of the pituitary gland; and (3) exerting direct neural control over the endocrine cells of the adrenal medullae. (*Figure 18–5*)
- **18-3** The bilobed pituitary gland is an endocrine organ that releases nine peptide hormones p. 619
- The pituitary gland, or hypophysis, releases nine important peptide hormones. All bind to membrane receptors and use cyclic AMP as a second messenger. (*Figures 18–6 through 18–9*; *Table 18–2*)
- 11. The **anterior lobe** of the pituitary gland, or **adenohypophysis**, can be subdivided into the **pars distalis**, the **pars intermedia**, and the **pars tuberalis**. (*Figure 18–6*)

- 12. At the median eminence of the hypothalamus, neurons release regulatory factors (either **releasing hormones**, **RH**, or **inhib-iting hormones**, **IH**) into the surrounding interstitial fluids through **fenestrated capillaries**. (*Figure 18–7*)
- **13.** The **hypophyseal portal system** ensures that these regulatory factors reach the intended target cells in the pituitary before they enter the general circulation. (*Figure 18–7*)
- 14. **Thyroid-stimulating hormone (TSH)** triggers the release of thyroid hormones. *Thyrotropin-releasing hormone (TRH)* from the hypothalamus promotes the pituitary's secretion of TSH. (*Figure 18–8*)
- **15. Adrenocorticotropic hormone (ACTH)** stimulates the release of *glucocorticoids* by the adrenal cortex. Corticotropin-releasing hormone (CRH) from the hypothalamus causes the pituitary to secrete ACTH. (*Figure 18–8*)
- 16. Follicle-stimulating hormone (FSH) stimulates follicle development and estrogen secretion in females and sperm production in males. Luteinizing hormone (LH) causes *ovulation* and *progesterone* production in females, and androgen production in males. Gonadotropin-releasing hormone (GnRH) from the hypothalamus promotes the pituitary's secretion of both FSH and LH. (*Figure 18–8*)
- 17. **Prolactin (PRL)** from the pituitary, together with other hormones, stimulates both the development of the mammary glands and milk production. (*Figure 18–8*)
- Growth hormone (GH, or somatotropin) from the pituitary stimulates cell growth and replication through the release of somatomedins or IGFs from liver cells. The production of GH is regulated by growth hormone–releasing hormone (GH–RH) and growth hormone–inhibiting hormone (GH–IH) from the hypothalamus. (*Figure 18–8*)
- **19. Melanocyte-stimulating hormone (MSH)** may be secreted by the pars intermedia of the pituitary during fetal development, early childhood, pregnancy, or certain diseases. This hormone stimulates melanocytes to produce melanin.
- 20. The posterior lobe of the pituitary gland, or neurohypophysis, contains the unmyelinated axons of hypothalamic neurons. Neurons of the supraoptic and paraventricular nuclei manufacture antidiuretic hormone (ADH) and oxytocin (OXT), respectively. ADH decreases the amount of water lost at the kidneys and, in higher concentrations, elevates blood pressure. In women, oxytocin stimulates contractile cells in the mammary glands and has a stimulatory effect on smooth muscles in the uterus. (*Figure 18–9; Table 18–2*)

18-4 The thyroid gland lies inferior to the larynx and requires iodine for hormone synthesis p. 626

- 21. The thyroid gland lies anterior to the *thyroid cartilage* of the larynx and consists of two **lobes** connected by a narrow **isthmus**. (*Figure* 18–10)
- **22.** The thyroid gland contains numerous **thyroid follicles**. Thyroid follicles release several hormones, including **thyroxine** and **triiodothyronine**. (*Figures 18–10, 18–11; Table 18–4*)
- **23.** Most of the thyroid hormones entering the bloodstream are attached to special **thyroid-binding globulins (TBGs)**; the rest are attached to either **transthyretin** or albumin. (*Figure* 18–11)
- 24. In target cells, thyroid hormones are held in storage in the cytoplasm, bound to mitochondria (where they increase ATP production), or bound to receptors activating genes that control energy utilization. They also exert a **calorigenic effect**. (*Table 18–3*)

- **25.** The **C cells** of the thyroid follicles produce **calcitonin (CT)**, which helps regulate Ca²⁺ concentrations in body fluids, especially during childhood and pregnancy. (*Figure 18–10; Table 18–4*)
- 18-5 The four parathyroid glands, embedded in the posterior surface of the thyroid gland, secrete parathyroid hormone to elevate blood Ca²⁺ p. 630
- **26.** Four **parathyroid glands** are embedded in the posterior surface of the thyroid gland. **Parathyroid chief cells** produce **parathyroid hormone (PTH)** in response to lower-thannormal concentrations of Ca²⁺. The parathyroid glands, aided by *calcitriol*, are the primary regulators of blood calcium levels in healthy adults. (*Figures 18–12, 18–13; Table 18–4*)

18-6 The adrenal glands, consisting of a cortex and medulla, cap the kidneys and secrete several hormones p. 631

- 27. One **adrenal** (*suprarenal*) **gland** lies along the superior border of each kidney. The gland is subdivided into the superficial **adrenal cortex** and the inner **adrenal medulla**. (*Figure 18–14*)
- 28. The adrenal cortex manufactures steroid hormones called corticosteroids. The cortex can be subdivided into three areas: (1) the zona glomerulosa, which releases mineralocorticoids, principally aldosterone; (2) the zona fasciculata, which produces glucocorticoids, notably cortisol and corticosterone; and (3) the zona reticularis, which produces androgens under ACTH stimulation. (*Figure 18–14*)
- 29. The adrenal medulla produces epinephrine (75–80 percent of medullary secretion) and norepinephrine (20–25 percent). *(Figure 18–14)*

18-7 The pineal gland, attached to the roof of the third ventricle, secretes melatonin p. 634

30. The **pineal gland** contains **pinealocytes**, which synthesize **melatonin**. Suggested functions include inhibiting reproductive functions, protecting against damage by free radicals, and setting circadian rhythms. (*Figure 18–15*)

18-8 The pancreas is both an exocrine organ and endocrine gland p. 635

- **31.** The pancreas contains both exorrine and endocrine cells. Cells of the endocrine pancreas form clusters called **pancreatic islets** *(islets of Langerhans)*. These islets contain **alpha cells**, which secrete the hormone glucagon; **beta cells**, which secrete **insulin**; **delta cells**, which secrete **somatostatin (GH–IH)**; and **F cells**, which secrete **pancreatic polypeptide**. *(Figure 18–16; Table 18–5)*
- **32.** Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells; glucagon raises blood glucose by increasing the rates of glycogen breakdown and glucose manufacture in the liver. (*Figure 18–17; Table 18–5*)
- **33. Diabetes mellitus** is an endocrine disorder characterized by high blood glucose levels. (*Spotlight Figure 18–18*)

18-9 Many organs have secondary endocrine functions p. 639

- 34. The intestines produce hormones important in coordinating digestive activities. *(Table 18–6)*
- **35.** Endocrine cells in the kidneys produce the hormones *calcitriol* and *erythropoietin* and the enzyme *renin*. (*Table 18–6*)
- **36. Calcitriol** stimulates calcium and phosphate ion absorption along the digestive tract. (*Figure 18–19*)
- **37. Erythropoietin (EPO)** stimulates red blood cell production by the red bone marrow. (*Figure 18–19*)

- 38. In the *renin-angiotensin-aldosterone system (RAAS)*, **renin** converts **angiotensinogen** to **angiotensin I**. In the capillaries of the lungs, angiotensin-converting enzyme (ACE) converts angiotensin I to **angiotensin II**, a hormone that (1) stimulates the adrenal production of aldosterone, (2) stimulates the pituitary release of ADH, (3) promotes thirst, and (4) elevates blood pressure. *(Figure 18–19)*
- **39.** Specialized muscle cells in the heart produce **natriuretic pep-tides** (*ANP* and *BNP*) when blood volume becomes excessive. In general, their actions oppose those of angiotensin II. (*Table 18–6*)
- **40.** The thymus produces several hormones, collectively known as **thymosins**, which play a role in developing and maintaining normal immune defenses. *(Table 18–6)*
- **41.** The **interstitial cells** of the testes produce androgens. **Testoster-one** is the most important sex hormone in males. (*Table 18–7*)
- 42. In females, *oocytes* develop in follicles, and follicle cells produce **estrogens**, especially **estradiol**. After ovulation, the remaining follicle cells reorganize into a *corpus luteum*. Those cells release a mixture of estrogens and **progesterone**. (*Table 18–7*)
- 43. Adipose tissue secretes leptin (a feedback control for appetite).

18-10 Hormones interact to produce coordinated physiological responses p. 643

44. Endocrine system hormones often interact, producing
(1) antagonistic (opposing) effects; (2) synergistic (additive)
effects; (3) permissive effects, in which one hormone is

necessary for another to produce its effect; or (4) **integrative effects**, in which hormones produce different, but complementary, results.

- **45.** Normal growth requires the cooperation of several endocrine organs. Several hormones are especially important: GH, thyroid hormones, insulin, PTH, calcitriol, and reproductive hormones.
- 46. Any condition that threatens homeostasis is a stress. Our bodies respond to a variety of stress-causing factors through the general adaptation syndrome (GAS), or stress response.
- 47. The GAS can be divided into three phases: (1) the alarm phase (an immediate, "fight or flight" response, under the direction of the sympathetic division of the ANS); (2) the resistance phase, dominated by glucocorticoids; and (3) the exhaustion phase, the eventual breakdown of homeostatic regulation and failure of one or more organ systems. (*Spotlight Figure 18–20*)
- **48.** Many hormones affect the CNS. Changes in the normal mixture of hormones can significantly alter intellectual capabilities, memory, learning, and emotional states.
- **49.** The endocrine system undergoes few functional changes with advanced age. The major changes include a decline in the concentration of growth hormone and reproductive hormones.
- **50.** The endocrine system provides long-term regulation and homeostatic adjustments that affect many body systems. *(Figure 18–21)*

Review Questions

18

LEVEL 1 Reviewing Facts and Terms

- The use of a chemical messenger to transfer information from cell to cell within a single tissue is referred to as _____ communication.
 (a) direct, (b) paracrine, (c) hormonal, (d) endocrine.
- 2. Cyclic AMP functions as a second messenger to (a) build proteins and catalyze specific reactions, (b) activate adenylate cyclase, (c) open ion channels and activate key enzymes in the cytoplasm, (d) bind the hormone–receptor complex to DNA segments.
- Adrenocorticotropic hormone (ACTH) stimulates the release of

 (a) thyroid hormones by the hypothalamus,
 (b) gonadotropins by the adrenal glands,
 (c) growth hormones by the hypothalamus,
 (d) steroid hormones by the adrenal glands.
- 4. FSH production in males supports (a) the maturation of sperm by stimulating nurse cells, (b) the development of muscles and strength, (c) the production of male sex hormones, (d) an increased desire for sexual activity.
- The two hormones released by the posterior lobe of the pituitary gland are (a) GH and gonadotropin, (b) estrogen and progesterone, (c) GH and prolactin, (d) ADH and oxytocin.
- 6. All of the following are true of the endocrine system, *except* that it (a) releases chemicals into the bloodstream for distribution throughout the body, (b) releases hormones that simultaneously alter the metabolic activities of many different tissues and organs, (c) produces effects that can last for hours, days, and even longer, (d) produces rapid, local, brief-duration responses to specific stimuli, (e) functions to control ongoing metabolic processes.
- 7. A cell's hormonal sensitivities are determined by the (a) chemical nature of the hormone, (b) quantity of circulating hormone, (c) shape of the hormone molecules, (d) presence or absence of appropriate receptors, (e) thickness of its plasma membrane.

8. Identify the endocrine glands and tissues in the following diagram.

See the blue Answers tab at the back of the book.

- 9. What three higher-level mechanisms are involved in integrating the activities of the nervous and endocrine systems?
- **10.** Which seven hormones are released by the anterior lobe of the pituitary gland?

- 11. What six hormones primarily affect growth?
- **12.** What five primary effects result from the action of thyroid hormones?
- **13.** What effects do calcitonin and parathyroid hormone have on blood calcium levels?
- 14. What three zones make up the adrenal cortex, and what kind of hormones does each zone produce?
- **15.** Which two hormones are released by the kidneys, and what is the importance of each hormone?
- **16.** What are the four opposing effects of natriuretic peptides and angiotensin II?
- **17.** What four cell populations make up the endocrine pancreas? Which hormone does each type of cell produce?

LEVEL 2 Reviewing Concepts

- **18.** What is the primary difference in the way the nervous and endocrine systems communicate with their target cells?
- 19. In what ways can a hormone modify the activities of its target cells?
- **20.** What is an endocrine reflex? Compare endocrine reflexes and neural reflexes.
- **21.** How would blocking the activity of phosphodiesterase (POE) affect a cell that responds to hormonal stimulation by the cAMP second-messenger system?
- **22.** How does control of the adrenal medulla differ from control of the adrenal cortex?
- 23. A researcher observes that stimulation by a particular hormone induces a marked increase in the activity of G proteins in the target plasma membrane. The hormone being studied is probably (a) a steroid, (b) a peptide, (c) testosterone, (d) estrogen, (e) aldosterone.
- Increased blood calcium levels would result in *increased* (a) secretion of calcitonin, (b) secretion of PTH, (c) retention of calcium by the kidneys, (d) osteoclast activity, (e) excitability of neural membranes.

25. In Type 2 diabetes, insulin levels are frequently normal, yet the target cells are less sensitive to the effects of insulin. This suggests that the target cells (a) are impermeable to insulin, (b) may lack enough insulin receptors, (c) cannot convert insulin to an active form, (d) have adequate internal supplies of glucose, (e) both b and c.

LEVEL 3 Critical Thinking and Clinical Applications

- **26.** Roger has been extremely thirsty. He drinks numerous glasses of water every day and urinates a great deal. Name two disorders that could produce these signs and symptoms. What test could a clinician perform to determine which disorder Roger has?
- **27.** Julie is pregnant but is not receiving prenatal care. She has a poor diet consisting mostly of fast food. She drinks no milk, preferring colas instead. How would this situation affect Julie's level of parathyroid hormone?
- 28. Sherry tells her physician that she has been restless and irritable lately. She has a hard time sleeping and complains of diarrhea and weight loss. During the examination, her physician notices a higher-thannormal heart rate and a fine tremor in her outstretched fingers. What tests could the physician perform to make a positive diagnosis of Sherry's condition?
- **29.** What are two benefits of having a portal system connect the median eminence of the hypothalamus with the anterior lobe of the pituitary gland?
- **30.** Pamela and her teammates are considering taking testosterone supplements (anabolic steroids) to enhance their competitive skills. What natural effects of this hormone are they hoping to gain? What additional side effects might these women expect should they begin an anabolic steroid regime?

CLINICAL CASE Wra

Stones, Bones, and Groans

The doctor jokes with Monica that she has a case of "stones, bones, and groans." He then shows her the lab results, which indicate elevated blood calcium (Ca^{2+}) levels—a pivotal key to diagnosing Monica's condition.

Calcium is critical in the control of many systems. It provides the means for cholinergic synapses to work, including those in the CNS, all neuron-to-neuron synapses in the PNS, and all neuromuscular junctions. Calcium also plays an essential role in the muscular contraction cycles of all skeletal, smooth, and cardiac muscles. It also strengthens the skeleton, which acts like a Ca²⁺ storage system. Calcium is the most closely regulated element in our bodies.

The parathyroid glands function to increase blood calcium. Normally four small parathyroid glands, each about the size of a grain of rice, produce parathyroid hormone (PTH). They are located on the posterior surface of the thyroid gland. Their chief cells monitor the circulating concentration of Ca²⁺ and produce PTH in a negative feedback control system.

Wrap-Up

It turns out that one of Monica's parathyroid glands has a benign tumor that is producing PTH without feedback control. The excess PTH causes the elevated blood Ca²⁺ levels, osteopenia, and bone pain. The elevated blood Ca²⁺ is responsible

for Monica's heart palpitations, kidney stones, muscle fatigue, memory loss, depression, and irritability.

Outpatient surgery is performed to remove the tumor. The remaining three parathyroid glands take over normal Ca^{2+} regulation. Monica soon begins to feel like her old self.

- 1. In addition to mobilizing calcium from bone, how else does PTH increase blood calcium levels?
- 2. What hormone counteracts PTH and decreases blood Ca²⁺ levels?

See the blue Answers tab at the back of the book.

Blood

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **19-1** Describe the components and major functions of blood, identify blood collection sites, and list the physical characteristics of blood.
- **19-2** Specify the composition and functions of plasma.
- 19-3 List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, and explain erythropoiesis.
- **19-4** Explain the importance of blood typing, and the basis for ABO and Rh incompatibilities.
- **19-5** Categorize white blood cell types based on their structures and functions, and discuss the factors that regulate the production of each type.
- **19-6** Describe the structure, function, and production of platelets.
- 19-7 Discuss the mechanisms that control blood loss after an injury, and describe the reaction sequences responsible for blood clotting.

SPOTLIGHTS

- Hemolytic Disease of the Newborn pp. 668–669

CLINICAL CASE

• A Mysterious Blood Disorder p. 653

Clinical Notes

- Collecting Blood for Analysis p. 656
- Plasma Expanders p. 657
- Abnormal Hemoglobin p. 660

A Mysterious Blood Disorder

Today is Jasmine's first day at her new job. She just graduated from college with a degree in biology.

Becoming a researcher for a pharmaceutical company is a dream come true. But today, she can't believe how bad she feels.

Jasmine is severely fatigued, even though she slept for 10 hours last night. Her gums bled when she brushed her teeth this morning. She is so short of breath that she can barely climb the flight of stairs leading into the office building. She feels her heart thumping rapidly with the slightest exertion.

Jasmine's menstrual periods have been lasting up to three weeks, and she has suffered several nosebleeds in the last month. She has big bruises on her legs that she cannot explain, and she has had a sore throat for the past six weeks.

Last week Jasmine saw her primary care physician, who drew blood for a complete blood count (CBC). Her physician calls

her back with some bad news. Instead of having 4.2–5.5 million red blood cells (RBCs) per μ L of blood, Jasmine has fewer than 800,000. Instead of having 5000–10,000 white blood cells (WBCs) per μ L of blood, she has fewer than 900. And instead of having 150,000–500,000 platelets per μ L of blood, she has only 25,000.

Jasmine's doctor refers her to a hematologist, a physician specializing in diseases of the blood. The hematologist evaluates Jasmine and recommends a bone marrow biopsy. What will Jasmine's bone marrow biopsy reveal? To find out, turn to the Clinical Case Wrap-Up on p. 683.

An Introduction to Blood and the Cardiovascular System

In this chapter we discuss the nature of blood, the fluid component of the **cardiovascular system**. This body system also includes a pump (the heart) that circulates the fluid and a series of conducting hoses (the blood vessels) that carry it throughout the body. In Chapter 18, we noted the importance of this system for transporting hormones, but that is only one of its many vital roles.

In adults, circulating blood provides each of the body's roughly 75 trillion cells a source of nutrients and oxygen, and a way of removing wastes. The blood also transports specialized cells that defend tissues from infection and disease. These services are essential—so much so that cells deprived of circulation may die in a matter of minutes. In this chapter we take a close look at the structure and functions of blood, a fluid connective tissue with remarkable properties. We discuss the heart in Chapter 20 and the blood vessels in Chapter 21.

19-1 Blood has several important functions and unique physical characteristics

Learning Outcome Describe the components and major functions of blood, identify blood collection sites, and list the physical characteristics of blood.

Blood is a specialized fluid connective tissue that contains cells suspended in a fluid matrix. In Chapter 4 we introduced the components and properties of this connective tissue. \bigcirc p. 131

The functions of blood include the following:

• Transporting Dissolved Gases, Nutrients, Hormones, and Metabolic Wastes. Blood carries oxygen from the lungs to

peripheral tissues, and carbon dioxide from those tissues back to the lungs. Blood distributes nutrients absorbed by the digestive tract or released from storage in adipose tissue or in the liver. It carries hormones from endocrine glands toward their target cells. It also absorbs the wastes produced by tissue cells and carries them to the kidneys for excretion.

- Regulating the pH and Ion Composition of Interstitial Fluids. Diffusion between interstitial fluids and blood eliminates local deficiencies or excesses of ions, such as calcium or potassium. Blood also absorbs and neutralizes acids generated by active tissues, such as lactic acid produced by skeletal muscles.
- *Restricting Fluid Losses at Injury Sites.* Blood contains enzymes and other substances that respond to breaks in vessel walls by initiating the process of *clotting*. A blood clot acts as a temporary patch that prevents further blood loss.
- Defending against Toxins and Pathogens. Blood transports white blood cells, specialized cells that migrate into other tissues to fight infections or remove debris. Blood also delivers antibodies, proteins that specifically attack invading organisms or foreign compounds.
- Stabilizing Body Temperature. Blood absorbs the heat generated by active skeletal muscles and redistributes it to other tissues. If body temperature is already high, that heat will be lost across the surface of the skin. If body temperature is too low, the warm blood is directed to the brain and to other temperature-sensitive organs.

Spotlight Figure 19–1 (p. 654) describes the composition of whole blood, which is made up of fluid *plasma* and *formed elements* (cells and cell fragments).

SPOTLIGHT Figure 19–1 The Composition of Whole Blood

A Fluid Connective Tissue

Blood is a fluid connective tissue with a unique composition. It consists of a matrix called **plasma** (PLAZ-muh) and formed elements (cells and cell fragments). The term **whole blood** refers to the combination of plasma and the formed elements. The cardiovascular system of an adult male contains 5–6 liters (5.3–6.4 quarts) of whole blood. An adult female contains 4–5 liters (4.2–5.3 quarts). The sex differences in blood

volume primarily reflect differences in average body size.

consists of

PLASMA

Plasma, the fluid matrix of blood, makes up 46–63% of the volume of whole blood. In many respects, the composition of plasma resembles that of interstitial fluid. This similarity exists because water, ions, and small solutes are continuously exchanged between plasma and interstitial fluids across the walls of capillaries. The primary differences between plasma and interstitial fluid involve (1) the levels of respiratory gases (oxygen and carbon dioxide, due to the respiratory activities of tissue cells), and (2) the concentrations and types of dissolved proteins (because plasma proteins cannot cross capillary walls).

7%

99.9%

	Plasma	Plasma Proteins	10/
	55% (Range 46-63%)	Other Solutes	1 %
		Water	92%
	+		
	Formed Elements 45% (Range 37–54%)	Platelets	<.1%
		White Blood Cells	
		Red Blood Cells	<.1%
	F	Formed elements are blood cells and cell	

The hematocrit (he-MAT-ō-krit) is the percentage of formed elements in a sample of blood. The normal hematocrit, or packed cell volume (PCV), in adult males is 46 and in adult females is 42. The sex difference in hematocrit primarily reflects the fact that androgens (male hormones) stimulate red blood cell production, whereas estrogens (female hormones) do not. Formed elements are blood cells and cell fragments that are suspended in plasma. These elements account for 37–54% of the volume of whole blood. Three types of formed elements exist: platelets, white blood cells, and red blood cells. Formed elements are produced through the process of **hemopoiesis** (hē-mō-poy-Ē-sis), also called **hematopoiesis**. Two populations of stem cells—myeloid stem cells and lymphoid stem cells—are responsible for the production of formed elements.

FORMED ELEMENTS

Plasma Proteins

Plasma proteins are in solution rather than forming insoluble fibers like those in other connective tissues, such as loose connective tissue or cartilage. On average, each 100 mL of plasma contains 7.6 g of protein, almost five times the concentration in interstitial fluid. The large size and globular shapes of most blood proteins prevent them from crossing capillary walls, so they remain trapped within the bloodstream. The liver synthesizes and releases more than 90% of the plasma proteins, including all albumins and fibrinogen, most globulins, and various prohormones.

Albumins

(al-BŪ-minz) constitute about 60% of the plasma proteins. As the most abundant plasma proteins, they are major contributors to the osmotic pressure of plasma.

Globulins

(GLOB-ū-linz) account for approximately 35% of the proteins in plasma. Important plasma globulins include antibodies and transport alobulins. Antibodies. also called immunoglobulins (i-mū-nō-GLOB-ū-linz), attack foreign proteins and pathogens. Transport globulins bind small ions, hormones, and other compounds.

Normal extracellular ion vital cellular activities. The major plasma electrolytes are Na⁺, K⁺, Ca²⁺, Mg²⁺, Cl⁻, HCO_3^- , HPO_4^- , and SO42-.

Fibrinogen

(fī-BRIN-ō-jen) functions in clotting, and normally accounts for roughly 4% of plasma proteins. Under certain conditions, fibrinogen molecules interact. forming large, insoluble strands of fibrin (FI-brin) that form the basic framework for a blood clot.

> Plasma also contains enzymes and hormones whose concentrations vary widely.

Other Solutes

Other solutes are generally present in concentrations similar to those in the interstitial fluids. However, because blood is a transport medium there may be differences in nutrient and waste product concentrations between arterial blood and venous blood.

Nutrients: Organic nutrients are used for ATP production, growth, and cell maintenance. This category includes lipids (fatty acids, cholesterol, glycerides), carbohydrates (primarily glucose), and amino acids.

Neutrophils

Organic

Electrolytes:

composition is essential for

Organic Wastes:

Wastes are carried to sites for break down or excretion. Examples of organic wastes include urea, uric acid, creatinine, bilirubin, and ammonium ions.

Platelets

Platelets (PLAT-lets) are small, membranebound cell fragments that contain enzymes and other substances important for clotting.

White Blood Cells

White blood cells (WBCs), or leukocytes (LŪ-kō-sīts; leukos, white + -cyte, cell), play a role in the body's defense mechanisms. There are five classes of leukocytes, each with slightly different functions that will be explored later in the chapter.

Eosinophils

Monocytes

Red Blood Cells

Red blood cells (RBCs), or erythrocytes (e-RITH-ro-sits; erythros, red + -cyte, cell), are the most abundant blood cells. These specialized cells are essential for the transport of oxygen in the blood.

The components of whole blood can be **fractionated**, or separated, for analytical or clinical purposes. We will see examples of uses for fractionated blood later in the chapter.

Whole blood from any source—veins, capillaries, or arteries—has the same basic physical characteristics:

- Blood temperature is about 38 °C (100.4 °F), slightly above normal body temperature.
- Blood is five times as viscous as water—that is, five times as sticky, five times as cohesive, and five times as resistant to flow as water. The high viscosity results from interactions among dissolved proteins, formed elements, and water molecules in plasma.
- Blood is slightly alkaline, with a pH between 7.35 and 7.45 (average: 7.4).

Adult males typically have more blood than do adult females. We can estimate blood volume in liters for an individual of either sex by calculating 7 percent of the body weight in kilograms. For example, a 75-kg (165-lb) person would have a blood volume of approximately 5.25 liters (5.4 quarts).

Collecting Blood for Analysis Fresh whole blood is generally collected from a superficial vein, such as the *median cubital vein* on the anterior surface of the elbow. The procedure is called **venipuncture** (VĒN-i-punk-chur; *vena*, vein + *punctura*, a piercing). It is a common sampling technique because (1) superficial veins are easy to locate, (2) the walls of veins are thinner than those of comparably sized arteries, and (3) blood pressure in the venous system is relatively low, so the puncture wound seals quickly. The most common clinical procedures examine venous blood.

A small drop of blood can be used to prepare a *blood smear*, a thin film of blood on a microscope slide. The blood smear is then stained with special dyes to show each type of formed element. Blood from peripheral capillaries can be obtained by puncturing the tip of a finger, an earlobe, or (in infants) the great toe or heel. Small amounts of capillary blood can also be used to test (among other items) glucose, cholesterol, and hemoglobin levels. This method is valuable when veins are difficult to access.

An **arterial puncture**, or "arterial stick," can be used for checking the efficiency of gas exchange at the lungs. Samples are generally drawn from the *radial artery* at the wrist or the *brachial artery* at the elbow.

CHECKPOINT

- 1. List five major functions of blood.
- 2. Identify the composition of the formed elements in blood.
- 3. What two components make up whole blood?
- 4. Why is venipuncture a common technique for obtaining a blood sample?
- See the blue Answers tab at the back of the book.

19-2 Plasma, the fluid portion of blood, contains significant quantities of plasma proteins

Learning Outcome Specify the composition and functions of plasma.

As shown in **Spotlight Figure 19–1**, plasma makes up about 55 percent of the volume of whole blood. The components of plasma include plasma proteins, other solutes, and water.

Plasma Proteins

Plasma contains significant quantities of dissolved proteins, namely albumins, globulins, and fibrinogen. These three types make up more than 99 percent of the plasma proteins. The others are circulating enzymes, hormones, and prohormones.

Albumins

Albumins make up the majority of the plasma proteins. For this reason, they are the major contributors to plasma osmolarity and osmotic pressure. Albumins are also important for transporting fatty acids, thyroid hormones, some steroid hormones, and other substances.

Globulins

Globulins are the second most-abundant proteins in plasma. Examples of plasma globulins include antibodies (immunoglobulins) that aid in body defense, and transport globulins. Transport globulins bind small ions, hormones, and compounds that might otherwise be removed by the kidneys or that have very low solubility in water. Important examples of transport globulins include:

- Hormone-binding proteins, which provide a reserve of hormones in the bloodstream. Examples include *thyroid-binding globulin* and *transthyretin*, which transport thyroid hormones, and *transcortin*, which transports ACTH.
 pp. 626, 631
- *Metalloproteins*, which transport metal ions. *Transferrin*, for example, transports iron (Fe²⁺).
- Apolipoproteins (ap-ō-lip-ō-PRŌ-tēnz), which carry triglycerides and other lipids in blood. When bound to lipids, an apolipoprotein becomes a **lipoprotein** (LĪ-pō-prō-tēn).

 Steroid-binding proteins, which transport steroid hormones in blood. For example, testosterone-binding globulin (TeBG) binds and transports testosterone.

Fibrinogen

The third major type of plasma protein, fibrinogen, functions in clotting. If steps are not taken to prevent clotting in a blood sample, the conversion of *fibrinogen* (a soluble protein) to *fibrin* (an insoluble protein) will take place. This conversion removes the clotting proteins, leaving a fluid known as **serum**. The clotting process also removes calcium ions and other materials from solution, so plasma and serum differ in several significant ways. (See Appendix.) For this reason, the results of a blood test generally indicate whether the sample was plasma or serum.

Other Plasma Proteins

The remaining 1 percent of plasma proteins is composed of specialized proteins whose levels vary widely. Peptide hormones—including insulin, prolactin (PRL), and the glycoproteins thyroid-stimulating hormone (TSH), follicle-

Plasma Expanders Plasma expanders can be used to increase blood volume temporarily, over a period of hours. They are often used to buy time for lab work to determine a person's blood type. (Transfusion of the wrong blood type can kill the recipient.) Isotonic electrolyte solutions such as normal (physiological) saline can be used as plasma expanders, but their effects are short-lived due to diffusion into interstitial fluid and cells. This fluid loss is slowed by the addition of solutes that cannot freely diffuse across plasma membranes. One example is lactated Ringer's solution, an isotonic saline also containing lactate, potassium chloride, and calcium chloride ions. The effects of Ringer's solution fade gradually as the liver, skeletal muscles, and other tissues absorb and metabolize the lactate ions. Another option is isotonic saline solution containing purified human albumin. However, the plasma expanders in clinical use often contain large carbohydrate molecules, rather than proteins, to maintain proper osmotic concentration. These carbohydrates are not metabolized, but phagocytes gradually remove them from the bloodstream, and blood volume slowly declines. Plasma expanders are easily stored. Their sterile preparation avoids viral or bacterial contamination, which can be a problem with donated plasma. Note that plasma expanders provide a temporary solution to low blood volume, but they do not increase the amount of oxygen carried by the blood. Red blood cells are needed for that function.

stimulating hormone (FSH), and luteinizing hormone (LH) are normally present in circulating blood. Their plasma concentrations rise and fall from day to day or even hour to hour.

Origins of the Plasma Proteins

The liver synthesizes and releases more than 90 percent of the plasma proteins, including all albumins and fibrinogen, most globulins, and various prohormones. For this reason, liver disorders can alter the composition and functional properties of blood. For example, some forms of liver disease can lead to uncontrolled bleeding due to the inadequate synthesis of fibrinogen and other proteins involved in clotting.

CHECKPOINT

- 5. List the three major types of plasma proteins.
- 6. What would be the effects of a decrease in the amount of plasma proteins?
- 7. Which specific plasma protein would you expect to be elevated during a viral infection?
- See the blue Answers tab at the back of the book.

19-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled

Learning Outcome List the characteristics and functions of red blood cells, describe the structure and functions of hemoglobin, describe how red blood cell components are recycled, and explain erythropoiesis.

The formed elements (blood cells and cell fragments) make up about 45 percent of whole blood volume (**Spotlight Figure 19–1**). The most abundant blood cells are the red blood cells (RBCs), which account for 99.9 percent of the formed elements. These cells give whole blood its deep red color because they contain the red pigment *hemoglobin* (HĒ-mō-glō-bin), which binds and transports oxygen and carbon dioxide.

Abundance of RBCs

RBCs make up roughly one-third of all cells in the human body. A standard blood test reports the number of RBCs per microliter (μ L) of whole blood as the *red blood cell count*. In adult males, 1 microliter, or 1 *cubic millimeter* (mm³), of whole blood contains 4.5–6.3 million RBCs. In adult females, 1 microliter contains 4.2–5.5 million. A single drop of whole blood contains approximately 260 million RBCs. The blood of an average adult has 25 trillion RBCs.

The percentage of a blood sample that consists of formed elements (most of which are red blood cells) is known as the hematocrit (Spotlight Figure 19–1). The hematocrit is determined by centrifuging a blood sample so that all the formed elements come out of suspension. Whole blood contains about surface of the slide.

Figure 19–2 The Anatomy of Red Blood Cells.

d When traveling through relatively narrow capillaries, RBCs may stack like dinner plates.

1000 red blood cells for each white blood cell. After centrifugation, the white blood cells and platelets form a very thin *buffy coat* above a thick layer of RBCs.

Many conditions can affect the hematocrit. For example, the hematocrit increases during dehydration, due to a reduction in plasma volume, or after *erythropoietin* (*EPO*) stimulation. **D p**. **640** The hematocrit decreases as a result of internal bleeding or problems with RBC formation. So, the hematocrit alone does not provide specific diagnostic information. Still, an abnormal hematocrit is an indication that other, more specific tests are needed. (We consider some of those tests later in the chapter.)

Structure of RBCs

Red blood cells are among the most specialized cells of the body. A red blood cell is very different from the "typical cell"

we discussed in Chapter 3. Each RBC is a biconcave disc with a thin central region and a thicker outer margin (Figure 19–2). An average RBC has a diameter of 7.8 μ m and a maximum thickness of 2.85 μ m, although the center narrows to about 0.8 μ m.

This unusual shape has three important effects on RBC function:

- 1. *Gives Each RBC a Large Surface-Area-to-Volume Ratio.* Each RBC carries oxygen bound to intracellular proteins. That oxygen must be absorbed or released quickly as the RBC passes through the capillaries of the lungs or peripheral tissues. The greater the surface area per unit volume, the faster the exchange between the RBC's interior and the surrounding plasma. The total surface area of all the RBCs in the blood of a typical adult is about 3800 square meters, (nearly 4600 square yards), some 2000 times the total surface area of the body.
- 2. Enables RBCs to Form Stacks, Like Dinner Plates, That Smooth the Flow through Narrow Blood Vessels. These stacks, known as rouleaux (roo-LŌ; rouleau, singular), form and dissociate repeatedly without affecting the cells involved. An entire stack can pass along a blood vessel that is only slightly larger than the diameter of a single RBC. In contrast, individual cells would bump the walls, bang together, and form logjams that could restrict or prevent blood flow. Such stacks are shown in Figure 19–2d.
- 3. Enables RBCs to Bend and Flex When Entering Small Capillaries and Branches. Red blood cells are very flexible. By changing shape, individual RBCs can squeeze through capillaries as narrow as $4 \mu m$.

19

When they differentiate, the RBCs of humans and other mammals lose most of their organelles, including their nuclei. The cells retain only the cytoskeleton. (The RBCs of vertebrates other than mammals have nuclei.) Without nuclei and ribosomes, circulating mammalian RBCs cannot divide or synthesize structural proteins or enzymes. As a result, the RBCs cannot perform repairs, so their life span is relatively short—normally less than 120 days. With few organelles and no ability to synthesize proteins, their energy demands are low. Without mitochondria, they obtain the energy they need through the anaerobic metabolism of glucose that is absorbed from the surrounding plasma. The lack of mitochondria ensures that absorbed oxygen will be carried to peripheral tissues, not "stolen" by mitochondria in the RBC.

Hemoglobin

A developing red blood cell loses any organelle not directly associated with the cell's primary function: the transport of respiratory gases. Molecules of **hemoglobin (Hb; Hgb)** make up more than 95 percent of its intracellular proteins. Hemoglobin is responsible for the cell's ability to transport oxygen and carbon dioxide.

The hemoglobin content of whole blood is reported in grams of Hb per deciliter (100 mL) of whole blood (g/dL). Normal ranges are 14-18 g/dL in males and 12-16 g/dL in females.

Hemoglobin Structure

Hb molecules have a complex quaternary structure. \supset p. 53 Each Hb molecule has two *alpha* (α) *chains* and two *beta* (β) *chains* of polypeptides (Figure 19–3). Each chain is a globular protein subunit that resembles the myoglobin in skeletal and cardiac muscle cells. Like myoglobin, each Hb chain contains a single molecule of **heme**, a nonprotein pigment complex. Each heme unit holds an iron ion in such a way that the iron can interact with an oxygen molecule, forming **oxyhemoglobin**, **HbO**₂. Blood that contains RBCs filled with oxyhemoglobin is bright red.

The binding of an oxygen molecule to the iron in a heme unit is completely reversible. The iron-oxygen interaction is very weak. The iron and oxygen can easily dissociate without damaging the heme unit or the oxygen molecule. A hemoglobin molecule whose iron is not bound to oxygen is called **deoxyhemoglobin**. Blood containing RBCs filled with deoxyhemoglobin is dark red—almost burgundy.

The RBCs of an embryo or a fetus contain a different form of hemoglobin, known as *fetal hemoglobin*. It binds oxygen more readily than does the hemoglobin of adults. For this reason, a developing fetus can "steal" oxygen from the maternal bloodstream at the placenta. The conversion from fetal hemoglobin to the adult form begins shortly before birth and continues over the next year. The production of fetal hemoglobin can be stimulated in adults by the administration of drugs such as *hydroxyurea* or *butyrate*. This is one method of treatment for conditions, such as *sickle cell anemia* or *thalassemia*, that result from the production of abnormal forms of adult hemoglobin.

Hemoglobin Function

Each RBC contains about 280 million Hb molecules. Because one Hb molecule contains four heme units, each RBC can

Figure 19–3 The Structure of Hemoglobin. Hemoglobin consists of four globular protein subunits. Each subunit contains a single molecule of heme—a nonprotein ring surrounding a single ion of iron.

Hemoglobin molecule

Clinical Note

Abnormal Hemoglobin Abnormal hemoglobin characterizes several inherited disorders. Two of the best known are thalassemia and sickle cell anemia (SCA).

The various forms of **thalassemia** (thal-ah-SĒ-mē-uh) result from an inability to produce adequate amounts of alpha or beta chains of hemoglobin (Hb). As a result, the rate of RBC production is slowed, and mature RBCs are fragile and short-lived. The scarcity of healthy RBCs reduces the oxygen-carrying capacity of the blood. It also leads to problems with the development and growth of systems throughout the body. Individuals with severe thalassemia must periodically undergo *transfusions*—the administration of blood components—to keep adequate numbers of RBCs in the bloodstream.

Sickle cell anemia results from a mutation affecting the amino acid sequence of the beta chains of the Hb molecule. When blood contains abundant oxygen, the Hb molecules and the RBCs that carry them appear normal. However, when the defective hemoglobin gives up enough of its bound oxygen, the adjacent Hb molecules interact and the cells become stiff and curved. This "sickling" makes the RBCs fragile and easily damaged. Moreover, an RBC that has folded to squeeze into a narrow capillary delivers its oxygen to the surrounding tissue, but the cell can become stuck as sickling occurs. A circulatory blockage results, and nearby tissues become starved for oxygen.

RBC Formation and Turnover

Sickling in ~

Red Blood Cells

An RBC is exposed to severe mechanical stresses. A single round trip from the heart, through the peripheral tissues, and back to the heart usually takes less than a minute. In that time, the RBC gets pumped out of the heart and forced along vessels, where it bounces off the walls and collides with other RBCs. It forms stacks, contorts, and squeezes through tiny capillaries. Then it is rushed back to the heart to make another round trip.

With all this wear and tear and no repair mechanisms, a typical RBC has a short life span. After it travels about 700 miles in 120 days, either its plasma membrane ruptures or some other damage is detected by phagocytes of the spleen, liver, and red bone marrow, which engulf the RBC. The continuous elimination of RBCs usually goes unnoticed, because new ones enter the bloodstream at a comparable rate. About 1 percent of the circulating RBCs are replaced each day, and in the process approximately 3 million new RBCs enter the bloodstream *each second*!

Hemoglobin Conservation and Recycling

Macrophages of the spleen, liver, and red bone marrow play a role in recycling red blood cell components. These phagocytes

potentially carry more than a billion molecules of oxygen at a time. Roughly 98.5 percent of the oxygen carried by the blood is bound to Hb molecules inside RBCs.

The amount of oxygen bound to hemoglobin depends mostly on the oxygen content of the plasma. When plasma oxygen levels are low, hemoglobin releases oxygen. Under these conditions, typical of peripheral capillaries, plasma carbon dioxide levels are elevated. The alpha and beta chains of hemoglobin then bind carbon dioxide, forming **carbaminohemoglobin**. In the capillaries of the lungs, plasma oxygen levels are high and carbon dioxide levels are low. Upon reaching these capillaries, RBCs absorb oxygen (which is then bound to hemoglobin) and release carbon dioxide. We will revisit these processes in Chapter 23.

Normal activity levels can be sustained only when tissue oxygen levels are kept within normal limits. If the hematocrit is low or the Hb content of the RBCs is reduced, a condition known as **anemia** results. Anemia interferes with oxygen delivery to peripheral tissues. Every system is affected as organ function deteriorates due to oxygen starvation. Anemic individuals become weak and lethargic. They may also become confused, because the brain is affected as well. also detect and remove Hb molecules from **hemolyzed**, or ruptured, red blood cells. Hemoglobin remains intact only under the conditions inside RBCs. If the Hb released by hemolysis is not phagocytized, its components will not be recycled. When hemolysis occurs, the Hb breaks down, and the alpha and beta chains are filtered by the kidneys and eliminated in urine. When abnormally large numbers of RBCs break down in the bloodstream, urine may turn red or brown. This condition is called **hemoglobinuria**. The presence of intact RBCs in urine—a sign called **hematuria** (hē-ma-TOO-rē-uh)—occurs only after kidney damage or damage to vessels along the urinary tract.

Once a phagocytic cell has engulfed and broken down an RBC, each part of the Hb molecule has a different fate (Figure 19–4). The globular proteins are broken apart into their component amino acids, which are then either metabolized by the cell or released into the bloodstream for use by other cells. Each heme unit is stripped of its iron and converted to **biliverdin** (bil-i-VER-din), an organic compound with a green color. (Bad bruises commonly develop a greenish tint when biliverdin forms in the blood-filled tissues.) Biliverdin is then converted to **bilirubin** (bil-i-ROO-bin), an orange-yellow pigment, and released into the bloodstream. There, the bilirubin binds to albumin and is transported to the liver for excretion in bile.

If the bile ducts are blocked or the liver cannot absorb or excrete bilirubin, circulating levels of the compound climb rapidly. Bilirubin then diffuses into peripheral tissues, giving them a yellow color that is most apparent in the skin and over the sclera of the eyes. This combination of signs (yellow skin and eyes) is called **jaundice** (JAWN-dis).

In the large intestine, bacteria convert bilirubin to related pigments called *urobilinogens* (ūr-ō-bī-LIN-ō-jens) and *sterco-bilinogens* (ster-kō-bī-LIN-ō-jens). Some of the urobilinogens are absorbed into the bloodstream and are then excreted into urine. When exposed to oxygen, some of the urobilinogens and stercobilinogens are converted to **urobilins** (ūr-ō-BĪ-lins) and **stercobilins** (ster-kō-BĪ-lins).

Iron

Large quantities of free iron are toxic to cells, so in the body iron is generally bound to transport or storage proteins. Iron ions (Fe²⁺) extracted from heme molecules may be bound and stored in a phagocytic cell or released into the bloodstream, where it binds to **transferrin** (trans-FER-in), a plasma protein. Red blood cells developing in the red bone marrow absorb the amino acids and transferrins from the bloodstream and use them to synthesize new Hb molecules. Excess transferrins are removed in the liver and spleen, and the iron is stored in two special protein–iron complexes: **ferritin** (FER-i-tin) and **hemosiderin** (hē-mō-SID-e-rin).

This recycling system is remarkably efficient. Although roughly 26 mg of iron is incorporated into new Hb molecules each day, a dietary supply of 1–2 mg can keep pace with the incidental losses that occur at the kidneys and digestive tract.

Any impairment in iron uptake or metabolism can cause serious clinical problems, because RBC formation will be affected. For example, *iron-deficiency anemia* results from a lack of iron in the diet or from problems with iron absorption. Too much iron can also cause problems, due to excessive buildup in secondary storage sites, such as the liver and cardiac muscle tissue. Excessive iron deposition in cardiac muscle cells has been linked to heart disease.

RBC Production

Embryonic blood cells appear in the bloodstream during the third week of development. These cells divide repeatedly, rapidly increasing in number. Blood forms primarily in the vessels of the embryonic *yolk sac* during the first eight weeks of development. As other organ systems appear, some of the embryonic blood cells move out of the bloodstream and into the liver, spleen, thymus, and bone marrow. These embryonic cells differentiate into stem cells that divide to produce blood cells.

The liver and spleen are the primary sites of hemopoiesis from the second to fifth months of development, but as the skeleton enlarges, the bone marrow becomes increasingly important. In adults, red bone marrow is the only site of red blood cell production, as well as the primary site of white blood cell formation.

Red blood cell formation, or **erythropoiesis** (e-rith-rōpoy-Ē-sis), takes place only in *red bone marrow*, or **myeloid** (MĪ-e-loyd; *myelos*, marrow) **tissue**. This tissue is located in portions of the vertebrae, sternum, ribs, skull, scapulae, pelvis, and proximal limb bones. Other marrow areas contain a fatty tissue known as *yellow bone marrow*. \supset **p**. 187 Under extreme stimulation, such as severe and sustained blood loss, areas of yellow marrow can convert to red marrow, increasing the rate of RBC formation.

Stages in RBC Maturation

A red blood cell matures in a series of stages. Blood specialists, known as **hematologists** (hē-ma-TOL-o-jists), have named key stages. Divisions of **hemocytoblasts** (*hemo-*, blood + *cyte*, cell + *blastos*, precursor), or **hematopoietic stem cells** (**HSCs**), in the red bone marrow produce (1) **myeloid stem cells**, which in turn divide to produce red blood cells and several classes of white blood cells, and (2) **lymphoid stem cells**, which divide to produce the various classes of lymphocytes. Cells destined to become RBCs first differentiate into **proerythroblasts** and then proceed through various **erythroblast** stages (**Figure 19–5**). Erythroblasts, which actively synthesize hemoglobin, are named based on total size, amount of hemoglobin, and size and appearance of the nucleus.

Figure 19–5 Stages of RBC Maturation. Red blood cells are produced in the red bone marrow. The color density in the cytoplasm indicates the abundance of hemoglobin. Note the reductions in the sizes of the cell and nucleus leading up to the formation of a reticulocyte.

After roughly four days of differentiation, the erythroblast, now called a *normoblast*, sheds its nucleus and becomes a **reticulocyte** (re-TIK-ū-lō-sīt), which contains 80 percent of the Hb of a mature RBC. Hb synthesis then continues for two to three more days. During this period, while the cell is synthesizing hemoglobin and other proteins, its cytoplasm still contains RNA, which can be seen under the microscope with certain stains. After two days in the red bone marrow, the reticulocyte enters the bloodstream. At this time, reticulocytes normally account for about 0.8 percent of the RBC population in the blood and can still be detected by staining. After 24 hours in circulation, the reticulocytes complete their maturation and become indistinguishable from other mature RBCs.

Regulation of Erythropoiesis

For erythropoiesis to proceed normally, the red bone marrow needs adequate supplies of amino acids, iron, and vitamins (including B_{12} , B_6 , and folic acid) for protein synthesis. We obtain **vitamin B**₁₂ from dairy products and meat. In order to absorb vitamin B_{12} , we need *intrinsic factor*, which is produced in the stomach. Without vitamin B_{12} from the diet, normal stem cell divisions cannot occur and *pernicious anemia* results. Thus, pernicious anemia is caused by a vitamin B_{12} deficiency, a problem with the production of intrinsic factor, or a problem with the absorption of vitamin B_{12} bound to intrinsic factor.

Erythropoiesis is stimulated directly by the peptide hormone erythropoietin (**'D p. 640**) and indirectly by several hormones, including thyroxine, androgens, and growth hormone. As noted earlier in **Spotlight Figure 19–1** on pp. 654–655, estrogens do not stimulate erythropoiesis. This fact accounts for the differences in hematocrit values between males and females.

Erythropoietin (EPO), also called **erythropoiesisstimulating hormone**, is a glycoprotein. It is formed by the kidneys and liver. EPO appears in the plasma when peripheral tissues, especially the kidneys, are exposed to low oxygen concentrations. A low oxygen level in tissues is called **hypoxia** (hī-POKS-ē-uh; *hypo-*, below + *oxy-*, presence of oxygen). Erythropoietin is released (1) during anemia; (2) when blood flow to the kidneys declines; (3) when the oxygen content of air in the lungs declines, due to disease or high altitude; and (4) when the respiratory surfaces of the lungs are damaged. Once in the bloodstream, EPO travels to the red bone marrow, where it stimulates stem cells and developing RBCs.

Erythropoietin has two major effects: (1) It stimulates cell division rates in erythroblasts and in the stem cells that produce erythroblasts, and (2) it speeds up the maturation of RBCs, mainly by accelerating Hb synthesis. Under maximum EPO stimulation, bone marrow can increase RBC formation tenfold, to about 30 million cells per second.

The ability to increase the rate of blood formation quickly and dramatically is important to a person recovering from a severe blood loss. But if EPO is administered to a healthy individual, as in the case of the cyclists mentioned in Chapter 18, the hematocrit may rise to 65 or more. **D p. 646** Such an increase can place an intolerable strain on the heart. Similar problems can occur after **blood doping**, a practice in which athletes elevate their hematocrits by reinfusing packed RBCs that were removed and stored at an earlier date. The goal is to improve oxygen delivery to muscles, thereby enhancing performance. The strategy can be dangerous, however, because it makes blood more viscous and increases the workload on the heart.

Blood tests provide information about the general health of an individual, usually with a minimum of trouble and expense. Several common blood tests focus on RBCs. These *RBC tests* assess the number, size, shape, and maturity of circulating RBCs, indicating the erythropoietic activities under way.

Table 19–1	RBC Tests and Related Terminology				
			Terms Associated with Abnormal Values		
Test		Determines	Elevated	Depressed	
Hematocrit (Hct)		Percentage of formed elements in whole blood Normal = $37-54\%$	Polycythemia (may reflect erythrocytosis or leukocytosis)	Anemia	
Reticulocyte count (Retic.)		Percentage of circulating reticulocytes Normal $= 0.8\%$	Reticulocytosis	Diminished erythropoiesis	
Hemoglobin cond	centration (Hb; Hgb)	Concentration of hemoglobin in blood Normal = $12-18 \text{ g/dL}$	Polycythemia	Anemia	
RBC count		Number of RBCs per μ L of whole blood Normal = 4.2–6.3 million cells/ μ L	Erythrocytosis/polycythemia	Anemia	
Mean corpuscula	r volume (MCV)	Average volume of one RBC Normal = 82–101 μ m ³ /cell (normocytic)	Macrocytic	Microcytic	
Mean corpuscula concentration (M	r hemoglobin CHC)	Average weight of Hb in one RBC Normal = 27–34 ug/RBC (normochromic)	Hyperchromic	Hypochromic	

The tests can also be useful in detecting problems, such as internal bleeding, that may not produce other obvious signs or symptoms. Table 19–1 lists examples of important blood tests and related terms.

CHECKPOINT

- 8. Describe hemoglobin.
- 9. How would the hematocrit change after an individual suffered a significant blood loss?
- 10. Dave develops a blockage in his renal arteries that restricts blood flow to the kidneys. What effect will this have on his hematocrit?
- 11. In what way would a disease that causes damage to the liver affect the level of bilirubin in the blood?

See the blue Answers tab at the back of the book.

19-4 The ABO blood types and Rh system are based on antigen–antibody responses

Learning Outcome Explain the importance of blood typing, and the basis for ABO and Rh incompatibilities.

Antigens are substances that can trigger a protective defense mechanism called an *immune response*. Most antigens are proteins, but some other types of organic molecules are antigens as well. Your plasma membranes contain **surface antigens**, substances that your immune system recognizes as "normal." In other words, your immune system ignores these substances rather than attacking them as "foreign."

Your **blood type** is determined by the presence or absence of specific surface antigens in RBC plasma membranes. The surface antigens involved are integral membrane glycoproteins or glycolipids whose characteristics are genetically determined. Red blood

cells have at least 50 kinds of surface antigens, but three surface antigens are of particular importance: **A**, **B**, and **Rh** (or **D**).

Based on RBC surface antigens, there are four blood types (Figure 19–6a): Type A blood has surface antigen A only, type B has surface antigen B only, type AB has both A and B, and type O has neither A nor B. Individuals with these blood types are not evenly distributed throughout the world. The average percentages for various populations in the United States are given in Table 19–2.

The term **Rh positive (Rh**⁺) indicates the presence of the Rh surface antigen, commonly called the *Rh factor*. The absence of this antigen is indicated as **Rh negative (Rh**⁻). When the complete blood type is recorded, the term *Rh* is usually omitted, and a positive or negative sign is used. For example, the data are reported as O negative (O⁻), A positive (A⁺), and so on. As in the distribution of A and B surface antigens, Rh type differs by ethnic group and by region (Table 19–2).

Your immune system ignores these surface antigenscalled agglutinogens (a-glū-TIN-ō-jenz)-on your own RBCs. However, your plasma contains antibodies, sometimes called agglutinins (a-GLU-ti-ninz), that will attack the antigens on "foreign" RBCs. When these antibodies attack, the foreign cells **agglutinate**, or clump together. This process is called **agglutination**. If you have type A blood, your plasma contains anti-B antibodies, which will attack type B surface antigens. If you have type B blood, your plasma contains anti-A antibodies. The RBCs of an individual with type O blood have neither A nor B surface antigens, and that person's plasma contains both anti-A and anti-B antibodies. A type AB individual has RBCs with both A and B surface antigens, and the plasma does not contain anti-A or anti-B antibodies. The presence of anti-A and/or anti-B antibodies is genetically determined. These antibodies are present throughout life, regardless of whether the individual has ever been exposed to foreign RBCs.

Figure 19–6 Blood Types and Cross-Reactions.

Туре А	Туре В	Туре АВ	Туре О	
Type A blood has RBCs with surface antigen A only.	Type B blood has RBCs with surface antigen B only.	Type AB blood has RBCs with both A and B surface antigens.	Type O blood has RBCs lacking both A and B surface antigens.	
Surface antigen A	Surface antigen B		0	
YLY	YLL		4444	
If you have type A blood, your plasma contains anti-B antibodies, which will attack type B surface antigens.	If you have type B blood, your plasma contains anti-A antibodies, which will attack type A surface antigens.	If you have type AB blood, your plasma has neither anti-A nor anti-B antibodies.	If you have type O blood, your plasma contains both anti-A and anti-B antibodies.	

a Blood type depends on the presence of surface antigens (agglutinogens) on RBC surfaces. The plasma contains antibodies (agglutinins) that will react with foreign surface antigens.

b In a cross-reaction, antibodies react with their target antigens causing agglutination and hemolysis of the affected RBCs.

Table 19–2	Differences in Blood Group Distribution					
		Percentage with Each Blood Type				
Population		0	А	В	AB	Rh ⁺
U.S. (AVERAGE)		46	40	10	4	85

NATIVE SOUTH AMERICAN		100	0	0	0	100
AUSTRALIAN ABORIGINE		44	56	0	0	100

In contrast, the plasma of an Rh-negative individual does not contain anti-Rh antibodies. These antibodies are present only if the individual has been **sensitized** by previous exposure to Rh⁺ RBCs. Such exposure can occur accidentally during a transfusion, but it can also accompany a seemingly normal pregnancy involving an Rh⁻ mother and an Rh⁺ fetus. (See **Spotlight Figure 19–8** on pp. 668–669.)

Cross-Reactions in Transfusions

When an antibody meets its specific surface antigen, the RBCs agglutinate and may also hemolyze. This is called a **cross-reaction (Figure 19–6b)**. For instance, an anti-A antibody that encounters A surface antigens will cause the RBCs bearing the A surface antigens to clump or even break up. Clumps and fragments of RBCs under attack form drifting masses that can plug small blood vessels in the kidneys, lungs, heart, or brain, damaging or destroying affected tissues. Such cross-reactions, or *transfusion reactions*, can be prevented by making sure that the blood types of the donor and the recipient are **compatible**—that is, that the donor's blood cells and the recipient's plasma will not cross-react.

In practice, the surface antigens on the donor's cells are more important in determining compatibility than are the antibodies in the donor's plasma. Why? Unless large volumes of whole blood or plasma are transferred, cross-reactions between the donor's plasma and the recipient's blood cells will not produce significant agglutination. This is because the donated plasma is diluted quickly through mixing with the larger plasma volume of the recipient. (One unit of whole blood, 500 mL, contains roughly 275 mL of plasma, only about 10 percent of normal plasma volume.) When the goal is to increase the blood's oxygen-carrying capacity rather than its plasma volume, packed RBCs, with a minimal amount of plasma, are often transfused. This practice minimizes the risk of a cross-reaction.

Testing for Transfusion Compatibility

Extra care must be taken to avoid potentially life-threatening cross-reactions between the donor's cells and the recipient's plasma. For this reason, a compatibility test is usually performed in advance. This process normally involves two steps: (1) a determination of blood type and (2) a cross-match test.

The standard test for blood type considers only the three surface antigens most likely to produce dangerous cross-reactions: A, B, and Rh (Figure 19–7). The test involves taking drops of blood and mixing them separately with solutions containing anti-A, anti-B, and anti-Rh (anti-D) antibodies. Any cross-reactions are then recorded. For example, if an individual's RBCs clump together when exposed to anti-A and to anti-B antibodies, the individual has type AB blood. If no reactions occur after exposure, that person must have type O blood.

The presence or absence of the Rh surface antigen is also noted, and the individual is classified as Rh positive or Rh **Figure 19–7 Blood Type Testing.** Test results for blood samples from four individuals. Drops are mixed with solutions containing antibodies to the surface antigens A, B, AB, and D (Rh). Clumping occurs when the sample contains the corresponding surface antigen(s). The individuals' blood types are shown at right.

negative on that basis. Type O^+ is the most common blood type. The RBCs of type O^+ individuals lack surface antigens A and B but have the Rh antigen.

Spotlight Figure 19–8 describes a serious condition known as hemolytic disease of the newborn (HDN). HDN involves Rh incompatibility between a pregnant mother and her developing fetus.

Standard blood-typing of both donor and recipient can be completed in a matter of minutes. However, in an emergency, there may not be time for preliminary testing. For example, a person with a severe gunshot wound may require 5 liters or more of blood before the damage can be repaired. Under these circumstances, type O blood (preferably O⁻) will be administered. Because the donated RBCs lack both A and B surface antigens, the recipient's blood can have anti-A antibodies, anti-B antibodies, or both and still not cross-react with the donor's blood. Because cross-reactions with type O blood are very unlikely, type O individuals are sometimes called universal donors. Type AB individuals were once called universal recipients, because they lack anti-A and anti-B antibodies that would attack donated RBCs, and so can safely receive blood of any type. However, now that blood supplies are usually adequate and compatibility testing is regularly done, the term has largely been dropped. If the recipient's blood type is known to be AB, type AB blood will be administered.

It is now possible to use enzymes to strip off the A or B surface antigens from RBCs and create type O blood in the laboratory. The procedure is expensive and time-consuming and has limited use in emergency treatment. Still, cross-reactions can occur, even to type O^- blood, because at least 48 other surface antigens are present. For this reason, whenever time and facilities permit, further testing is performed to ensure complete compatibility between donor blood and recipient blood. **Cross-match testing** involves exposing the donor's RBCs to a sample of the recipient's plasma under controlled conditions. This procedure reveals significant cross-reactions involving surface antigens other than A, B, or Rh. Another way to avoid compatibility problems is to replace lost blood with synthetic blood substitutes, which do not contain surface antigens that can trigger a cross-reaction.

Because blood groups are inherited, blood tests are also used as paternity tests and in crime detection. The blood collected cannot prove that a particular individual *is* a certain child's father or *is* guilty of a specific crime, but it can prove that the individual is *not* involved. It is impossible, for example, for an adult with type AB blood to be the parent of an infant with type O blood. Testing for additional surface antigens, other than the standard ABO groups, can increase the accuracy of the conclusions. When available, DNA identity testing, which has nearly 100 percent accuracy, has replaced blood type identity testing.

- CHECKPOINT

- 12. What is the function of surface antigens on RBCs?
- 13. Which blood type can be safely transfused into a person with type O blood?
- 14. Why can't a person with type A blood safely receive blood from a person with type B blood?

See the blue Answers tab at the back of the book.

19–5 ■ The various types of white blood cells contribute to the body's defenses

Learning Outcome Categorize white blood cell types based on their structures and functions, and discuss the factors that regulate the production of each type.

Unlike red blood cells, white blood cells (WBCs) have nuclei and other organelles, and they lack hemoglobin. White blood cells, or leukocytes, help defend the body against invasion by pathogens. They also remove toxins, wastes, and abnormal or damaged cells.

Several types of WBCs can be distinguished microscopically in a blood smear by using either of two standard stains: *Wright's stain* or *Giemsa stain*. Traditionally, WBCs have been divided into two groups based on their appearance after staining: (1) *granular leukocytes*, or *granulocytes* (with abundant stained granules)—the *neutrophils*, *eosinophils*, and *basophils*; and (2) *agranular leukocytes*, or *agranulocytes* (with few, if any, stained granules)—the *monocytes* and *lymphocytes*. This categorization is convenient but somewhat misleading. In reality, the granules in "granular leukocytes" are secretory vesicles and lysosomes, and the "agranular leukocytes" also contain vesicles and lysosomes, but they are just smaller and difficult to see with the light microscope.

A typical microliter of blood contains 5000 to 10,000 WBCs, compared with 4.2 to 6.3 million RBCs. Most of the WBCs in the body at any moment are in connective tissue proper or in organs of the lymphatic system. Circulating WBCs are only a small fraction of the total WBC population.

WBC Circulation and Movement

Unlike RBCs, WBCs circulate for only a short time in their life span. White blood cells migrate through the loose and dense connective tissues of the body. They use the bloodstream to travel from one organ to another and for rapid transportation to areas of infection or injury. As they travel along the miles of capillaries, WBCs can detect the chemical signs of damage to surrounding tissues. When these cells detect problems, they leave the bloodstream and enter the damaged area.

Circulating WBCs have four characteristics:

- 1. All Can Migrate Out of the Bloodstream. When WBCs in the bloodstream are activated, they contact and adhere to the vessel walls in a process called *margination*. After further interaction with endothelial cells, the activated WBCs squeeze between adjacent endothelial cells and enter the surrounding tissue. This process is called *emigration*, or *diapedesis* (*dia*, through + *pedesis*, a leaping).
- 2. All Are Capable of Amoeboid Movement. Amoeboid movement is a gliding motion made possible by the flow of cytoplasm into slender cellular processes extended in the direction of movement. (The movement is so named because it is similar to that of an *amoeba*, a type of protozoan.) The mechanism is not fully understood, but it involves the continuous rearrangement of bonds between actin filaments in the cytoskeleton. It also requires calcium ions and ATP. This mobility allows WBCs to move through the endothelial lining and into peripheral tissues.
- **3.** All Are Attracted to Specific Chemical Stimuli. This characteristic, called **positive chemotaxis** (kē-mō-TAK-sis), guides WBCs to invading pathogens, damaged tissues, and other active WBCs.
- 4. Neutrophils, Eosinophils, and Monocytes Are Capable of Phagocytosis. These cells may engulf pathogens, cell debris, or other materials. Neutrophils and eosinophils are sometimes called *microphages*, to distinguish them from the larger macrophages in connective tissues. Macrophages are monocytes that have moved out of the bloodstream and have become actively phagocytic. ⊃ p. 127

SPOTLIGHT

Figure 19-8 Hemolytic Disease of the Newborn

Hemolytic disease of the newborn is an RBC-related disorder caused by a cross-reaction between fetal and maternal blood types. Genes controlling the presence or absence of any surface antigen in the plasma membrane of a red blood cell are provided by both parents, so a child can have a blood type different from that of either parent. During pregnancy, when fetal and maternal vascular systems are closely intertwined, the mother's antibodies may cross the placenta, attacking and destroying fetal RBCs. The resulting condition, called hemolytic disease of the newborn (HDN), has many forms, some quite dangerous and others so mild as to remain undetected.

ST PREGNA

Problems seldom develop during a first pregnancy,

enter the maternal blood-

stream then, and thus the

not stimulated to produce anti-Rh antibodies.

The most common form of hemolytic disease of the newborn develops after an Rh⁻ woman has carried an Rh⁺ fetus.

Rh⁺ fetus Rh⁻

mother

2

Exposure to fetal red blood cell antigens generally occurs during delivery, when bleeding takes place at the placenta and uterus. Such mixing of fetal and maternal blood can stimulate the mother's immune system to produce anti-Rh antibodies, leading to sensitization.

3

About 20% of Rh⁻ mothers who carried Rh⁺ children become sensitized within six months of delivery. Because the anti-Rh antibodies are not produced in significant amounts until after delivery, a woman's first infant is not affected.

SECOND PREGNANCY

If a future pregnancy involves an Rh⁺ fetus, maternal anti-Rh antibodies produced after the first delivery cross the placenta and enter the fetal bloodstream. These antibodies destroy fetal RBCs, producing a dangerous anemia. The fetal demand for blood cells increases, and they leave the bone marrow and enter the bloodstream before completing their development. Because these immature RBCs are erythroblasts, HDN is also known as ervthroblastosis fetalis (e-rith-rō-blas-TŌ-sis fē-TAL-is). Without treatment, the fetus may die before delivery or shortly thereafter. A newborn with severe HDN is anemic, and the high concentration of circulating bilirubin produces jaundice. Because the maternal antibodies remain active in the newborn for one to two months after delivery, the infant's entire blood volume may require replacement to remove the maternal anti-Rh antibodies, as well as the damaged RBCs. Fortunately, the mother's anti-Rh antibody production can be prevented if such antibodies (available under the name RhoGAM) are administered to the mother in weeks 26–28 of pregnancy and during and after delivery. These antibodies destroy any fetal RBCs that cross the placenta before they can stimulate a maternal immune response. Because maternal sensitization does not occur, no anti-Rh antibodies are produced. In the United States, this relatively simple procedure has almost entirely eliminated HDN mortality caused by Rh incompatibilities.

Types of WBCs

Neutrophils, eosinophils, basophils, and monocytes are part of the body's *nonspecific defenses*. A variety of stimuli activate such defenses, which do not discriminate between one type of threat and another. Lymphocytes, in contrast, are responsible for *specific defenses*, which mount a counterattack against specific types of invading pathogens or foreign proteins. We discuss the interactions among WBCs and the relationships between specific and nonspecific defenses in Chapter 22.

Neutrophils

Fifty to 70 percent of the circulating WBCs are **neutrophils** (NOO-trō-filz). This name reflects the fact that the granules of these WBCs are chemically neutral and thus are difficult to stain with either acidic or basic (alkaline) dyes. A mature neutrophil has a very dense, segmented nucleus with two to five lobes resembling beads on a string (Figure 19–9a). This structure has given neutrophils another name: **polymorphonuclear** (pol-ē-mor-fō-NOO-klē-ar) **leukocytes** (*poly*, many + *morphe*, form), or *PMNs*. "Polymorphs," or "polys," as they are often called, are roughly 12 μ m in diameter. Their cytoplasm is packed with pale granules containing lysosomal enzymes and bactericidal (bacteria-killing) compounds.

Neutrophils are highly mobile. They are generally the first of the WBCs to arrive at the site of an injury. These very active cells specialize in attacking and digesting bacteria that have been "marked" with antibodies or with *complement proteins* plasma proteins involved in tissue defenses. (We discuss the complement system in Chapter 22.)

Upon encountering a bacterium, a neutrophil quickly engulfs it, and the metabolic rate of the neutrophil increases dramatically. Along with this *respiratory burst*, the neutrophil produces highly reactive, destructive chemical agents, including *hydrogen peroxide* (H₂O₂) and *superoxide anions* (O₂⁻), which can kill bacteria. Meanwhile, the vesicle containing the engulfed pathogen fuses with lysosomes that contain digestive enzymes and small peptides called **defensins**. This process is called **degranulation** because it reduces the number of granules in the cytoplasm. Defensins kill a variety of pathogens, including bacteria, fungi, and enveloped viruses, by combining to form large channels in their plasma membranes. The digestive enzymes then break down the bacterial remains.

While actively attacking bacteria, a neutrophil releases prostaglandins and leukotrienes. \bigcirc p. 613 The prostaglandins increase capillary permeability in the affected region, contributing to local inflammation and restricting the spread of injury and infection. Leukotrienes are hormones that attract other phagocytes and help coordinate the immune response.

Most neutrophils have a short life span. They survive in the bloodstream for only about 10 hours. When actively engulfing debris or pathogens, they may last 30 minutes or less. A neutrophil dies after engulfing one to two dozen bacteria, but its breakdown releases chemicals that attract other neutrophils to the site. A mixture of dead neutrophils, cellular debris, and other waste products form the *pus* associated with infected wounds.

T I P S & T R I C K S

Remember that *neu*trophils are the most *nu*merous of the white blood cells.

Eosinophils

Eosinophils (ē-ō-SIN-ō-filz) have granules that stain darkly with *eosin*, a red dye. The granules also stain with other acid dyes, so the name **acidophils** (a-SID-ō-filz) applies as well. Eosinophils generally represent 2–4 percent of the circulating WBCs. They are similar in size to neutrophils. However, the combination of deep red granules and a typically bilobed (two-lobed) nucleus makes eosinophils easy to identify (**Figure 19–9b**).

Eosinophils attack objects that are coated with antibodies. They will engulf antibody-marked bacteria, protozoa, or cellular debris, but their primary mode of attack is the exocytosis of toxic compounds, including nitric oxide and cytotoxic enzymes. This is particularly effective against multicellular parasites that are too big to engulf, such as flukes or parasitic roundworms. The number of circulating eosinophils increases dramatically during a parasitic infection.

Eosinophils increase in number during allergic reactions as well, because they are sensitive to circulating *allergens* (materials that trigger allergies). Eosinophils are also attracted to sites of injury, where they release enzymes that reduce inflammation produced by mast cells and neutrophils. This controls the spread of inflammation to adjacent tissues.

Basophils

Basophils (BĀ-sō-fil*z; baso-,* base + *phileo,* to love) have numerous granules that stain darkly with basic dyes. In a standard blood smear, the inclusions are deep purple or blue (Figure 19–9c). Measuring 8–10 μ m in diameter, basophils are smaller than neutrophils or eosinophils. They are also relatively rare, accounting for less than 1 percent of the circulating WBC population.

Basophils migrate to injury sites and cross the capillary endothelium to accumulate in the damaged tissues. There they discharge their granules into the interstitial fluids. The granules contain *histamine*, which dilates blood vessels, and *heparin*, a compound that prevents blood clotting. Stimulated basophils release these chemicals into the interstitial fluids to enhance the local inflammation initiated by mast cells. \bigcirc p. 127 Although mast cells release the same compounds in damaged connective tissues, mast cells and basophils are distinct populations with separate origins. Stimulated basophils also release other chemicals that attract eosinophils and other basophils to the area.

Monocytes

Monocytes (MON- \bar{o} -s \bar{s} ts) are spherical cells that may exceed 15 μ m in diameter, nearly twice the diameter of a typical RBC. When flattened in a blood smear, they look even larger, so monocytes are fairly easy to identify. The nucleus is large and tends to be oval or kidney bean–shaped rather than lobed (**Figure 19–9d**). Monocytes normally account for 2–8 percent of circulating WBCs.

An individual monocyte is transported in the bloodstream. It remains in circulation for only about 24 hours before entering peripheral tissues to become a tissue macrophage. Macrophages are aggressive phagocytes. They often attempt to engulf items as large as or larger than themselves. When active, they release chemicals that attract and stimulate neutrophils, monocytes, and other phagocytic cells. Active macrophages also secrete substances that draw fibroblasts into the region. The fibroblasts then begin producing scar tissue to wall off the injured area.

TIPS&TRICKS

A *mon*ocyte is the *mon*ster cell that engulfs debris and pathogens.

Lymphocytes

Typical **lymphocytes** (LIM-fō-sīts) are slightly larger than RBCs and lack abundant, deeply staining granules. In blood smears, lymphocytes typically have a large, round nucleus surrounded by a thin halo of cytoplasm (Figure 19–9e).

Lymphocytes account for 20–40 percent of the circulating WBC population. Lymphocytes continuously migrate from the bloodstream, through peripheral tissues, and back to the bloodstream. Circulating lymphocytes represent only a small fraction of all lymphocytes. At any moment, most of your body's lymphocytes are in other connective tissues and in organs of the lymphatic system.

The circulating blood contains three functional classes of lymphocytes. They cannot be distinguished with a light microscope:

- 1. **T cells** are responsible for *cell-mediated immunity*, a specific defense mechanism against invading foreign cells, and for the coordination of the immune response. T cells either enter peripheral tissues and attack foreign cells directly, or control the activities of other lymphocytes.
- 2. **B cells** are responsible for *humoral immunity*, a specific defense mechanism that involves the production of antibodies. These antibodies are distributed by blood, lymph, and interstitial fluid and are capable of attacking foreign antigens throughout the body. Activated B cells differentiate into **plasma cells**, which are specialized to synthesize and secrete antibodies. The T cells responsible for cellular immunity must migrate to their targets, but the antibodies produced by plasma cells in one location can destroy antigens almost anywhere in the body.
- 3. Natural killer (NK) cells carry out *immune surveillance* the detection and subsequent destruction of abnormal cells. NK cells, sometimes known as *large granular lymphocytes*, are important in preventing cancer.

TIPS&TRICKS

To remember the various white blood cell populations, think "Never let monkeys eat bananas" for neutrophils, lymphocytes, monocytes, eosinophils, and basophils.

The Differential Count and Changes in WBC Profiles

A variety of conditions, including infection, inflammation, and allergic reactions, cause characteristic changes in circulating populations of WBCs. By examining a stained blood smear, we can obtain a **differential count** of the WBC population. The values reported indicate the number of each type of cell in a sample of 100 WBCs. The normal range of abundance for each type of WBC is shown in Table 19–3.

The term **leukopenia** (loo-kō-PĒ-nē-uh; *penia*, poverty) indicates inadequate numbers of WBCs. **Leukocytosis** (loo-kōsi-TŌ-sis) refers to excessive numbers of WBCs. A modest leukocytosis is normal during an infection. Extreme leukocytosis (100,000/ μ L or more) generally indicates the presence of some form of **leukemia** (loo-KĒ-mē-uh), a cancer of the WBCs. The endings *-penia* and *-osis* can also indicate low or high numbers of specific types of WBCs. For example, *lymphopenia* means too few lymphocytes, and *lymphocytosis* means too many.

WBC Production

Stem cells that produce WBCs originate in the red bone marrow, with the divisions of hemocytoblasts (Figure 19–10). As we have noted, hemocytoblast divisions produce myeloid stem cells and lymphoid stem cells. Myeloid stem cells divide to create **progenitor cells**, which give rise to all the formed elements except lymphocytes. One type of progenitor cell produces

Table 19–3	Formed	med Elements of the Blood				
Cell		Abundance (average number per μ L)	Appearance in a Stained Blood Smear	Functions	Remarks	
RED BLOOD CELLS		5.2 million (range: 4.2–6.3 million)	Flattened, circular cell; no nucleus, mitochondria, or ribosomes; red	Transport oxygen from lungs to tissues and carbon dioxide from tissues to lungs	Remain in bloodstream; 120-day life expectancy; amino acids and iron recycled; produced in red bone marrow	
WHITE BLOOD CE	LLS	7000 (range: 5000–10,000)				
Neutrophils)	4150 (range: 1800–7300) Differential count: 50–70%	Round cell; nucleus lobed and may resemble a string of beads; cytoplasm contains large, pale inclusions	Phagocytic: Engulf pathogens or debris in tissues, release cytotoxic enzymes and chemicals	Move into tissues after several hours; may survive minutes to days, depending on tissue activity; produced in red bone marrow	
Eosinophils		165 (range: 0–700) Differential count: 2–4%	Round cell; nucleus generally in two lobes; cytoplasm contains large granules that generally stain bright red	Phagocytic: Engulf antibody- labeled materials, release cytotoxic enzymes, reduce inflammation; increase in allergic and parasitic situations	Move into tissues after several hours; survive minutes to days, depending on tissue activity; produced in red bone marrow	
Basophils		44 (range: 0–150) Differential count: <1%	Round cell; nucleus generally cannot be seen through dense, blue-stained granules in cytoplasm	Enter damaged tissues and release histamine and other chemicals that promote inflammation	Survival time unknown; assist mast cells of tissues in producing inflammation; produced in red bone marrow	
Monocytes		456 (range: 200–950) Differential count: 2–8%	Very large cell; kidney bean–shaped nucleus; abundant pale cytoplasm	Enter tissues to become macrophages; engulf pathogens or debris	Move into tissues after 1–2 days; survive for months or longer; produced primarily in red bone marrow	
Lymphocytes		2185 (range: 1500–4000) Differential count: 20–40%	Generally round cell, slightly larger than RBC; round nucleus; very little cytoplasm	Cells of lymphatic system, providing defense against specific pathogens or toxins	Survive for months to decades; circulate from blood to tissues and back; produced in red bone marrow and lymphatic tissues	
PLATELETS	R.	350,000 (range: 150,000–500,000)	Round to spindle-shaped cytoplasmic fragment; contain enzymes, proenzymes, actin, and myosin; no nucleus	Hemostasis: Clump together and stick to vessel wall (platelet phase); activate intrinsic pathway of coagulation phase	Remain in bloodstream or in vascular organs; remain intact for 7–12 days; produced by megakaryocytes in red bone marrow	

Figure 19–10 The Origins and Differentiation of Formed Elements. Hemocytoblast divisions give rise to myeloid stem cells or lymphoid stem cells. Lymphoid stem cells produce the various lymphocytes. Myeloid stem cells produce progenitor cells that divide to produce the other classes of formed elements. The targets of EPO and the four colony-stimulating factors (CSFs) are indicated.

daughter cells that mature into RBCs. A second type produces cells that manufacture platelets. A third type produces daughter cells that develop into neutrophils, eosinophils, basophils, and monocytes.

Granulocytes (basophils, eosinophils, and neutrophils) complete their development in the red bone marrow. These WBCs go through a series of maturational stages, proceeding from *blast cells* to *myelocytes* to *band cells* before becoming mature WBCs. For example, a cell differentiating into a neutrophil goes from a myeloblast to a *neutrophilic myelocyte* and then becomes a *neutrophilic band cell*. Some band cells enter the bloodstream before completing their maturation. Normally, 3–5 percent of all circulating WBCs are band cells.

Monocytes begin to differentiate in the red bone marrow. Then they enter the bloodstream and complete development when they become free macrophages in peripheral tissues.

The process of lymphocyte production is called **lympho-poiesis**. Some lymphocytes are derived from lymphoid stem cells that remain in red bone marrow. These lymphocytes differentiate into either B cells or natural killer cells.

Many of the lymphoid stem cells that produce lymphocytes migrate from the red bone marrow to peripheral **lymphatic tissues**, including the thymus, spleen, and lymph nodes. As a result, lymphocytes are produced in these organs as well as in the red bone marrow. Lymphoid stem cells migrating to the thymus mature into T cells. We discuss lymphocytes further in Chapter 22.

Regulation of WBC Production

Factors that regulate lymphocyte maturation are incompletely understood. Until adulthood, hormones produced by the thymus promote the differentiation and maintenance of T cell populations. The importance of the thymus in adults, especially with respect to aging, remains controversial. In adults, the production of B and T lymphocytes is regulated primarily by exposure to antigens (foreign proteins, cells, or toxins). When antigens appear, lymphocyte production escalates. We describe the control mechanisms in Chapter 22.

Several hormones, called **colony-stimulating factors (CSFs)**, are involved in regulating other WBC populations. Four CSFs have been identified. Each stimulates the formation of WBCs or both WBCs and RBCs. The designation for each factor indicates its target, as shown in Figure 19–10:

- 1. M-CSF stimulates the production of monocytes.
- 2. **G-CSF** stimulates the production of granulocytes (neutrophils, eosinophils, and basophils).
- **3. GM-CSF** stimulates the production of both granulocytes and monocytes.
- 4. **Multi-CSF** accelerates the production of granulocytes, monocytes, platelets, and RBCs.

Chemical communication between lymphocytes and other WBCs helps to coordinate the immune response. For example, active macrophages release chemicals that make lymphocytes more sensitive to antigens and also accelerate the development of specific immunity. In turn, active lymphocytes release multi-CSF and GM-CSF, reinforcing nonspecific defenses.

Immune system hormones are currently under intensive study because of their potential clinical importance. The molecular structures of many of the stimulating factors have been identified, and several can be produced by genetic engineering. The U.S. Food and Drug Administration approved the administration of synthesized forms of EPO, G-CSF, and GM-CSF to stimulate the production of specific blood cell lines. For instance, a genetically engineered form of G-CSF, sold under the name *filgrastim* (*Neupogen*), is used to stimulate the production of neutrophils in patients undergoing cancer chemotherapy.

CHECKPOINT

- 15. Identify the five types of white blood cells.
- **16**. Which type of white blood cell would you find in the greatest numbers in an infected cut?
- 17. Which type of cell would you find in elevated numbers in a person who is producing large amounts of circulating antibodies to combat a virus?
- 18. How do basophils respond to an injury?

See the blue Answers tab at the back of the book.

19-6 Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process

Learning Outcome Describe the structure, function, and production of platelets.

In a blood smear, platelets appear as spindle-shaped cell fragments. They average about 4 μ m in diameter and are roughly 1 μ m thick. Platelets in nonmammalian vertebrates are nucleated cells called **thrombocytes** (THROM-bō-sīts; *thrombos*, clot). In humans they are cell fragments rather than individual cells, so the term *platelet* is preferred when referring to our blood. Platelets play a major role in a vascular *clotting system* that also includes plasma proteins and the cells and tissues of the blood vessels.

Platelets are continuously replaced. Each platelet circulates for 9–12 days before being removed by phagocytes, mainly in the spleen. Each microliter of circulating blood contains 150,000–500,000 platelets. The average concentration is 350,000/ μ L. About one-third of the platelets in the body at any moment are in the spleen and other vascular organs, rather than in the bloodstream. These reserves are mobilized during a circulatory crisis, such as severe bleeding.

An abnormally low platelet count $(80,000/\mu$ L or less) is known as **thrombocytopenia** (throm-bō-sī-tō-PĒ-nē-uh). Thrombocytopenia generally indicates excessive platelet destruction or inadequate platelet production. Signs include bleeding along the digestive tract, within the skin, and occasionally inside the CNS.

In **thrombocytosis** (throm- $b\bar{o}-s\bar{s}$ -TO-sis), platelet counts can exceed 1,000,000/ μ L. Thrombocytosis usually results from accelerated platelet formation in response to infection, inflammation, or cancer.

Platelet Functions

The functions of platelets include:

- *Releasing Chemicals Important to the Clotting Process.* By releasing enzymes and other factors at the appropriate times, platelets help initiate and control the clotting process.
- Forming a Temporary Patch in the Walls of Damaged Blood Vessels. Platelets clump together at an injury site, forming a platelet plug, which can slow blood loss while clotting takes place.
- *Reducing the Size of a Break in the Vessel Wall.* Platelets contain filaments of actin and myosin. After a blood clot has formed, platelet filaments contract to shrink the clot and reduce the size of the break in the vessel wall.

Platelet Production

Platelet production, or **thrombocytopoiesis**, takes place in the red bone marrow. Normal red bone marrow contains **mega-karyocytes** (meg-a-KAR- \bar{e} - \bar{o} -s \bar{s} ts; *mega-*, big + *karyon*, nucleus + -*cyte*, cell), enormous cells (up to 160 μ m in diameter) with large nuclei (Figure 19–10). During their development and growth, megakaryocytes manufacture structural proteins, enzymes, and membranes. They then begin shedding cytoplasm in small membrane-enclosed packets. These packets are the platelets that enter the bloodstream. A mature megakaryocyte gradually loses all of its cytoplasm, producing about 4000 platelets before phagocytes engulf its nucleus for breakdown and recycling.

Three substances influence the rate of megakaryocyte activity and platelet formation. They are: (1) *thrombopoietin* (TPO), or *thrombocyte-stimulating factor*, a peptide hormone produced in the kidneys (and perhaps other sites) that accelerates platelet formation and stimulates the production of megakaryocytes; (2) *interleukin-6* (IL-6), a hormone that stimulates platelet formation; and (3) multi-CSF, which stimulates platelet production by promoting the formation and growth of megakaryocytes.

CHECKPOINT

- 19. Define thrombocytopoiesis.
- **20.** Explain the difference between platelets and thrombocytes.
- 21. List the three primary functions of platelets.
- See the blue Answers tab at the back of the book.

19-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation

Learning Outcome Discuss the mechanisms that control blood loss after an injury, and describe the reaction sequences responsible for blood clotting.

The process of **hemostasis** (*haima*, blood + *stasis*, halt), the stopping of bleeding, halts the loss of blood through the walls of damaged vessels. At the same time, it establishes a framework for tissue repairs. Hemostasis has three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*. The boundaries of these phases are somewhat arbitrary. In reality, hemostasis is a complex *cascade*, or chain reaction, in which many things happen at once, and all of them interact to some degree.

The Vascular Phase

Cutting the wall of a blood vessel triggers a contraction in the smooth muscle fibers of the vessel wall (Figure 19–11 1). This local contraction of the vessel is a **vascular spasm**, which decreases the diameter of the vessel at the site of injury. Such a constriction can slow or even stop the loss of blood through the wall of a small vessel. The vascular spasm lasts about 30 minutes, a period called the **vascular phase** of hemostasis.

During the vascular phase, changes take place in the endothelium of the vessel at the injury site:

- The Endothelial Cells Contract and Expose the Underlying Basement Membrane to the Bloodstream.
- The Endothelial Cells Begin Releasing Chemical Factors and Local Hormones. We will discuss several of these factors, including ADP, tissue factor, and prostacyclin, in later sections. Endothelial cells also release peptide hormones called endothelins. These local hormones (1) stimulate smooth muscle contraction and promote vascular spasms, and (2) stimulate the division of endothelial cells, smooth muscle cells, and fibroblasts to accelerate the repair process.
- The Endothelial Plasma Membranes Become "Sticky." A tear in the wall of a small artery or vein may be partially sealed off by the attachment of endothelial cells on either side of the break. In small capillaries, endothelial cells on opposite sides of the vessel may stick together and prevent

Figure 19–11 The Vascular, Platelet, and Coagulation Phases of Hemostasis and Clot Retraction.

Vascular Phase **Platelet Phase** The vascular phase of hemostasis lasts for The platelet phase of hemostasis begins with the about 30 minutes after the injury occurs. The attachment of platelets to sticky endothelial surfaces, to endothelial cells contract and release the basement membrane, to exposed collagen fibers, and to each other. As they become activated, platelets endothelins, which stimulate smooth muscle contraction and endothelial division. The release a variety of chemicals that promote aggregation, endothelial cells become "sticky" and adhere vascular spasm, clotting, and vessel repair. to platelets and each other. Knife blade Release of chemicals (ADP. PDGF. Ca²⁺. platelet factors) Plasma in vessel lumen Platelet aggregation Endothelium Platelet Blood vessel injury adhesion to () damaged vesse **Basement** membrane Vascular spasm /essel wall Contracted smooth Platelet plug muscle cells may form Interstitial Cut edge of fluid vessel wall

blood flow along the damaged vessel. The stickiness is also important because it helps platelets to attach as the platelet phase gets under way.

The Platelet Phase

The attachment of platelets to sticky endothelial surfaces, to the basement membrane, and to exposed collagen fibers marks the start of the **platelet phase** of hemostasis (Figure 19–11 2). The attachment of platelets to exposed surfaces is called **platelet adhesion**. As more and more platelets arrive, they begin sticking to one another as well. This process, called **platelet aggregation**, forms a **platelet plug** that may close the break in the vessel wall if the damage is not severe or the vessel is relatively small. Platelet aggregation begins within 15 seconds after an injury occurs.

As they arrive at the injury site, the platelets become activated. The first sign of activation is that they become more spherical and develop cytoplasmic processes that extend toward nearby platelets. At this time, the platelets begin releasing a wide variety of compounds. These compounds include (1) *adenosine diphosphate (ADP)*, which stimulates platelet aggregation and secretion; (2) *thromboxane* A_2 and *serotonin*, which stimulate vascular spasms; (3) *clotting factors*, proteins that play a role in blood clotting; (4) *platelet-derived growth factor (PDGF)*, a peptide that promotes vessel repair; and (5) calcium ions, which are required for platelet aggregation and in several steps in the clotting process.

The platelet phase proceeds quickly, as ADP, thromboxane, and calcium ions released from each arriving platelet stimulate further aggregation. This positive feedback loop ultimately produces a platelet plug that will be reinforced as clotting occurs.

19

However, platelet aggregation must be controlled and restricted to the injury site.

Several key factors limit the growth of the platelet plug: (1) **prostacyclin**, a prostaglandin that inhibits platelet aggregation and is released by endothelial cells; (2) inhibitory compounds released by WBCs entering the area; (3) circulating plasma enzymes that break down ADP near the plug; (4) compounds that, when abundant, inhibit plug formation (for example, serotonin, which at high concentrations blocks the action of ADP); and (5) the development of a blood clot, which reinforces the platelet plug, but isolates it from the general circulation.

The Coagulation Phase

The vascular and platelet phases begin within a few seconds after the injury. The **coagulation** (cō-ag-ū-LĀ-shun) **phase**,

or blood clotting, does not start until 30 seconds or more after the vessel has been damaged. (Figure 19–11 (3) shows the sequence of steps involved in the formation and structure of a blood clot.

Clotting Factors

Normal blood clotting depends on the presence of **clotting factors**, or **procoagulants**, in the plasma. Important clotting factors include Ca^{2+} and 11 different proteins (Table 19–4).

Many of the proteins are **proenzymes**, or inactive enzymes. When converted to active enzymes, these proteins direct essential reactions in the clotting response. During the coagulation phase, enzymes and proenzymes interact successively. The activation of one proenzyme commonly creates an enzyme that activates a second proenzyme, and so on in a cascade.

Table 19	9–4	Clotting Fact	ors			
Factor	Struct	ure	Name	Source	Concentration in Plasma (µg/mL)	Pathway
I	Plasm	a protein	Fibrinogen	Liver	2500-3500	Common
П	Plasm	a protein	Prothrombin	Liver, requires vitamin K	100	Common
III	Glycoprotein		Tissue factor (TF)	Damaged tissue, activated platelets	0	Extrinsic
IV	lon		Calcium ions (Ca ²⁺)	Bone, diet, platelets	100	Entire process
V	Protei	n	Proaccelerin	Liver, platelets	10	Extrinsic and intrinsic
VI	(No longer used)					
VII	Plasma protein		Proconvertin	Liver, requires vitamin K	0.5	Extrinsic
VIII	Plasma protein		Antihemophilic factor (AHF)	Liver, lung endothelial cells	15	Intrinsic
IX	Plasma protein		Plasma thromboplastin component (PTC), Christmas factor	Liver, requires vitamin K	3	Intrinsic
Х	Plasma protein		Stuart–Prower factor	Liver, requires vitamin K	10	Extrinsic and intrinsic
XI	Plasma protein		Plasma thromboplastin antecedent (PTA)	Liver	<5	Intrinsic
XII	Plasm	a protein	Hageman factor	Liver	<5	Intrinsic; also activates plasmin
XIII	Plasm	a protein	Fibrin-stabilizing factor (FSF)	Liver, platelets	20	Stabilizes fibrin, slows fibrinolysis

Figure 19–11 3 shows the cascades involved in the *extrinsic, intrinsic,* and *common pathways*. The extrinsic pathway begins outside the bloodstream, in the vessel wall. The intrinsic pathway begins inside the bloodstream, with the activation of a circulating proenzyme. These two pathways converge at the common pathway.

The Extrinsic Pathway

The **extrinsic pathway** begins when damaged endothelial cells or peripheral tissues release **Factor III**, also known as **tissue factor (TF)**. The greater the damage, the more tissue factor is released and the faster clotting takes place. Tissue factor then combines with Ca²⁺ and another clotting factor (Factor VII) to form an enzyme complex capable of activating Factor X, the first step in the common pathway.

The Intrinsic Pathway

The **intrinsic pathway** begins with the activation of proenzymes (usually Factor XII) exposed to collagen fibers at the injury site (or to a glass surface of a slide or collection tube). This pathway proceeds with the assistance of **PF-3**, a platelet factor released by aggregating platelets. Platelets also release a variety of other factors that accelerate the reactions of the intrinsic pathway. After a series of linked reactions, activated Factors VIII and IX combine to form an enzyme complex capable of activating Factor X.

The Common Pathway

The **common pathway** begins when enzyme complexes from either pathway activate Factor X. Activated Factor X activates a complex called **prothrombin activator**. Prothrombin activator converts the proenzyme prothrombin into the enzyme **thrombin** (THROM-bin). Thrombin then completes the clotting process by converting fibrinogen, a soluble plasma protein, to insoluble strands of fibrin.

Interactions among the Pathways

When a blood vessel is damaged, both the extrinsic and the intrinsic pathways respond. The extrinsic pathway is shorter and faster than the intrinsic pathway, and it is usually the first to initiate clotting. In essence, the extrinsic pathway produces a small amount of thrombin very quickly. This quick patch is reinforced by the intrinsic pathway, which later produces more thrombin.

The time required to complete clot formation varies with the site and the nature of the injury. In tests of the clotting system, blood held in fine glass tubes normally clots in 8–18 minutes (the *coagulation time*). A small puncture wound typically stops bleeding in 1–4 minutes (the *bleeding time*).

Feedback Control of Blood Clotting

The activity of the common pathway stimulates both the intrinsic and extrinsic pathways. This positive feedback loop accelerates the clotting process, and speed can be very important in reducing blood loss after a severe injury. Thrombin generated in the common pathway stimulates blood clotting by (1) stimulating the formation of tissue factor (TF) and (2) stimulating the release of PF-3 by platelets (Figure 19–11 3).

How is clotting controlled or stopped? Blood clotting is restricted by substances that either deactivate or remove clotting factors and other stimulatory agents from the blood. Examples include the following:

- Normal plasma contains several anticoagulants enzymes that inhibit clotting. One, antithrombin-III, inhibits several clotting factors, including thrombin.
- **Heparin**, a compound released by basophils and mast cells, is a cofactor that accelerates the activation of anti-thrombin-III. Heparin is also used clinically to impede or prevent clotting.
- **Thrombomodulin** is released by endothelial cells. This protein binds to thrombin and converts it to an enzyme that activates protein C. **Protein C** is a plasma protein that inactivates several clotting factors and stimulates the formation of *plasmin*, an enzyme that gradually breaks down fibrin strands.
- Prostacyclin released during the platelet phase inhibits platelet aggregation and opposes the stimulatory action of thrombin, ADP, and other factors.
- Other plasma proteins with anticoagulant properties include *alpha-2-macroglobulin*, which inhibits thrombin, and *C*₁ *inactivator*, which inhibits several clotting factors involved in the intrinsic pathway.

The clotting process involves a complex chain of events, and disorders that affect any individual clotting factor can disrupt the entire process. For this reason, managing many clinical conditions involves controlling or manipulating the clotting response. Aspirin, for example, is a common drug that interferes with blood clotting and prolongs bleeding time. It acts by inhibiting platelets from producing prostaglandins and thromboxane A_2 , which stimulates new platelet activation and aggregation.

Calcium Ions, Vitamin K, and Blood Clotting

Calcium ions and **vitamin K** affect almost every aspect of the clotting process. All three pathways (intrinsic, extrinsic, and common) require Ca^{2+} , so any disorder that lowers plasma Ca^{2+} concentrations will impair blood clotting.

Adequate amounts of vitamin K must be present for the liver to synthesize four of the clotting factors, including prothrombin. Vitamin K is a fat-soluble vitamin, present in green vegetables, grain, and organ meats, that is absorbed with dietary lipids. We obtain roughly half of our daily requirement from the diet. Bacteria in the large intestine manufacture the other half. A vitamin K deficiency may arise from a diet inadequate in fats or in vitamin K, or a disorder that affects fat digestion and absorption (such as problems with bile production), or prolonged use of antibiotics that kill normal intestinal bacteria. Vitamin K deficiency will cause the eventual breakdown of the common pathway due to a lack of clotting factors. Ultimately, the deficiency can deactivate the entire clotting system.

Clot Retraction

Clot retraction, or *syneresis* (si-NER-e-sis; "a drawing together"), pulls the torn edges of the vessel closer together. This process reduces residual bleeding and stabilizes the injury site. The process also reduces the size of the damaged area, making it easier for fibroblasts, smooth muscle cells, and endothelial cells to complete repairs (Figure 19–11 **4**).

Fibrinolysis

As the repairs proceed, the clot gradually dissolves in a process called **fibrinolysis** (fi-bri-NOL-i-sis). The process begins when two enzymes activate the proenzyme **plasminogen**. These enzymes are thrombin, produced by the common pathway, and **tissue plasminogen activator** (t-PA), released by damaged tissues at the site of injury. The activation of plasminogen produces the enzyme **plasmin** (PLAZ-min), which begins digesting the fibrin strands and eroding the clot.

To perform its vital functions, blood must be kept in motion. On average, an RBC completes two circuits around the cardiovascular system each minute. Blood begins to circulate in the third week of embryonic development and continues throughout life. If the blood supply is cut off, dependent tissues may die in a matter of minutes. In Chapter 20, we examine the structure and function of the heart—the pump that maintains this vital blood flow.

CHECKPOINT

- 22. A sample of red bone marrow has unusually few megakaryocytes. What body process would you expect to be impaired as a result?
- **23**. Vitamin K is fat soluble, and some dietary fat is required for its absorption. How could a diet of fruit juice and water have an effect on blood clotting?
- 24. Unless chemically treated, whole blood will coagulate in a test tube. This clotting process begins when Factor XII becomes activated. Which clotting pathway is involved in this process?

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **arterial stick:** The taking of a blood sample from an artery rather than a vein. It is usually more painful due to arteries being deeper, having more nerves, and having thicker walls.
- **blood bank:** Place where blood is collected, typed, separated into components, stored, and prepared for transfusion to recipients.
- **bone marrow biopsy:** The removal of a small piece of bone marrow for either laboratory analysis, to diagnose and stage some forms of cancer, to diagnose other blood disorders, to find the source of unexplained fever, or to diagnose fibrosis of bone marrow or myeloma, a tumor composed of cells normally found in the bone marrow.
- **disseminated intravascular coagulation:** A serious disorder in which the proteins that control blood clotting become abnormally active, causing small blood clots to form, which can prevent blood from reaching vital organs.
- **dyscrasia:** An abnormal condition, especially of the blood.
- **ecchymosis:** Skin discoloration caused by the escape of blood into tissues from ruptured blood vessels.
- **embolism:** A condition in which a drifting blood clot (an embolus) becomes stuck in a blood vessel, blocking circulation to the area downstream.
- **hematology:** The science concerned with the medical study of blood and blood-producing organs.
- **hemochromatosis:** A rare metabolic disorder wherein the skin has a bronze coloration; accompanied by cirrhosis and severe diabetes mellitus; caused by the deposit of the protein-iron complex hemosiderin in tissues.
- **hemophilia:** Inherited disorders characterized by the inadequate production of clotting factors.
- **hemopoietic growth factor:** A group of proteins that cause blood cells to grow and mature.

- **hemosiderosis:** An increase in tissue iron stores without any associated damage.
- hypervolemic: Having an excessive blood volume.
- **hypovolemic:** Having a low blood volume.
- **iron overload:** Pathology in which iron accumulates in the tissues; characterized by bronzed skin, enlarged liver, diabetes mellitus, and abnormalities of the pancreas.
- **myeloproliferative disorder:** A group of slow-growing blood cancers, including chronic myelogenous leukemia, characterized by large numbers of abnormal RBCs, WBCs, or platelets growing and spreading in the bone marrow and the peripheral blood.
- normovolemic: Referring to a normal blood volume.
- **phlebotomist:** Medical technician who extracts blood by venipuncture for treatment or for laboratory analysis.
- **plaque:** An abnormal accumulation of large quantities of lipids within a blood vessel wall.
- **plasmapheresis:** A procedure consisting of the removal of blood from a person, separating the blood cells from plasma, and returning these blood cells to the person's circulation, diluted with fresh plasma or a substitute. Used to treat autoimmune disorders.
- **Schilling test:** The test to determine whether the body absorbs vitamin B₁₂ normally.
- **septicemia:** Systemic toxic illness due to bacterial invasion of the bloodstream from a local infection. Signs and symptoms include chills, fever, and exhaustion. The disorder is treated with massive doses of antibiotics. Also known as blood poisoning.
- **thrombolytic:** An agent that causes the breakup of a thrombus (clot).
- **thrombus:** A blood clot attached to the luminal (inner) surface of a blood vessel.

An Introduction to Blood and the Cardiovascular System p. 653

1. The **cardiovascular system** enables the rapid transport of nutrients, respiratory gases, waste products, and cells within the body.

- 19-1 Blood has several important functions and unique physical characteristics p. 653
- 2. **Blood** is a specialized fluid connective tissue. Its functions include (1) transporting dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulating the pH and ion composition of interstitial fluids; (3) restricting fluid losses at injury sites; (4) defending the body against toxins and pathogens; and (5) regulating body temperature by absorbing and redistributing heat.
- Blood contains plasma and formed elements—red blood cells (RBCs), white blood cells (WBCs), and platelets. The plasma and formed elements make up whole blood, which can be fractionated for analytical or clinical purposes. (Spotlight Figure 19–1)
- 4. **Hemopoiesis**, or **hematopoiesis**, is the process of blood cell formation. Myeloid and lymphoid stem cells divide to form all types of blood cells. (*Spotlight Figure 19-1*)
- 5. Whole blood from any region of the body has roughly the same temperature, viscosity, and pH.

19-2 Plasma, the fluid portion of blood, contains significant quantities of plasma proteins p. 656

- 6. Plasma accounts for 55 percent of the volume of blood; roughly 92 percent of plasma is water. (*Spotlight Figure 19–1*)
- **7.** Plasma differs from interstitial fluid in terms of its oxygen and carbon dioxide levels and the concentrations and types of dissolved proteins.
- 8. The three major types of plasma proteins are *albumins*, *globulins*, and *fibrinogen*.
- 9. Albumins make up about 60 percent of plasma proteins. Globulins constitute roughly 35 percent of plasma proteins; they include antibodies (immunoglobulins), which attack foreign proteins and pathogens, and transport globulins, which bind ions, hormones, and other compounds. Fibrinogen molecules are converted to fibrin in the clotting process. Serum is plasma without fibrinogen.
- **10.** The liver synthesizes and releases more than 90 percent of the plasma proteins.

19-3 Red blood cells, formed by erythropoiesis, contain hemoglobin that can be recycled p. 657

- 11. Red blood cells make up slightly less than half of the blood volume and 99.9 percent of the formed elements. The hematocrit value indicates the percentage of formed elements within whole blood. It is commonly reported as the *volume of packed red cells (VPRC)* or the *packed cell volume (PCV)*. (Spotlight Figure 19–1; Table 19–1)
- **12.** Each RBC is a biconcave disc, providing a large surface-tovolume ratio. This shape allows RBCs to stack, bend, and flex. (*Figure 19–2*)
- **13.** Red blood cells lack most organelles, including mitochondria and nuclei, retaining only the cytoskeleton. They typically degenerate after about 120 days in the bloodstream.
- Molecules of hemoglobin (Hb; Hgb) make up more than 95 percent of the proteins in RBCs. Hemoglobin is a globular protein formed from two pairs of polypeptide subunits. Each subunit contains a single molecule of heme, which also has an iron atom that can reversibly bind an oxygen molecule. Phagocytes recycle damaged or dead RBCs. (*Figures 19–3, 19–4*)
- **15.** Damaged RBCs are continuously replaced at a rate of approximately 3 million new RBCs entering the bloodstream per second. They are replaced before they **hemolyze**.
- 16. The components of hemoglobin are individually recycled. The heme is stripped of its iron and converted to **biliverdin**, which is converted to **bilirubin**. If bile ducts are blocked, bilirubin builds up in skin and eyes, resulting in **jaundice**. (*Figure 19–4*)
- **17.** Iron is recycled by being stored in phagocytic cells or transported through the bloodstream, bound to **transferrin**.
- 18. Erythropoiesis, the formation of red blood cells, occurs only in *red bone marrow* (myeloid tissue). The process speeds up under stimulation by erythropoietin (EPO or erythropoiesisstimulating hormone). Stages in RBC development include erythroblasts and reticulocytes. (*Figure 19–5*)

19-4 The ABO blood types and Rh system are based on antigen-antibody responses p. 664

Blood type is determined by the presence or absence of specific surface antigens (*agglutinogens*) in the RBC plasma membranes: antigens A, B, and Rh (D). Antibodies (*agglutinis*) in the plasma will react with RBCs that have different

surface antigens. When an antibody meets its specific surface antigen, a **cross-reaction** results. (*Figures 19–6 to Spotlight Figure 19–8; Table 19–2*)

19-5 The various types of white blood cells contribute to the body's defenses **p.** 667

- **20.** White blood cells, or **leukocytes**, have nuclei and other organelles. They defend the body against pathogens and remove toxins, wastes, and abnormal or damaged cells.
- **21.** White blood cells are capable of *margination*, amoeboid movement, and **positive chemotaxis**. Some WBCs are also capable of *phagocytosis*.
- **22.** *Granular leukocytes* (*granulocytes*) are subdivided into **neutrophils**, **eosinophils**, and **basophils**. Fifty to 70 percent of circulating WBCs are neutrophils, which are highly mobile phagocytes. The much less common eosinophils are phagocytes attracted to foreign compounds that have reacted with circulating antibodies. The fairly rare basophils migrate to damaged tissues and release *histamine* and *heparin*, aiding the inflammatory response. (*Figure 19–9*)
- 23. Agranular leukocytes (agranulocytes) include **monocytes** and **lymphocytes**. Monocytes that migrate into peripheral tissues become tissue macrophages. Lymphocytes, the primary cells of the lymphatic system, include **T cells** (which enter peripheral tissues and attack foreign cells directly, or affect the activities of other lymphocytes); **B cells** (which produce antibodies); and **natural killer (NK) cells** (which destroy abnormal cells). (*Figure 19–9; Table 19–3*)
- 24. A **differential count** of the WBC population can indicate a variety of disorders. **Leukemia** is indicated by extreme **leukocytosis**—that is, excessive numbers of WBCs. (*Table 19–3*)
- 25. Granulocytes and monocytes are produced by myeloid stem cells in the red bone marrow that divide to create **progenitor cells**. Lymphoid stem cells also originate in the red bone marrow, but many migrate to peripheral **lymphatic tissues**. (*Figure 19–10*)
- **26.** Factors that regulate lymphocyte maturation are not completely understood. Several **colony-stimulating factors** (CSFs) are involved in regulating other WBC populations and in coordinating RBC and WBC production. (*Figure 19–10*)

19-6 Platelets, disc-shaped structures formed from megakaryocytes, function in the clotting process p. 674

- 27. Platelets are spindle-shaped cell fragments. They circulate for 9–12 days before being removed by phagocytes. (*Figure 19–11*)
- 28. The functions of platelets include (1) transporting and releasing chemicals important to the clotting process, (2) forming a temporary patch in the walls of damaged blood vessels, and (3) reducing the size of a break in the vessel wall.
- **29.** During **thrombocytopoiesis**, **megakaryocytes** in the red bone marrow release packets of cytoplasm (platelets) into the circulating blood. The rate of platelet formation is stimulated by thrombopoietin or thrombocyte-stimulating factor, interleukin-6, and multi-CSF.

19-7 Hemostasis involves vascular spasm, platelet plug formation, and blood coagulation p. 675

- **30. Hemostasis** halts the loss of blood through the walls of damaged vessels. It consists of three phases: the *vascular phase*, the *platelet phase*, and the *coagulation phase*.
- **31.** The **vascular phase** is a period of local blood vessel constriction, or **vascular spasm**, at the injury site. (*Figure 19–11*)

- **32.** The **platelet phase** follows as platelets are activated, aggregate at the site, and adhere to the damaged surfaces. (*Figure 19–11*)
- **33.** The **coagulation phase** occurs as factors released by platelets and endothelial cells interact with **clotting factors** (through either the **extrinsic pathway**, the **intrinsic pathway**, or the **common pathway**) to form a **blood clot**. In this reaction

sequence, soluble fibrinogen is converted to large, insoluble fibers of fibrin. (*Figure 19–11; Table 19–4*)

- **34.** During **clot retraction**, platelets contract and pull the torn edges of the damaged vessel closer together. (*Figure 19–11*)
- **35.** During **fibrinolysis**, the clot gradually dissolves through the action of **plasmin**, the activated form of circulating **plasminogen**.

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the five types of white blood cells in the following photographs,

19

- The formed elements of the blood include (a) plasma, fibrin, and serum, (b) albumins, globulins, and fibrinogen, (c) WBCs, RBCs, and platelets, (d) a, b, and c.
- Blood temperature is approximately _____, and blood pH averages _____. (a) 36°C, 7.0, (b) 39°C, 7.8, (c) 38°C, 7.4, (d) 37°C, 7.0.
- Plasma contributes approximately ______ percent of the volume of whole blood, and water accounts for ______ percent of the plasma volume. (a) 55, 92, (b) 25, 55, (c) 92, 55, (d) 35, 72.
- 5. Serum is (a) the same as blood plasma, (b) plasma minus the formed elements, (c) plasma minus the proteins, (d) plasma minus fibrinogen, (e) plasma minus the electrolytes.
- 6. A hemoglobin molecule is composed of (a) two protein chains,
 (b) three protein chains, (c) four protein chains and nothing else,
 (d) four protein chains and four heme groups, (e) four heme groups but no protein.
- **7.** The following is a list of the phases involved in the process of hemostasis.
 - (1) coagulation
 - (2) fibrinolysis
 - (3) vascular spasm
 - (4) retraction
 - (5) platelet phase
 - The correct sequence of these phases is
 - (a) 5, 1, 4, 2, 3, (b) 3, 5, 1, 4, 2, (c) 2, 3, 5, 1, 4, (d) 3, 5, 4, 1, 2, (e) 4, 3, 5, 2, 1.

See the blue Answers tab at the back of the book.

- 8. Stem cells responsible for lymphopoiesis are located in (a) the thymus and spleen, (b) the lymph nodes, (c) the red bone marrow, (d) all of these structures.
- ______ and ______ affect almost every aspect of the clotting process. (a) Calcium, vitamin K, (b) Calcium, vitamin B₁₂, (c) Sodium, vitamin K, (d) Sodium, vitamin B₁₂.
- 10. What five major functions are performed by blood?
- **11.** Name the three major types of plasma proteins and identify their functions,
- **12.** Which type of antibodies does plasma contain for each of the following blood types? **(a)** type A, **(b)** type B, **(c)** type AB, **(d)** type O.
- **13.** What four characteristics of WBCs are important to their response to tissue invasion or injury?
- 14. Which kinds of WBCs contribute to the body's nonspecific defenses?
- 15. Name the three types of lymphocytes and identify their functions,
- **16.** What is the difference between prothrombin and thrombin?
- 17. What four conditions cause the release of erythropoietin?
- **18.** What contribution from the intrinsic and the extrinsic pathways is necessary for the common pathway to begin?

LEVEL 2 Reviewing Concepts

- 19. Dehydration would (a) cause an increase in the hematocrit, (b) cause a decrease in the hematocrit, (c) have no effect on the hematocrit, (d) cause an increase in plasma volume.
- 20. Erythropoietin directly stimulates RBC formation by (a) increasing rates of mitotic divisions in erythroblasts, (b) speeding up the maturation of red blood cells, (c) accelerating the rate of hemoglobin synthesis, (d) a, b, and c.
- 21. The waste product bilirubin is formed from (a) transferrin,(b) globin, (c) heme, (d) hemosiderin, (e) ferritin.
- 22. A difference between the A, B, and O blood types and the Rh factor is
 (a) Rh agglutinogens are not found on the surface of red blood cells,
 (b) Rh agglutinogens do not produce a cross-reaction, (c) individuals who are Rh⁻ do not carry agglutinins to Rh factor unless they have been previously sensitized, (d) Rh agglutinogens are found free in the plasma, (e) Rh agglutinogens are found bound to plasma proteins.
- **23.** How do red blood cells differ from white blood cells in both form and function?
- 24. How do elements of blood defend against toxins and pathogens in the body?
- **25.** What is the role of blood in the stabilization and maintenance of body temperature?
- 26. Relate the structure of hemoglobin to its function,
- **27.** Why is aspirin sometimes prescribed for the prevention of vascular problems?

LEVEL 3 Critical Thinking and Clinical Applications

- **28.** A test for prothrombin time is used to identify deficiencies in the extrinsic clotting pathway; prothrombin time is prolonged if any of the factors are deficient. A test for activated partial thromboplastin time is used in a similar fashion to detect deficiencies in the intrinsic clotting pathway. Which factor would be deficient if a person had a prolonged prothrombin time but a normal partial thromboplastin time?
- **29.** In the disease mononucleosis ("mono"), the spleen enlarges because of increased numbers of phagocytes and other cells. Common signs and symptoms of this disease include pale complexion, a tired feeling, and a lack of energy sometimes to the point of not being able to get out of bed. What might cause these signs and symptoms?
- **30.** Almost half of our vitamin K is synthesized by bacteria that inhabit the large intestine. Based on this information, how could taking a broad-spectrum antibiotic for a long time cause frequent nosebleeds?
- **31.** After Randy was diagnosed with stomach cancer, nearly all of his stomach had to be removed. Postoperative treatment included regular injections of vitamin B₁₂. Why was this vitamin prescribed, and why were injections specified?

CLINICAL CASE

A Mysterious Blood Disorder

Jasmine's hematologist takes a thorough medical history. Jasmine has no known family history or

close relatives because she was adopted from an orphanage as a young girl. Her health was completely normal until six months ago. On physical examination, she appears pale, tired, and has a rapid heartbeat. Her bruises are clearly visible.

The hematologist performs a bone marrow aspirate and biopsy by inserting a large bore needle into the red bone marrow of Jasmine's posterior iliac crest and extracting cells. The specimen shows that there are not enough blood-making cells in Jasmine's bone marrow. Normally 30 percent of the red bone marrow is cellular and is involved in making all the blood cell precursors. But Jasmine's red bone marrow shows very little hemopoiesis and virtually no hemocytoblasts, myeloid stem cells, or lymphoid stem cells. The hemopoietic marrow was replaced

Wrap-Up

by adipose tissue. No wonder she has so few red cells, white cells, and platelets in her blood. None of these cells are being made.

The hematologist diag-

noses Jasmine with aplastic anemia. This serious red bone marrow failure often develops for no apparent reason (idiopathic). Without any known blood relatives, Jasmine appeals to the National Marrow Donor Program to find a compatible, unrelated donor for a bone marrow transplant, which is a type of stem cell transplant.

- 1. Why does Jasmine bleed and bruise so easily?
- 2. Why is Jasmine short of breath climbing stairs?

See the blue Answers tab at the back of the book.

20 The Heart

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **20-1** Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.
- **20-2** Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram.
- **20-3** Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.
- **20-4** Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

SPOTLIGHTS

- Heart Disease and Heart Attacks pp. 698–699
- Cardiac Arrhythmias p. 704

CLINICAL CASE

• A Needle to the Chest p. 685

Clinical Note

 Abnormal Conditions Affecting Cardiac Output p. 708

CLINICAL CASE

A Needle to the Chest

It has been a slow night in the emergency department. Dr. Jim is reading an emergency medicine journal and nodding off. He perks up when he hears the speakerphone crackle.

"We have a male, mid-40s, driver of a vehicle involved in a head-on collision with a truck," reports an EMT. "He was unconscious at the scene, but is now semi-alert, complaining of severe chest pain. His respirations are 30 and shallow. His blood pressure is 80/58. Pulse 130. Carotid pulses are present, but barely palpable. He has massive jugular venous distension (the veins in his neck are backed up with blood). The seat belt was broken and he has a steering wheel contusion on his anterior chest."

Dr. Jim instructs the EMTs to take the victim directly into Trauma Room 1. The patient is loaded supine on the trauma cart and Dr. Jim quickly introduces himself to the barely conscious man. A chest x-ray shows a fractured sternum and several fractured ribs, but the heart shadow (outline on the x-ray) appears normal. The heart

sounds are distant and muffled through a stethoscope. After a rapid bedside ultrasound, Dr. Jim puts on sterile gloves, does a skin prep of the patient's anterior chest, and sticks a large bore needle with a 100-mL syringe attached into the man's sub-xiphoid space, directing the needle toward his left shoulder. The syringe fills with dark blood twice. What is Dr. Jim doing? To find out, turn to the Clinical Case Wrap-Up on p. 722.

An Introduction to the Cardiovascular System

In this chapter we consider the structure and function of the heart. This extraordinary organ beats approximately 100,000 times each day.

Blood flows through a network of blood vessels that extend between the heart and peripheral tissues. Those blood vessels make up a **pulmonary circuit**, which carries blood to and from the gas exchange surfaces of the lungs, and a **systemic circuit**, which transports blood to and from the rest of the body (Figure 20–1). Each circuit begins and ends at the heart, and blood travels through these circuits in sequence. Thus, blood returning to the heart from the systemic circuit must complete the pulmonary circuit before re-entering the systemic circuit.

Arteries, or *efferent vessels*, carry blood away from the heart, and **veins**, or *afferent vessels*, return blood to the heart. Microscopic thin-walled vessels called **capillaries** interconnect the smallest arteries and the smallest veins. Capillaries are called **exchange vessels**, because their thin walls permit the exchange of nutrients, dissolved gases, and wastes between the blood and surrounding tissues.

Each day the heart pumps about 8000 liters of blood enough to fill forty 55-gallon drums, or 8800 quart-sized milk cartons. Try transferring a gallon of water by using a squeeze pump, and you'll appreciate just how hard the heart has to work to keep you alive. Despite its impressive workload, the heart is a small organ, about the size of a clenched fist.

The heart has four muscular chambers, two associated with each circuit. The **right atrium** (Ā-trē-um; entry chamber; plural, *atria*) receives blood from the systemic circuit and passes it to the **right ventricle** (VEN-tri-kl; little belly), which then pumps blood into the pulmonary circuit. The **left atrium**

Figure 20–1 An Overview of the Cardiovascular System.

Driven by the pumping of the heart, blood flows through the pulmonary and systemic circuits in sequence. Each circuit begins and ends at the heart and contains arteries, capillaries, and veins.

collects blood from the pulmonary circuit and empties it into the **left ventricle**, which pumps blood into the systemic circuit. When the heart beats, first the atria contract, and then the ventricles contract. The two ventricles contract at the same

685

time and eject equal volumes of blood into the pulmonary and systemic circuits.

20-1 ■ The heart is a four-chambered organ, supplied by the coronary circulation, that pumps oxygen-poor blood to the lungs and oxygen-rich blood to the rest of the body

Learning Outcome Describe the anatomy of the heart, including vascular supply and pericardium structure, and trace the flow of blood through the heart, identifying the major blood vessels, chambers, and heart valves.

The heart is located near the anterior chest wall, directly posterior to the sternum (Figure 20-2a). The great veins and arteries are connected to the superior end of the heart at its base. The base sits posterior to the sternum at the level of the third costal cartilage, centered about 1.2 cm (0.5 in.) to the left side. The inferior, pointed tip of the heart is the **apex** (A-peks). A typical adult heart measures approximately 12.5 cm (5 in.) from the base to the apex, which reaches the fifth intercostal space approximately 7.5 cm (3 in.) to the left of the midline. A midsagittal section through the trunk does not divide the heart into two equal halves. Note that (1) the center of the base lies slightly to the left of the midline, (2) a line drawn between the center of the base and the apex points further to the left, and (3) the entire heart is rotated to the left around this line, so that the right atrium and right ventricle dominate an anterior view of the heart.

The heart sits in the anterior portion of the mediastinum. The **mediastinum** is the region between the two pleural cavities. It also contains the *great vessels* (the largest veins and arteries in the body), thymus, esophagus, and trachea. Figure 20–2b is a sectional, superior view that shows the position of the heart relative to other structures in the mediastinum.

The Pericardium

The **pericardial** (per-i-KAR-dē-al) **sac**, or *fibrous pericardium*, surrounds the heart. The pericardial sac consists of a dense network of collagen fibers. It stabilizes the position of the heart and associated vessels within the mediastinum.

The lining of the pericardial cavity is called the **pericardium**. To visualize the relationship between the heart and the pericardial cavity, imagine pushing your fist toward the center of a large, partially inflated balloon (Figure 20–2c). The balloon represents the pericardium, and your fist is the heart. Your wrist, where the balloon folds back on itself, corresponds to the **base** of the heart, where the great vessels are attached. The air space inside the balloon corresponds to the pericardial cavity. The pericardium is lined by a delicate serous membrane that can be subdivided into two portions. The **visceral pericardium**, or *epicardium*, covers and adheres closely to the outer surface of the heart. The **parietal pericardium** lines the inner surface of the tough pericardial sac surrounding the heart (Figure 20–2c).

The potential space between the parietal and visceral surfaces is the pericardial cavity. It normally contains 15–50 mL of **pericardial fluid**, secreted by the pericardial membranes. This fluid acts as a lubricant, reducing friction between the opposing surfaces as the heart beats. Pathogens can infect the pericardium, producing inflammation and the condition **pericarditis**. The inflamed pericardial surfaces rub against one another, making a distinctive scratching sound that can be heard through a stethoscope. The pericardial inflammation also commonly results in increased production of pericardial fluid. Fluid then collects in the pericardial cavity, restricting the movement of the heart. This condition, called **cardiac tamponade** (tam-po-NĀD; *tampon*, plug), can also result from traumatic injuries (such as stab wounds) that produce bleeding into the pericardial cavity.

Superficial Anatomy of the Heart

You can easily identify the position of the heart within the rib cage and the four chambers of the heart in a superficial view (Figure 20–3a,b). The two atria have relatively thin muscular walls and are highly expandable. When not filled with blood, the outer portion of each atrium deflates and becomes a lumpy, wrinkled flap. This expandable extension of an atrium is called an *atrial appendage*, or an **auricle** (AW-ri-kl; *auris*, ear), because it reminded early anatomists of the external ear (Figure 20–3b). The **coronary sulcus**, a deep groove, marks the border between the atria and the ventricles. The **anterior interventricular sul-cus** and the **posterior interventricular sulcus** are shallower depressions that mark the boundary between the left and right ventricles (Figure 20–3b,c).

Substantial amounts of fat generally lie in the coronary and interventricular sulci. In fresh or preserved hearts, this fat must be stripped away to expose the underlying grooves. These sulci also contain the arteries and veins that carry blood to and from the cardiac muscle.

The Heart Wall

A section through the wall of the heart reveals three distinct layers: an outer epicardium, a middle myocardium, and an inner endocardium. Figure 20–4a illustrates these three layers:

1. The **epicardium** is the visceral pericardium that covers the outer surface of the heart. This serous membrane consists of an exposed mesothelium and an underlying layer of loose areolar connective tissue that is attached to the myocardium.

b A superior view of the organs in the mediastinum; portions of the lungs have been removed to reveal blood vessels and airways. The heart is located in the anterior part of the mediastinum, immediately posterior to the sternum.

c The relationship between the heart and the pericardial cavity; compare with the fist-and-balloon example.

c Anterior surface of the heart, cadaver dissection.

2. The **myocardium**, or muscular wall of the heart, forms the atria and ventricles. This layer contains cardiac muscle tissue, blood vessels, and nerves. The myocardium consists of concentric layers of cardiac muscle tissue. The atrial myocardium contains muscle bundles that wrap around the atria and form figure eights that encircle the great vessels (Figure 20–4b). Superficial ventricular muscles wrap

around both ventricles, and deeper muscle layers spiral around and between the ventricles toward the apex in a figure-eight pattern.

red; coronary veins are shown in blue.

3. The **endocardium** covers the inner surfaces of the heart, including those of the heart valves. This simple squamous epithelium is continuous with the endothelium of the attached great vessels.

Figure 20–4 The Heart Wall.

Cardiac Muscle Tissue

As noted in Chapter 10, **cardiac muscle cells** are interconnected by **intercalated discs** (Figure 20–5). At an intercalated disc, the interlocking membranes of adjacent cells are held together by desmosomes and linked by gap junctions (Figure 20–5b). Intercalated discs transfer the force of contraction from cell to cell and propagate action potentials. Table 20–1 provides a quick review of the structural and functional differences between cardiac muscle cells and skeletal muscle fibers. Histological characteristics that distinguish cardiac muscle cells from skeletal muscle fibers include (1) small size; (2) a single, centrally located nucleus; (3) branching interconnections between cells; and (4) the presence of intercalated discs.

TIPS&TRICKS

The term *intercalated* means "inserted between other elements." So, intercalated discs appear to have been inserted between cardiac muscle cells. Next let's examine the major landmarks and structures visible on the interior surface of the heart. In a sectional view, you can see that the right atrium communicates with the right ventricle, and the left atrium with the left ventricle (Figure 20–6a,c). The atria are separated by the **interatrial septum** (*septum*, wall), and the ventricles are separated by the much thicker **interventricular septum**. Each septum is a muscular partition. **Atrioventricular (AV) valves** are folds of fibrous tissue that extend into the openings between the atria and ventricles. These valves permit blood to flow only in one direction: from the atria to the ventricles.

The Right Atrium

The right atrium receives blood from the systemic circuit through the two great veins: the **superior vena cava** (VĒ-na KĀ-vuh; *venae cavae*, plural) and the **inferior vena cava**. The superior vena cava opens into the posterior and superior portion of the right atrium. It delivers blood to the right atrium from the head, neck, upper limbs, and chest. The inferior vena cava opens into the posterior and inferior portion of the right atrium. It carries blood to the right atrium from the rest of the trunk, the viscera, and the lower limbs. The *cardiac veins* draining the myocardium return blood to the **coronary sinus**, a

large, thin-walled vein that opens into the right atrium inferior to the connection with the superior vena cava.

The opening of the coronary sinus lies near the posterior edge of the interatrial septum. From the fifth week of embryonic development until birth, an oval opening called the **foramen ovale** penetrates the interatrial septum and connects the two atria of the fetal heart. Before birth, the foramen ovale permits blood to flow from the right atrium to the left atrium while the lungs are developing. At birth, the foramen ovale closes, and the opening is permanently sealed off within three months of delivery. (If the foramen ovale does not close, serious cardiovascular problems may result. We consider these in Chapter 21.) A small, shallow depression called the **fossa ovalis** remains at this site in the adult heart (**Figure 20–6a**). ATLAS: Embryology Summary 15: The Development of the Heart

The posterior walls of the right atrium and the interatrial septum have smooth surfaces. In contrast, the anterior atrial wall and the inner surface of the auricle contain prominent muscular ridges called the **pectinate muscles** (*pectin*, comb), or *musculi pectinati* (Figure 20–6a).

The Right Ventricle

Blood travels from the right atrium into the right ventricle through a broad opening bordered by three fibrous flaps. These flaps, called **cusps**, are part of the **right atrioventricular (AV) valve**, also known as the **tricuspid** (trī-KUS-pid; *tri*, three) **valve**. The free edge of each cusp is attached to connective tissue fibers called the **chordae tendineae** (KOR-dē TEN-di-nē-ē; tendinous cords). The fibers originate at the **papillary** (PAP-iler-ē) **muscles**, conical muscular projections that arise from the inner surface of the right ventricle (**Figure 20–6a,b,c**). The right AV valve closes when the right ventricle contracts, preventing the backflow of blood into the right atrium. Without the chordae tendineae to anchor their free edges, the cusps would be like swinging doors that permit blood flow in both directions.

The internal surface of the ventricle also contains a series of muscular ridges: the **trabeculae carneae** (tra-BEK- \bar{u} -le KARne- \bar{e} ; *carneus*, fleshy). The *moderator band* is a muscular ridge that extends horizontally from the inferior portion of the interventricular septum and connects to the anterior papillary muscle. This ridge contains part of the *conducting system*, an internal network that coordinates the contractions of cardiac muscle cells. The moderator band delivers the stimulus for contraction to the papillary muscles. As a result, they begin tensing the chordae tendineae before the rest of the ventricle contracts.

TIPS&TRICKS

The saying "To tug on your heartstrings" may help you remember the functions of the papillary muscles and the chordae tendineae: Contractions of the papillary muscles pull on the chordae tendineae, which "tug" on your heart's valves. The superior end of the right ventricle tapers to the **conus arteriosus**, a cone-shaped pouch that ends at the **pulmonary valve**, or *pulmonary semilunar valve*. The pulmonary valve consists of three semilunar (half-moon-shaped) cusps of thick connective tissue. Blood flowing from the right ventricle passes through this valve into the **pulmonary trunk**, the start of the pulmonary circuit. The cusps prevent backflow as the right ventricle relaxes. Once in the pulmonary trunk, blood flows into the **left pulmonary arteries** and the **right pulmonary arteries**. These vessels branch repeatedly within the lungs before supplying the capillaries, where gas exchange occurs.

The Left Atrium

From the respiratory capillaries, blood collects into small veins that ultimately unite to form the four pulmonary veins. The posterior wall of the left atrium receives blood from two **left** and two **right pulmonary veins**. Like the right atrium, the left atrium has an auricle. A valve, the **left atrioventricular (AV) valve**, or **bicuspid** (bī-KUS-pid) **valve**, guards the entrance to the left ventricle (**Figure 20–6a,c**). As the name *bicuspid* implies, the left AV valve contains two cusps, not three. Clinicians often call this valve the **mitral** (MĪ-tral; *mitre*, a bishop's hat) **valve**. The left AV valve permits blood to flow from the left atrium into the left ventricle, but it prevents backflow when the left ventricle contracts.

TIPS&TRICKS

To remember the locations of the tricuspid and bicuspid (mitral) valves, think **"try** to be **right**" for the *tri*cuspid, and associate the *I* in mitra*I* with the *I* in *I*eft.

The Left Ventricle

Even though the two ventricles hold and pump equal amounts of blood, the left ventricle is much larger than the right ventricle. What's the reason? It has thicker walls. These thick, muscular walls enable the left ventricle to push blood through the large systemic circuit. In contrast, the right ventricle needs to pump blood, at lower pressure, only about 15 cm (6 in.) to and from the lungs.

The internal organization of the left ventricle resembles that of the right ventricle, but it has no moderator band (Figure 20–6a). The trabeculae carneae are prominent. A pair of large papillary muscles tenses the chordae tendineae that anchor the cusps of the AV valve and prevent blood from flowing back into the left atrium.

Blood leaves the left ventricle through the **aortic valve**, or *aortic semilunar valve*, and goes into the **ascending aorta**. The arrangement of cusps in the aortic valve is the same as that in the pulmonary valve. Once the blood has been pumped out of the heart and into the systemic circuit, the aortic valve prevents

backflow into the left ventricle. From the ascending aorta, blood flows through the **aortic arch** and into the **descending aorta** (Figure 20–6a). The pulmonary trunk is attached to the aortic arch by the *ligamentum arteriosum*, a fibrous band left over from an important fetal blood vessel that once linked the pulmonary and systemic circuits.

Structural Differences between the Left and Right Ventricles

The function of the atria is to collect blood that is returning to the heart and to convey it to the ventricles. The demands on the right and left atria are similar, and the two chambers look almost identical. The demands on the right and left ventricles, however, are very different, and the two have significant structural differences.

Anatomical differences between the left and right ventricles are easiest to see in a three-dimensional view (Figure 20–7a). The lungs are close to the heart, and the pulmonary blood vessels are relatively short and wide. For these reasons, the right ventricle normally does not need to work very hard to push blood through the pulmonary circuit. Accordingly, the muscular wall of the right ventricle is relatively thin. In sectional view, it resembles a pouch attached to the massive wall of the left ventricle. When the right ventricle contracts, it acts like a bellows, squeezing the blood against the thick wall of the left ventricle. This action moves blood very efficiently with minimal effort, but it develops relatively low pressures.

A comparable pumping arrangement would not work well for the left ventricle. Four to six times as much pressure must be exerted to push through the systemic circuit as through the pulmonary circuit. The left ventricle has an extremely thick muscular wall and is round in cross section (Figure 20–7a). When this ventricle contracts, it shortens and narrows. In other words, (1) the distance between the base and apex decreases, and (2) the diameter of the ventricular chamber decreases. The effect is similar to simultaneously squeezing and rolling up the end of a toothpaste tube. The pressure generated is more than enough to open the aortic valve and eject blood into the ascending aorta.

As the powerful left ventricle contracts, it bulges into the right ventricular cavity (Figure 20–7b). This action makes the right ventricle more efficient. Individuals with severe damage to the right ventricle may survive, because the contraction of the left ventricle helps push blood into the pulmonary circuit. We return to this topic in Chapter 21, where we consider the integrated functioning of the cardiovascular system.

The Heart Valves

As we have seen, the heart has two pairs of one-way valves that prevent the backflow of blood as the chambers contract. Let's look at the structure and function of these heart valves. The Atrioventricular Valves. The atrioventricular (AV) valves prevent the backflow of blood from the ventricles to the atria when the ventricles are contracting. The chordae tendineae and papillary muscles play important roles in the normal function of the AV valves. When the ventricles are relaxed, the chordae tendineae are loose, and the AV valves offer no resistance as blood flows from the atria into the ventricles (Figure 20–8a). When the ventricles contract, blood moving back toward the atria swings the cusps together, closing the valves (Figure 20–8b). At the same time, the contraction of the papillary muscles tenses the chordae tendineae, stopping the cusps before they swing into the atria. If the chordae tendineae were cut or the papillary muscles were damaged, backflow, called **regurgitation**, of blood into the atria would occur each time the ventricles contracted.

Figure 20–7 Structural Differences between the Left and Right Ventricles. ATLAS: Plate 45d

20

The Semilunar Valves. The pulmonary and aortic valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles, respectively. Unlike the AV valves, the semilunar valves do not need muscular braces, because the arterial walls do not contract and the relative positions of the cusps are stable. When the semilunar valves close, the three symmetrical cusps support one another like the legs of a tripod (Figure 20–8a).

Adjacent to each cusp of the aortic valve are saclike expansions of the base of the ascending aorta. These sacs, called **aortic sinuses**, prevent the individual cusps from sticking to the wall of the aorta when the valve opens (Figure 20–8b). The *right* and *left coronary arteries*, which deliver blood to the myocardium, originate at the right and left aortic sinuses. (The posterior aortic sinus does not give rise to any blood vessel.)

Serious valve problems can interfere with the working of the heart. If valve function deteriorates to the point at which the heart cannot maintain adequate circulatory flow, symptoms of **valvular heart disease (VHD)** appear. Congenital malformations may be responsible, but in many cases the condition develops after **carditis**, an inflammation of the heart, occurs. One important cause of carditis is **rheumatic** (rū-MAT-ik) **fever**, an inflammatory autoimmune response to an infection by streptococcal bacteria. It most often occurs in children.

Connective Tissues and the Cardiac Skeleton

The connective tissues of the heart include large numbers of collagen and elastic fibers. Each cardiac muscle cell is wrapped in a strong, but elastic, sheath. Adjacent cells are tied together by fibrous cross-links, or "struts." These fibers are, in turn, interwoven into sheets that separate the superficial and deep muscle layers. The connective tissue fibers (1) provide physical support for the cardiac muscle fibers, blood vessels, and nerves of the myocardium; (2) help distribute the forces of contraction; (3) add strength and prevent overexpansion of the heart; and (4) provide elasticity that helps return the heart to its original size and shape after a contraction.

The **cardiac skeleton** (sometimes called the *fibrous skeleton*) of the heart consists of four dense bands of tough elastic tissue that encircle the heart valves and the bases of the pulmonary trunk and aorta (Figure 20–8). These bands stabilize the positions of the heart valves and ventricular muscle cells. They also electrically insulate the ventricular cells from the atrial cells.

The Blood Supply to the Heart

The heart works continuously, so cardiac muscle cells need reliable supplies of oxygen and nutrients. A great volume of blood flows through the chambers of the heart, but the myocardium has its own, separate blood supply. The **coronary** **circulation** supplies blood to the muscle tissue of the heart. During maximum exertion, the heart's demand for oxygen rises considerably. The blood flow to the myocardium may then increase to nine times that of resting levels. The coronary circulation includes an extensive network of coronary blood vessels (Figure 20–9).

The Coronary Arteries

The left and right **coronary arteries** originate at the base of the ascending aorta, at the aortic sinuses (Figure 20–9a). Blood pressure here is the highest in the systemic circuit. Each time the left ventricle contracts, it forces blood into the aorta. The arrival of this blood at high pressures stretches the elastic walls of the aorta. When the left ventricle relaxes, blood no longer flows into the aorta, pressure declines, and the walls of the aorta recoil. This recoil, called *elastic rebound*, pushes blood both forward, into the systemic circuit, and backward, through the left and right aortic sinuses and then into the respective coronary arteries. In this way, the combination of elevated blood pressure and elastic rebound ensures a continuous flow of blood to meet the demands of active cardiac muscle tissue. Yet myocardial blood flow is not steady. It peaks while the heart muscle is relaxed, and almost ceases while it contracts.

The **right coronary artery** follows the coronary sulcus around the heart. It supplies blood to (1) the right atrium, (2) portions of both ventricles, and (3) portions of the conducting system of the heart, including the *sinoatrial (SA) node* and the *atrioventricular (AV) node*. The cells of these nodes are essential to establishing the normal heart rate. We focus on them in a later section.

Inferior to the right atrium, the right coronary artery generally gives rise to one or more **marginal arteries**, which extend across the surface of the right ventricle (Figure 20–9a,b). The right coronary artery then continues across the posterior surface of the heart. It supplies the **posterior interventricular artery**, or *posterior descending artery*, which runs toward the apex within the posterior interventricular sulcus (Figure 20–9b,c). The posterior interventricular artery supplies blood to the interventricular septum and adjacent portions of the ventricles.

The **left coronary artery** supplies blood to the left ventricle, left atrium, and interventricular septum. As it reaches the anterior surface of the heart, it gives rise to a circumflex branch and an anterior interventricular branch. The **circumflex artery** curves to the left around the coronary sulcus. It eventually meets and fuses with small branches of the right coronary artery (**Figure 20–9a–c**). The much larger **anterior interventricular artery**, or *left anterior descending artery* (*LAD*), swings around the pulmonary trunk and runs along the surface within the anterior interventricular sulcus (**Figure 20–9a**).

The anterior interventricular artery supplies small tributaries continuous with those of the posterior interventricular artery. Such interconnections between arteries are called **arterial anastomoses** (a-nas-tō-MŌ-sēz; *anastomosis*, outlet). Because the arteries are interconnected in this way, the blood supply to the cardiac muscle remains relatively constant despite pressure fluctuations in the left and right coronary arteries as the heart beats.

a Coronary vessels supplying

and draining the anterior surface of the heart.

The Cardiac Veins

Small

cardiac vein

Marginal

arterv

The various cardiac veins are shown in Figure 20–9. The great cardiac vein begins on the anterior surface of the ventricles, along the interventricular sulcus. This vein drains blood from the region supplied by the anterior interventricular artery, a branch of the left coronary artery. The great cardiac vein reaches the level of the atria and then curves around the left side of the heart within the coronary sulcus. The vein empties into the coronary sinus, which lies in the posterior portion of the coronary sulcus. The coronary sinus opens into the right atrium near the base of the inferior vena cava.

Other cardiac veins empty into the great cardiac vein or the coronary sinus. These veins include (1) the **posterior cardiac vein**, draining the area served by the circumflex artery; (2) the **middle cardiac vein**, draining the area supplied by the posterior interventricular artery; and (3) the **small cardiac vein**, which receives blood from the posterior surfaces of the right atrium and ventricle. The **anterior cardiac**

 A posterior view of the heart; the vessels have been injected with colored latex (liquid rubber).

veins, which drain the anterior surface of the right ventricle, empty directly into the right atrium.

Coronary artery disease is characterized by interrupted blood flow to the myocardium. **Spotlight Figure 20–10** describes this condition, along with myocardial infarction.

CHECKPOINT

- 1. Damage to the semilunar valve of the right ventricle would affect blood flow into which vessel?
- 2. What prevents the AV valves from swinging into the atria?
- 3. Why is the left ventricle more muscular than the right ventricle?

See the blue Answers tab at the back of the book.

20-2 The conducting system distributes electrical impulses through the heart, and an electrocardiogram records the associated electrical events

Learning Outcome Explain the events of an action potential in cardiac muscle, indicate the importance of calcium ions to the contractile process, describe the conducting system of the heart, and identify the electrical events associated with a normal electrocardiogram.

Next we look at several aspects of the contraction of the heart. We begin with an overview of how the heart works—cardiac physiology. Then we examine the structure and function of the conducting system, the electrical events as recorded in an electrocardiogram, and the functioning of contractile cells.

Cardiac Physiology

In a single cardiac contraction, or heartbeat, the entire heart contracts in series—first the atria and then the ventricles. Two types of cardiac muscle cells are involved in a normal heartbeat. (1) Specialized muscle cells of the *conducting system* control and coordinate the heartbeat, and (2) *contractile cells* produce the powerful contractions that propel blood.

Each heartbeat begins with an action potential generated at a pacemaker called the *SA node*, which is part of the conducting system. The conducting system then propagates and distributes this electrical impulse to stimulate contractile cells to push blood in the right direction at the proper time. A procedure known as *electrocardiography* can monitor the electrical events of the conducting system from the surface of the body. The printed record of the result is called an *electrocardiogram* (*ECG* or *EKG*).

The arrival of an electrical impulse at a cardiac muscle cell's plasma membrane produces an action potential that is comparable to an action potential in a skeletal muscle fiber. As in a skeletal muscle fiber, this action potential triggers the contraction of the cardiac muscle cell. Thanks to the coordination provided by the conducting system, the atria contract first, driving blood into the ventricles through the AV valves, and the ventricles contract next, driving blood out of the heart through the semilunar valves.

The SA node generates impulses at regular intervals, and one heartbeat follows another throughout your life. After each

heartbeat comes a brief pause—less than half a second—before the next heartbeat begins. The period from the start of one heartbeat to the start of the next is called the *cardiac cycle*.

A heartbeat lasts only about 370 msec. Although brief, it is a very busy period! Let's follow the steps that produce a single heartbeat, from the generation of an action potential at the SA node through the contractions of the atria and ventricles.

The Conducting System

Unlike skeletal muscle, cardiac muscle tissue contracts on its own, without neural or hormonal stimulation. This property is called **automaticity**, or *autorhythmicity*. The cells that initiate and distribute the stimulus to contract are part of the heart's **conducting system**, also known as the *cardiac conduction system* or the *nodal system*. This system is a network of specialized cardiac muscle cells that initiates and distributes electrical impulses. The actual contraction lags behind the beginning of an electrical impulse (the action potential). The delay comes from the time it takes for calcium ions to enter the sarcoplasm and activate the contraction process, as described in Chapter 10. \supset p. 309

The conducting system includes the following elements (Figure 20–11a):

- The *sinoatrial (SA) node*, located in the wall of the right atrium.
- The *atrioventricular (AV) node*, located at the junction between the atria and ventricles.
- Conducting cells interconnect the two nodes and distribute the contractile stimulus throughout the myocardium. In the atria, conducting cells are found in **internodal pathways**, which distribute the contractile stimulus to atrial muscle cells as this electrical impulse travels from the SA node to the AV node. (The importance of these pathways in relaying the signal to the AV node remains in dispute, because an impulse can also spread from contractile cell to contractile cell, reaching the AV node at about the same time as an impulse that travels an internodal pathway.) In the ventricles, conducting cells include those in the AV bundle and the bundle branches, as well as the Purkinje (pur-KIN-jē) fibers, which distribute the stimulus to the ventricular myocardium.

Most of the cells of the conducting system are smaller than the contractile cells of the myocardium and contain very few myofibrils. Purkinje cells, however, are much larger in diameter than the contractile cells. As a result, they conduct action potentials more quickly than other conducting cells.

Conducting cells of the SA and AV nodes share a special characteristic. Their excitable membranes do not have a stable resting potential. Each time it repolarizes, the membrane then drifts toward threshold. This gradual depolarization is called a

SPOTLIGHT Figure 20–10 Heart Disease and Heart Attacks

Coronary Artery Disease

The term coronary artery disease (CAD) refers to areas of partial or complete blockage of coronary circulation. Cardiac muscle cells need a constant supply of oxygen and nutrients, so any reduction in blood flow to the heart muscle produces a corresponding reduction in cardiac performance. Such reduced circulatory supply, known as coronary ischemia (is-KĒ-mē-uh), generally results from partial or complete blockage of the coronary arteries. The usual cause is the formation of a fatty deposit, or atherosclerotic plaque, in the wall of a coronary vessel. The plaque, or an associated thrombus (clot), then narrows the passageway and reduces blood flow. Spasms in the smooth muscles of the vessel wall can further decrease or even stop blood flow. One of the first symptoms of CAD is commonly angina pectoris (an-JĪ-nuh PEK-tor-is; angina, pain spasm + pectoris, of the chest). In its most common form, a temporary ischemia develops when the workload of the heart increases. Although the individual may feel comfortable at rest, exertion or emotional stress can produce a sensation of pressure, chest constriction, and pain that may radiate from the sternal area to the arms, back, and neck.

Plaques may be visible by **angiography** or high-resolution ultrasound, and the effects on coronary blood flow can be detected in digital subtraction angiography (DSA) scans of the heart as shown above.

.

In a myocardial (mī-ō-KAR-dē-al) infarction (MI), or heart attack, part of the coronary circulation becomes blocked, and cardiac muscle cells die from lack of oxygen. The death of affected tissue creates a nonfunctional area known as an infarct. Heart attacks most commonly result from severe coronary artery disease (CAD). The consequences depend on the site and nature of the circulatory blockage. If it occurs near the start of one of the coronary arteries, the damage will be widespread and the heart may stop beating. If the blockage involves one of the smaller arterial branches, the individual may survive the immediate crisis but may have many complications such as reduced contractility and cardiac arrhythmias.

A crisis often develops as a result of thrombus formation at a plaque (the most common cause of an MI), a condition called **coronary thrombosis**. A vessel already narrowed by plaque formation may also become blocked by a sudden spasm in the smooth muscles of the vascular wall.

Individuals having an MI experience intense pain, similar to that felt in angina, but persisting even at rest. However, pain does not always accompany a heart attack, and silent heart attacks may be even more dangerous than more apparent attacks, because the condition may go undiagnosed and may not be treated before a fatal MI occurs. A myocardial infarction can usually be diagnosed with an ECG and blood studies. Damaged myocardial cells release enzymes into the circulation, and these elevated enzymes can be measured in diagnostic blood tests. The enzymes include cardiac troponin T, cardiac troponin I, and a special form of creatinine phosphokinase, **CK-MB**.

Myocardial Infarction KI ATT

Treatment of CAD and Myocardial Infarction

About 25% of MI patients die before obtaining medical assistance, and 65% of MI deaths among those under age 50 occur within an hour after the initial infarction.

Risk Factor Modification

Stop smoking, high blood pressure treatment, dietary modification to lower cholesterol and promote weight loss, stress reduction, and increased physical activity (where appropriate)

Drug Treatment

- Drugs that reduce coagulation and therefore the risk of thrombosis, such as aspirin and coumadin
 - Drugs that block sympathetic stimulation (propranolol or metoprolol) Drugs that cause vasodilation, such as **nitroglycerin**
 - (nī-trō-GLIS-er-in)
 - Drugs that block calcium movement into the cardiac and vascular smooth muscle cells (calcium channel blockers)
 - In a myocardial infarction, drugs to relieve pain, fibrinolytic agents to help dissolve clots, and oxygen

Noninvasive Surgery

- Atherectomy. Blockage by a single, soft plaque may be reduced with the aid of a long, slender catheter (KATH-e-ter) inserted into a coronary artery to the plague. A variety of surgical tools can be slid into the catheter, and the plaque can then be removed.
- Balloon angioplasty (AN-jē-ō-plas-tē; angeion, vessel). In balloon angioplasty, the tip of the catheter contains an inflatable balloon. Once in position, the balloon is inflated, pressing the plague against the vessel walls. Because plagues commonly redevelop after angioplasty, a fine tubular wire mesh called a stent may be inserted into the vessel, holding it open.

Coronary Artery Bypass Graft (CABG)

In a coronary artery bypass graft, a small section is removed from either a small artery or a peripheral vein and is used to create a detour around the obstructed portion of a coronary artery. As many as four coronary arteries can be rerouted this way during a single operation. The procedures are named according to the number of vessels repaired, so we speak of single, double, triple, or quadruple coronary bypasses.

a Components of the conducting system.

prepotential or *pacemaker potential* (Figure 20–11b). The prepotential results from a slow inflow of Na^+ without a compensating outflow of K^+ .

The rate of spontaneous depolarization differs in various parts of the conducting system. It is fastest at the SA node. Without neural or hormonal stimulation, the SA node generates action potentials at a rate of 80–100 per minute. Isolated cells of the AV node depolarize more slowly, generating 40–60 action potentials per minute. Because the SA node reaches threshold first, it establishes the heart rate. In other words, the impulse generated by the SA node brings the AV nodal cells to threshold faster than does the prepotential of the AV nodal cells. The normal resting heart rate is somewhat slower than 80–100 beats per minute, however, due to the effects of parasympathetic innervation. (We discuss the influence of autonomic innervation on heart rate in a later section.)

If the SA node or any of the atrial pathways becomes damaged, the heart continues to beat, but at a slower rate, usually 40–60 beats per minute, as dictated by the AV node. Certain cells in the Purkinje fiber network depolarize spontaneously at an even slower rate. If the rest of the conducting system is damaged, these cells can stimulate a heart rate of 20–40 beats per minute. Under normal conditions, cells of the AV bundle, the bundle branches, and most Purkinje fibers do not depolarize spontaneously. If, due to damage or disease, these cells *do* begin depolarizing spontaneously, the heart may no longer pump blood effectively. Death can result if the problem persists.

Now let's trace the path of an impulse from its initiation at the SA node, examining its effects on the surrounding myocardium as we proceed.

The Sinoatrial (SA) Node

The **sinoatrial** (sī-nō-Ā-trē-al) **node** (SA node) is embedded in the posterior wall of the right atrium, near the entrance of the superior vena cava (Figure 20–12 1). The SA node contains **pacemaker cells**, which establish the heart rate. As a result, the SA node is also known as the *cardiac pacemaker* or the *natural pacemaker*.

The SA node is connected to the larger AV node by the internodal pathways in the atrial walls. An action potential takes approximately 50 msec to travel from the SA node to the AV node along these pathways. Along the way, the conducting cells pass the stimulus to contractile cells of both atria. The action potential then spreads across the atrial surfaces by cell-to-cell contact (Figure 20–12 2). The stimulus affects only the atria, because the cardiac skeleton isolates the atrial myocardium from the ventricular myocardium.

The Atrioventricular (AV) Node

The relatively large **atrioventricular** (AV) node (Figure 20–12 2) sits within the floor of the right atrium near the opening of the coronary sinus. The impulse slows as it leaves the internodal pathways and enters the AV node, because the nodal cells are smaller in diameter than the conducting cells. (Chapter 12 discussed the relationship between diameter and propagation speed. \bigcirc p. 413) In addition, the connections between nodal cells are less efficient than those between conducting cells at relaying the impulse from one cell to another. As a result, the impulse takes about 100 msec to pass through the AV node (Figure 20–12 3). This delay is important because it allows the atria to contract before the ventricles do. Otherwise, contraction

Figure 20–12 Impulse Conduction through the Heart.

of the powerful ventricles would close the AV valves and prevent blood flow from the atria into the ventricles.

After this brief delay, the impulse is conducted along the atrioventricular bundle and the bundle branches to the Purkinje fibers and the papillary muscles (Figure 20–12 4). The Purkinje fibers then distribute the impulse to the ventricular myocardium, and ventricular contraction begins (Figure 20–12 5).

The cells of the AV node can conduct impulses at a maximum rate of 230 per minute. Because each impulse results in a ventricular contraction, this value is the maximum normal heart rate. Even if the SA node generates impulses at a faster rate, the ventricles will still contract at 230 beats per minute (bpm). This limitation is important, because mechanical factors (discussed later) begin to decrease the pumping efficiency of the heart at rates above approximately 180 bpm. Rates above 230 bpm occur only when the heart or the conducting system has been damaged or stimulated by drugs. As ventricular rates increase toward their theoretical maximum limit of 300–400 bpm, pumping effectiveness becomes dangerously, if not fatally, reduced.

A number of clinical problems result from abnormal pacemaker function. **Bradycardia** (brād-ē-KAR-dē-uh; *bradys*, slow) is a condition in which the heart rate is slower than normal. **Tachycardia** (tak-ē-KAR-dē-uh; *tachys*, swift) is a faster-thannormal heart rate. These terms are relative, and in clinical practice the definitions vary with the normal resting heart rate of the individual.

The AV Bundle, Bundle Branches, and Purkinje Fibers

The connection between the AV node and the **AV bundle**, also called the *bundle of His* (hiss), is normally the only electrical connection between the atria and the ventricles. Once an impulse enters the AV bundle, it travels to the interventricular septum and enters the **right** and **left bundle branches**. The left bundle branch, which supplies the massive left ventricle, is much larger than the right bundle branch. Both branches extend toward the apex of the heart, turn, and fan out deep to the endocardial surface. As the branches diverge, they conduct the impulse to **Purkinje fibers** and, through the moderator band, to the papillary muscles of the right ventricle.

Purkinje fibers conduct action potentials very rapidly—as fast as small myelinated axons. Within about 75 msec, the signal to begin a contraction has reached all the ventricular cardiac muscle cells. By this time, the atria have completed their contractions and ventricular contraction can safely occur. The entire process, from the generation of an impulse at the SA node to the complete depolarization of the ventricular myocardium, normally takes around 225 msec.

Because the bundle branches deliver the impulse across the moderator band to the papillary muscles directly, rather than by way of Purkinje fibers, the papillary muscles begin contracting before the rest of the ventricular musculature does. Contraction of the papillary muscles applies tension to the chordae tendineae, bracing the AV valves. By limiting the movement of the cusps, tension in the chordae tendineae prevents the backflow of blood into the atria when the ventricles contract.

The Purkinje fibers radiate from the apex toward the base of the heart. As a result, the ventricles contract in a wave that begins at the apex and spreads toward the base. The contraction pushes blood toward the base of the heart, into the aorta and pulmonary trunk.

Damage to the conducting pathways disturbs the normal rhythm of the heart. The resulting problems are called *conduction deficits*. If the SA node or internodal pathways are damaged, the AV node assumes command. The heart continues beating normally, but at a slower rate.

If an abnormal conducting cell or ventricular muscle cell begins generating action potentials at a higher rate, the impulses can override those of the SA or AV node. The origin of these abnormal signals is called an **ectopic** (ek-TOP-ik; out of place) **pacemaker**. The activity of an ectopic pacemaker partially or completely bypasses the conducting system, disrupting the timing of ventricular contraction. The result may be a dangerous reduction in the pumping efficiency of the heart. Such conditions are commonly diagnosed with the aid of an *electrocardiogram*.

20 The Electrocardiogram

The electrical events in the heart are powerful enough to be detected by electrodes on the surface of the body. A recording of these events is an **electrocardiogram** (\bar{e} -lek-tr \bar{o} -KAR-d \bar{e} - \bar{o} -gram), also called an **ECG** or **EKG**. Each time the heart beats, a wave of depolarization spreads through the atria, pauses at the AV node, then travels down the interventricular septum to the apex, turns, and spreads through the ventricular myocardium toward the base (Figure 20–12).

An ECG integrates electrical information from electrodes placed at different locations on the body surface. Clinicians can use an ECG to assess the performance of specific nodal, conducting, and contractile components. When a portion of the heart has been damaged by a heart attack, for example, the ECG reveals an abnormal pattern of impulse conduction.

The appearance of the ECG varies with the placement of the monitoring electrodes, or *leads*. Figure 20–13a shows the leads in one of the standard configurations. Figure 20–13b depicts the important features of an ECG recorded with that configuration. Note the following ECG features:

• The small **P wave**, which accompanies the depolarization of the atria. The atria begin contracting about 25 msec after the start of the P wave.

- The **QRS complex**, which appears as the ventricles depolarize. This electrical signal is relatively strong, because the ventricular muscle is much more massive than that of the atria. It is also a complex signal, largely because of the complex pathway that the spread of depolarization takes through the ventricles. The ventricles begin contracting shortly after the peak of the **R wave**.
- The smaller **T wave**, which indicates ventricular repolarization. Atrial repolarization is not apparent, because it takes place while the ventricles are depolarizing, and the QRS complex masks the electrical events.

To analyze an ECG, you must measure the size of the voltage changes and determine the durations and temporal (time) relationships of the various components. The amount of depolarization during the P wave and the QRS complex is particularly important in making a diagnosis. For example, an excessively large QRS complex often indicates that the heart has become enlarged. A smaller-than-normal electrical signal may mean that the mass of the heart muscle has decreased (although monitoring problems are more often responsible). The size and shape of the T wave may also be affected by any condition that slows ventricular repolarization. For example, starvation and low cardiac energy reserves, coronary ischemia, or abnormal ion concentrations reduce the size of the T wave.

The times between waves are reported as *segments* and *intervals*. Segments generally extend from the end of one wave to the start of another. Intervals are more variable, but always include at least one entire wave. Commonly used segments and intervals are labeled in Figure 20–13b. The names, however, can be somewhat misleading. For example:

- The **P–R interval** extends from the start of atrial depolarization to the start of the QRS complex (ventricular depolarization) rather than to R, because in abnormal ECGs the peak at R can be difficult to determine. Extension of the P–R interval to more than 200 msec can indicate damage to the conducting pathways or AV node.
- The **Q-T interval** indicates the time required for the ventricles to undergo a single cycle of depolarization and repolarization. It is usually measured from the end of the P-R interval rather than from the bottom of the Q wave. The Q-T interval can be lengthened by electrolyte disturbances, some medications, conduction problems, coronary ischemia, or myocardial damage. A congenital heart defect that can cause sudden death without warning may be detectable as a prolonged Q-T interval.

An *arrhythmia* (ā-RITH-mē-uh) is an irregularity in the normal rhythm or force of the heartbeat. Serious arrhythmias may indicate damage to the myocardium, injuries to the pacemakers or conduction pathways, exposure to drugs, or

Figure 20–13 An Electrocardiogram.

An ECG printout is a strip of graph paper containing a record of the electrical events monitored by the electrodes. The placement of electrodes on the body surface affects the size and shape of the waves recorded. The example is a normal ECG; the enlarged section indicates the major components of the ECG and the measurements most often taken during clinical analysis.

abnormalities in the electrolyte composition of extracellular fluids. **Spotlight Figure 20–14** describes cardiac arrhythmias.

Contractile Cells

The Purkinje fibers distribute the stimulus to the **contractile cells**, which form the bulk of the atrial and ventricular walls. These cells account for about 99 percent of the muscle cells in the heart. In both cardiac muscle cells and skeletal muscle fibers, (1) an action potential leads to the appearance of Ca^{2+} among the myofibrils, and (2) the binding of Ca^{2+} to troponin on the thin filaments initiates the contraction. But skeletal and cardiac muscle cells differ in terms of the nature of the action potential, the source of the Ca^{2+} , and the duration of the resulting contraction. $\Box p$. 327

The Action Potential in Cardiac Muscle Cells

The resting potential of a ventricular contractile cell is approximately –90 mV, comparable to that of a resting skeletal muscle fiber (–85 mV). (The resting potential of an atrial

contractile cell is about -80 mV, but the basic principles described here apply to atrial cells as well.) An action potential begins when the membrane of the ventricular muscle cell reaches threshold, usually at about -75 mV. Threshold is normally reached in a portion of the membrane next to an intercalated disc. The typical stimulus is the excitation of an adjacent muscle cell. Once threshold has been reached, the action potential proceeds in three basic steps (Figure 20–15a):

• Rapid Depolarization. The stage of rapid depolarization in a cardiac muscle cell resembles that in a skeletal muscle fiber. At threshold, voltage-gated sodium channels open, and the membrane suddenly becomes permeable to Na⁺. A massive influx of sodium ions rapidly depolarizes the sarcolemma. The channels involved are called **fast sodium channels**, because they open quickly and remain open for only a few milliseconds.

2 *The Plateau.* As the membrane potential approaches +30 mV, the voltage-gated sodium channels close. They

SPOTLIGHT

Figure 20–14 Cardiac Arrhythmias

Despite the variety of sophisticated equipment available to assess or visualize cardiac function, in the majority of cases the ECG provides the most important diagnostic information. ECG analysis is especially useful in detecting and diagnosing **cardiac arrhythmias** (ā-RITH-mē-uz)— abnormal patterns of cardiac electrical activity. Momentary arrhythmias are not inherently dangerous, but clinical problems appear when arrhythmias reduce the pumping efficiency of the heart.

Premature Atrial Contractions (PACs)

Paroxysmal Atrial Tachycardia (PAT)

Premature atrial contractions (PACs) often occur in healthy individuals. In a PAC, the normal atrial rhythm is momentarily interrupted by a "surprise" atrial contraction. Stress, caffeine, and various drugs may

In paroxysmal (par-ok-SIZ-mal) atrial tachycardia, or PAT, a premature atrial contraction triggers a flurry of atrial activity. The ventricles are still able to keep pace, and the heart rate jumps to about 180 beats per minute.

During atrial fibrillation (fib-ri-LĀ-shun), the

impulses move over the atrial surface at rates

cardiac muscle plasma membranes.

Ventricular fibrillation (VF) is responsible for the condition known as **cardiac arrest**. VF is rapidly fatal, because the ventricles quiver and stop pumping blood.

Figure 20–15 The Action Potentials in Skeletal and Cardiac Muscle.

a Events in an action potential in a ventricular muscle cell.

remain closed and inactivated until the membrane potential drops to -60 mV. The cell now begins actively pumping Na⁺ out of the cell. However, a net loss of positive charges does not continue, because as the sodium channels are closing, voltage-gated calcium channels are opening. These channels are called **slow calcium channels**, because they open slowly and remain open for a relatively long period-roughly 175 msec. While the slow calcium channels are open, calcium ions enter the cytosol. The entry of positive charges through the calcium channels, in the form of Ca^{2+} , roughly balances the loss of positive ions through the active transport of Na⁺, and the membrane potential remains near 0 mV for an extended period. This portion of the action potential curve is called the *plateau*. The presence of a plateau is the major difference between action potentials in cardiac muscle cells and in skeletal muscle fibers. In a skeletal muscle fiber, rapid depolarization is immediately followed by rapid repolarization.

3 *Repolarization.* As the plateau continues, slow calcium channels begin closing, and **slow potassium channels** begin opening. As these channels open, potassium ions (K⁺) rush out of the cell, and the net result is a period of rapid repolarization that restores the resting potential.

The Refractory Period. As with skeletal muscle contractions, the membrane will not respond normally to a second stimulus

relative (beige) refractory periods.

for some time after an action potential begins. This time is called the refractory period. Initially, in the absolute refractory period, the membrane cannot respond at all, because the sodium channels are either already open or closed and inactivated. In a ventricular muscle cell, the absolute refractory period lasts approximately 200 msec. It includes the plateau and the initial period of rapid repolarization.

The absolute refractory period is followed by a shorter (50 msec) relative refractory period. During this period, the voltage-gated sodium channels are closed, but can open. The membrane will respond to a stronger-than-normal stimulus by initiating another action potential.

In total, an action potential in a ventricular contractile cell lasts 250–300 msec, about 30 times as long as a typical action potential in a skeletal muscle fiber.

The Role of Calcium Ions in Cardiac Contractions

The appearance of an action potential in the cardiac muscle plasma membrane produces a contraction by causing an increase in the concentration of Ca^{2+} around the myofibrils. This process takes place in two steps:

- 1. Calcium ions crossing the plasma membrane during the plateau phase of the action potential provide roughly 20 percent of the Ca^{2+} required for a contraction.
- 2. The arrival of this extracellular Ca²⁺ triggers the release of additional Ca²⁺ from reserves in the sarcoplasmic reticulum (SR).

Extracellular calcium ions thus have both direct and indirect effects on cardiac muscle cell contraction. For this reason, cardiac muscle tissue is highly sensitive to changes in the Ca²⁺ concentration of the extracellular fluid.

In a skeletal muscle fiber, the action potential is relatively brief and ends as the resulting twitch contraction begins (Figure 20–15b). The twitch contraction is short and ends as the SR reclaims the Ca²⁺ it released. In a cardiac muscle cell, as we have seen, the action potential is prolonged, and calcium ions continue to enter the cell throughout the plateau. As a result, the muscle cell actively contracts until the plateau ends. As the slow calcium channels close, the intracellular calcium ions are absorbed by the SR or are pumped out of the cell, and the muscle cell relaxes.

In skeletal muscle fibers, the refractory period ends before peak tension develops. As a result, twitches can summate and tetanus can occur. In cardiac muscle cells, the absolute refractory period continues until relaxation is under way. Because summation is not possible, tetanic contractions cannot occur in a normal cardiac muscle cell, regardless of the frequency or intensity of stimulation. This feature is vital: A heart in tetany could not pump blood. With a single twitch lasting 250 msec or longer, a normal cardiac muscle cell could reach 300–400 contractions per minute under maximum stimulation. This rate is not reached in a normal heart, due to limitations imposed by the conducting system.

The Energy for Cardiac Contractions

When a normal heart is beating, it gets energy as the mitochondria break down fatty acids (stored as lipid droplets) and glucose (stored as glycogen). These aerobic reactions can occur only when oxygen is readily available. \bigcirc p. 317

In addition to obtaining oxygen from the coronary circulation, cardiac muscle cells maintain their own sizable reserves of oxygen. In these cells, oxygen molecules are bound to the heme units of myoglobin molecules. (We discussed this globular protein, which reversibly binds oxygen molecules, and its function in muscle fibers in Chapter 10.) \bigcirc p. 320 Normally, the combination of circulatory supplies plus myoglobin reserves is enough to meet the oxygen demands of the heart, even when it is working at maximum capacity.

20-3 Events during a complete heartbeat make up a cardiac cycle

Learning Outcome Explain the events of the cardiac cycle, including atrial and ventricular systole and diastole, and relate the heart sounds to specific events in the cycle.

A brief resting phase follows each heartbeat, allowing time for the chambers to relax and prepare for the next heartbeat. The period between the start of one heartbeat and the beginning of the next is a single **cardiac cycle**. It includes alternating periods of contraction and relaxation. For any one chamber in the heart, the cardiac cycle can be divided into two phases: (1) systole and (2) diastole. During **systole** (SIS-tō-lē), or contraction, the chamber contracts and pushes blood into an adjacent chamber or into an arterial trunk. Systole is followed by **diastole** (dī-AS-tō-lē), or relaxation. During diastole, the chamber fills with blood and prepares for the next cardiac cycle.

TIPS&TRICKS

To remember that systole is contraction, relate "*syst*" to "*syst*em," as in during systole, a contraction sends blood out of the heart and into the bloodstream. The word part "*di*" can mean two, so during *di*astole, the heart "puts two feet up" and relaxes.

Fluids move from an area of higher pressure to an area of lower pressure. In the cardiac cycle, the pressure within each chamber rises during systole and falls during diastole. Valves between adjacent chambers help ensure that blood flows in the required direction, but blood flows from one chamber to another only if the pressure in the first chamber exceeds that in the second. This basic principle governs the movement of blood between atria and ventricles, between ventricles and arterial trunks, and between major veins and atria.

The correct pressure relationships depend on the careful timing of contractions. For example, blood could not move in the proper direction if an atrium and its attached ventricle contracted at precisely the same moment. The heart's elaborate pacemaking and conducting systems normally provide the required spacing between atrial systole and ventricular systole. At a representative heart rate of 75 bpm, a sequence of systole and diastole in either the atria or the ventricles lasts 800 msec.

Phases of the Cardiac Cycle

The phases of the cardiac cycle—atrial systole, atrial diastole, ventricular systole, and ventricular diastole—are diagrammed in Figure 20–16 for a heart rate of 75 bpm. When the cardiac cycle begins, all four chambers are relaxed, and the ventricles are partially filled with blood. Let's start by focusing on

the atria. During atrial systole, the atria contract, filling the ventricles completely with blood (Figure 20–16a,b). Atrial systole lasts 100 msec. Over this period, blood cannot flow into the atria because atrial pressure exceeds venous pressure. Yet there is very little backflow into the veins, even though the connections with the venous system lack valves. The reason is that blood takes the path of least resistance. Resistance to blood flow through the broad AV connections and into the ventricles is less than that through the smaller, angled openings of the large veins.

Figure 20–16 Phases of the Cardiac Cycle. Thin black arrows indicate blood flow, green arrows indicate contractions, and the red-hued areas indicate which heart chambers are in systole.

The atria next enter atrial diastole, which continues until the start of the next cardiac cycle. Atrial diastole and ventricular systole begin at the same time. Ventricular systole lasts 270 msec. During this period, the ventricles push blood through the systemic and pulmonary circuits and toward the atria (Figure 20–16c,d). The heart then enters ventricular diastole (Figure 20–16c,f), which lasts 530 msec (the 430 msec remaining in this cardiac cycle, plus the first 100 msec of the next, when the atria are again contracting). For the rest of this cycle, filling occurs passively, and both the atria and the ventricles are relaxed. The next cardiac cycle begins with atrial systole, which completes the filling of the ventricles.

When the heart rate increases, all the phases of the cardiac cycle are shortened. The greatest reduction occurs in the length of time spent in diastole. When the heart rate climbs from 75 bpm to 200 bpm, the time spent in systole drops by less than 40 percent, but the duration of diastole is reduced by almost 75 percent.

Pressure and Volume Changes in the Cardiac Cycle

Figure 20–17 plots the pressure and volume changes during the cardiac cycle. It also shows an ECG for the cardiac cycle. The circled numbers in the figure correspond to numbered paragraphs in the text. The figure shows pressure and volume within the left atrium and left ventricle, but our discussion applies to both sides of the heart. Although pressures are lower in the right atrium and right ventricle, both sides of the heart contract at the same time, and they eject equal volumes of blood.

Atrial Systole

The cardiac cycle begins with atrial systole, which lasts about 100 msec in a resting adult:

1 As the atria contract, rising atrial pressures push blood into the ventricles through the open right and left AV valves.

2 At the start of atrial systole, the ventricles are already filled to about 70 percent of their normal capacity, due to passive blood flow during the end of the previous cardiac cycle. As the atria contract, rising atrial pressures provide the remaining 30 percent by pushing blood through the open AV valves. Atrial systole essentially "tops off" the ventricles.

3 At the end of atrial systole, each ventricle contains the maximum amount of blood that it will hold in this cardiac cycle. That quantity is called the **end-diastolic volume** (EDV). In an adult who is standing at rest, the end-diastolic volume is typically about 130 mL (about 4.4 oz).

Ventricular Systole

As atrial systole ends, ventricular systole begins. It lasts approximately 270 msec in a resting adult. As the pressures in the

Clinical Note

Abnormal Conditions Affecting Cardiac Output

Various drugs, abnormal variations in extracellular ion concentrations, and changes in body temperature can alter the basic rhythm of contraction established by the SA node. In Chapter 12, we noted that several drugs, including caffeine and nicotine, have a stimulatory effect on the excitable membranes in the nervous system. \bigcirc **p.** 422 These drugs also cause an increase in heart rate. Caffeine acts directly on the conducting system. It increases the rate of depolarization at the SA node. Nicotine directly stimulates the activity of sympathetic neurons that innervate the heart.

Disorders affecting ion concentrations or body temperature can have direct effects on cardiac output by changing the stroke volume, the heart rate, or both. Abnormal ion concentrations can change both the contractility of the heart (the strength of contractions), by affecting the cardiac muscle cells, and the heart rate, by affecting the SA nodal cells. The most obvious and clinically important examples of problems with ion concentrations involve K⁺ and Ca²⁺.

Temperature changes also affect metabolic operations throughout the body. For example, a reduction in temperature slows the rate of depolarization at the SA node, lowers the heart rate, and reduces the strength of cardiac contractions. (In open-heart surgery, the exposed heart may be deliberately chilled until it stops beating.) An elevated body temperature accelerates the heart rate and the contractile force. That is one reason your heart may seem to race and pound when you have a fever.

ventricles rise above those in the atria, the AV valves are pushed closed.

Ouring the early stage of ventricular systole, the ventricles are contracting, but blood flow has yet to occur. Ventricular pressures are not yet high enough to force open the semilunar valves and push blood into the pulmonary or aortic trunk. Over this period, the ventricles contract isometrically. They generate tension and pressures rise inside them, but blood does not flow out. The ventricles are in **isovolumetric contraction**: All the heart valves are closed, the volumes of the ventricles do not change, and ventricular pressures are rising.

Once pressure in the ventricles exceeds that in the arterial trunks, the semilunar valves open and blood flows into the pulmonary and aortic trunks. This point marks the beginning of **ventricular ejection**. The ventricles now contract isotonically: The muscle cells shorten, and tension production remains relatively constant. (To review isotonic versus isometric contractions, see Figure 10−18, p. 315.)

Figure 20–17 Pressure and Volume Relationships in the Cardiac Cycle. Major features of the cardiac cycle are shown for a heart rate of 75 bpm. The circled numbers correspond to those in the associated box. For further details, see the numbered list in the text.

After reaching a peak, ventricular pressures gradually decline near the end of ventricular systole. Figure 20–17 shows values for the left ventricle and aorta. The right ventricle also goes through periods of isovolumetric contraction and ventricular ejection, but pressures in the right ventricle and pulmonary trunk are much lower. During ventricular ejection, each ventricle ejects 70–80 mL of blood, the **stroke volume (SV)** of the heart. The stroke volume at rest is roughly 60 percent of the end-diastolic volume. This percentage, known as the *ejection fraction*, varies in response to changing demands on the heart. (We discuss the regulatory mechanisms involved in the next section.)

6 As the end of ventricular systole approaches, ventricular pressures fall rapidly. Blood in the aorta and pulmonary trunk now starts to flow back toward the ventricles, and this movement closes the semilunar valves. As the backflow begins, pressure decreases in the aorta. When the semilunar valves close, pressure rises again as the elastic arterial walls recoil. This small, temporary rise produces a valley in the pressure tracing, called a *dicrotic* (dī-KROT-ik; *dikrotos*, double beating) *notch*. The amount of blood remaining in the ventricle when the semilunar valve closes is the **end-systolic volume (ESV)**. At rest, the end-systolic volume is 50 mL, about 40 percent of the end-diastolic volume.

Ventricular Diastole

The period of ventricular diastole lasts for the 430 msec remaining in the current cardiac cycle and continues through atrial systole in the next cycle.

All the heart valves are now closed, and the ventricular myocardium is relaxing. Because ventricular pressures are still higher than atrial pressures, blood cannot flow into the ventricles. This is **isovolumetric relaxation**. Ventricular pressures drop rapidly over this period, because the elasticity of the connective tissues of the heart and cardiac skeleton helps re-expand the ventricles toward their resting dimensions.

³ When ventricular pressures fall below those of the atria, the atrial pressures force the AV valves open. Blood now flows from the atria into the ventricles. Both the atria and the ventricles are in diastole, but the ventricular pressures continue to fall as the ventricular chambers expand. Throughout this period, pressures in the ventricles are so far below those in the major veins that blood pours through the relaxed atria and on through the open AV valves into the ventricular filling. The ventricles become nearly three-quarters full before the cardiac cycle ends.

The relatively minor contribution that atrial systole makes to ventricular volume explains why individuals can survive quite normally when their atria have been so severely damaged that they can no longer function. In contrast, damage to one or both ventricles can leave the heart unable to pump enough blood through peripheral tissues and organs. A condition of **heart failure** then exists.

Heart Sounds

Listening to the heart, a technique called *auscultation*, is a simple and effective method of cardiac assessment. Clinicians use an instrument called a **stethoscope** to listen for normal and abnormal heart sounds. Where the stethoscope is placed depends on which valve is under examination (Figure 20–18a).

Figure 20–18 Heart Sounds.

individual valves

Valve sounds must pass through the pericardium, surrounding tissues, and the chest wall, and some tissues muffle sounds more than others. For this reason, the placement of the stethoscope differs somewhat from the position of the valve under review.

There are four heart sounds, named S_1 through S_4 (Figure 20–18b). If you listen to your own heart with a stethoscope, you will clearly hear the *first* and *second heart sounds*. These sounds accompany the closing of your heart valves. The first heart sound, known as "lubb" (S_1), lasts a little longer than the second, called "dupp" (S_2). S_1 marks the start of ventricular contraction, when the AV valves close and the semilunar valves open. S_2 occurs at the beginning of ventricular filling, when the semilunar valves close and the AV valves open.

Third and fourth heart sounds are usually very faint and are seldom audible in healthy adults. These sounds are associated with blood flowing into the ventricles (S_3) and atrial contraction (S_4) , rather than with valve action.

If the valve cusps are malformed or there are problems with the papillary muscles or chordae tendineae, the heart valves may not close properly. AV valve regurgitation then occurs during ventricular systole. The surges, swirls, and eddies that accompany regurgitation create a rushing, gurgling sound known as a **heart murmur**. Minor heart murmurs are common and inconsequential.

20-4 Cardiodynamics examines the factors that affect cardiac output

Learning Outcome Define cardiac output, describe the factors that influence heart rate and stroke volume, and explain how adjustments in stroke volume and cardiac output are coordinated at different levels of physical activity.

The term **cardiodynamics** refers to the movements and forces generated during cardiac contractions. Each time the heart beats, the two ventricles eject equal amounts of blood. Earlier we introduced these terms:

• *End-Diastolic Volume (EDV)*: The amount of blood in each ventricle at the end of ventricular diastole (the start of ventricular systole).

- *End-Systolic Volume (ESV):* The amount of blood remaining in each ventricle at the end of ventricular systole (the start of ventricular diastole).
- Stroke Volume (SV): The amount of blood pumped out of each ventricle during a single beat. It can be expressed as SV = EDV - ESV.
- *Ejection Fraction:* The percentage of the EDV represented by the SV.

Stroke volume is the most important factor in an examination of a single cardiac cycle. If the heart were a simple hand pump, the stroke volume would be the amount of water pumped in one up-down cycle of the handle (Figure 20–19). Where you stop when you lift the handle determines how much water the pump contains—the end-diastolic volume. How far down you push the handle determines how much water remains in the pump at the end of the cycle—the end-systolic volume. You pump the maximum amount of water when you pull the handle all the way to the top and then push it all the way to the bottom. In other words, you get the largest stroke volume when the EDV is as large as it can be and the ESV is as small as it can be.

When considering cardiac function over time, physicians generally are most interested in the **cardiac output (CO)**, the amount of blood pumped by the left ventricle in one minute. In essence, cardiac output is an indication of the blood flow through peripheral tissues—and without adequate blood flow, homeostasis cannot be maintained. The cardiac output provides a useful indication of ventricular efficiency over time. We can calculate it by multiplying the heart rate (HR) by the average stroke volume (SV):

CO =	$HR \times$	SV SV
cardiac	heart	stroke
output	rate	volume
(mL/min)	(beats/min)	(mL/beat)

For example, if the heart rate is 75 bpm and the stroke volume is 80 mL per beat, the cardiac output is

 $CO = 75 \text{ bpm} \times 80 \text{ mL/beat} = 6000 \text{ mL/min} (6 \text{ L/min})$

The body precisely adjusts cardiac output to supply peripheral tissues with enough blood as conditions change. When necessary, the heart rate can increase by 250 percent, and stroke volume in a normal heart can almost double.

Overview: Factors Affecting Cardiac Output

Figure 20–20 summarizes the factors involved in the normal regulation of cardiac output. Cardiac output can be adjusted by changes in either heart rate or stroke volume. For convenience, we will consider these independently as we discuss the

Figure 20–19 A Simple Model of Stroke Volume. The stroke volume of the heart can be compared to the amount of water ejected from a simple pump. The amount of water ejected varies with the amount of movement of the pump handle.

20

individual factors involved. However, changes in cardiac output generally reflect changes in both heart rate and stroke volume.

The heart rate can be adjusted by the activities of the autonomic nervous system or by circulating hormones. The stroke volume can be adjusted by changes in the end-diastolic volume (how full a ventricle is when it starts to contract), the end-systolic volume (how much blood remains in a ventricle after it contracts), or both. As we saw in Figure 20–19, stroke volume peaks when EDV is highest and ESV is lowest. A variety

of other factors can influence cardiac output under abnormal circumstances, and we consider several examples in the Clinical Note on p. 708.

Factors Affecting the Heart Rate

Under normal circumstances, autonomic activity and circulating hormones make homeostatic adjustments to the heart rate as cardiovascular demands change. These factors act by modifying the natural rhythm of the heart. Even a heart removed for a

Figure 20–20 Factors Affecting Cardiac Output.

Figure 20–21 Autonomic Innervation of the Heart.

heart transplant continues to beat unless it is kept chilled in a preservation solution.

Autonomic Innervation

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the heart by means of the nerve network known as the *cardiac plexus* (Figure 16–8, p. 548, and Figure 20–21). Postganglionic sympathetic neurons are located in the cervical and upper thoracic ganglia. The vagus nerves (N X) carry parasympathetic preganglionic fibers to small ganglia in the cardiac plexus. Both ANS divisions innervate the SA and AV nodes and the atrial muscle cells. Both divisions also innervate ventricular muscle cells, but sympathetic fibers far outnumber parasympathetic fibers there.

The *cardiac centers* of the medulla oblongata contain the autonomic headquarters for cardiac control. \bigcirc **p**. 470 The **cardioacceleratory center** controls sympathetic neurons that

increase the heart rate. The adjacent **cardioinhibi-tory center** controls the parasympathetic neurons that slow the heart rate. Reflex pathways regulate the cardiac centers. They also receive input from higher centers, especially from the parasympathetic and sympathetic headquarters in the hypothalamus.

TIPS&TRICKS

To remember the effect of the sympathetic nervous system on cardiac performance, remember that **s**ympathetic input **s**peeds and **s**trengthens the heartbeat.

Cardiac Reflexes. Information about the status of the cardiovascular system arrives over visceral sensory fibers accompanying the vagus nerve and the sympathetic nerves of the cardiac plexus. The cardiac centers monitor baroreceptors and chemoreceptors innervated by the glossopharyngeal (N IX) and vagus (N X) nerves. ⁽⁾ pp. 499, 500 On the basis of the information received, the cardiac centers adjust the heart's activity to maintain adequate circulation to vital organs, such as the brain.

The cardiac centers respond to changes in blood pressure as reported by baroreceptors, and to changes in arterial concentrations of dissolved oxygen and carbon dioxide as reported by chemoreceptors. For example, a decline in blood pressure or oxygen concentrations or an increase in carbon dioxide levels generally means that the heart must work harder to meet the demands of peripheral tissues. The cardiac centers then call for an increase in cardiac activity. We detail these reflexes and their effects on the heart and peripheral vessels in Chapter 21.

Figure 20–22 Autonomic Regulation of Pacemaker Function.

Pacemaker cells have membrane potentials closer to threshold than those of other cardiac muscle cells (-60 mV versus -90 mV). Their plasma membranes undergo spontaneous depolarization to threshold, producing action potentials at a frequency determined by (1) the membrane potential and (2) the rate of depolarization.

b Parasympathetic stimulation releases ACh, which extends repolarization and decreases the rate of spontaneous depolarization. The heart rate slows.

Sympathetic stimulation releases NE, which shortens repolarization and accelerates the rate of spontaneous depolarization. As a result, the heart rate increases.

Autonomic Tone. Like other organs with dual innervation, the heart has a resting autonomic tone. Both autonomic divisions are normally active at a steady background level, releasing ACh and NE at the nodes and into the myocardium. For this reason,

cutting the vagus nerves increases the heart rate, and sympathetic blocking agents slow the heart rate.

Parasympathetic effects dominate in a healthy, resting individual. Without autonomic innervation, the pacemaker cells of the SA node establish the heart rate. Such a heart beats at a rate of 80–100 bpm. At rest, a typical adult heart with normal innervation beats more slowly, at 70–80 bpm, due to activity in the parasympathetic nerves innervating the SA node. If parasympathetic activity increases, the heart rate declines further. Conversely, the heart rate increases if parasympathetic activity decreases, or if sympathetic activation occurs. Through dual innervation and adjustments in autonomic tone, the ANS can make very delicate adjustments in cardiovascular function to meet the demands of other systems.

Effects on the SA Node. How do the sympathetic and parasympathetic divisions alter the heart rate? They do so by changing the ionic permeabilities of cells in the conducting system. The most dramatic effects take place at the SA node, which affects the heart rate through changes in the rate at which impulses are generated.

Consider the SA node of a resting individual whose heart is beating at 75 bpm (Figure 20–22a). Any factor that changes the rate of spontaneous depolarization or the duration of repolarization in nodal cells will alter the heart rate by changing the time required for these cells to reach threshold. Acetyl-choline released by parasympathetic neurons opens chemically gated K^+ channels in the plasma membrane. Then K^+ leaves the nodal cells, dramatically slowing their rate of spontaneous depolarization and also slightly extending their duration of repolarization. (Figure 20–22b). As a result, heart rate declines.

Norepinephrine released by sympathetic neurons binds to beta-1 receptors, leading to the opening of sodium ion channels and calcium ion channels. Then an influx of positively charged ions increases the rate of depolarization and shortens the period of repolarization. The nodal cells reach threshold more quickly, and the heart rate increases (Figure 20–22c).

The Atrial Reflex. The **atrial reflex**, or *Bainbridge reflex*, involves adjustments in heart rate in response to an increase in the **venous return** (the amount of blood returning to the heart through veins). When the walls of the right atrium are stretched, stretch

receptors there trigger a reflexive increase in heart rate by stimulating sympathetic activity (Figure 20–22). Thus, when the rate of venous return to the heart increases, so does the heart rate, and for this reason the cardiac output increases as well.

Hormones

Epinephrine, norepinephrine, and thyroid hormone increase heart rate by their effect on the SA node. The effects of epinephrine on the SA node are similar to those of norepinephrine. Epinephrine also affects the contractile cells. After massive sympathetic stimulation of the adrenal medullae, the myocardium may become so excitable that abnormal contractions occur.

Venous Return

In addition to its indirect effect on heart rate by the atrial reflex, venous return also directly affects nodal cells. When venous return increases, the atria receive more blood and the walls are stretched. Stretching of the cardiac muscle fibers of the SA node leads to more rapid depolarization and an increase in the heart rate.

Factors Affecting the Stroke Volume

The stroke volume is the difference between the end-diastolic volume and the end-systolic volume. Changes in either EDV or ESV can change the stroke volume, and thus cardiac output. The factors involved in the regulation of stroke volume are indicated in Figure 20–23.

The EDV

Recall that the EDV is the amount of blood in a ventricle at the end of diastole, just before a contraction begins. Two factors affect this volume: the filling time and the venous return. **Filling time** is the duration of ventricular diastole. It depends entirely on the heart rate: The faster the heart rate, the shorter is the time available for filling. Venous return is variable over this period. It varies in response to changes in cardiac output, blood volume, patterns of peripheral circulation, skeletal muscle activity, and other factors that affect the rate of blood flow back to the heart. (We explore these factors in Chapter 21.)

Preload. The degree of stretching in ventricular muscle cells during ventricular diastole is called the **preload**. The preload is directly proportional to the EDV: The greater the EDV, the larger the preload. Preload matters because it affects the ability of muscle cells to produce tension. As sarcomere length increases past resting length, the amount of force produced during systole increases.

The amount of preload, and hence the degree of myocardial stretching, varies with the demands on the heart. When you are standing at rest, your EDV is low. The ventricular muscle is stretched very little, and the sarcomeres are relatively short. During ventricular systole, the cardiac muscle cells develop little power, and the ESV (the amount of blood in the ventricle after contraction) is relatively high because the muscle cells contracted only a short distance. If you begin exercising, venous return increases and more blood flows into your heart. Your EDV increases, and the myocardium stretches further. As the sarcomeres approach optimal lengths, the ventricular muscle cells can contract more efficiently and produce more forceful contractions. They also shorten more, and more blood is pumped out of your heart.

Figure 20–23 Factors Affecting Stroke Volume. The arrows indicate the nature of the effects: \uparrow = increases, \downarrow = decreases.

The EDV and Stroke Volume. In general, the greater the EDV, the larger the stroke volume. Stretching the cardiac muscle cells *past* their optimal length would *reduce* the force of contraction, but this degree of stretching does not normally take place. Myocardial connective tissues, the cardiac skeleton, and the pericardial sac all limit the expansion of the ventricles.

The relationship between the amount of ventricular stretching and the contractile force means that, within normal physiological limits, increasing the EDV results in a corresponding increase in the stroke volume. This general rule of "more in = more out" was first proposed by Ernest H. Starling based on his studies and research by Otto Frank. The relationship is known as the **Frank–Starling principle**, or *Starling's law of the heart*.

Autonomic adjustments to cardiac output normally make the effects of the Frank–Starling principle difficult to see. However, we can see the effects more clearly in individuals who have received a heart transplant, because the implanted heart is not innervated by the ANS. The most obvious effect of the Frank–Starling principle in these hearts is that the outputs of the left and right ventricles remain balanced under a variety of conditions.

Consider, for example, an individual at rest, with the two ventricles ejecting equal volumes of blood. Although the ventricles contract together, they work in series: When the heart contracts, blood leaving the right ventricle heads to the lungs. During the next ventricular diastole, that volume of blood passes through the left atrium, to be ejected by the left ventricle at the next contraction. If the venous return decreases, the EDV of the right ventricle will decline. During ventricular systole, the right ventricle will then pump less blood to the lungs. In the next cardiac cycle, the EDV of the left ventricle will be reduced, and that ventricle will eject a smaller volume of blood. The output of the two ventricles will again be in balance, but both will have smaller stroke volumes than they did initially.

The ESV

After the ventricle has contracted and ejected the stroke volume, the amount of blood that remains in the ventricle at the end of ventricular systole is the ESV. Three factors that influence the ESV are the *preload* (discussed earlier), the *contractility* of the ventricle, and the *afterload*.

Contractility. Contractility is the amount of force produced during a contraction, at a given preload. Under normal circumstances, autonomic innervation or circulating hormones can alter contractility. Under special circumstances, drugs or abnormal ion concentrations in the extracellular fluid can alter contractility.

Factors that increase contractility are said to have a *positive inotropic action* (*ino-*, fiber). Factors that decrease contractility have a *negative inotropic action*. Positive inotropic agents typically stimulate Ca^{2+} entry into cardiac muscle cells, thus

increasing the force and duration of ventricular contractions. Negative inotropic agents may block Ca²⁺ movement or depress cardiac muscle metabolism. Positive and negative inotropic factors include ANS activity, hormones, and changes in extracellular ion concentrations.

Effects of Autonomic Activity on Contractility. Autonomic activity alters the degree of contraction and changes the ESV in the following ways:

- Sympathetic stimulation has a positive inotropic effect. It causes the release of norepinephrine (NE) by postganglionic fibers of the cardiac nerves and the secretion of epinephrine (E) and NE by the adrenal medullae. These hormones affect heart rate, as we will discuss shortly. They also stimulate alpha and beta receptors in cardiac muscle plasma membranes. This stimulation increases cardiac muscle cell metabolism and the force and degree of contraction. The net effect is that the ventricles contract more forcefully, increasing the ejection fraction and decreasing the ESV.
- Parasympathetic stimulation from the vagus nerves has a negative inotropic effect. The primary effect of acetylcholine (ACh) is at the membrane surface, where it produces hyperpolarization and inhibition. As a result, the force of cardiac contractions is reduced. The atria show the greatest changes in contractile force because the ventricles are not extensively innervated by the parasympathetic division. However, under strong parasympathetic stimulation or after the administration of drugs that mimic the actions of ACh, the ventricles contract less forcefully, the ejection fraction decreases, and the ESV becomes larger.

Hormones. Many hormones affect the contractility of the heart. For example, epinephrine, norepinephrine, and thyroid hormones all have positive inotropic effects. Glucagon also has a positive inotropic effect. Before synthetic inotropic agents were available, glucagon was widely used to stimulate cardiac function. It is still used in cardiac emergencies and to treat some forms of heart disease.

The drugs *isoproterenol, dopamine,* and *dobutamine* mimic the action of E and NE by stimulating beta-1 receptors on cardiac muscle cells. \bigcirc **p.** 541 Dopamine (at high doses) and dobutamine also stimulate Ca²⁺ entry through alpha-1 receptor stimulation. *Digitalis* and related drugs elevate intracellular Ca²⁺ concentrations, but by a different mechanism. They interfere with the removal of Ca²⁺ from the cytosol of cardiac muscle cells.

Many of the drugs used to treat hypertension (high blood pressure) have a negative inotropic action. Beta-blocking drugs such as *propranolol, timolol, metoprolol, atenolol,* and *labetalol* block beta receptors, alpha receptors, or both, and prevent sympathetic

stimulation of the heart. Calcium channel blockers such as *nifedipine* or *verapamil* also have a negative inotropic effect.

Afterload. The **afterload** is the amount of tension that the contracting ventricle must produce to force open the semilunar valve and eject blood. Afterload increases with increased resistance to blood flow out of the ventricle. The greater the afterload, the longer the period of isovolumetric contraction, the shorter the duration of ventricular ejection, and the larger the ESV. In other words, as the afterload increases, the stroke volume decreases.

Any factor that restricts blood flow through the arterial system increases afterload. For example, either the constriction of peripheral blood vessels or a circulatory blockage elevates arterial blood pressure and increases the afterload. If the afterload is too great, the ventricle cannot eject blood. Such a high afterload is rare in a normal heart. However, damage to the heart muscle can weaken the myocardium enough that even a modest rise in arterial blood pressure can reduce stroke volume to dangerously low levels, producing symptoms of heart failure. Damage to the semilunar valve that restricts blood flow will also increase afterload.

Summary: The Control of Cardiac Output

Figure 20–24 summarizes the factors that regulate heart rate and stroke volume, which interact to determine cardiac output under normal conditions.

The heart rate is influenced by the autonomic nervous system, circulating hormones, and the venous return.

Sympathetic stimulation increases the heart rate, and parasympathetic stimulation decreases it. Under resting conditions, parasympathetic tone dominates, and the heart rate is slightly slower than the intrinsic heart rate. When activity levels rise, venous return increases and triggers the atrial reflex. The result is an increase in sympathetic tone and an increase in heart rate.

Figure 20–24 A Summary of the Factors Affecting Cardiac Output.

20

- Circulating hormones, specifically E, NE, and T₃, accelerate heart rate.
- An increase in venous return stretches the nodal cells and increases heart rate.
- The stroke volume is the difference between the enddiastolic volume (EDV) and the end-systolic volume (ESV).
- The EDV is determined by the available filling time and the rate of venous return.
- The ESV is determined by the amount of preload (the degree of myocardial stretching), the degree of contractility (adjusted by hormones and autonomic innervation), and the afterload (the arterial resistance to blood flow out of the heart).

In most healthy people, increasing both the stroke volume and the heart rate, such as occurs during heavy exercise, can raise the cardiac output by 300–500 percent, to 18–30 L/min. The difference between resting and maximal cardiac outputs is the **cardiac reserve**. Trained athletes exercising at maximal levels may increase cardiac output by nearly 700 percent, to 40 L/min.

Cardiac output cannot increase indefinitely, primarily because the available filling time shortens as the heart rate increases. At heart rates up to 160–180 bpm, the combination of increased rate of venous return and increased contractility compensates for the reduction in filling time. Over this range, cardiac output and heart rate increase together. But if the heart rate continues to climb, the stroke volume begins to drop. Cardiac output first plateaus and then declines.

20

The Heart and the Cardiovascular System

The purpose of cardiovascular regulation is to maintain adequate blood flow to all body tissues. The heart cannot accomplish this by itself, and it does not work in isolation. For example, when blood pressure changes, the cardiovascular centers adjust not only the heart rate but also the diameters of peripheral blood vessels. These adjustments work together to keep the blood pressure within normal limits and to maintain circulation to vital tissues and organs. In Chapter 21 we complete this story by detailing the cardiovascular responses to changing activity patterns and circulatory emergencies. We then conclude our discussion of the cardiovascular system by examining the anatomy of the pulmonary and systemic circuits.

CHECKPOINT

- **12**. Define cardiac output.
- **13**. Caffeine has effects on conducting cells and contractile cells that are similar to those of NE. What effect would drinking large amounts of caffeinated drinks have on the heart?
- 14. If the cardioinhibitory center of the medulla oblongata were damaged, which part of the autonomic nervous system would be affected, and how would the heart be influenced?
- **15**. How does a drug that increases the length of time required for the repolarization of pacemaker cells affect the heart rate?
- **16**. Why is it a potential problem if the heart beats too rapidly?
- 17. What effect would stimulating the acetylcholine receptors of the heart have on cardiac output?
- **18**. What effect would an increase in venous return have on the stroke volume?
- **19**. How would an increase in sympathetic stimulation of the heart affect the end-systolic volume?
- 20. Joe's end-systolic volume is 40 mL, and his enddiastolic volume is 125 mL. What is Joe's stroke volume?

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **artificial pacemaker:** A small, battery-operated device that keeps one's heart beating in a regular rhythm. It may be permanently implanted internally or for temporary usage it may be an external device.
- **asystole:** The absence of cardiac activity with no contraction and no output.
- **automated external defibrillator (AED):** A device that, when applied, automatically checks the function of the heart. Upon detecting a condition that may respond to an electric shock, it delivers a shock to restore normal heartbeat rhythm.
- **automatic implantable cardioverter defibrillator (AICD):** A surgically implanted battery-operated device that monitors the

function of the heart. Upon detecting a condition that may respond to an electric shock, such as a disorganized heartbeat, the device delivers a shock to restore normal heartbeat rhythm.

- **cardiac arrest:** Sudden stopping of the pumping action of the heart causing the loss of arterial blood pressure.
- **cardiology:** The branch of medicine dealing with the diagnosis and treatment of heart disorders and related conditions.
- **cardiomegaly:** An enlarged heart, which is a sign of some other condition such as stress, weakening of the heart muscle, coronary artery disease, heart valve problems, or abnormal heart rhythms.

- **cardiomyoplasty:** A surgical procedure that uses stimulated latissimus dorsi muscle to assist with cardiac function. The latissimus dorsi muscle is relocated and wrapped around the left and right ventricles and stimulated to contract during cardiac systole by means of an implanted burst-stimulator.
- **commotio cordis:** Sudden cardiac arrest as the result of a blunt hit or impact to the chest.
- **congestive heart failure:** The heart condition of weakness, edema, and shortness of breath caused by the inability of the heart to maintain adequate blood circulation in the peripheral tissues and the lungs.
- **cor pulmonale:** Weakness of the right ventricle of the heart due to prolonged high blood pressure in the pulmonary artery and right ventricle; or any disease or malfunction that affects the pulmonary circuit in the lungs.
- echocardiography: A noninvasive diagnostic test that uses ultrasound to make images of the heart chambers, valves, and surrounding structures. This diagnostic tool can also measure cardiac output, detect inflammation around the heart, identify abnormal anatomy, and detect infections of the heart valves.

- **endocarditis:** Inflammation or infection of the endocardium, the inner lining of the heart muscle.
- **fibrillation:** Fast twitching of the heart muscle fibers with little or no movement of the muscle as a whole. Atrial fibrillation occurs in the atria of the heart and is characterized by chaotic quivers and irregular ventricular beating with both atria and ventricles being out of sync.
- **heart block:** Delay in the normal electrical pulses that cause the heart to beat.
- **mitral valve prolapse:** A condition in which the mitral (bicuspid) valve cusps do not close properly and are pushed back toward the left atrium.
- **myocarditis:** Inflammation of the myocardium, the middle layer of the heart wall tissue.

palpitation: Irregular and rapid beating of the heart.

- **percutaneous transluminal coronary angioplasty (PTCA):** The surgical use of a balloon-tipped catheter to enlarge a narrowed artery.
- **sick sinus syndrome:** A group of heart rhythm disorders or problems in which the sinoatrial node does not work properly to regulate the heart rhythms.

An Introduction to the Cardiovascular System p. 685

- The blood vessels can be subdivided into the **pulmonary** circuit (which carries blood to and from the lungs) and the systemic circuit (which transports blood to and from the rest of the body).
- 2. **Arteries** carry blood away from the heart; **veins** return blood to the heart. **Capillaries**, or *exchange vessels*, are thin-walled, narrow-diameter vessels that connect the smallest arteries and veins. (*Figure 20–1*)
- 3. The heart has four chambers: the **right atrium** and **right ventricle**, and the **left atrium** and **left ventricle**.
- 20-1 The heart is a four-chambered organ, supplied by the coronary circulation, that pumps oxygen-poor blood to the lungs and oxygen-rich blood to the rest of the body p. 686
- 4. The heart is surrounded by the **pericardial cavity** and lies within the anterior portion of the **mediastinum**, which separates the two pleural cavities. (*Figure 20–2*)

- 5. The pericardial cavity is lined by the **pericardium**. The **vis-ceral pericardium (epicardium)** covers the heart's outer surface, and the **parietal pericardium** lines the inner surface of the **pericardial sac**, which surrounds the heart. (*Figure 20–2*)
- 6. The **coronary sulcus**, a deep groove, marks the boundary between the atria and the ventricles. Other surface markings also provide useful reference points in describing the heart and associated structures. (*Figure 20–3*)
- The bulk of the heart consists of the muscular myocardium. The endocardium lines the inner surfaces of the heart, and the epicardium covers the outer surface. (*Figure 20–4*)
- 8. Cardiac muscle cells are interconnected by intercalated discs, which convey the force of contraction from cell to cell and conduct action potentials. (*Figure 20–5; Table 20–1*)
- 9. The atria are separated by the **interatrial septum**, and the ventricles are divided by the **interventricular septum**. The right atrium receives blood from the systemic circuit via two large veins, the **superior vena cava** and the **inferior vena cava**. (The atrial walls contain the **pectinate muscles**, prominent muscular ridges.) (*Figure 20–6*)
- Blood flows from the right atrium into the right ventricle by the right atrioventricular (AV) valve (tricuspid valve). This opening is bounded by three cusps of fibrous tissue braced by the chordae tendineae, which are connected to papillary muscles. (*Figure 20–6*)
- 11. Blood leaving the right ventricle enters the **pulmonary trunk** after passing through the **pulmonary valve**. The pulmonary trunk divides to form the **left** and **right pulmonary arteries**. The **left** and **right pulmonary veins** return blood from the lungs to the left atrium. Blood leaving the left atrium flows into the left ventricle by the **left atrioventricular (AV) valve** (**bicuspid**, or **mitral**, **valve**). Blood leaving the left ventricle passes through the **aortic valve** and into the systemic circuit via the **ascending aorta**. (*Figure 20–6*)

- **12.** Anatomical differences between the ventricles reflect the functional demands placed on them. The wall of the right ventricle is relatively thin, whereas the left ventricle has a massive muscular wall. (*Figure 20–7*)
- **13.** Valves normally permit blood flow in only one direction, preventing the **regurgitation** (backflow) of blood. (*Figure 20–8*)
- 14. The connective tissues of the heart (mainly collagen and elastic fibers) and the **cardiac skeleton** support the heart's contractile cells and valves. (*Figure 20–8*)
- **15.** The **coronary circulation** meets the high oxygen and nutrient demands of cardiac muscle cells. The **coronary arteries** originate at the base of the ascending aorta. Interconnections between arteries, called **arterial anastomoses**, ensure a constant blood supply. The **great**, **posterior**, **small**, **anterior**, and **middle cardiac veins** are epicardial vessels that carry blood from the coronary capillaries to the **coronary sinus**. (*Figure 20–9*)
- 16. In coronary artery disease (CAD), portions of the coronary circulation undergo partial or complete blockage. A myocar-dial infarction (MI), or heart attack, occurs when part of the coronary circulation becomes blocked and muscle tissue dies when it cannot be oxygenated. (*Spotlight Figure 20–10*)
- **20-2** The conducting system distributes electrical impulses through the heart, and an electrocardiogram records the associated electrical events p. 697
- Two general classes of cardiac muscle cells are involved in the normal heartbeat: cells of the conducting system and contractile cells.
- **18.** The **conducting system** is composed of the *sinoatrial node*, the *atrioventricular node*, and *conducting cells*. The conducting system initiates and distributes electrical impulses within the heart. Nodal cells establish the rate of cardiac contraction, and conducting cells distribute the contractile stimulus from the SA node to the atrial myocardium and the AV node (along *internodal pathways*), and from the AV node to the ventricular myocardium. (*Figure 20–11*)
- Unlike skeletal muscle, cardiac muscle contracts without neural or hormonal stimulation. Pacemaker cells in the sinoatrial (SA) node (*cardiac pacemaker*) normally establish the rate of contraction. From the SA node, the stimulus travels to the atrioventricular (AV) node, and then to the AV bundle, which divides into bundle branches. From there, Purkinje fibers convey the impulses to the ventricular myocardium. (*Figures 20–11, 20–12*)
- 20. A recording of electrical activities in the heart is an electrocardiogram (ECG or EKG). Important landmarks of an ECG include the P wave (atrial depolarization), the QRS complex (ventricular depolarization), and the T wave (ventricular repolarization). (*Figure 20–13*)

- **21. Cardiac arrhythmias** are abnormal patterns of electrical activity in the heart. (*Spotlight Figure 20–14*)
- 22. **Contractile cells** form the bulk of the atrial and ventricular walls. Cardiac muscle cells have a long refractory period, so rapid stimulation produces twitches rather than tetanic contractions. (*Figure 20–15*)
- **20-3** Events during a complete heartbeat make up a cardiac cycle p. 706
- **23.** The **cardiac cycle** includes periods of **atrial** and **ventricular systole** (contraction) and **atrial** and **ventricular diastole** (relaxation). (*Figure 20–16*)
- 24. When the heart beats, the two ventricles eject equal volumes of blood. (*Figure 20–17*)
- **25.** The closing of valves and rushing of blood through the heart cause characteristic heart sounds, which can be heard during *auscultation*. (*Figure 20–18*)
- **20-4** Cardiodynamics examines the factors that affect cardiac output p. 711
- 26. The amount of blood ejected by a ventricle during a single beat is the stroke volume (SV). The amount of blood pumped by a ventricle each minute is the cardiac output (CO). (*Figure 20–19*)
- 27. Cardiac output can be adjusted by changes in either stroke volume or heart rate. (*Figure 20–20*)
- 28. The **cardioacceleratory center** in the medulla oblongata activates sympathetic neurons; the **cardioinhibitory center** controls the parasympathetic neurons that slow the heart rate. These cardiac centers receive inputs from higher centers and from receptors monitoring blood pressure and the concentrations of dissolved gases. (*Figure 20–21*)
- **29.** The basic heart rate is established by the pacemaker cells of the SA node, but it can be modified by the autonomic nervous system. The **atrial reflex** accelerates the heart rate when the walls of the right atrium are stretched. (*Figure 20–22*)
- **30.** Sympathetic activity produces more powerful contractions that reduce the ESV. Parasympathetic stimulation slows the heart rate, reduces the contractile strength, and raises the ESV.
- **31.** Cardiac output is affected by various factors, including autonomic innervation and hormones. (*Figure 20–22*)
- **32.** The stroke volume is the difference between the **end-diastolic volume (EDV)** and the **end-systolic volume (ESV)**. The **filling time** and **venous return** interact to determine the EDV. Normally, the greater the EDV, the more powerful is the succeeding contraction (the **Frank–Starling principle**). (*Figure 20–23*)
- **33.** The difference between resting and maximal cardiac outputs is the **cardiac reserve**. (*Figure 20–24*)
- 34. The heart does not work in isolation in maintaining adequate blood flow to all tissues.

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the superficial structures in the following diagram of the heart.

2. Identify the structures in the following diagram of a sectional view of the heart.

- 3. The great cardiac vein drains blood from the heart muscle to the (a) left ventricle, (b) right ventricle, (c) right atrium, (d) left atrium.
- The autonomic centers for cardiac function are located in (a) the myocardial tissue of the heart, (b) the cardiac centers of the medulla oblongata, (c) the cerebral cortex, (d) all of these structures.

See the blue Answers tab at the back of the book.

- The serous membrane covering the outer surface of the heart is the

 (a) parietal pericardium,
 (b) endocardium,
 (c) myocardium,
 (d) visceral pericardium.
- The simple squamous epithelium covering the heart valves is the (a) epicardium, (b) endocardium, (c) myocardium, (d) cardiac skeleton.
- The heart is surrounded by the (a) pleural cavity, (b) peritoneal cavity,
 (c) abdominopelvic cavity, (d) mediastinum, (e) abdominal cavity.
- The cardiac skeleton of the heart has which *two* of the following functions? (a) It physically isolates the muscle fibers of the atria from those of the ventricles, (b) It maintains the normal shape of the heart, (c) It helps distribute the forces of cardiac contraction, (d) It allows more rapid contraction of the ventricles, (e) It strengthens and helps prevent overexpansion of the heart.
- Cardiac output is equal to the (a) difference between the end-diastolic volume and the end-systolic volume, (b) product of heart rate and stroke volume, (c) difference between the stroke volume at rest and the stroke volume during exercise, (d) stroke volume less the end-systolic volume, (e) product of heart rate and blood pressure.
- During diastole, a chamber of the heart (a) relaxes and fills with blood, (b) contracts and pushes blood into an adjacent chamber, (c) experiences a sharp increase in pressure, (d) reaches a pressure of approximately 120 mm Hg.
- During the cardiac cycle, the amount of blood ejected from the left ventricle when the semilunar valve opens is the (a) stroke volume (SV),
 (b) end-diastolic volume (EDV), (c) end-systolic volume (ESV),
 (d) cardiac output (CO).
- **12.** What role do the chordae tendineae and papillary muscles play in the normal function of the AV valves?
- 13. Describe the three distinct layers that make up the heart wall.
- 14. What are the valves in the heart, and what is the function of each?
- **15.** Trace the normal pathway of an electrical impulse through the conducting system of the heart.
- **16.** What is the cardiac cycle? What phases and events are necessary to complete a cardiac cycle?
- 17. What three factors regulate stroke volume to ensure that the left and right ventricles pump equal volumes of blood?

LEVEL 2 Reviewing Concepts

- 18. The cells of the conducting system differ from the contractile cells of the heart in that (a) conducting cells are larger and contain more myofibrils, (b) contractile cells exhibit prepotentials, (c) contractile cells do not normally exhibit automaticity, (d) both a and b are correct.
- **19.** Which of the following is *longer*? **(a)** the refractory period of cardiac muscle, **(b)** the refractory period of skeletal muscle.
- 20. If the papillary muscles fail to contract, (a) the ventricles will not pump blood, (b) the atria will not pump blood, (c) the semilunar valves will not open, (d) the AV valves will not close properly, (e) none of these happen.
- Cardiac output cannot increase indefinitely because (a) the available filling time becomes shorter as the heart rate increases, (b) the cardiovascular centers adjust the heart rate, (c) the rate of spontaneous depolarization decreases, (d) the ion concentrations of pacemaker plasma membranes decrease.
- **22.** Describe the function of the SA node in the cardiac cycle. How does this function differ from that of the AV node?
- 23. What are the sources and significance of the four heart sounds?
- 24. Differentiate between stroke volume and cardiac output. How is cardiac output calculated?
- 25. What factors influence cardiac output?
- **26.** What effect does sympathetic stimulation have on the heart? What effect does parasympathetic stimulation have on the heart?
- **27.** Describe the effects of epinephrine, norepinephrine, glucagon, and thyroid hormones on the contractility of the heart.

LEVEL 3 Critical Thinking and Clinical Applications

- **28.** Vern is suffering from cardiac arrhythmias and is brought into the emergency room of a hospital. In the emergency room he begins to exhibit tachycardia and as a result loses consciousness. Explain why Vern lost consciousness.
- **29.** Harvey has a heart murmur in his left ventricle that produces a loud "gurgling" sound at the beginning of systole. Which valve is probably faulty?
- **30.** The following measurements were made on two individuals (the values recorded remained stable for one hour):

Person 1: heart rate, 75 bpm; stroke volume, 60 mL Person 2: heart rate, 90 bpm; stroke volume, 95 mL

Which person has the greater venous return? Which person has the longer ventricular filling time?

31. Karen is taking the medication verapamil, a drug that blocks the calcium channels in cardiac muscle cells. What effect should this medication have on Karen's stroke volume?

CLINICAL CASE

A Needle to the Chest

With the force of the head-on collision, the patient's chest first broke the seat belt and then collided with the steering wheel. This caused fractures of the anterior chest wall, including the sternum and ribs.

The heart, located just deep to the sternum, then hit the steering wheel hard enough to cause bleeding into the pericardial sac. As the delicate parietal and visceral pericardial linings bled into the pericardial cavity, the tough, fibrous pericardial sac itself did not expand.

The blood in the pericardial cavity compressed the heart, squeezing the atria and ventricles. During atrial diastole, the atria could not fill. This caused a backup of the venous system that was obvious in the veins of the patient's neck. The compressed ventricles could not fill with blood during ventricular diastole. Because the end-diastolic volume (EDV) was so low, the stroke volume (SV) was also very low. This was evident in the blood pressure of 80/58, with a narrow difference between the

systolic blood pressure and the diastolic blood pressure. The ultrasound confirmed fluid in the pericardial cavity that was compressing the heart.

Wrap-Up

Dr. Jim knew this victim was suffering from cardiac tamponade due to blood in the pericardial space. He also knew the problem was severe enough that with the decreasing stroke volume, the heart could not pump adequate blood to the patient's brain. So he removed the blood from the pericardial space with a needle, a procedure known as pericardiocentesis, and saved this patient's life.

- 1. Why do you think the heart sounds were muffled and distant?
- What other cardiac structures were likely to be injured by this collision?

See the blue Answers tab at the back of the book.

Blood Vessels and Circulation

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **21-1** Distinguish among the types of blood vessels based on their structure and function, and describe how and where fluid and dissolved materials enter and leave the cardiovascular system.
- 21-2 Explain the mechanisms that regulate blood flow through vessels, describe the factors that influence blood pressure, and discuss the mechanisms that regulate movement of fluids between capillaries and interstitial spaces.
- 21-3 Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.
- **21-4** Explain the cardiovascular system's homeostatic response to exercise and hemorrhaging, and identify the principal blood vessels and functional characteristics of the special circulation to the brain, heart, and lungs.
- **21-5** Describe the three general functional patterns seen in the pulmonary and systemic circuits of the cardiovascular system.
- 21-6 Identify the major arteries and veins of the pulmonary circuit.
- 21-7 Identify the major arteries and veins of the systemic circuit.
- **21-8** Identify the differences between fetal and adult circulation patterns, and describe the changes in the patterns of blood flow that occur at birth.
- **21-9** Discuss the effects of aging on the cardiovascular system, and give examples of interactions between the cardiovascular system and other organ systems.

SPOTLIGHT

CLINICAL CASE

Did Ancient Mummies Have Atherosclerosis?

Dr. lacullo is part of a research team studying ancient mummies from Egypt, Peru, New Mexico, and the Aleutian Islands in Alaska. The study spans 4000 years of human history and cultures from three different continents. Some of the mummies were once members of Egypt's upper class, while others were likely common people from the Americas. Their diets varied greatly and included nuts, berries, farmed corn, domesticated animals, wild game, sea otters, and whales. Their activity patterns varied the wealthy Egyptians, for instance, were much more sedentary than the hunter-gatherers of the Americas.

Dr. lacullo is studying the incidence of atherosclerosis (the buildup of arterial plaque) in mummies. Her team uses

computerized tomography (CT) scans to look for calcifications in the walls of the mummies' arteries. They discover that one-third of the mummies have CT evidence of plaque buildup. This finding spans all four geographic populations, all diets, and all lifestyle activity levels. Why do you think these ancient people developed atherosclerosis, which

today we usually associate with the

unhealthy diet and inactivity of a modern lifestyle? To find out, turn to the Clinical Case Wrap-Up on p. 780.

An Introduction to Blood Vessels and Circulation

Blood circulates throughout the body, moving from the heart through the tissues and back to the heart, in blood vessels. In this chapter we examine the organization of blood vessels and consider the integrated functions of the cardiovascular system as a whole. We begin with a description of the histological organization of arteries, capillaries, and veins. Then we explore the functions of these vessels, the basic principles of cardiovascular regulation, and the distribution of major blood vessels in the body. We will then be ready to consider the organization and function of the lymphatic system, the focus of Chapter 22.

21-1 Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and functional properties

Learning Outcome Distinguish among the types of blood vessels based on their structure and function, and describe how and where fluid and dissolved materials enter and leave the cardiovascular system.

The cardiovascular system has five general classes of blood vessels. **Arteries** carry blood away from the heart. As they enter peripheral tissues, arteries branch repeatedly, and the branches decrease in diameter. The smallest arterial branches are called **arterioles** (ar-TĒR-ē-ols). From the arterioles, blood moves into **capillaries**, where diffusion takes place between blood and interstitial fluid. From the capillaries, blood enters small **venules** (VEN-ūls), which unite to form larger **veins** that return blood to the heart. Blood leaves the heart through the pulmonary trunk, which originates at the right ventricle, and the aorta, which originates at the left ventricle. Each of these arterial trunks has an internal diameter of about 2.5 cm (1 in.). The pulmonary arteries that branch from the pulmonary trunk carry blood to the lungs. The systemic arteries that branch from the aorta distribute blood to all other organs. Within these organs, the vessels branch into several hundred million tiny arterioles that provide blood to more than 10 billion capillaries within their own branching networks. These capillaries are barely the diameter of a single red blood cell. If all the capillaries in your body were placed end to end, their combined length would be more than 25,000 miles, enough to circle the planet.

The vital functions of the cardiovascular system depend entirely on events at the capillary level: All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls. Cells rely on capillary diffusion to obtain nutrients and oxygen and to remove metabolic wastes, such as carbon dioxide and urea. Diffusion takes place very rapidly, because the distances involved are very short. Few cells lie farther than 125 μ m (0.005 in.) from a capillary. As we will see, homeostatic mechanisms operating at the local, regional, and systemic levels adjust blood flow through the capillaries to meet the demands of peripheral tissues.

Blood vessels must be resilient enough to withstand changes in pressure, and flexible enough to move with underlying tissues and organs. The pressures inside vessels vary with distance from the heart, and the structures of different vessels reflect this fact. The arteries, veins, and capillaries also differ in function, and these functional differences are associated with distinctive anatomical features.

The Structure of Vessel Walls

The walls of arteries and veins have three distinct layers—the tunica intima, tunica media, and tunica externa (Figure 21–1):

- 1. The **tunica intima** (IN-ti-muh), or *tunica interna*, is the inner layer of a blood vessel. It includes the endothelial lining and a surrounding layer of connective tissue with a variable number of elastic fibers. In arteries, the outer margin of the tunica intima contains a thick layer of elastic fibers called the **internal elastic membrane**.
- 2. The **tunica media** is the middle layer of a blood vessel. It contains concentric sheets of smooth muscle tissue in a framework of loose connective tissue. The collagen fibers bind the tunica media to the tunica intima and tunica externa. The tunica media is commonly the thickest layer in a small artery. It is separated from the surrounding tunica

externa by a thin band of elastic fibers called the **external elastic membrane**. The smooth muscle cells of the tunica media encircle the endothelium that lines the lumen of the blood vessel. When these smooth muscles contract, the vessel decreases in diameter, and when they relax, the diameter increases. Large arteries also contain layers of longitudinally arranged smooth muscle cells.

3. The **tunica externa** (eks-TER-nuh), or *tunica adventitia* (ad-ven-TISH-uh), is the outer layer of a blood vessel. It is a connective tissue sheath. In arteries, it contains collagen fibers with scattered bands of elastic fibers. In veins, it is generally thicker than the tunica media and contains networks of elastic fibers and bundles of smooth muscle cells. The connective tissue fibers of the tunica externa typically blend into those of adjacent tissues, stabilizing and anchoring the blood vessel.

Figure 21–1 Comparisons of a Typical Artery and a Typical Vein.

Feature	Typical Artery	Typical Vein
GENERAL APPEARANCE IN SECTIONAL VIEW	Usually round, with relatively thick wall	Usually flattened or collapsed, with relatively thin wall
TUNICA INTIMA		
Endothelium	Usually rippled, due to vessel constriction	Often smooth
Internal elastic membrane	Present	Absent
TUNICA MEDIA	Thick, dominated by smooth muscle cells and elastic fibers	Thin, dominated by smooth muscle cells and collagen fibers
External elastic membrane	Present	Absent

Their layered walls give arteries and veins considerable strength. The muscular and elastic components also permit controlled changes in diameter as blood pressure or blood volume changes. However, the walls of arteries and veins are too thick to allow diffusion between the bloodstream and surrounding tissues, or even between the blood and the tissues of the vessel itself. For this reason, the walls of large vessels contain small arteries and veins that supply the smooth muscle cells and fibroblasts of the tunica media and tunica externa. These blood vessels are called the **vasa vasorum** ("vessels of vessels").

Differences between Arteries and Veins

Arteries and veins supplying the same region lie side by side (Figure 21–1). In sectional view, you can distinguish arteries and veins by the following features:

- *Vessel walls* In general, the walls of arteries are thicker than those of veins. The tunica media of an artery contains more smooth muscle and elastic fibers than does that of a vein. These components help resist the arterial pressure generated by the heart as it pumps blood into the pulmonary trunk and aorta.
- *Vessel lumen* When not opposed by blood pressure, the elastic fibers in the arterial walls recoil, constricting the lumen. Thus, seen on dissection or in sectional view, the lumen of an artery often looks smaller than that of the corresponding vein. Because the walls of arteries are relatively thick and strong, they keep their circular shape when sectioned. In contrast, cut veins tend to collapse. In section, these veins often look flattened or grossly distorted.
- Vessel lining The endothelial lining of an artery cannot contract, so when an artery constricts, its endothelium becomes folded and the sectioned arteries have a pleated appearance. The lining of a vein lacks these folds.

In gross dissection, arteries and veins can generally be distinguished because:

- The thicker walls of arteries can be felt if the vessels are compressed.
- Arteries usually keep their cylindrical shape, but veins often collapse.
- Arteries are more resilient: When stretched, they keep their shape and lengthen. When released, they snap back. A small vein cannot tolerate as much distortion without collapsing or tearing.
- Veins typically contain *valves*—internal structures that prevent the backflow of blood toward the capillaries. In an intact vein, the location of each valve is marked by a slight distension of the vessel wall. (We consider valve structure in a later section.)

Arteries

Their relatively thick, muscular walls make arteries elastic and contractile. Elasticity permits the vessel diameter to change passively in response to changes in blood pressure. For example, it allows arteries to absorb the surging pressure waves that accompany the contractions of the ventricles.

The contractility of the arterial walls enables them to actively change diameter. This change takes place primarily under the control of the sympathetic division of the autonomic nervous system. When stimulated, arterial smooth muscles contract, constricting the artery—a process called **vasoconstriction**. When these smooth muscles relax, the diameter of the lumen increases—a process called **vasodilation**. Vasoconstriction and vasodilation affect (1) the afterload on the heart, (2) peripheral blood pressure, and (3) capillary blood flow. We explore these effects in a later section. Contractility is also important during the vascular phase of hemostasis, when the contraction of a damaged vessel wall helps reduce bleeding. \supset **p**. 675

In traveling from the heart to peripheral capillaries, blood passes through *elastic arteries, muscular arteries,* and *arterioles* (Figure 21–2).

Elastic Arteries

Elastic arteries are also known as *conducting arteries* because they carry large volumes of blood away from the heart. They are large vessels with diameters up to 2.5 cm (1 in.) (Figure 21–2). The pulmonary trunk and aorta, as well as their major branches (the *pulmonary, common carotid, subclavian,* and *common iliac arteries*), are elastic arteries.

The walls of elastic arteries are extremely resilient because the tunica media contains a high density of elastic fibers and relatively few smooth muscle cells. As a result, elastic arteries can tolerate the pressure changes of the cardiac cycle. We have already seen that elastic rebound in the aorta helps to maintain blood flow in the coronary arteries. \bigcirc p. 695 Elastic rebound also occurs to some degree in all elastic arteries. During ventricular systole, pressures rise rapidly and the elastic arteries expand as the stroke volume is ejected. During ventricular diastole, blood pressure within the arterial system falls and the elastic fibers recoil to their original dimensions. Their expansion cushions the sudden rise in pressure during ventricular diastole. In this way, elastic arteries help to make blood flow continuous.

This function is important because blood pressure is the driving force behind blood flow: The greater the fluctuations in pressure, the greater the changes in blood flow. The elasticity of the arterial system dampens the pressure peaks and valleys that accompany the heartbeat. By the time blood reaches the arterioles, the pressure fluctuations have disappeared, and blood flow is continuous.

Figure 21–2 Histological Structure of Blood Vessels. Representative diagrammatic views of arteries, veins, and capillaries.

Clinical Note

Arteriosclerosis Arteriosclerosis (ar-tēr-ē-ō-skler-Ō-sis; arterio-, artery + sklerosis, hardness) is a thickening and toughening of arterial walls. Complications related to arteriosclerosis account for about half of all deaths in the United States. For example, arteriosclerosis of coronary vessels is responsible for *coronary artery disease (CAD)*, and arteriosclerosis of arteries supplying the brain can lead to strokes. D p. 698 Arteriosclerosis takes two major forms:

- 1. Focal calcification is the deposition of calcium salts following the gradual degeneration of smooth muscle in the tunica media. Some focal calcification is a part of the aging process. It may also develop in association with atherosclerosis (described next).
- 2. Atherosclerosis (ath-er-ō-skler-Ō-sis; athero-, fatty degeneration) is the formation of lipid deposits in the tunica media associated with damage to the endothelial lining. It is the most common form of arteriosclerosis.

Atherosclerosis tends to develop in people whose blood contains elevated levels of plasma lipids—specifically, cholesterol. Circulating cholesterol is transported to peripheral tissues in *lipoproteins*, which are protein–lipid complexes. (We will discuss the various types of lipoproteins in Chapter 25.)

When plasma cholesterol levels are chronically elevated, cholesterol-rich lipoproteins remain in circulation for an extended period. Circulating monocytes then begin removing them from the bloodstream. Eventually, the monocytes become filled with lipid droplets. Now called *foam cells*, they attach themselves to the endothelial lining of blood vessels. There they release cytokines. These growth factors stimulate smooth muscle cells near the tunica intima to divide, thickening the vessel wall. Other monocytes then invade the area, migrating between the endothelial cells. As these changes take place, the monocytes, smooth muscle cells, and endothelial cells begin phagocytizing lipids as well. The result is an atherosclerotic **plaque**, a fatty mass of tissue that projects into the lumen of the vessel. At this point, the plaque has a relatively simple structure, and evidence suggests that the process can be reversed with appropriate dietary adjustments.

If the conditions persist, the endothelial cells become swollen with lipids, and gaps appear in the endothelial lining. Platelets now begin sticking to the exposed collagen fibers, forming a localized blood clot that restricts arterial blood flow. The structure of the plaque is now relatively complex.

A typical plaque is shown in Figures a and b. Elderly people—especially elderly men—are most likely to develop atherosclerotic plaques. Estrogen may slow plaque formation. This may account for the lower incidence of CAD, myocardial infarctions (MIs), and strokes in women. After menopause, when estrogen production decreases, the risks of CAD, MIs, and strokes in women increase markedly.

In addition to advanced age and male sex, other important risk factors for atherosclerosis include high blood cholesterol levels, high blood pressure, and cigarette smoking. About 20 percent of middle-aged men have all three of these risk factors. They are four times more likely to experience an MI or a cardiac arrest than other men in their age group. Fewer women develop atherosclerotic plaques, but elderly female smokers with high blood cholesterol and high blood pressure are at much greater risk than other women. Diabetes mellitus, obesity, and stress can promote the development of atherosclerosis in both men and women. Evidence also indicates that at least some forms of atherosclerosis may be linked

Muscular Arteries

Muscular arteries, or *medium-sized arteries*, are also known as *distribution arteries* because they distribute blood to the body's skeletal muscles and internal organs. Most of the vessels of the arterial system are muscular arteries. They are characterized by a thick tunica media. It contains more smooth muscle cells than does the tunica media of elastic arteries (Figures 21–1 and 21–2). A typical muscular artery has a lumen diameter of approximately 0.4 cm (0.16 in.), but some have diameters as small as 0.05 cm. The *external carotid arteries* of the neck, the *brachial arteries* of the arms, the *mesenteric arteries* of the abdomen, and the *femoral arteries* of the thighs are examples of muscular arteries. Superficial muscular arteries are important as *pressure points*—places in the body where muscular arteries can be pressed against deeper bones to reduce blood flow and control severe bleeding. Major arterial pressure points are the

common carotid, radial, brachial, femoral, popliteal, posterior tibial, and dorsal pedal.

Arterioles

Arterioles, with an internal diameter of 30 μ m or less, are considerably smaller than muscular arteries. Arterioles have a poorly defined tunica externa. In the larger arterioles, the tunica media consists of one or two layers of smooth muscle cells (Figure 21–2). In the smallest arterioles, the tunica media contains scattered smooth muscle cells that do not form a complete layer.

The diameters of smaller muscular arteries and arterioles change in response to local conditions or to sympathetic or endocrine stimulation. For example, arterioles in most tissues vasodilate when oxygen levels are low. Also, as we saw in Chapter 16, arterioles vasoconstrict under sympathetic

Plaque deposit in vessel wall

b A section of a coronary artery narrowed by a plaque

to chronic infection with *Chlamydia pneumoniae*, a bacterium responsible for several types of respiratory infections, including some forms of pneumonia.

We discussed potential treatments for atherosclerotic plaques, such as catheterization with balloon angioplasty and stenting, and bypass surgery, in Chapter 20. \bigcirc p. 699 In the many cases where changes in diet do not lower circulating cholesterol levels sufficiently, drug therapies can bring them under control. Genetic engineering techniques have been used to treat an inherited form of *hypercholesterolemia* (high blood cholesterol) linked to extensive plaque formation. (People with this condition are unable to absorb and recycle

stimulation. \bigcirc p. 541 Changes in their diameter affect the amount of force required to push blood around the cardiovascular system: More pressure is required to push blood through a constricted vessel than through a dilated one. The force opposing blood flow is called **resistance (R)**, so arterioles are also called **resistance vessels**.

Vessel characteristics change gradually with distance from the heart. Each type of vessel described here actually represents the midpoint in a portion of a continuum. Thus, the largest muscular arteries contain a considerable amount of elastic tissue, and the smallest resemble heavily muscled arterioles.

Arteries carry blood under great pressure, and their walls are adapted to handle that pressure. Occasionally, local arterial pressure exceeds the capacity of the elastic components of the tunics. The result is an **aneurysm** (AN-yū-rizm), or bulge in the weakened wall of an artery. The bulge is like a bubble in the wall of a tire—and like a bad tire, the artery can suffer a catastrophic cholesterol in the liver.) In this experimental procedure, circulating cholesterol levels declined after copies of appropriate genes were inserted into some of the individual's liver cells.

Without question, the best approach to atherosclerosis is to avoid it by eliminating or reducing associated risk factors. Suggestions include (1) reducing your intake of dietary cholesterol, saturated fats, and trans fatty acids by restricting consumption of fatty meats (such as beef, lamb, and pork), egg yolks, and cream; (2) not smoking; (3) checking your blood pressure and taking steps to lower it if necessary; (4) having your blood cholesterol levels checked annually; (5) controlling your weight; and (6) exercising regularly.

blowout. The most dangerous aneurysms occur in arteries of the brain (where they cause strokes) or in the aorta (where a rupture will cause fatal bleeding in a matter of minutes).

Capillaries

When we think of the cardiovascular system, we think first of the heart or the great blood vessels connected to it. But the microscopic capillaries that permeate most tissues do the real work of the cardiovascular system. These delicate vessels weave throughout active tissues, forming intricate networks that surround muscle fibers. Capillaries radiate through connective tissues, and branch beneath the basement membrane of epithelia.

Capillaries are the *only* blood vessels whose walls permit exchange between the blood and the surrounding interstitial fluids. Exchange can take place quickly because capillary walls are thin and diffusion distances are short. In addition, blood flows through capillaries relatively slowly, allowing sufficient time for the diffusion or active transport of materials across the capillary walls. In this way, the histological structure of capillaries permits a two-way exchange of substances between blood and interstitial fluid.

A typical capillary consists of an endothelial tube inside a thin basement membrane. Neither a tunica media nor a tunica externa is present (Figure 21–2). The average diameter of a capillary is a mere 8 μ m, very close to that of a single red blood cell. The two major types of capillaries are *continuous capillaries* and *fenestrated capillaries*.

Continuous Capillaries

Continuous capillaries supply most regions of the body. In a **continuous capillary**, the endothelium is a complete lining. A cross section through a large continuous capillary cuts across several endothelial cells (Figure 21–3a). In a small continuous capillary, a single endothelial cell may completely encircle the lumen.

Continuous capillaries are located in all tissues except epithelia and cartilage. Continuous capillaries permit the water, small solutes, and lipid-soluble materials to diffuse into the interstitial fluid. At the same time, they prevent the loss of blood cells and plasma proteins. In addition, some exchange may occur between blood and interstitial fluid by *bulk transport*— the movement of materials by endocytosis (by endosomes) or exocytosis at the inner endothelial surface. \supset p. 96

In specialized continuous capillaries in most of the central nervous system and in the thymus, the endothelial cells are bound together by tight junctions. These capillaries have very restricted permeability. We discussed one example—the capillaries responsible for the *blood-brain barrier*—in Chapters 12 and 14. \bigcirc pp. 393, 469

Fenestrated Capillaries

Fenestrated (FEN-es-trā-ted; *fenestra*, window) **capillaries** contain "windows," or pores, that penetrate the endothelial lining (Figure 21–3b). The pores allow rapid exchange of water and solutes between blood and interstitial fluid. Examples of fenestrated capillaries include the *choroid plexus* of the brain and the blood vessels in a variety of endocrine organs, such as the hypothalamus and the pituitary, pineal, and thyroid glands. Fenestrated capillaries are also found along absorptive areas of

Figure 21–3 Capillary Structure.

the intestinal tract and at filtration sites in the kidneys. Both the number of pores and their permeability characteristics may vary from one region of the capillary to another.

Sinusoids (SĪ-nuh-soydz), also called **sinusoidal capillaries**, resemble fenestrated capillaries that are flattened and irregularly shaped (Figure 21–3c). In addition to being fenestrated, sinusoids commonly have gaps between adjacent endothelial cells, and the basement membrane is either thinner or absent. As a result, sinusoids permit the free exchange of water and solutes as large as plasma proteins between blood and interstitial fluid.

Blood moves through sinusoids relatively slowly, maximizing the time available for exchange across the sinusoidal walls. Sinusoids occur in the liver, bone marrow, spleen, and many endocrine organs, including the pituitary and adrenal glands. At liver sinusoids, plasma proteins secreted by liver cells enter the bloodstream. Along sinusoids of the liver, spleen, and bone marrow, phagocytic cells monitor the passing blood, engulfing damaged red blood cells, pathogens, and cellular debris.

Capillary Beds

Capillaries function not as individual units, but rather, as part of an interconnected network called a **capillary bed**, or

Figure 21–4 The Organization of a Capillary Bed.

capillary plexus (Figure 21–4). A single arteriole generally gives rise to dozens of capillaries. They empty into several *venules*, the smallest vessels of the venous system. A **precapillary sphincter** guards the entrance to each capillary. Contraction of the smooth muscle cells of this sphincter narrows the capillary entrance, reducing or stopping the flow of blood. When one precapillary sphincter constricts, blood is diverted into other branches of the network. When a precapillary sphincter relaxes, the entrance dilates, and blood flows into the capillary.

A capillary bed contains several direct connections between arterioles and venules. The wall in the first part of such a passageway contains smooth muscle that can change its diameter. This segment is called a **metarteriole** (met-ar-TĒR-ē-ōl) or **precapillary arteriole**. The rest of the passageway resembles a typical capillary in structure and is called a **thoroughfare channel**.

More than one artery may supply blood to a capillary bed. The multiple arteries are called **collaterals**. They fuse before giving rise to arterioles. The fusion of two collateral arteries that supply a capillary bed is an example of an **arterial anastomosis**. (An *anastomosis* is the joining of blood vessels.) The interconnections between the *anterior* and *posterior interventricular arteries* of the heart are arterial anastomoses. \supset **p**. 696 An arterial

b A micrograph of a number of capillary beds.

21

anastomosis acts like an insurance policy: If one artery is compressed or blocked, capillary circulation will continue.

Arteriovenous (ar-tēr-ē-o-VĒ-nus) **anastomoses** are direct connections between arterioles and venules. When an arteriovenous anastomosis is dilated, blood bypasses the capillary bed and flows directly into the venous circulation. The pattern of blood flow through an arteriovenous anastomosis is regulated primarily by sympathetic innervation under the control of the cardiovascular center of the medulla oblongata.

Angiogenesis (an-jē-ō-JEN-e-sis; *angio*-, blood vessel + *genesis*, production) is the formation of new blood vessels from pre-existing vessels and occurs under the direction of **vascular endothelial growth factor (VEGF)**. Angiogenesis occurs in the embryo as tissues and organs develop. It may also occur at other times in any body tissue in response to factors released by cells that are *hypoxic*, or oxygen-starved. Clinically, angiogenesis is probably most important in cardiac muscle, where it takes place in response to a chronically constricted or occluded vessel.

Vasomotion

Although blood normally flows from arterioles to venules at a constant rate, the flow within each capillary is quite variable. Each precapillary sphincter alternately contracts and relaxes, perhaps a dozen times per minute. These rhythmic changes in vessel diameter are called **vasomotion**. As a result, the blood flow within any capillary occurs in pulses rather than as a steady and constant stream. The net effect is that blood may reach the venules by one route now and by a different route later.

Vasomotion is controlled locally by changes in the concentrations of chemicals and dissolved gases in the interstitial fluids. For example, when dissolved oxygen concentrations decrease within a tissue, the capillary sphincters relax, so blood flow to the area increases. This process is an example of capillary *autoregulation*. We focus on it in a later section.

When you are at rest, blood flows through about 25 percent of the vessels within a typical capillary bed in your body. Your cardiovascular system does not contain enough blood to maintain adequate blood flow to all the capillaries in all the capillary beds in your body at the same time. As a result, when many tissues become active, the blood flow through capillary beds must be coordinated. We describe the mechanisms by which the cardiovascular center performs this coordination later in the chapter.

Veins

Veins collect blood from all tissues and organs and return it to the heart. The walls of veins can be thinner than those of corresponding arteries because the blood pressure in veins is lower than that in arteries. We classify veins on the basis of their size. Even though their walls are thinner, in general veins are larger in diameter than their corresponding arteries. (Review Figure 21–2 to compare typical arteries and veins.)

Venules

Venules are the smallest venous vessels. They collect blood from capillary beds. They vary widely in size and structure. An average venule has an internal diameter of roughly 20 μ m. Venules smaller than 50 μ m lack a tunica media, and the smallest venules resemble expanded capillaries.

Medium-Sized Veins

Medium-sized veins are comparable in size to muscular arteries. They range from 2 to 9 mm in internal diameter. Their tunica media is thin and contains relatively few smooth muscle cells. The thickest layer of a medium-sized vein is the tunica externa, which contains longitudinal bundles of elastic and collagen fibers.

Large Veins

Large veins include the superior and inferior venae cavae and their branches within the abdominopelvic and thoracic cavities. All large veins have all three layers. The slender tunica media is surrounded by a thick tunica externa composed of a mixture of elastic and collagen fibers.

Venous Valves

The arterial system is a high-pressure system: Almost all the force developed by the heart is required to push blood along the network of arteries and through miles of capillaries. Blood pressure in a peripheral venule is only about 10 percent of that in the ascending aorta, and pressures continue to fall along the venous system.

The blood pressure in venules and medium-sized veins is so low that it cannot overcome the force of gravity. In the limbs, veins of this size contain **valves**, folds of the tunica intima that project from the vessel wall and point in the direction of blood flow. These valves, like those in the heart, permit blood flow in one direction only. Venous valves prevent blood from moving back toward the capillaries (Figure 21–5).

As long as the valves function normally, any movement that distorts or compresses a vein pushes blood toward the heart. This effect improves *venous return*, the rate of blood flow to the heart. \bigcirc p. 714 The mechanism is particularly important when you are standing, because blood returning from your feet must overcome gravity to ascend to the heart. Valves compartmentalize the blood within the veins, dividing the weight of the blood among the compartments. Any contraction of the surrounding skeletal muscles squeezes the blood toward the heart. Although you are probably not aware of it, when you stand, rapid cycles of contraction and relaxation occur within your leg muscles, helping to push blood toward the trunk. When you lie down, venous valves play a smaller part in venous return, because your heart and major vessels are at the same level.

The Distribution of Blood in the Cardiovascular

Figure 21–5 The Function of Valves in the Venous System.

noral ateles 30 Large veins Parone 1 collates 29 18% Systemic venous system $6_{4_{0_{o}}}$ Pulmonary vains 4% Large venous Heart 7% networks (liver. bone marrow, skin) Heart 7 21% Aorta 2% Elastic arteries 4% Muscular arteries 5% Venules and medium-sized veins 25% Systemic capillaries 7%

Figure 21–6

If the walls of the veins near the valves weaken or become stretched and distorted, the valves may not work properly. Blood then pools in the veins, and the vessels become grossly distended. The effects range from mild discomfort and a cosmetic problem, as in superficial **varicose veins** in the thighs and legs, to painful distortion of adjacent tissues, as in **hemorrhoids**.

The Distribution of Blood

Our total blood volume is unevenly distributed among arteries, veins, and capillaries (Figure 21–6). The heart, arteries, and capillaries in the pulmonary and systemic circuits normally contain 30–35 percent of the blood volume (roughly 1.5 liters of whole blood). The venous system contains the rest (65–70 percent, or about 3.5 liters). About one-third of the blood in the venous system (about a liter) is circulating within the liver, bone marrow, and skin. These organs have extensive venous networks that at any moment contain large volumes of blood.

Veins are much more *distensible*, or expandable, than arteries because their walls are thinner, with less smooth muscle. For a given rise in blood pressure, a typical vein stretches about eight times as much as a corresponding artery. The *capacitance* of a blood vessel is the relationship between the volume of blood it contains and the blood pressure. If a vessel behaves like a balloon, expanding easily at low pressures, it has high capacitance. If it behaves more like a truck tire, expanding only at high pressures, it has low capacitance. Veins, which expand easily, are called **capacitance vessels**. Because veins have high capacitance, they can accommodate large changes in blood volume. If the blood volume rises or falls, the elastic walls stretch or recoil, changing the volume of blood in the venous system.

If serious hemorrhaging (blood loss) occurs, the *vasomotor center* of the medulla oblongata stimulates sympathetic nerves that innervate smooth muscle cells in the walls of medium-sized veins. This activity has two major effects:

- Systemic veins constrict. This process, called venoconstriction (vē-nō-kon-STRIK-shun), decreases the amount of blood within the venous system, increasing the volume within the arterial system and capillaries. Venoconstriction can keep the blood volume within the arteries and capillaries at near-normal levels despite a significant blood loss.
- 2. The constriction of veins in the liver, skin, and lungs redistributes a significant proportion of the total blood volume. As a result, blood flow to delicate organs (such as the brain) and to active skeletal muscles can be increased or maintained after blood loss. The amount of blood that can be shifted from veins in the liver, skin, and lungs to the general circulation is called the **venous reserve**. It is normally about 20 percent of total blood volume.

CHECKPOINT

- 1. List the five general classes of blood vessels.
- 2. Which type of vessel is characterized by thin walls with very little smooth muscle tissue in the tunica media?
- 3. Why are valves located in veins but not in arteries?
- 4. Where in the body would you find fenestrated capillaries?

- See the blue Answers tab at the back of the book.

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange

Learning Outcome Explain the mechanisms that regulate blood flow through vessels, describe the factors that influence blood pressure, and discuss the mechanisms that regulate movement of fluids between capillaries and interstitial spaces.

The purpose of cardiovascular regulation is the maintenance of adequate blood flow through the capillaries in peripheral tissues and organs. Under normal circumstances, blood flow is equal to cardiac output. When cardiac output goes up, so does the blood flow through capillary beds, and when cardiac output declines, capillary blood flow is reduced.

Capillary blood flow is determined by the interplay between *pressure (P)* and *resistance (R)* in the cardiovascular network. To keep blood moving, the heart must generate enough pressure to overcome the resistance to blood flow in the pulmonary and systemic circuits. In general terms, flow (*F*) is directly proportional to the pressure (increased pressure \rightarrow increased flow), and inversely proportional to resistance (increased resistance \rightarrow decreased flow). However, the absolute pressure is less important than the pressure *gradient*—the difference in pressure from one end of the vessel to the other. This relationship can be summarized as

$$F \propto \frac{\Delta P}{R}$$

where the symbol \propto means "is proportional to" and Δ means "the difference in." The largest pressure gradient is found between the base of the aorta and the proximal ends of peripheral capillary beds. The cardiovascular center can alter this pressure gradient, and change the rate of capillary blood flow, by adjusting cardiac output and peripheral resistance.

Blood leaving the peripheral capillaries enters the venous system. The pressure gradient across the venous system is relatively small, but venous resistance is very low. The low venous blood pressure—aided by valves, skeletal muscle contraction, gravity, and other factors—is enough to return the blood to the heart. When necessary, cardiovascular control centers can raise venous pressure (through venoconstriction) to improve venous return and maintain adequate cardiac output. We will begin this section by examining blood pressure and resistance more closely. We will then consider the mechanisms of *capillary exchange*, the transfer of liquid and solutes between the blood and interstitial fluid. Capillary exchange provides tissues with oxygen and nutrients and removes the carbon dioxide and waste products generated by active cells.

Active tissues need more blood flow than inactive ones. Even something as simple as a change in position—going from sitting to standing, for instance—triggers a number of cardiovascular changes. We will end this section with a discussion of what those changes are and how they are coordinated.

Pressure

When talking about cardiovascular pressures, three values are usually reported:

- Blood Pressure. The term blood pressure (BP) refers to arterial pressure, usually reported in millimeters of mercury (mm Hg). Systemic arterial pressures in adults average 120 mm Hg at the entrance to the aorta to roughly 35 mm Hg at the start of a capillary network.
- Capillary Hydrostatic Pressure. Hydrostatic pressure is the force exerted by a fluid pressing against a wall. Capillary hydrostatic pressure (CHP), or capillary pressure, is the pressure within capillary walls. Along the length of a typical capillary, pressures decline from roughly 35 mm Hg to about 18 mm Hg.
- 3. *Venous Pressure*. **Venous pressure** is the pressure within the venous system. Venous pressure is quite low: The pressure gradient from the venules to the right atrium is only about 18 mm Hg.

The difference in pressure (ΔP) across the entire systemic circuit, sometimes called the *circulatory pressure*, averages about 100 mm Hg. For circulation to occur, the circulatory pressure must overcome the **total peripheral resistance**—the resistance of the entire cardiovascular system. The arterial network has by far the largest pressure gradient (85 mm Hg), and this primarily reflects the relatively high resistance of the arterioles.

Total Peripheral Resistance

The total peripheral resistance of the cardiovascular system reflects a combination of factors: *vascular resistance*, *blood viscosity*, and *turbulence* (Figure 21–7).

Vascular Resistance

Vascular resistance, the forces that oppose blood flow in the blood vessels, is the largest component. The most important factor in vascular resistance is friction between blood and the vessel walls. The amount of friction depends on two factors: vessel length and vessel diameter.

Figure 21–7 Factors Affecting Friction and Vascular Resistance.

Vessel Length. Increasing the length of a blood vessel increases friction: The longer the vessel, the greater the surface area in contact with blood. You can easily blow the water out of a snorkel that is 2.5 cm (1 in.) in diameter and 25 cm (10 in.) long, but you cannot blow the water out of a 15 m (16 yard) long garden hose, because the total friction is too great. The most dramatic changes in blood vessel length occur between birth and maturity, as individuals grow to adult size.

In adults, vessel length can increase or decrease gradually when individuals gain or lose weight, but on a day-to-day basis this component of vascular resistance can be considered constant.

Vessel Diameter. The effects of friction on blood act in a narrow zone closest to the vessel wall. In a small-diameter vessel, friction with the walls slows nearly all the blood. Resistance is therefore relatively high. Blood near the center of a large-diameter vessel does not encounter friction with the walls, so the resistance in large vessels is fairly low.

Differences in diameter have much more significant effects on resistance than do differences in length. If two vessels are equal in radius (one-half the diameter) but one is twice as long as the other, the longer vessel offers twice as much resistance to blood flow. But for two vessels of equal length, one twice the radius of the other, the narrower one offers 16 times as much resistance to blood flow. This relationship, expressed in terms of the vessel radius *r* and resistance *R*, can be summarized as $R \propto 1/r^4$.

More significantly, there is no way to control vessel length, but vessel diameter can change quickly through vasoconstriction or vasodilation. Most of the peripheral resistance occurs in arterioles, the smallest vessels of the arterial system. As noted earlier in the chapter, arterioles are extremely muscular: The wall of an arteriole with an inner diameter of 30 μ m can have a 20- μ m-thick layer of smooth muscle. When these smooth muscles contract or relax, peripheral resistance increases or decreases. Because a small change in diameter produces a large change in resistance, mechanisms that alter the diameters of arterioles provide control over peripheral resistance and blood flow.

Blood Viscosity

Viscosity is the resistance to flow caused by interactions among molecules and suspended materials in a liquid. Liquids of low viscosity, such as water (viscosity 1.0), flow at low pressures. Thick, syrupy fluids, such as molasses (viscosity 300), flow only under higher pressures. Whole blood has a viscosity about five times that of water, due to its plasma proteins and blood cells. Under normal conditions, the viscosity of blood remains stable. Anemia, polycythemia, and other disorders that affect the hematocrit also change blood viscosity, and thus peripheral resistance.

Turbulence

High flow rates, irregular surfaces, and sudden changes in vessel diameter upset the smooth flow of blood, creating eddies and swirls. This phenomenon, called **turbulence**, increases resistance and slows blood flow.

Turbulence normally occurs when blood flows between the atria and the ventricles, and between the ventricles and the aortic and pulmonary trunks. It also develops in large arteries, such as the aorta, when cardiac output and arterial flow rates are very high. However, turbulence seldom occurs in smaller vessels unless their walls are damaged. For example, an atherosclerotic plaque creates abnormal turbulence and restricts blood flow. Because turbulence makes a distinctive sound, or *bruit* (brū- \bar{E}), plaques in large blood vessels can often be detected with a stethoscope.

Table 21–1 provides a review of the terms and relationships discussed in this section.

An Overview of Cardiovascular Pressures

Look at the graphs in Figure 21–8 for an overview of the vessel diameters, cross-sectional areas, pressures, and velocity of blood flow in the systemic circuit.

- *Vessel Diameters*. As blood proceeds from the aorta toward the capillaries, vessels diverge. The arteries branch repeatedly, and each branch is smaller in diameter than the preceding one (Figure 21–8a). As blood proceeds from the capillaries toward the venae cavae, vessels converge. Vessel diameters increase as venules combine to form small and medium-sized veins.
- *Total Cross-Sectional Areas.* Although the arterioles, capillaries, and venules are small in diameter, the body has large numbers of them. All the blood flowing through the aorta also flows through peripheral capillaries. Blood pressure

and the speed of blood flow are proportional to the crosssectional area of the vessels involved. What is important is not the cross-sectional area of each individual vessel, but the *combined* cross-sectional area of *all* the vessels (Figure 21–8b). In effect, your blood moves from one big pipe (the aorta, with a cross-sectional area of 4.5 cm²) into countless tiny ones (the peripheral capillaries, with a total cross-sectional area of 5000 cm²), and then blood travels back to the heart through two large pipes (the venae cavae).

- Pressures. As arteries branch, their total cross-sectional area increases, and blood pressure falls rapidly (Figure 21–8c). Most of the decline takes place in the small arteries and arterioles. Venous pressures are relatively low.
- Velocity of Blood Flow. As the total cross-sectional area of the vessels increases from the aorta toward the capillaries, the velocity of blood flow decreases (Figure 21–8d). Blood flow velocity then increases as the total cross-sectional area drops from the capillaries toward the venae cavae.

Figure 21–9 graphs the blood pressure throughout the cardiovascular system. Systemic pressures are highest in the aorta, peaking at about 120 mm Hg. Pressures reach a minimum of 2 mm Hg at the entrance to the right atrium. Pressures in the pulmonary circuit are much lower than those in the systemic circuit. The right ventricle does not ordinarily develop high pressures because the pulmonary vessels are much shorter and more distensible than the systemic vessels, thus providing less resistance to blood flow.

Table 21–1 Key Terms and	Relationships Pertaining to Blood Circulation			
Blood Flow (F)	The volume of blood flowing per unit of time through a vessel or a group of vessels; may refer to circulation through a capillary, a tissue, an organ, or the entire vascular network. Total blood flow is equal to cardiac output.			
Blood Pressure (BP)	The hydrostatic pressure in the arterial system that pushes blood through capillary beds.			
Circulatory Pressure	The pressure difference between the base of the ascending aorta and the entrance to the right atrium.			
Hydrostatic Pressure	A pressure exerted by a liquid in response to an applied force.			
Peripheral Resistance (PR)	The resistance of the arterial system; affected by such factors as vascular resistance, viscosity, and turbulence.			
Resistance (R)	A force that opposes movement (in this case, blood flow).			
Total Peripheral Resistance	The resistance of the entire cardiovascular system.			
Turbulence	A resistance due to the irregular, swirling movement of blood at high flow rates or exposure to irregular surfaces.			
Vascular Resistance	A resistance due to friction within a blood vessel, primarily between the blood and the vessel walls. Increases with increasing length or decreasing diameter; vessel length is constant, but vessel diameter can change.			
Venous Pressure	The hydrostatic pressure in the venous system.			
Viscosity	A resistance to flow due to interactions among molecules within a liquid.			
RELATIONSHIPS AMONG THE PRECEDING TERMS				
F∝P	Flow is proportional to the pressure gradient.			
<i>F</i> ∝ 1/ <i>R</i>	Flow is inversely proportional to resistance.			
$F \propto P/R$	Flow is directly proportional to the pressure gradient, and inversely proportional to resistance.			
F ∝ BP/PR	Flow is directly proportional to blood pressure, and inversely proportional to peripheral resistance.			
$R \propto 1/r^4$	Resistance is inversely proportional to the fourth power of the vessel radius.			

Figure 21–9 Pressures within the Systemic Circuit. Notice the general reduction in circulatory pressure within the systemic circuit and the elimination of the pulse pressure within the arterioles.

Arterial Blood Pressure

Arterial pressure is important because it maintains blood flow through capillary beds. To do this, it must always be high enough to overcome the peripheral resistance. Arterial pressure is not constant. Rather, it rises during ventricular systole and falls during ventricular diastole. The peak blood pressure measured during ventricular systole is called **systolic pressure**, and the minimum blood pressure at the end of ventricular diastole is called **diastolic pressure**. In recording blood pressure, we separate systolic and diastolic pressures by a slash, as in "120/80" ("one-twenty over eighty") or "110/75."

A *pulse* is a rhythmic fluctuation in pressure that accompanies each heartbeat. The difference between the systolic and diastolic pressures is the **pulse pressure** (Figure 21–9). To report a single blood pressure value, we use the **mean arterial pressure (MAP)**. It is calculated by adding one-third of the pulse pressure to the diastolic pressure:

MAP = diastolic pressure +
$$\frac{\text{pulse pressure}}{3}$$

For a systolic pressure of 120 mm Hg and a diastolic pressure of 90 mm Hg, we calculate MAP as follows:

MAP =
$$90 + \frac{(120 - 90)}{3} = 90 + 10 = 100 \text{ mm Hg}$$

A normal range of systolic and diastolic pressures occurs in healthy individuals. When pressures shift outside the normal range, clinical problems develop. Abnormally high blood pressure is termed **hypertension**. Abnormally low blood pressure is **hypotension**. Hypertension is much more common. In fact, many cases of hypotension result from overly aggressive drug treatment for hypertension.

The usual criterion established by the American Heart Association for stage 1 hypertension in adults is a systolic blood pressure range of 140–159 and a diastolic range of 90–99. Values from 120–139 for systolic pressure and 80–89 for diastolic pressure indicate *pre-hypertension*. Blood pressure less than 120/80 is normal. Cardiologists often recommend some combination of diet modification and drug therapy for people whose blood pressures are consistently pre-hypertensive.

Hypertension significantly increases the workload on the heart, and the left ventricle gradually enlarges. More muscle mass means a greater demand for oxygen. When the coronary circulation cannot keep pace, signs and symptoms of coronary ischemia appear. \bigcirc p. 698 Increased arterial pressures also place a physical stress on the walls of blood vessels throughout the body. This stress promotes or accelerates the development of arteriosclerosis. It also increases the risk of aneurysms, heart attacks, and strokes.

Elastic Rebound

As systolic pressure climbs, the arterial walls stretch, just as an extra puff of air expands a partially inflated balloon. This expansion allows the arterial system to accommodate some of the blood provided by ventricular systole. When diastole begins and blood pressures fall, the arteries recoil to their original dimensions. This phenomenon is called **elastic rebound**. Some blood is forced back toward the left ventricle, closing the aortic valve and helping to drive additional blood into the coronary arteries. However, most of the push from elastic rebound forces blood toward the capillaries. This maintains blood flow along the arterial network while the left ventricle is in diastole.

Pressures in Small Arteries and Arterioles

The mean arterial pressure and the pulse pressure become smaller as the distance from the heart increases (Figure 21–9):

• The mean arterial pressure declines as the arterial branches become smaller and more numerous. In essence, blood pressure decreases as it overcomes friction and produces blood flow. • The pulse pressure lessens due to the cumulative effects of elastic rebound along the arterial system. The effect can be likened to a series of ever-softer echoes following a loud shout. Each time an echo is produced, the reflecting surface absorbs some of the sound energy. Eventually, the echo disappears. The pressure surge accompanying ventricular ejection is like the shout, and it is reflected by the wall of the aorta, echoing down the arterial system until it finally disappears at the level of the small arterioles. By the time blood reaches a precapillary sphincter, no pressure fluctuations remain, and the blood pressure is steady at approximately 35 mm Hg.

Venous Pressure and Venous Return

Venous pressure, although low, determines venous return—the amount of blood arriving at the right atrium each minute. Venous return has a direct impact on cardiac output. \bigcirc p. 715 Blood pressure at the start of the venous system is only about one-tenth that at the start of the arterial system, but the blood must still travel through a vascular network as complex as the arterial system before returning to the heart.

Pressures at the entrance to the right atrium fluctuate, but they average about 2 mm Hg. Thus, the effective pressure in the venous system is roughly 16 mm Hg (from 18 mm Hg in the venules to 2 mm Hg in the venae cavae). This pressure compares with 65 mm Hg in the arterial system (from 100 mm Hg at the aorta to 35 mm Hg at the capillaries). Yet, although venous pressures are low, veins offer comparatively little resistance, so pressure declines very slowly as blood moves through the venous system. As blood moves toward the heart, the veins become larger, resistance drops, and the velocity of blood flow increases (Figure 21–8).

When you stand, the venous blood returning from your body inferior to the heart must overcome gravity as it travels up the inferior vena cava. Two factors assist the low venous pressures in propelling blood toward your heart: *muscular compression* of peripheral veins and the *respiratory pump* during inhalation.

Muscular Compression. The contractions of skeletal muscles near a vein compress it, helping to push blood toward the heart. The valves in small and medium-sized veins ensure that blood flows in one direction only (Figure 21–5). When you are standing and walking, the cycles of contraction and relaxation that accompany your normal movements assist venous return. If you stand at attention, with knees locked and leg muscles immobilized, that assistance is lost. The reduction in venous return then leads to a fall in cardiac output, which reduces the blood supply to the brain. This decline is sometimes enough to cause fainting, a temporary loss of consciousness. You would then collapse, but while you were in the horizontal position, both venous return and cardiac output would return to normal.

The Respiratory Pump. As you inhale, your thoracic cavity expands, reducing the pressure within the pleural cavities. This drop in pressure pulls air into your lungs. At the same time, it also pulls blood into the inferior vena cava and right atrium from the smaller veins of your abdominal cavity and lower body. The effect on venous return through the superior vena cava is less pronounced, because blood in that vessel is normally assisted by gravity. As you exhale, your thoracic cavity decreases in size. Internal pressure then rises, forcing air out of your lungs and pushing venous blood into the right atrium. This mechanism is called the **respiratory pump**. Such pumping action becomes more important during heavy exercise, when respirations are deep and frequent.

Capillary Pressures and Capillary Exchange

Capillary exchange plays a key role in homeostasis. The most important processes that move materials across typical capillary walls are *diffusion*, *filtration*, and *reabsorption*.

Diffusion

As we saw in Chapter 3, *diffusion* is the net movement of ions or molecules from an area where their concentration is higher to an area where their concentration is lower. \bigcirc **p**. 89 The difference between the high and low concentrations represents a *concentration gradient*. Diffusion tends to eliminate that gradient. Diffusion occurs most rapidly when (1) the distances involved are short, (2) the concentration gradient is large, and (3) the ions or molecules involved are small.

Different substances diffuse across capillary walls by different routes:

- 1. Water, ions, and small organic molecules, such as glucose, amino acids, and urea, can usually enter or leave the bloodstream by diffusion between adjacent endothelial cells or through the pores of fenestrated capillaries.
- **2.** *Many ions, including sodium, potassium, calcium, and chloride,* can diffuse across endothelial cells by passing through channels in plasma membranes.
- **3.** *Large water-soluble compounds* are unable to enter or leave the bloodstream except at fenestrated capillaries, such as those of the hypothalamus, the kidneys, many endocrine organs, and the intestinal tract.
- 4. Lipids, such as fatty acids and steroids, and lipid-soluble materials, including soluble gases such as oxygen and carbon dioxide, can cross capillary walls by diffusion through the endothelial plasma membranes.
- 5. *Plasma proteins* are normally unable to cross the endothelial lining anywhere except in sinusoids, such as those of the liver, where plasma proteins enter the bloodstream.

Filtration

Filtration is the removal of solutes as a solution flows across a porous membrane. Solutes too large to pass through the pores are filtered out of the solution. The driving force for filtration is hydrostatic pressure. As we saw earlier, it pushes water from an area of higher pressure to an area of lower pressure.

In *capillary filtration*, water and small solutes are forced across a capillary wall, leaving larger solutes and suspended proteins in the bloodstream (Figure 21–10). The solute molecules that leave the bloodstream are small enough to pass between adjacent endothelial cells or through the pores in a fenestrated capillary. Filtration takes place primarily at the arterial end of a capillary, where capillary hydrostatic pressure (CHP) is highest.

Reabsorption

Reabsorption occurs as the result of osmosis. *Osmosis* is a special term for the diffusion of water across a selectively permeable membrane that separates two solutions of differing solute concentrations. Water molecules tend to diffuse across a membrane *toward* the solution containing the higher solute concentration (Figure 3–16, p. 93).

Figure 21–10 Capillary Filtration. Capillary hydrostatic pressure (CHP) forces water and solutes through the gaps between adjacent endothelial cells in continuous capillaries. The sizes of solutes that move across the capillary wall are determined by the dimensions of the gaps.

The **osmotic pressure (OP)** of a solution is an indication of the force of osmotic water movement. In other words, it represents the pressure that must be applied to prevent osmotic movement across a membrane. The higher the solute concentration of a solution, the greater is the solution's osmotic pressure. The presence of suspended proteins that cannot cross capillary walls creates an osmotic pressure called *blood colloid osmotic pressure (BCOP)*. Clinicians often use the term *oncotic pressure* (*onkos*, a swelling) when referring to the colloid osmotic pressure of body fluids. The two terms are equivalent. Osmotic water movement continues until either the solute concentrations are equalized or an opposing hydrostatic pressure prevents the movement.

Now let's look at the interplay between filtration and reabsorption along the length of a typical capillary. In this discussion, remember that hydrostatic pressure forces water *out of* a solution, and osmotic pressure draws water *into* a solution.

The Interplay between Filtration and Reabsorption

The continuous movement of water out of the capillaries, through peripheral tissues, and then back to the bloodstream by way of the lymphatic system has four important functions:

1. It ensures that plasma and interstitial fluid, two major components of extracellular fluid, are in constant communication and mutual exchange.

- 2. It accelerates the distribution of nutrients, hormones, and dissolved gases throughout tissues.
- **3.** It assists in the transport of insoluble lipids and tissue proteins that cannot enter the bloodstream by crossing the capillary walls.
- 4. It has a flushing action that carries bacterial toxins and other chemical stimuli to lymphatic tissues and organs responsible for providing immunity to disease.

Capillary blood pressure declines as blood flows from the arterial end to the venous end of a capillary. As a result, the rates of filtration and reabsorption gradually change as blood passes along the length of a capillary. The factors involved are diagrammed in Figure 21–11.

Net hydrostatic pressure is the difference between the pressure inside the capillary wall and the hydrostatic pressure outside the capillary. The *net capillary hydrostatic pressure* tends to push water and solutes out of capillaries and into the interstitial fluid. Factors that contribute to the net hydrostatic pressure include

- 1. the *capillary hydrostatic pressure (CHP)*, which ranges from 35 mm Hg at the arterial end of a capillary to 18 mm Hg at the venous end, and
- 2. the *interstitial fluid hydrostatic pressure (IHP)*. Measurements of IHP have yielded very small values that differ from tissue

Figure 21–11 Forces Acting across Capillary Walls. At the arterial end of the capillary, capillary hydrostatic pressure (CHP) is greater than blood colloid osmotic pressure (BCOP), so fluid moves out of the capillary (filtration). Near the venule, CHP is lower than BCOP, so fluid moves into the capillary (reabsorption). In this model, interstitial fluid colloid osmotic pressure (ICOP) and interstitial fluid hydrostatic pressure (IHP) are assumed to be 0 mm Hg and so are not shown.

to tissue—from +6 mm Hg in the brain to -6 mm Hg in subcutaneous tissues. A positive IHP opposes CHP, and the tissue hydrostatic pressure must be overcome before fluid can move out of a capillary. A negative IHP assists CHP, and additional fluid will be pulled out of the capillary. However, under normal circumstances the average IHP is 0 mm Hg, and we can assume that the net hydrostatic pressure is equal to CHP. (For this reason, IHP is not included in Figure 21–11.)

Plasma proteins in capillary blood create capillary colloid osmotic pressure. The *net capillary colloid osmotic pressure* tends to pull water and solutes into a capillary from the interstitial fluid. The net colloid osmotic pressure is the difference between

- 1. the *blood colloid osmotic pressure (BCOP)*, which is about 25 mm Hg, and
- 2. the *interstitial fluid colloid osmotic pressure (ICOP)*. The ICOP is as variable and low as the IHP, because the interstitial fluid in most tissues contains negligible quantities of suspended proteins. Reported values of ICOP are from 0 to 5 mm Hg, within the range of pressures recorded for the IHP. It is thus safe to assume that under normal circumstances the net colloid osmotic pressure is equal to the BCOP. (For this reason, ICOP is not included in Figure 21–11.)

The **net filtration pressure (NFP)** is the difference between the net hydrostatic pressure and the net osmotic pressure. In terms of the factors just listed, this means that

net filtration	=	net hydrostatic	—	net colloid
pressure		pressure		osmotic pressure
NFP	=	(CHP – IHP)	_	(BCOP – ICOP)

At the arterial end of a capillary, the net filtration pressure can be calculated as follows:

NFP = (35 - 0) - (25 - 0) = 35 - 25 = 10 mm Hg

Because this value is positive, it indicates that fluid will tend to move *out of* the capillary and into the interstitial fluid. At the venous end of the capillary, the net filtration pressure will be

NFP = (18 - 0) - (25 - 0) = 18 - 25 = -7 mm Hg

The minus sign indicates that fluid tends to move *into* the capillary; that is, reabsorption is occurring.

The transition between filtration and reabsorption occurs where the CHP is 25 mm Hg, because at that point the hydrostatic and osmotic forces are equal—that is, the NFP is 0 mm Hg. If the maximum filtration pressure at the arterial end of the capillary were equal to the maximum reabsorption pressure at the venous end, this transition point would lie midway along the length of the capillary. Under these circumstances, filtration would occur along the first half of the capillary, and an identical Clinical Note

Edema Edema (e-DĒ-muh) is an abnormal accumulation of interstitial fluid. Edema has many causes, and we will encounter specific examples in later chapters. The underlying problem in all types of edema is a disturbance in the normal balance between hydrostatic and osmotic forces at the capillary level. For instance:

- You usually have swelling at a bruise. When a capillary is damaged, plasma proteins can cross the capillary wall and enter the interstitial fluid. The resulting rise in the interstitial fluid colloid osmotic pressure (ICOP) reduces the rate of capillary reabsorption and produces a localized edema.
- In starvation, the liver cannot synthesize enough plasma proteins to maintain normal concentrations in the blood. Blood colloid osmotic pressure (BCOP) declines. Fluids then begin moving from the blood into peripheral tissues. In children, fluid builds up in the abdominopelvic cavity, producing the swollen bellies typical of starvation victims. A reduction in BCOP also takes place after severe burns and in several types of liver and kidney diseases.
- In the U.S. population, most serious cases of edema result from increases in arterial blood pressure, venous pressure, or total circulatory pressure. The increase may be due to heart problems such as heart failure, venous blood clots that elevate venous pressures, or other cardiovascular abnormalities. The net result is an increase in capillary hydrostatic pressure (CHP) that accelerates fluid movement into the tissues.

amount of reabsorption would occur along the second half. However, the maximum filtration pressure is higher than the maximum reabsorption pressure, so the transition point between filtration and reabsorption normally lies closer to the venous end of the capillary than to the arterial end. As a result, more filtration than reabsorption occurs along the capillary. Of the nearly 24 liters of fluid that move out of the plasma and into the interstitial fluid each day, 20.4 liters (85 percent) are reabsorbed. The remainder (3.6 liters) flows through the tissues and into lymphatic vessels, for eventual return to the venous system (Figure 21–11).

Any condition that affects hydrostatic or osmotic pressures in the blood or tissues will shift the balance between hydrostatic and osmotic forces. We can then predict the effects on the basis of an understanding of capillary dynamics. For example,

 If hemorrhaging occurs, both blood volume and blood pressure decrease. This reduction in CHP lowers the NFP and increases the amount of reabsorption. The result is a decrease in the volume of interstitial fluid and an increase in the circulating plasma volume. This process is known as a *recall of fluids*.

- If dehydration occurs, the plasma volume decreases due to water loss, and the concentration of plasma proteins increases. The increase in BCOP accelerates reabsorption and a recall of fluids that delays the onset and severity of clinical signs and symptoms.
- If the CHP rises or the BCOP declines, fluid moves out of the blood and builds up in peripheral tissues, a condition called *edema*.

CHECKPOINT

- 5. Identify the factors that contribute to total peripheral resistance.
- 6. In a healthy person, where is blood pressure greater: at the aorta or at the inferior vena cava? Explain.
- 7. While standing in the hot sun, Sally begins to feel light-headed and faints. Explain what happened.
- 8. Mike's blood pressure is 125/70. What is his mean arterial pressure?

See the blue Answers tab at the back of the book.

21–3 Cardiovascular regulatory mechanisms involve autoregulation, neural mechanisms, and endocrine responses

Learning Outcome Describe the control mechanisms that regulate blood flow and pressure in tissues, and explain how the activities of the cardiac, vasomotor, and respiratory centers are coordinated to control blood flow through the tissues.

Homeostatic mechanisms regulate cardiovascular activity to ensure that blood flow through tissues, called **tissue perfusion**, meets the demand for oxygen and nutrients. The factors that affect tissue perfusion are (1) cardiac output, (2) peripheral resistance, and (3) blood pressure. We discussed cardiac output in Chapter 20 (p. 711). We considered peripheral resistance and blood pressure earlier in this chapter.

Most cells are relatively close to capillaries. When a group of cells becomes active, the circulation to that region must increase to bring the necessary oxygen and nutrients, and to carry away the waste products and carbon dioxide they generate. The purpose of cardiovascular regulation is to ensure that these blood flow changes occur (1) at an appropriate time, (2) in the right area, and (3) without drastically changing blood pressure and blood flow to vital organs.

The regulatory mechanisms focus on controlling cardiac output and blood pressure to restore adequate blood flow after

blood pressure decreases. We can group these mechanisms as follows:

- Autoregulation. Local factors change the pattern of blood flow within capillary beds as precapillary sphincters open and close in response to chemical changes in interstitial fluids. This is an example of autoregulation at the tissue level. Autoregulation causes immediate, localized homeostatic adjustments. If autoregulation fails to normalize conditions at the tissue level, neural mechanisms and endocrine factors are activated.
- *Neural Mechanisms*. Neural mechanisms respond to changes in arterial pressure or blood gas levels sensed at specific sites. When those changes occur, the cardiovascular center of the autonomic nervous system adjusts cardiac output and peripheral resistance to maintain blood pressure and ensure adequate blood flow.
- *Endocrine Mechanisms*. The endocrine system releases hormones that enhance short-term adjustments and that direct long-term changes in cardiovascular performance.

Now let's see how each of these regulatory mechanisms responds to inadequate perfusion of skeletal muscles. The regulatory relationships are diagrammed in Figure 21–12.

Autoregulation of Blood Flow within Tissues

Under normal resting conditions, cardiac output remains stable, and peripheral resistance within individual tissues is adjusted to control local blood flow.

Factors that promote the dilation of precapillary sphincters are called **vasodilators**. **Local vasodilators** act at the tissue level to accelerate blood flow through their tissue of origin. Examples of local vasodilators include the following:

- Decreased tissue oxygen levels or increased CO₂ levels.
- Lactic acid or other acids generated by tissue cells.
- Nitric oxide (NO) released from endothelial cells.
- Rising concentrations of potassium ions or hydrogen ions in the interstitial fluid.
- Chemicals released during local inflammation, including histamine and NO. つ p. 144
- Elevated local temperature.

These factors work by relaxing the smooth muscle cells of the precapillary sphincters. All of them indicate that tissue conditions are in some way abnormal. An increase in blood flow, which brings oxygen, nutrients, and buffers, may be sufficient to restore homeostasis.

As noted in Chapter 19, aggregating platelets and damaged tissues produce compounds that stimulate precapillary sphincters to constrict. These compounds are **local vasoconstrictors**. Examples include prostaglandins and thromboxanes released Figure 21–12 Short-Term and Long-Term Cardiovascular Responses. This diagram indicates general mechanisms that compensate for a reduction in blood pressure and blood flow.

Central Regulation

origin.

Central regulation involves both neural and endocrine mechanisms. Activation of the cardiovascular center involves both the cardioacceleratory center (which stimulates the heart) and the vasomotor center (which controls the degree of peripheral vasoconstriction). Neural mechanisms elevate cardiac output and reduce blood flow to nonessential or inactive tissues. The primary vasoconstrictor involved in neural regulation is norepinephrine (NE). Endocrine mechanisms involve long-term increases in blood volume and blood pressure.

by activated platelets and white blood cells, and the endothelins released by damaged endothelial cells.

Neural Mechanisms

Increased tissue activity

Local vasodilators and vasoconstrictors control blood flow within a single capillary bed (Figure 21-4). In high concentrations, these factors also affect arterioles, increasing or decreasing blood flow to all the capillary beds in a given area.

The nervous system adjusts cardiac output and peripheral resistance to maintain adequate blood flow to vital tissues and organs. Centers responsible for these regulatory activities include the cardiac centers and the vasomotor center of the medulla oblongata. **D** p. 470

It is difficult to distinguish the cardiac and vasomotor centers anatomically. They are often considered to form a complex **cardiovascular (CV) center**, composed of the cardioinhibitory center, cardioacceleratory center, and the vasomotor center. In functional terms, however, the cardiac and vasomotor centers often act independently.

As noted in Chapter 20, the *cardioacceleratory center* increases cardiac output through sympathetic innervation. The *cardioinhibitory center* decreases cardiac output through parasympathetic innervation. \bigcirc p. 713

The vasomotor center contains two populations of neurons: (1) a very large group responsible for widespread vasoconstriction and (2) a smaller group responsible for the vasodilation of arterioles in skeletal muscles and the brain. The vasomotor center controls the activity of sympathetic motor neurons:

- Control of Vasoconstriction. The neurons innervating peripheral blood vessels in most tissues are *adrenergic*; that is, they release the neurotransmitter norepinephrine (NE). NE stimulates smooth muscles in the walls of arterioles, producing vasoconstriction.
- 2. *Control of Vasodilation.* Vasodilator neurons innervate blood vessels in skeletal muscles and in the brain. The stimulation of these neurons relaxes smooth muscle cells in the walls of arterioles, producing vasodilation. This relaxation is triggered by the appearance of NO in the surroundings. The vasomotor center may control NO release indirectly or directly. The most common vasodilator synapses are *cholinergic*—their axon terminals release ACh. In turn, ACh stimulates endothelial cells in the area to release NO, causing local vasodilation. Other vasodilator synapses are *nitroxidergic*—their axon terminals release NO as a neurotransmitter. Nitric oxide has an immediate and direct relaxing effect on the vascular smooth muscle cells in the area.

Vasomotor Tone

In Chapter 16, we saw how autonomic tone sets a background level of neural activity that can increase or decrease on demand. **D p**. **548** The sympathetic vasoconstrictor nerves are always active, producing a significant **vasomotor tone**. This vasoconstrictor activity normally keeps the arterioles partially constricted. Under maximal stimulation, arterioles constrict to about half their resting diameter. To dilate fully, an arteriole increases its resting diameter by about 1.5 times.

Constriction has a large effect on resistance, because, as we saw earlier, resistance increases sharply as luminal diameter decreases. The resistance of a maximally constricted arteriole is roughly 80 *times* that of a fully dilated arteriole. Because blood pressure varies directly with peripheral resistance, the vasomotor center can control arterial blood pressure very effectively by making modest adjustments in vessel diameters. Extreme stimulation of the vasomotor center also produces venoconstriction and mobilizes the venous reserve.

Reflex Control of Cardiovascular Function

The cardiovascular center detects changes in tissue demand by monitoring arterial blood, especially its blood pressure, pH, and concentrations of dissolved gases. The *baroreceptor reflexes* (*baro-*, pressure) respond to changes in blood pressure, and the *chemoreceptor reflexes* (*chemo-*, chemical) monitor changes in the chemical composition of arterial blood. These reflexes are regulated through a negative feedback loop: The stimulation of a receptor by an abnormal condition leads to a response that counteracts the stimulus and restores normal conditions.

Baroreceptor Reflexes. Baroreceptors are specialized receptors that monitor the degree of stretch in the walls of expandable organs. \bigcirc p. 516 The baroreceptors involved in cardiovascular regulation are found in the walls of (1) the **carotid sinuses**, expanded chambers near the bases of the *internal carotid arteries* of the neck (Figure 21–21); (2) the **aortic sinuses**, pockets in the walls of the ascending aorta adjacent to the heart (Figure 20–8b, p. 694); and (3) the wall of the right atrium. These receptors are part of the **baroreceptor reflexes**, which adjust cardiac output and peripheral resistance to maintain normal arterial pressures.

Aortic baroreceptors monitor blood pressure within the ascending aorta. Any changes trigger the **aortic reflex**, which adjusts blood pressure to maintain adequate blood pressure and blood flow through the systemic circuit. Carotid sinus baroreceptors trigger reflexes that maintain adequate blood flow to the brain. The carotid sinus receptors are extremely sensitive because blood flow to the brain must remain constant. **Figure 21–13** presents the basic organization of the baroreceptor reflexes triggered by changes in blood pressure at the carotid and aortic sinuses.

When blood pressure rises, the increased output from the baroreceptors alters activity in the CV center and produces two major effects (Figure 21–13):

- 1. *A decrease in cardiac output*, due to parasympathetic stimulation and the inhibition of sympathetic activity.
- 2. *Widespread peripheral vasodilation,* due to the inhibition of excitatory neurons in the vasomotor center.

The decrease in cardiac output reflects primarily a reduction in heart rate due to the release of acetylcholine at the sinoatrial (SA) node. \bigcirc p. 714 The widespread vasodilation lowers peripheral resistance, and this effect, combined with a reduction in cardiac output, leads to a fall in blood pressure to normal levels.

When blood pressure falls below normal, baroreceptor output is reduced accordingly (Figure 21–13). This change has two major effects working together to raise blood pressure:

1. An increase in cardiac output, through the stimulation of sympathetic innervation to the heart. This results from

the stimulation of the cardioacceleratory center and is accompanied by an inhibition of the cardioinhibitory center.

2. *Widespread peripheral vasoconstriction,* caused by the stimulation of sympathetic vasoconstrictor neurons by the vasomotor center.

The effects on the heart result from the release of NE by sympathetic neurons innervating the SA node, the atrioventricular (AV) node, and the general myocardium. In a crisis, sympathetic activation occurs, and its effects are enhanced by the release of both NE and epinephrine (E) from the adrenal medullae. The net effect is an immediate increase in heart rate and stroke volume, and a corresponding increase in cardiac output.

The vasoconstriction, which also results from the release of NE by sympathetic neurons, increases peripheral resistance. These adjustments—increased cardiac output and increased peripheral resistance—work together to raise blood pressure.

Atrial baroreceptors monitor blood pressure at the end of the systemic circuit—at the venae cavae and the right atrium. Recall from Chapter 20 that the **atrial reflex** responds to a stretching of the wall of the right atrium. \bigcirc p. 714

Under normal circumstances, the heart pumps blood into the aorta at the same rate at which blood arrives at the right atrium. When blood pressure rises at the right atrium, blood is arriving at the heart faster than it is being pumped out. The atrial baroreceptors correct the situation by stimulating the CV centers to increase cardiac output until the backlog of venous blood is removed. Atrial pressure then returns to normal.

A procedure known as the Valsalva maneuver is a simple way to check for normal cardiovascular responses to changes in arterial pressure and venous return. The Valsalva maneuver involves trying to exhale forcefully with closed lips and nostrils so that no air can leave the lungs and pressure in the thoracic cavity rises sharply. This action causes reflexive changes in blood pressure and cardiac output due to increased intrathoracic pressure, which impedes venous return to the right atrium. When internal pressures rise, the venae cavae collapse, and the venous return decreases. The resulting drop in cardiac output and blood pressure stimulates the aortic and carotid baroreceptors, causing a reflexive increase in heart rate and peripheral vasoconstriction. When the glottis opens and pressures return to normal, venous return increases suddenly and so does cardiac output. Because vasoconstriction has occurred, blood pressure rises sharply, and this inhibits the baroreceptors. As a result, cardiac output, heart rate, and blood pressure quickly return to normal levels.

Chemoreceptor Reflexes. The **chemoreceptor reflexes** respond to changes in carbon dioxide, oxygen, or pH levels in blood and cerebrospinal fluid (CSF) (Figure 21–14). The chemoreceptors involved are sensory neurons. They are located in the **carotid bodies**, situated in the neck near the carotid sinus, and the **aortic bodies**, near the arch of the aorta. ⊃ p. 517 These receptors monitor the composition of arterial blood. Additional chemoreceptors located on the ventrolateral surfaces of the medulla oblongata monitor the composition of CSF.

When chemoreceptors in the carotid bodies or aortic bodies detect either an increase in the carbon dioxide content or a decrease in the pH of the arterial blood, the cardioacceleratory and vasomotor centers are stimulated. At the same time, the cardioinhibitory center is inhibited. This dual effect causes an increase in cardiac output, peripheral vasoconstriction, and an increase in blood pressure. A decrease in the oxygen level at the aortic bodies has the same effects. Strong stimulation of the carotid or aortic chemoreceptors causes widespread sympathetic activation, with more dramatic increases in heart rate and cardiac output. The chemoreceptors of the medulla oblongata are involved primarily with the control of respiratory function, and secondarily with regulating blood flow to the brain. For example, a steep rise in CSF carbon dioxide levels triggers the vasodilation of cerebral vessels, but produces vasoconstriction in most other organs. The result is increased blood flow—and increased oxygen delivery—to the brain.

Coordination of cardiovascular and respiratory activities is vital, because accelerating blood flow in the tissues is useful only if the circulating blood contains an adequate amount of oxygen. Arterial CO_2 levels can be decreased and O_2 levels increased most effectively by coordinating cardiovascular and respiratory activities. Chemoreceptor stimulation also stimulates the respiratory centers, and the increase in cardiac output and blood pressure is associated with an increased respiratory rate. In addition, an increase in the respiratory rate accelerates venous return through the action of the respiratory pump. (We consider other aspects of chemoreceptor activity and respiratory control in Chapter 23.)

CNS Activities and the Cardiovascular Center

The output of the cardiovascular center can also be influenced by activities in other areas of the brain. For example, the activation of either division of the autonomic nervous system affects output from the cardiovascular center. A general sympathetic activation stimulates the cardioacceleratory and vasomotor centers. As a result, cardiac output and blood pressure increase. In contrast, when the parasympathetic division is activated, the cardioinhibitory center is stimulated. The result is a decrease in cardiac output. Parasympathetic activity does not directly affect the vasomotor center, but vasodilation takes place as sympathetic activity declines.

The higher brain centers can also affect blood pressure. Our thought processes and emotional states can produce significant changes in blood pressure by influencing cardiac output and vasomotor tone. For example, strong emotions of anxiety, fear, and rage are accompanied by an increase in blood pressure, due to cardiac stimulation and vasoconstriction.

Hormones and Cardiovascular Regulation

The endocrine system regulates cardiovascular performance in both the short term and the long term. As we have seen, E and NE from the adrenal medullae stimulate cardiac output and peripheral vasoconstriction. Other hormones important in regulating cardiovascular function include (1) antidiuretic hormone (ADH), (2) angiotensin II, (3) erythropoietin (EPO), and (4) the natriuretic peptides (ANP and BNP). \bigcirc p. 640 All four are concerned primarily with the long-term regulation of blood volume (Figure 21–15). ADH and angiotensin II also affect blood pressure.

Antidiuretic Hormone

Antidiuretic hormone (ADH) is released at the posterior lobe of the pituitary gland in response to a decrease in blood volume, to an increase in the osmotic concentration of the plasma, or (secondarily) to circulating angiotensin II. It brings about a peripheral vasoconstriction that elevates blood pressure. This hormone also stimulates water conservation by the kidneys, thus preventing a reduction in blood volume that would further reduce blood pressure (Figure 21–15a).

Angiotensin II

Angiotensin II appears in the blood when specialized kidney cells, called *juxtaglomerular cells*, release the enzyme *renin* (RĒ-nin) in response to a fall in renal blood pressure (Figure 21–15a). Once in the bloodstream, renin starts an enzymatic chain reaction. In

the first step, renin converts *angiotensinogen*, a plasma protein produced by the liver, to *angiotensin I*. In the capillaries of the lungs, *angiotensin-converting enzyme (ACE)* then modifies angiotensin I to angiotensin II, an active hormone with diverse effects.

Angiotensin II has four important functions: (1) It stimulates the adrenal production of aldosterone, causing Na⁺ retention and K⁺ loss by the kidneys; (2) it stimulates the secretion of ADH, in turn stimulating water reabsorption by the kidneys and complementing the effects of aldosterone; (3) it stimulates thirst, resulting in increased fluid consumption (the presence of ADH and aldosterone ensures that the additional water consumed will be retained, increasing blood volume); and (4) it stimulates cardiac output and triggers the constriction of arterioles, in turn increasing the systemic blood pressure. The effect of angiotensin II on blood pressure is four to eight times greater than the effect of norepinephrine.

Erythropoietin

The kidneys release *erythropoietin (EPO)* if blood pressure falls or if the oxygen content of the blood becomes abnormally low (Figure 21–15a). EPO acts directly on blood vessels, causing vasoconstriction, thereby increasing blood pressure. EPO also stimulates the production and maturation of red blood cells. These cells increase the volume and viscosity of the blood and improve its oxygen-carrying capacity.

Natriuretic Peptides

Cardiac muscle cells in the wall of the right atrium of the heart produce *atrial natriuretic peptide* (nā-trē-ū-RET-ik; *natrium*, sodium + *ouresis*, urination), or *ANP*, in response to excessive stretching during diastole. Ventricular muscle cells exposed to comparable stimuli produce a related hormone called *brain natriuretic peptide*, or *BNP*. These peptide hormones reduce blood volume and blood pressure. They do so by (1) increasing sodium ion excretion by the kidneys; (2) promoting water losses by increasing the volume of urine produced; (3) reducing thirst; (4) blocking the release of ADH, aldosterone, epinephrine, and norepinephrine; and (5) stimulating peripheral vaso-dilation (Figure 21–15b). As blood volume and blood pressure decrease, the stresses on the walls of the heart are removed, and natriuretic peptide production ceases.

CHECKPOINT

- 9. Describe the actions of vasodilators and local vasodilators.
- **10**. How would applying slight pressure to the common carotid artery affect your heart rate?
- 11. What effect would the vasoconstriction of the renal artery have on blood pressure and blood volume?

- See the blue Answers tab at the back of the book.

21-4 The cardiovascular system adapts to physiological stress and maintains a special vascular supply to the brain, heart, and lungs

Learning Outcome Explain the cardiovascular system's homeostatic response to exercise and hemorrhaging, and identify the principal blood vessels and functional characteristics of the special circulation to the brain, heart, and lungs.

In this chapter and the previous two, we have considered the blood, the heart, and the cardiovascular system as individual entities. Yet in our day-to-day lives, the cardiovascular system operates as an integrated complex. The interactions are fascinating and very important when physical or physiological conditions are changing rapidly.

In this section we begin by looking at the patterns of cardiovascular responses to exercise and blood loss. These two common stresses provide examples of the cardiovascular system's adaptability in maintaining homeostasis. The homeostatic responses involve interplay among the cardiovascular system, the endocrine system, and other systems. These responses are aided by autoregulation at the tissue level. Then we consider the patterns of blood supply to the brain, heart, and lungs, in which blood flow is controlled by separate mechanisms.

The Cardiovascular Response to Exercise

At rest, cardiac output averages about 5.8 liters per minute. That amount changes dramatically during exercise. In addition, the pattern of blood distribution changes markedly, as detailed in Table 21–2.

Light Exercise

Before you begin to exercise, your heart rate increases slightly due to a general rise in sympathetic activity as you think about the workout ahead. As you begin light exercise, three interrelated changes take place:

- *Extensive vasodilation occurs* as skeletal muscles consume oxygen more quickly. Peripheral resistance decreases, blood flow through the capillaries increases, and blood enters the venous system at a faster rate.
- *The venous return increases* as skeletal muscle contractions squeeze blood along the peripheral veins and faster breathing pulls blood into the venae cavae by the respiratory pump.
- *Cardiac output rises*, primarily in response to (1) the rise in venous return (the Frank–Starling principle ⊃ p. 716) and (2) atrial stretching (the atrial reflex). Some sympathetic stimulation occurs, leading to increases in heart rate and contractility, but there is no massive sympathetic activation. The increased cardiac output keeps pace with the elevated demand, and arterial pressures are maintained despite the drop in peripheral resistance.

Table 21–2	Changes in Blood Distribution during Exercise					
		Tissue Blood Flow (mL/min)				
Organ	Rest	Light Exer	cise Strenuous Exe	ercise		
Skeletal muscles	1200	4500	12,500			
Heart	250	350	750			
Brain	750	750	750			
Skin	500	1500	1900			
Kidney	1100	900	600			
Abdominal viscer	a 1400	1100	600			
Miscellaneous	600	400	400			
Total cardiac outp	5800	9500	17,500			

This regulation by venous feedback produces a gradual increase in cardiac output to about double resting levels. The increase supports accelerated blood flow to skeletal muscles, cardiac muscle, and the skin. The flow to skeletal and cardiac muscles increases as arterioles and precapillary sphincters dilate in response to local factors. The flow to the skin increases in response to the rise in body temperature.

Heavy Exercise

At higher levels of exertion, other physiological adjustments take place as the cardiac and vasomotor centers activate the sympathetic nervous system. Cardiac output increases toward maximal levels. Major changes in the peripheral distribution of blood improve blood flow to active skeletal muscles.

Under massive sympathetic stimulation, the cardioacceleratory center can increase cardiac output to levels as high as 20–25 liters per minute. But that is still not enough to meet the demands of active skeletal muscles unless the vasomotor center severely restricts the blood flow to "nonessential" organs, such as those of the digestive system. During exercise at maximal levels, your blood essentially races between the skeletal muscles and the lungs and heart. Although blood flow to most tissues is diminished, skin perfusion increases further, because body temperature continues to climb. Only the blood supply to the brain remains unaffected.

Exercise, Cardiovascular Fitness, and Health

Cardiovascular performance improves significantly with training. Table 21–3 compares the cardiac performance of athletes with that of nonathletes. Trained athletes have larger hearts and greater stroke volumes than do nonathletes, and these are important functional differences.

Recall that cardiac output is equal to the stroke volume times the heart rate. For the same cardiac output, the person with a greater stroke volume has a slower heart rate. An athlete at rest can maintain normal blood flow to peripheral tissues at a heart rate as low as 32 bpm (beats per minute). When necessary, the athlete's cardiac output can increase to levels 50 percent higher than those of nonathletes. Thus, a trained athlete can tolerate sustained levels of activity that are well beyond the capabilities of nonathletes.

Exercise and Cardiovascular Disease

Regular exercise has several beneficial effects. Even a moderate exercise routine (jogging 5 miles a week, for example) can lower total blood cholesterol levels. Exercise lowers cholesterol by stimulating enzymes that help move low-density lipoproteins (LDLs, or so-called "bad cholesterol") from the blood to the liver. In the liver, the cholesterol is converted to bile and excreted from the body. Exercise also increases the size of the lipoprotein particles that carry cholesterol, making it harder for small proteins to lodge in the vessel walls. A high cholesterol level is one of the major risk factors for atherosclerosis, which leads to cardiovascular disease and strokes. In addition, a healthy lifestyle that includes regular exercise, a balanced diet, weight control, and not smoking reduces stress, lowers blood pressure, and slows the formation of plaques.

Regular moderate exercise (30 minutes most days of the week) may cut the incidence of heart attacks almost in half. However, only an estimated 8 percent of adults in the United States currently exercise at recommended levels. Exercise also speeds recovery after a heart attack. Regular light-to-moderate exercise (such as walking, jogging, or bicycling), coupled with a low-fat diet and a low-stress lifestyle, reduces symptoms of coronary artery disease (such as angina). Such exercise also improves a person's mood and overall quality of life. However, exercise does not remove underlying medical problems. For example, atherosclerotic plaques, described on p. 728, do not disappear and seldom grow smaller with exercise.

There is no evidence that *intense* athletic training lowers the incidence of cardiovascular disease. On the contrary, the strains placed on all body systems—including the cardiovascular system—during an ultramarathon, Ironman Triathlon, or other extreme athletic event can be severe. People with congenital aneurysms, cardiomyopathy, or cardiovascular disease risk fatal cardiovascular problems, such as an arrhythmia or heart attack, during severe exercise. Even healthy individuals can develop acute physiological disorders, such as kidney failure, after extreme exercise. We discuss the effects of exercise on other systems in later chapters.

Table 21–3	Effects of Training on Cardiovascular Performance							
Subject		Heart Weight (g)	Stroke Volume (mL)	Heart Rate (bpm)	Cardiac Output (L/min)	Blood Pressure (systolic/diastolic)		
Nonathlete (rest)	300	60	83	5.0	120/80		
Nonathlete (max	kimum)		104	192	19.9	187/75		
Trained athlete (rest)	500	100	53	5.3	120/80		
Trained athlete (maximum)		167	182	30.4	200/90*		

* Diastolic pressures in athletes during maximal activity have not been accurately measured.

The Cardiovascular Response to Hemorrhaging

In Chapter 19, we considered the local cardiovascular reaction to a break in the wall of a blood vessel. \bigcirc p. 675 When hemostasis fails to prevent significant blood loss, the entire cardiovascular system makes adjustments (Figure 21–16). The immediate problem is to maintain adequate blood pressure and peripheral blood flow. The long-term problem is to restore normal blood volume.

Short-Term Elevation of Blood Pressure

Almost as soon as the pressures start to decrease, several shortterm responses appear:

 In the initial neural response, carotid and aortic reflexes increase cardiac output and cause peripheral vasoconstriction. With blood volume reduced, an increase in heart rate, typically up to 180–200 bpm, maintains cardiac output.

- The combination of stress and anxiety stimulates the sympathetic nervous system headquarters in the hypothalamus, which in turn triggers a further increase in vasomotor tone, constricting the arterioles and raising blood pressure. At the same time, venoconstriction mobilizes the venous reserve and quickly improves venous return.
- Short-term hormonal effects also occur. For instance, sympathetic activation causes the adrenal medullae to secrete E and NE. These hormones increase cardiac output and extend peripheral vasoconstriction. In addition, the release of ADH by the posterior lobe of the pituitary gland and the production of angiotensin II enhance vasoconstriction as part of the long-term response.

Figure 21–16 Cardiovascular Responses to Blood Loss. These mechanisms can cope with blood losses equivalent to approximately 30 percent of total blood volume.

This combination of short-term responses elevates blood pressure and improves peripheral blood flow. It often restores normal arterial pressures and peripheral circulation after blood losses of up to 20 percent of total blood volume. Such adjustments are more than enough to compensate for the blood loss when you donate blood. (Most blood banks collect 500 mL of whole blood, roughly 10 percent of your total blood volume.) If compensatory mechanisms fail, the individual develops signs of *shock*.

Long-Term Restoration of Blood Volume

Short-term responses temporarily compensate for a reduction in blood volume. Long-term responses are geared to restoring normal blood volume. This process can take several days after a serious hemorrhage. The steps include the following:

- The decrease in capillary blood pressure triggers a recall of fluids from the interstitial spaces.
- Aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume.
- Thirst increases, and the digestive tract absorbs additional water. This intake of fluid increases the blood volume and ultimately replaces the interstitial fluids "borrowed" at the capillaries.
- Erythropoietin targets the bone marrow. It stimulates the maturation of red blood cells, which increases blood volume and improves oxygen delivery to peripheral tissues.

21 Vascular Supply to Special Regions

The vasoconstriction that takes place in response to a decrease in blood pressure or an increase in CO_2 levels affects many tissues and organs at the same time. The term *special circulation* refers to the vascular supply through organs in which blood flow is controlled by separate mechanisms. Let's consider three important examples: the blood flow to the brain, the heart, and the lungs.

Blood Flow to the Brain

In Chapter 14, we noted that the blood-brain barrier isolates most CNS tissue from the general circulation. **D p**. 469 The brain has a very high demand for oxygen and receives a substantial supply of blood. Under a variety of conditions, blood flow to the brain remains steady at about 750 mL/min. That means that about 12 percent of the cardiac output is delivered to an organ that is less than 2 percent of body weight.

Neurons do not have significant energy reserves, and in functional terms the cardiovascular system treats blood flow to the brain as the top priority. Even during a cardiovascular crisis, blood flow through the brain remains as near normal as possible: While the cardiovascular center is calling for widespread peripheral vasoconstriction, the cerebral vessels are instructed to dilate. Total blood flow to the brain remains relatively constant, but blood flow to specific regions of the brain changes from moment to moment. These changes occur in response to local changes in the composition of interstitial fluid that accompany neural activity. When you read, write, speak, or walk, specific regions of your brain become active. Blood flow to those regions increases almost instantaneously. These changes ensure that the active neurons will receive the oxygen and nutrients they require.

The brain receives arterial blood through four arteries. An interruption of flow in any one of these large vessels does not significantly reduce blood flow to the brain as a whole because these arteries form anastomoses inside the cranium. However, a plaque or a blood clot may still block a small artery, and weak-ened arteries may rupture. Such incidents temporarily or permanently shut off blood flow to a localized area of the brain, damaging or killing the dependent neurons. Signs and symptoms of a *stroke*, or *cerebrovascular accident (CVA)*, then appear.

Blood Flow to the Heart

We described the anatomy of the coronary circulation in Chapter 20. \bigcirc p. 695 The coronary arteries arise at the base of the ascending aorta, where systemic pressures are highest. Each time the heart contracts, it squeezes the coronary vessels, so blood flow is reduced. In the left ventricle, systolic pressures are high enough that blood can flow into the myocardium only during diastole. Over this period, elastic rebound helps drive blood along the coronary vessels. Normal cardiac muscle cells can tolerate these brief circulatory interruptions because they have substantial oxygen reserves.

When you are at rest, coronary blood flow is about 250 mL/min. When the workload on your heart increases, local factors, such as reduced O_2 levels and increased lactic acid, dilate the coronary vessels and increase blood flow. Epinephrine released during sympathetic stimulation promotes the vasodilation of coronary vessels. It also increases heart rate and the strength of cardiac contractions. As a result, coronary blood flow increases while vasoconstriction occurs in other tissues.

For reasons that are not clear, some people have *coronary spasms*. These spasms can temporarily restrict coronary circulation and produce symptoms of angina. The heart's ability to increase its output, even under maximal stimulation, can be limited by certain conditions. These conditions include a permanent restriction or blockage of coronary vessels (as in coronary artery disease) and tissue damage (as caused by a myocardial infarction). When the cardiac workload increases much above resting levels, individuals with these conditions experience signs and symptoms of heart failure.

Blood Flow to the Lungs

The lungs have roughly 300 million *alveoli* (al-VĒ-ō-lī; *alveolus*, sac), delicate epithelial pockets where gas exchange takes place.

An extensive capillary network surrounds each alveolus. Local responses to oxygen levels within individual alveoli regulate blood flow through the lungs. How does this local regulation work? When an alveolus contains plenty of oxygen, its blood vessels dilate. Blood flow then increases, promoting the absorption of oxygen from air inside the alveolus. When the oxygen content of the air is very low, the vessels constrict. They shunt blood to other alveoli that contain more oxygen. This local mechanism makes the respiratory system very efficient. There is no benefit in circulating blood through the capillaries of an alveolus that contains little oxygen.

This mechanism is precisely the opposite of that in other tissues, where a decline in oxygen levels causes local vasodilation rather than vasoconstriction. The difference makes functional sense, but its physiological basis remains a mystery.

Blood pressure in pulmonary capillaries (average: 10 mm Hg) is lower than that in systemic capillaries. The BCOP (25 mm Hg) is the same as elsewhere in the bloodstream. As a result, reabsorption exceeds filtration in pulmonary capillaries. Fluid moves continuously into the pulmonary capillaries across the alveolar surfaces. This flow prevents fluid from building up in the alveoli and interfering with the diffusion of respiratory gases. If the blood pressure in pulmonary capillaries rises above 25 mm Hg, fluid enters the alveoli, causing *pulmonary edema*.

CHECKPOINT

- 12. Why does blood pressure increase during exercise?
- **13**. Name the immediate and long-term problems related to the cardiovascular response to hemorrhaging.
- 14. Explain the role of aldosterone and ADH in long-term restoration of blood volume.

See the blue Answers tab at the back of the book.

21-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns

Learning Outcome Describe the three general functional patterns seen in the pulmonary and systemic circuits of the cardiovascular system.

You already know that the cardiovascular system consists of the *pulmonary circuit* and the *systemic circuit*. The pulmonary circuit consists of arteries and veins that transport blood between the heart and the lungs. This circuit begins at the right ventricle and ends at the left atrium. From the left ventricle, the arteries of the systemic circuit transport oxygenated blood and nutrients to all organs and tissues. Veins of the systemic circuit ultimately return deoxygenated blood to the right atrium. **Figure 21–17** summarizes the main distribution routes within the pulmonary and systemic circuits.

In the pages that follow, we examine the vessels of the pulmonary and systemic circuits further. Three major patterns of blood vessel organization are worth noting:

1. The peripheral distributions of arteries and veins on the body's left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles. Corresponding arteries and veins usually follow the same path. For example, the left and right subclavian *arteries* parallel the left and right subclavian *veins*.

754 UNIT 4 Fluids and Transport

- 2. A single vessel may have several names as it crosses specific anatomical boundaries. These names make accurate anatomical descriptions possible when the vessel extends far into the periphery. For example, the *external iliac artery* becomes the *femoral artery* as it leaves the trunk and enters the lower limb.
- **3.** Several arteries and veins usually service tissues and organs. Often, anastomoses between adjacent arteries or veins reduce the impact of a temporary or even permanent blockage, or *occlusion*, in a single blood vessel.

CHECKPOINT

- 15. Identify the two circuits of the cardiovascular system.
- Identify the three major patterns of blood vessel organization seen in the pulmonary and systemic circuits of the cardiovascular system.

• See the blue Answers tab at the back of the book.

21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins

Learning Outcome Identify the major arteries and veins of the pulmonary circuit.

Blood entering the right atrium has just returned from the peripheral capillary beds, where it released oxygen and absorbed carbon dioxide. After traveling through the right atrium and ventricle, this deoxygenated blood enters the pulmonary trunk, the start of the pulmonary circuit (Figure 21–18). At the lungs, oxygen is replenished, and carbon dioxide is released. The oxygenated blood returns to the heart for distribution by the systemic circuit.

Figure 21–18 The Pulmonary Circuit. The pulmonary circuit consists of pulmonary arteries, which deliver deoxygenated blood from the right ventricle to the lungs; pulmonary capillaries, where gas exchange occurs; and pulmonary veins, which deliver oxygenated blood to the left atrium. As the enlarged view shows, diffusion across the capillary walls at alveoli removes carbon dioxide and provides oxygen to the blood. ATLAS: Plates 42a; 44c; 47b

Compared with the systemic circuit, the pulmonary circuit is short: The base of the pulmonary trunk and the lungs are only about 15 cm (6 in.) apart.

The arteries of the pulmonary circuit differ from those of the systemic circuit in that they carry deoxygenated blood. (For this reason, most color-coded diagrams show the pulmonary arteries in blue, the same color as systemic veins.) As the pulmonary trunk curves over the superior border of the heart, it gives rise to the **left** and **right pulmonary arteries**. These large arteries enter the lungs before branching repeatedly, giving rise to smaller and smaller arteries. The smallest branches, the pulmonary arterioles, provide blood to capillary networks that surround alveoli. The walls of these small air pockets are thin enough for gas to be exchanged between the capillary blood and inspired air. As oxygenated blood leaves the alveolar capillaries, it enters venules that in turn unite to form larger vessels carrying blood toward the **pulmonary veins**. These four veins, two from each lung, empty into the left atrium, to complete the pulmonary circuit.

TIPS&TRICKS

Arteries and veins are defined by the direction of blood flow relative to the heart, not by the oxygen content of the blood they carry. So if you remember that **a**rteries carry blood **a**way from the heart, and veins carry blood toward the heart, you can remember that the pulmonary **a**rteries carry oxygen-poor blood **a**way from the heart to the lungs, and the pulmonary veins deliver oxygen-rich blood to the heart.

CHECKPOINT

- Name the blood vessels that enter and exit the lungs, and whether they contain primarily oxygenated or deoxygenated blood.
- Trace the path of a drop of blood through the lungs, beginning at the right ventricle and ending at the left atrium.

• See the blue Answers tab at the back of the book.

21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the pulmonary exchange surfaces, and returns deoxygenated blood to the right atrium

Learning Outcome Identify the major arteries and veins of the systemic circuit.

The systemic circuit supplies the capillary beds in all parts of the body not serviced by the pulmonary circuit. This circuit begins at

the left ventricle and ends at the right atrium. At any moment the systemic circuit contains about 84 percent of total blood volume.

Systemic Arteries

Figure 21–19 provides an overview of the systemic arterial system and shows the relative locations of major systemic arteries. **Figures 21–20** to **21–25** show the detailed distribution of these vessels and their branches. By convention, several large arteries are called *trunks*. Examples are the *pulmonary*, *brachiocephalic*, *thyrocervical*, and *celiac trunks*. Most of the major arteries are paired, with one artery of each pair on either side of the body. For this reason, the terms *right* and *left* appear in figures only when the arteries on both sides are labeled.

The Ascending Aorta

The **ascending aorta** (Figure 21–20) begins at the aortic valve of the left ventricle. The left and right coronary arteries originate in the aortic sinus at the base of the ascending aorta, just superior to the aortic valve. The distribution of coronary vessels was described in Chapter 20 and illustrated in Figure 20–9, p. 696.

The Aortic Arch

The **aortic arch** curves like the handle of a cane across the superior surface of the heart, connecting the ascending aorta with the *descending aorta* (Figure 21–19). Three elastic arteries originate along the aortic arch and deliver blood to the head, neck, shoulders, and upper limbs: (1) the **brachiocephalic** (brā-kē-ō-se-FAL-ik) **trunk**, (2) the **left common carotid artery**, and (3) the **left subclavian artery** (Figures 21–20 and 21–21). The brachiocephalic trunk, also called the *innominate artery* (i-NOM-i-nat; unnamed), ascends for a short distance before branching to form the **right subclavian artery** and the **right common carotid artery**.

We have only one brachiocephalic trunk, with the left common carotid and left subclavian arteries arising separately from the aortic arch. However, in terms of their peripheral distribution, the vessels on the left side are mirror images of those on the right side. Figures 21–20 and 21–22 illustrate the major branches of these arteries.

The Subclavian Arteries. The subclavian arteries supply blood to the arms, chest wall, shoulders, back, and CNS (**Figures 21–19** and **21–20**). Three major branches arise before a subclavian artery leaves the thoracic cavity: (1) the **internal thoracic artery**, supplying the pericardium and anterior wall of the chest; (2) the **vertebral artery**, which provides blood to the brain and spinal cord; and (3) the **thyrocervical trunk**, which provides blood to muscles and other tissues of the neck, shoulder, and upper back.

After leaving the thoracic cavity and passing across the superior border of the first rib, the subclavian is called the **axillary artery**. This artery crosses the axilla to enter the arm, where it gives

Figure 21–20 Arteries of the Chest and Upper Limb. ATLAS: Plates 27a-c; 29c; 30; 45a

Figure 21–21 Arteries of the Neck and Head. Shown as seen from the right side. ATLAS: Plates 3c,d; 15b; 18a–c; 45a

rise to *humeral circumflex arteries*, which supply structures near the head of the humerus. Distally, it becomes the **brachial artery**, which supplies blood to the rest of the upper limb. The brachial artery gives rise to the *deep brachial artery*, which supplies deep structures on the posterior aspect of the arm, and the *ulnar collateral arteries*, which supply the area around the elbow.

As it approaches the coronoid fossa of the humerus, the brachial artery divides into the **radial artery**, which follows the radius, and the **ulnar artery**, which follows the ulna to the wrist. These arteries supply blood to the forearm and, through the *ulnar recurrent arteries*, the region around the elbow. At the wrist, the radial and ulnar arteries fuse to form the **superficial** and **deep palmar arches**, which supply blood to the hand and to the **digital arteries** of the thumb and fingers.

The Carotid Artery and the Blood Supply to the Brain. The common carotid arteries ascend deep in the tissues of the neck. You can usually locate the carotid artery by pressing gently along either side of the windpipe (trachea) until you feel a strong pulse.

Each common carotid artery divides into an **external carotid artery** and an **internal carotid artery** (Figure 21–21). The **carotid sinus**, located at the base of the internal carotid artery, may extend along a portion of the common carotid. The external carotid arteries supply blood to the structures of the neck, esophagus, pharynx, larynx, lower jaw, and face. The internal carotid arteries enter the skull through the carotid canals of the temporal bones, delivering blood to the brain (Figure 7–3 and Spotlight Figure 7–4, pp. 210–213).

TIPS&TRICKS

Remember that the *external* carotid artery supplies the face (which is external), and that the *internal* carotid supplies the brain (which is internal).

The internal carotid arteries ascend to the level of the optic nerves, where each artery divides into three branches: (1) an **ophthalmic artery**, which supplies the eyes; (2) an **anterior cerebral artery**, which supplies the frontal and parietal lobes of the brain; and (3) a **middle cerebral artery**, which supplies the midbrain and lateral surfaces of the cerebral hemispheres (Figures 21–21 and 21–22).

The brain is extremely sensitive to changes in blood supply. An interruption of blood flow for several seconds produces unconsciousness. After four minutes some permanent neural damage can occur. Such crises are rare, because blood reaches the brain through the vertebral arteries as well as by way of the internal carotid arteries. The left and right vertebral arteries arise from the subclavian arteries and ascend within the transverse foramina of the cervical vertebrae (Figure 7–19b,c, p. 230). The vertebral arteries enter the cranium at the foramen magnum, where they fuse along the ventral surface of the medulla oblongata to form the **basilar artery**. The vertebral arteries and the basilar artery supply blood to the spinal cord, medulla

Figure 21–22 Arteries of the Brain. ATLAS: Plates 15a–c

oblongata, pons, and cerebellum. They then divide into the **posterior cerebral arteries**, which in turn branch off into the **posterior communicating arteries** (Figure 21–22).

The internal carotid arteries normally supply the arteries of the anterior half of the cerebrum, and the rest of the brain receives blood from the vertebral arteries. But this pattern of blood flow can easily change, because the internal carotid arteries and the basilar artery are interconnected. They form a ring-shaped anastomosis called the **cerebral arterial circle**, or *circle of Willis*, which encircles the infundibulum of the pituitary gland (**Figure 21–22**). With this arrangement, the brain can receive blood from either the carotid or the vertebral arteries, reducing the likelihood of a serious interruption of circulation.

Strokes, or *cerebrovascular accidents (CVAs)*, are interruptions of the vascular supply to a portion of the brain. The *middle cerebral artery*, a major branch of the cerebral arterial circle, is the most common site of a stroke. Superficial branches deliver blood to the temporal lobe and large portions of the frontal

and parietal lobes. Deep branches supply the basal nuclei and portions of the thalamus. If a stroke blocks the middle cerebral artery on the left side of the brain, aphasia and a sensory and motor paralysis of the right side of the body result. In a stroke affecting the middle cerebral artery on the right side, the individual experiences a loss of sensation and motor control over the left side of the body and has difficulty drawing or interpreting spatial relationships. Strokes affecting vessels that supply the brain stem also produce distinctive symptoms. Strokes affecting the lower brain stem are commonly fatal.

The Descending Aorta

The **descending aorta** is continuous with the aortic arch. The diaphragm divides the descending aorta into a superior **thoracic aorta** and an inferior **abdominal aorta** (Figures 21–23 and 21–24).

The Thoracic Aorta. The thoracic aorta begins at the level of vertebra T_5 and penetrates the diaphragm at the level of vertebra T_{12} .

Figure 21–23 Major Arteries of the Trunk. ATLAS: Plates 47d; 53c,e; 62a,b

Figure 21–23 Major Arteries of the Trunk (Continued)

It travels within the mediastinum, on the posterior thoracic wall, slightly to the left of the vertebral column. This vessel supplies blood to branches that service the tissues and organs of the mediastinum, the muscles of the chest and the diaphragm, and the thoracic spinal cord.

We group the branches of the thoracic aorta anatomically as either visceral or somatic (Figure 21–23):

- Visceral branches supply the organs of the chest. The bronchial arteries supply the tissues of the lungs not involved in gas exchange. The pericardial arteries supply the pericardium. The esophageal arteries supply the esophagus, and the mediastinal arteries supply the tissues of the mediastinum.
- Somatic branches supply the chest wall. The **intercostal arteries** supply the chest muscles and the vertebral column area. The **superior phrenic** (FREN-ik) **arteries** deliver blood to the superior surface of the diaphragm, which separates the thoracic and abdominopelvic cavities.

The Abdominal Aorta. The abdominal aorta is a continuation of the thoracic aorta (Figure 21–23). It begins immediately inferior to the diaphragm and descends slightly to the left of the vertebral column but posterior to the peritoneal cavity. A cushion of adipose tissue commonly surrounds the abdominal aorta. At the level of vertebra L_4 , the abdominal aorta splits into two major arteries—the *left* and *right common iliac arteries*—that supply deep pelvic structures and the lower limbs. The region where the abdominal aorta splits is called the *terminal segment of the aorta*.

The abdominal aorta delivers blood to all the abdominopelvic organs and structures. The major branches to visceral organs are unpaired. They arise on the anterior surface of the abdominal aorta and extend into the mesenteries. By contrast, branches to the body wall, the kidneys, the urinary bladder, and other structures outside the peritoneal cavity are paired. They originate along the lateral surfaces of the abdominal aorta. **Figure 21–23** shows the major arteries of the trunk after most thoracic and abdominal organs have been removed. **Figure 21–24** shows the distribution of those arteries to abdominopelvic organs.

TIPS&TRICKS

The aorta resembles a walking cane: the ascending aorta, aortic arch, and the start of the descending aorta form the cane's handle, while the thoracic and abdominal segments of the descending aorta form the cane's shaft.

The abdominal aorta gives rise to three unpaired arteries (Figures 21–23 and 21–24).

- The celiac (SĒ-lē-ak) trunk delivers blood to the liver, stomach, and spleen. The celiac trunk divides into three branches: (a) The left gastric artery supplies the stomach and the inferior portion of the esophagus. (b) The splenic artery supplies the spleen and arteries to the stomach (*left gastroepiploic artery*) and pancreas (*pancreatic arteries*). (c) The common hepatic artery supplies arteries to the liver (*hepatic artery proper*), stomach (*right gastroepiploic artery*), gall-bladder (*cystic artery*), and duodenal area (*gastroduodenal, right gastroepiploic*, and *superior pancreaticoduodenal arteries*).
- 2. The **superior mesenteric** (mez-en-TER-ik) **artery** arises about 2.5 cm (1 in.) inferior to the celiac trunk. It supplies arteries to the pancreas and duodenum (*inferior pancreaticoduodenal artery*), small intestine (*intestinal arteries*), and most of the large intestine (*right* and *middle colic* and the *ileocolic arteries*).

3. The **inferior mesenteric artery** arises about 5 cm (2 in.) superior to the terminal aorta. It delivers blood to the terminal portions of the colon *(left colic and sigmoid arteries)* and the rectum *(rectal arteries)*.

The abdominal aorta also gives rise to five paired arteries (Figure 21–23):

- 1. The **inferior phrenic arteries** supply the inferior surface of the diaphragm and the inferior portion of the esophagus.
- 2. The **adrenal arteries** originate on either side of the aorta near the base of the superior mesenteric artery. Each adrenal artery supplies one adrenal gland, which caps the superior part of a kidney.
- 3. The short (about 7.5 cm) **renal arteries** arise along the posterolateral surface of the abdominal aorta, about 2.5 cm (1 in.) inferior to the superior mesenteric artery. They

travel posterior to the peritoneal lining to reach the adrenal glands and kidneys. We consider the branches of the renal arteries in Chapter 26.

- 4. The **gonadal** (gō-NAD-al) **arteries** originate between the superior and inferior mesenteric arteries. In males, they are called *testicular arteries* and are long, thin arteries that supply blood to the testes and scrotum. In females, they are termed *ovarian arteries* and supply blood to the ovaries, uterine tubes, and uterus. The distribution of gonadal vessels (both arteries and veins) differs by gender. We describe the differences in Chapter 28.
- 5. Small **lumbar arteries** arise on the posterior surface of the aorta. They supply the vertebrae, spinal cord, and abdominal wall.

Arteries of the Pelvis and Lower Limbs

Near the level of vertebra L₄, the terminal segment of the abdominal aorta divides to form a pair of elastic arteries-the right and left common iliac (IL-ē-ak) arteries-plus the small median sacral artery (Figure 21-23). The common iliac arteries carry blood to the pelvis and lower limbs. They descend posterior to the cecum and sigmoid colon along the inner surface of the ilium. At the level of the lumbosacral joint, each common iliac divides to form an internal iliac artery and an external iliac artery (Figure 21-24). The internal iliac arteries enter the pelvic cavity to supply the urinary bladder, the internal and external walls of the pelvis, the external genitalia, the medial side of the thigh, and, in females, the uterus and vagina. The major branches of the internal iliac artery are the *gluteal*, internal pudendal, obturator, and lateral sacral arteries. The external iliac arteries supply blood to the lower limbs. They are much larger in diameter than the internal iliac arteries.

Arteries of the Thigh and Leg. Each external iliac artery crosses the surface of an iliopsoas muscle and penetrates the abdominal wall midway between the anterior superior iliac spine and the pubic symphysis on that side. It emerges on the anterior, medial surface of the thigh as the **femoral artery (Figure 21–25a,b)**. Roughly 5 cm (2 in.) distal to the emergence of the femoral artery, the **deep femoral artery** branches off its lateral surface. The deep femoral artery supplies blood to the ventral and lateral regions of the skin and deep muscles of the thigh. It gives rise to the *femoral circumflex arteries*.

The femoral artery continues inferiorly and posterior to the femur. As it approaches the knee, it gives rise to the *descending genicular artery*, which supplies the area around the knee. At the popliteal fossa, posterior to the knee joint, the femoral artery becomes the **popliteal** (pop-LIT-ē-al) **artery**, which then branches to form the **posterior** and **anterior tibial arteries**. The posterior tibial artery gives rise to the **fibular artery**, or *peroneal* (*perone*, fibula) *artery*, and then continues inferiorly along the posterior surface of the tibia. The anterior tibial artery passes between the tibia and fibula. It emerges on the anterior surface of the tibia. As it descends toward the foot, the anterior tibial artery provides blood to the skin and muscles of the anterior portion of the leg.

Arteries of the Foot. At the ankle, the anterior tibial artery becomes the **dorsalis pedis artery**. It then branches repeatedly, supplying the ankle and dorsal portion of the foot (**Figure 21–25a,b**). **Figure 21–25c** charts the flow of blood from the external iliac artery to the lower limbs.

At the ankle, the posterior tibial artery divides to form the **medial** and **lateral plantar arteries**. They supply blood to the plantar surface of the foot. These arteries are connected to the dorsalis pedis artery through a pair of anastomoses. The arrangement produces a **dorsal arch** (*arcuate arch*) and a **plantar arch**. Small arteries branching off these arches supply the distal portions of the foot and the toes.

Systemic Veins

Veins collect blood from the tissues and organs of the body by means of an elaborate venous network that drains into the right atrium of the heart by the superior and inferior venae cavae (Figure 21–26). The branching pattern of peripheral veins is much more variable than is the branching pattern of arteries. We base the discussion that follows on the most common arrangement of veins. Complementary arteries and veins commonly run side by side. In many cases they have comparable names.

One significant difference between the arterial and venous systems involves the distribution of major veins in the neck and limbs. Arteries in these areas are deep beneath the skin, protected by bones and surrounding soft tissues. In contrast, the neck and limbs generally have two sets of peripheral veins, one superficial and the other deep. This dual venous drainage is important for controlling body temperature. In hot weather, venous blood flows through superficial veins, where heat can easily be lost. In cold weather, blood is routed to the deep veins to minimize heat loss.

The Superior Vena Cava

All the body's systemic veins (except the cardiac veins) ultimately drain into either the superior vena cava or the inferior vena cava. The **superior vena cava (SVC)** receives blood from the tissues and organs of the head, neck, chest, shoulders, and upper limbs.

Venous Return from the Cranium. Numerous veins drain the cerebral hemispheres. The *superficial cerebral veins* and small veins of the brain stem empty into a network of dural sinuses (Figure 21–27a,b). These sinuses include the *superior* and *inferior sagittal sinuses*, the *petrosal sinuses*, the *occipital sinus*, the *left* and *right transverse sinuses*, and the *straight sinus* (Figure 21–27c).
Figure 21–25 Arteries of the Lower Limb. ATLAS: Plates 68c; 70b; 78b-g

Figure 21–27 Major Veins of the Head, Neck, and Brain. ATLAS: Plates 3c,d; 18a-c

The largest, the **superior sagittal sinus**, is in the falx cerebri (Figure 14–3, p. 466). Most of the *inferior cerebral veins* converge within the brain to form the **great cerebral vein**. It delivers blood from the interior of the cerebral hemispheres and the choroid plexus to the **straight sinus**. Other cerebral veins drain into the **cavernous sinus** with numerous small veins from the orbit. Blood from the cavernous sinus reaches the internal jugular vein through the petrosal sinuses.

The venous sinuses converge within the dura mater in the region of the lambdoid suture. The left and right transverse sinuses begin at the confluence of the occipital, sagittal, and straight sinuses. Each transverse sinus drains into a **sigmoid sinus**, which penetrates the jugular foramen and leaves the skull as the **internal jugular vein**. It descends parallel to the common carotid artery in the neck. \supset p. 757

Vertebral veins drain the cervical spinal cord and the posterior surface of the skull. These vessels descend within the transverse foramina of the cervical vertebrae, along with the vertebral arteries. The vertebral veins empty into the *brachiocephalic veins* of the chest (discussed later in the chapter).

Superficial Veins of the Head and Neck. The superficial veins of the head converge to form the **temporal**, **facial**, and **maxillary veins (Figure 21–27c)**. The temporal vein and the maxillary vein drain into the **external jugular vein**. The facial vein drains into the internal jugular vein. A broad anastomosis between the external and internal jugular veins at the angle of the mandible provides dual venous drainage of the face, scalp, and cranium. The external jugular vein descends toward the chest just deep to the skin on the anterior surface of the sternocleidomastoid muscle. Posterior to the clavicle, the external jugular vein empties into the *subclavian vein*. In healthy individuals, the external jugular vein is easily palpable. A *jugular venous pulse (JVP)* is sometimes detectable at the base of the neck.

Venous Return from the Upper Limbs. The digital veins empty into the superficial and deep palmar veins of the hand, which interconnect to form the palmar venous arches (Figure 21–28). The superficial arch empties into the cephalic vein, which ascends along the radial side of the forearm; the median antebrachial vein; and the basilic vein, which ascends on the ulnar side. Anterior to the elbow is the superficial median cubital vein, which passes from the cephalic vein, medially and at an oblique angle, to connect to the basilic vein. (Venous blood samples are typically collected from the median cubital.) From the elbow, the basilic vein passes superiorly along the medial surface of the biceps brachii muscle.

The deep palmar veins drain into the **radial vein** and the **ulnar vein**. These veins fuse to form the **brachial vein**, running parallel to the brachial artery. As the brachial vein continues toward the trunk, it merges with the basilic vein and becomes the **axillary vein**, which enters the axilla. **Formation of the Superior Vena Cava.** The cephalic vein joins the axillary vein on the lateral surface of the first rib, forming the **subclavian vein**, which continues into the chest. The subclavian vein passes superior to the first rib and along the superior margin of the clavicle. It merges with the external and internal jugular veins of that side. This fusion creates the **brachiocephalic vein**, or *innominate vein*, which penetrates the body wall and enters the thoracic cavity.

Each brachiocephalic vein receives blood from the vertebral vein of the same side, which drains the back of the skull and spinal cord. Near the heart, at the level of the first and second ribs, the left and right brachiocephalic veins join, creating the superior vena cava. Close to the point of fusion, the **internal thoracic vein** empties into the brachiocephalic vein.

The **azygos** (AZ- $\bar{1}$ -gos) **vein** is the major branch of the superior vena cava. This vein ascends from the lumbar region over the right side of the vertebral column to enter the thoracic cavity through the diaphragm. The azygos vein joins the superior vena cava at the level of vertebra T_2 . On the left side, the azygos receives blood from the smaller **hemiazygos vein**, which in many people also drains into the left brachiocephalic vein through the *highest intercostal vein*.

The azygos and hemiazygos veins are the chief collecting vessels of the thorax. They receive blood from (1) **intercostal veins**, which in turn receive blood from the chest muscles; (2) **esophageal veins**, which drain blood from the inferior portion of the esophagus; and (3) smaller veins draining other mediastinal structures.

Figure 21–29 diagrams the venous branches of the superior vena cava.

The Inferior Vena Cava

The **inferior vena cava (IVC)** collects most of the venous blood from organs inferior to the diaphragm. (A small amount reaches the superior vena cava by the azygos and hemiazygos veins.)

Veins Draining the Lower Limbs. Blood leaving capillaries in the sole of each foot collects into a network of **plantar veins**, which supply the **plantar venous arch** (Figure 21–30a). The plantar network sends blood to the deep veins of the leg: the **anterior tibial vein**, the **posterior tibial vein**, and the **fibular vein**. The **dorsal venous arch** collects blood from capillaries on the superior surface of the foot and the **digital veins** of the toes. The plantar arch and the dorsal arch are extensively interconnected, and the path of blood flow can easily shift from superficial to deep veins.

The dorsal venous arch is drained by two superficial veins: the **great saphenous** (sa-FĒ-nus; saphenes, prominent) **vein** and the **small saphenous vein**. The great saphenous vein ascends along the medial aspect of the leg and thigh, draining into the *femoral vein* near the hip joint. The small saphenous

abdominal wall, the femoral vein receives blood from (1) the great saphenous vein; (2) the deep femoral vein, which collects blood from deeper structures in the thigh; and (3) the **fem**oral circumflex vein, which drains the region around the neck and head of the femur. The femoral vein penetrates the body wall and emerges in the pelvic cavity as the **external iliac vein**.

Veins Draining the Pelvis. The external iliac veins receive blood from the lower limbs, the pelvis, and the lower abdomen.

As the left and right external iliac veins cross the inner surface of the ilium, they are joined by the **internal iliac veins**, which drain the pelvic organs (Figure 21–29). The internal iliac veins are formed by the fusion of the gluteal, internal pudendal, obturator, and lateral sacral veins (Figure 21–30a).

The union of external and internal iliac veins forms the **common iliac vein**. Its right and left branches ascend at an oblique angle. The left common iliac vein receives blood from the *median sacral vein*, which drains the area supplied by the middle sacral artery (Figure 21–28). Anterior to vertebra L_5 , the common iliac veins unite to form the inferior vena cava.

Veins Draining the Abdomen. The inferior vena cava ascends posterior to the peritoneal cavity, parallel to the aorta. The abdominal portion of the inferior vena cava collects blood from six major veins (Figures 21–28 and 21–29):

1. **Lumbar veins** drain the lumbar portion of the abdomen, including the spinal cord and body wall muscles. Superior branches of these veins are connected to the azygos vein (right side) and hemiazygos vein (left side), which empty into the superior vena cava.

- 2. **Gonadal** (*ovarian* or *testicular*) **veins** drain the ovaries or testes. The right gonadal vein empties into the inferior vena cava. The left gonadal vein generally drains into the left renal vein.
- 3. **Hepatic veins** from the liver empty into the inferior vena cava at the level of vertebra T_{10} .
- 4. **Renal veins**, the largest branches of the inferior vena cava, collect blood from the kidneys.
- 5. **Adrenal veins** drain the adrenal glands. In most people, only the right adrenal vein drains into the inferior vena cava. The left adrenal vein drains into the left renal vein.

Figure 21–31 The Hepatic Portal System. (See also Figure 24–24, p. 918.) ATLAS: Plates 53b; 54a–c; 55; 57a,b

6. **Phrenic veins** drain the diaphragm. Only the right phrenic vein drains into the inferior vena cava. The left drains into the left renal vein.

Figure 21–29 diagrams the branches of the inferior vena cava.

The Hepatic Portal System

The **hepatic portal system** begins in the capillaries of the digestive organs and ends in the liver sinusoids (Figure 21–31). (As you may recall from Chapter 18, a blood vessel connecting two capillary beds is called a *portal vessel*. The network is a *portal system*.) Blood flowing in the hepatic portal system is quite different from blood in other systemic veins, because it contains substances absorbed from the stomach and intestines. For example, levels of blood glucose and amino acids in the hepatic portal vein often exceed those found anywhere else in the

cardiovascular system. The hepatic portal system delivers these and other absorbed compounds directly to the liver for storage, metabolic conversion, or excretion.

The largest vessel of the hepatic portal system is the **hepatic portal vein** (Figure 21–31). It delivers venous blood to the liver. It receives blood from three large veins draining organs within the peritoneal cavity:

- The **inferior mesenteric vein** collects blood from capillaries along the inferior portion of the large intestine. Its branches include the *left colic vein* and the *superior rectal veins*. They drain the descending colon, sigmoid colon, and rectum.
- The **splenic vein** is formed by the union of the inferior mesenteric vein and veins from the spleen, the lateral border of the stomach *(left gastroepiploic vein)*, and the pancreas *(pancreatic veins)*.

• The **superior mesenteric vein** collects blood from veins draining the stomach (*right gastroepiploic vein*), the small intestine (*intestinal* and *pancreaticoduodenal veins*), and two-thirds of the large intestine (*ileocolic*, *right colic*, and *middle colic veins*).

The hepatic portal vein forms through the fusion of the superior mesenteric, inferior mesenteric, and splenic veins. The superior mesenteric vein normally contributes the greater volume of blood and most of the nutrients. As it proceeds, the hepatic portal vein receives blood from the left and right **gastric veins**, which drain the medial border of the stomach, and from the **cystic vein** of the gallbladder.

After passing through liver sinusoids, blood collects in the hepatic veins, which empty into the inferior vena cava.

The composition of the blood in the systemic circuit is relatively stable despite changes in diet and digestive activity. The reason for this stability is that blood from the intestines goes to the liver first, and the liver regulates the nutrient content of the blood before it enters the inferior vena cava.

CHECKPOINT

- **19**. A blockage of which branch from the aortic arch would interfere with blood flow to the left arm?
- **20**. Why would compression of the common carotid arteries cause a person to lose consciousness?
- 21. Grace is in an automobile accident, and her celiac trunk is ruptured. Which organs will be affected most directly by this injury?
- 22. Whenever Tim gets angry, a large vein bulges in the lateral region of his neck. Which vein is this?
- **23**. A thrombus that blocks the popliteal vein would interfere with blood flow in which other veins?

See the blue Answers tab at the back of the book.

21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials, and independence occurs at birth

Learning Outcome Identify the differences between fetal and adult circulation patterns, and describe the changes in the patterns of blood flow that occur at birth.

The fetal cardiovascular system differs from the adult cardiovascular system because the fetus and the adult have different sources of respiratory and nutritional support. Most strikingly, the fetal lungs are collapsed and nonfunctional, and the digestive tract has nothing to digest. Instead, diffusion across the placenta provides for the respiratory and nutritional needs of the fetus.

Placental Blood Supply

Fetal patterns of blood flow are diagrammed in Figure 21–32a. Blood flows to the placenta through a pair of **umbilical arteries**. They arise from the internal iliac arteries and enter the umbilical cord. Blood returns from the placenta in the single **umbilical vein**, bringing oxygen and nutrients to the developing fetus. The umbilical vein drains into the **ductus venosus**, a vascular connection to an intricate network of veins within the developing liver. The ductus venosus collects blood from the veins of the liver and from the umbilical vein, and empties into the inferior vena cava. When the placental connection is broken at birth, blood stops flowing in the umbilical vessels, and they soon degenerate. Remnants of these vessels persist throughout life as fibrous cords.

Fetal Circulation in the Heart and Great Vessels

One of the most interesting aspects of cardiovascular development reflects the differences between the life of an embryo or fetus and that of an infant. Throughout embryonic and fetal life, the lungs are collapsed. Yet after delivery, the newborn infant must extract oxygen from inhaled air rather than across the placenta. ATLAS: Embryology Summary 16: The Development of the Cardiovascular System

The interatrial and interventricular septa develop early in fetal life, but the interatrial partition remains functionally incomplete until birth. The **foramen ovale**, or *interatrial opening*, is associated with a long flap that acts as a valve. Blood can flow freely from the right atrium to the left atrium, but any backflow closes the valve and isolates the two chambers from one another. Thus, blood entering the heart at the right atrium can bypass the pulmonary circuit. A second short-circuit exists between the pulmonary and aortic trunks. This connection, the **ductus arteriosus**, consists of a short, muscular vessel.

With the lungs collapsed, the capillaries are compressed and little blood flows through the lungs. During diastole, blood enters the right atrium and flows into the right ventricle, but it also passes into the left atrium through the foramen ovale. About 25 percent of the blood arriving at the right atrium bypasses the pulmonary circuit in this way. In addition, more than 90 percent of the blood leaving the right ventricle passes through the ductus arteriosus and enters the systemic circuit rather than continuing to the lungs.

Figure 21–32 Fetal Circulation.

Cardiovascular Changes at Birth

At birth, dramatic changes take place. When an infant takes the first breath, the lungs expand, and so do the pulmonary vessels. The resistance in the pulmonary circuit declines suddenly, and blood rushes into the pulmonary vessels. Within a few seconds, rising O_2 levels stimulate the constriction of the ductus arteriosus, isolating the pulmonary and aortic trunks from one another. As pressures rise in the left atrium, the valvular flap closes the foramen ovale. In adults, the interatrial septum bears the *fossa ovalis*, a shallow depression that marks the site of the foramen ovale (Figure 20–6a, p. 691). The remnants of the ductus arteriosus persist throughout life as the *ligamentum arteriosum*, a fibrous cord.

If the proper cardiovascular changes do not take place at birth or shortly after, problems eventually develop. Their severity depends on which connection remains open and on the size of the opening. Treatment may involve surgery to close the foramen ovale, the ductus arteriosus, or both. Other congenital heart defects result from abnormal cardiac development or inappropriate connections between the heart and major arteries and veins. **Spotlight Figure 21–33** focuses on congenital heart problems.

CHECKPOINT

- 24. Name the three vessels that carry blood to and from the placenta.
- 25. A blood sample taken from the umbilical cord contains high levels of oxygen and nutrients, and low levels of carbon dioxide and waste products. Is this sample from an umbilical artery or from the umbilical vein? Explain.
- **26**. Name the structures in the fetal circulation that stop functioning at birth. What becomes of these structures?

• See the blue Answers tab at the back of the book.

SPOTLIGHT Figure 21–33 Congenital Heart Problems

Although minor individual variations in the vascular network are quite common, congenital heart problems serious enough to threaten homeostasis are relatively rare.

Patent Foramen Ovale and Patent Ductus Arteriosus

If the foramen ovale remains open, or patent, blood recirculates through the pulmonary circuit instead of entering the left ventricle. The movement, driven by the relatively high systemic pressure, is called a "left-to-right shunt." Arterial oxygen content is normal, but the left ventricle must work much harder than usual to provide adequate blood flow through the systemic circuit. Hence, pressures rise in the pulmonary circuit. If the pulmonary pressures rise enough, they may force blood into the systemic circuit through the ductus arteriosus. This condition—a patent ductus arteriosus—creates a "right-to-left shunt." Because the circulating blood is not adequately oxygenated, it develops a deep red color. The skin then develops the blue tones typical of cyanosis and the infant is known as a "blue baby."

Tetralogy of Fallot

The tetralogy of Fallot (fa-LÕ) is a complex group of heart and circulatory defects that affect 0.10% of newborn infants. In this condition, (1) the pulmonary trunk is abnormally narrow (pulmonary stenosis), (2) the interventricular septum is incomplete, (3) the aorta originates where the interventricular septum normally ends, and (4) the right ventricle is enlarged and both ventricles thicken in response to the increased workload.

Ventricular Septal Defect

A ventricular septal defect is an abnormal opening in the wall (septum) between the left and right ventricles. It affects 0.12% of newborns. The opening between the two ventricles has an effect similar to a connection between the atria: When the more powerful left ventricle beats, it ejects blood into the right ventricle and pulmonary circuit.

Atrioventricular Septal Defect

In an atrioventricular septal defect, both the atria and ventricles are incompletely separated. The results are quite variable, depending on the extent of the defect and the effects on the atrioventricular valves. This type of defect most commonly affects infants with Down's syndrome, a disorder caused by the presence of an extra copy of chromosome 21.

Transposition of the Great Vessels

In the transposition of the great vessels, the aorta is connected to the right ventricle instead of to the left ventricle, and the pulmonary artery is connected to the left ventricle instead of the right ventricle. This malformation affects 0.05% of newborn infants.

Normal Heart Structure

Most congenital heart problems result from abnormal formation of the heart or problems with the connections between the heart and the great vessels.

21-9 Aging affects the blood, heart, and blood vessels

Learning Outcome Discuss the effects of aging on the cardiovascular system, and give examples of interactions between the cardiovascular system and other organ systems.

The capabilities of the cardiovascular system gradually decline. As you age, your cardiovascular system undergoes the following major changes:

- Age-related changes in blood may include (1) a decreased hematocrit; (2) constriction or blockage of peripheral veins by a stationary blood clot called a *thrombus*, which can become detached, pass through the heart, and become wedged in a small artery (commonly in the lungs), causing *pulmonary embolism*; and (3) pooling of blood in the veins of the legs because valves are not working effectively.
- Age-related changes in the heart include (1) a reduction in maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the elasticity of the cardiac (fibrous) skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) replacement of damaged cardiac muscle cells by scar tissue.
- **Age-related changes in blood vessels** may be linked to arteriosclerosis: (1) The inelastic walls of arteries become

less tolerant of sudden pressure increases, which can lead to an *aneurysm*, whose rupture may (depending on the vessel) cause a stroke, myocardial infarction, or massive blood loss; (2) calcium salts can be deposited on weakened vascular walls, increasing the risk of a stroke or myocardial infarction; (3) lipid deposits in the tunica media associated with a damaged endothelial lining and calcium salts can form atherosclerotic plaques; and (4) thrombi can form at atherosclerotic plaques.

The cardiovascular system is both anatomically and functionally linked to all other systems. Figure 21–34 shows the relationships between the cardiovascular system and the other body systems we have studied so far.

CHECKPOINT

- **27**. Identify components of the cardiovascular system that are affected by age.
- 28. Define thrombus.
- 29. Define aneurysm.
- **30**. Describe what the cardiovascular system provides for all other body systems.
- **31**. What is the relationship between the skeletal system and the cardiovascular system?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

angiogram: An x-ray of a blood vessel that becomes visible due to a prior injection of dye into the subject's bloodstream.

- **carotid sinus massage:** A procedure that involves rubbing the large part of the arterial wall at the point where the common carotid artery divides into its two main branches.
- **deep vein thrombosis (DVT):** A blood clot in a major vein, usually in the legs. They often occur after extended periods of inactivity, such as long airplane flights. The clot can break free and travel as an embolus to the lungs, where it can cause respiratory distress or failure.
- **intermittent claudication:** A limp that results from cramping leg pain that is typically caused by obstruction of the arteries. **normotensive:** Having normal blood pressure.
- **orthostatic hypotension:** A form of low blood pressure that occurs when you stand up from sitting or lying down. It can cause dizziness or a light-headed feeling.

phlebitis: Inflammation of a vein.

Raynaud's phenomenon: A condition resulting in the discoloration of the fingers and/or the toes when a person is subjected to changes in temperature or to emotional stress.

- **sclerotherapy:** The treatment of varicose veins in which an irritant is injected to cause inflammation, coagulation of blood, and a narrowing of the blood vessel wall.
- **sounds of Korotkoff:** Distinctive sounds, caused by turbulent arterial blood flow, heard through the stethoscope while measuring blood pressure.
- **sphygmomanometer:** A device that measures blood pressure using an inflatable cuff placed around a limb.
- **syncope:** A temporary loss of consciousness due to a sudden drop in blood pressure.
- **thrill:** A vibration felt in a blood vessel that usually occurs due to abnormal blood flow. It is also often noticed at the fistula of a hemodialysis patient.
- **thrombophlebitis:** An inflammation in a vein associated with the formation of a thrombus (clot).
- **vascular murmur:** Periodic abnormal sounds heard upon auscultation that are produced as a result of turbulent blood flow.
- white coat hypertension: A short-term increase in blood pressure triggered by the sight of medical personnel in white coats or other medical attire.

Figure 21–34 diagrams the functional relationships between the cardiovascular system and the other body systems we have studied so far.

21-1 Arteries, arterioles, capillaries, venules, and veins differ in size, structure, and functional properties p. 724

- 1. Blood flows through a network of arteries, veins, and capillaries. All chemical and gaseous exchange between blood and interstitial fluid takes place across capillary walls.
- 2. Arteries and veins form an internal distribution system through which the heart propels blood. Arteries branch repeatedly, decreasing in size until they become **arterioles**. From the arterioles, blood enters **capillary** networks. Blood flowing from the capillaries enters small **venules** before entering larger veins.
- **3.** The walls of arteries and veins contain three layers: the innermost **tunica intima**, the **tunica media**, and the outermost **tunica externa**. (*Figure 21–1*)
- 4. In general, the walls of arteries are thicker than those of veins. Arteries constrict when blood pressure does not distend them, but veins constrict very little. The endothelial lining cannot contract, so when constriction occurs, the lining of an artery becomes folded. (*Figure 21–1*)
- 5. The arterial system includes the large **elastic arteries**, medium-sized **muscular arteries**, and smaller arterioles. As blood proceeds toward the capillaries, the number of vessels increases, but the diameters of the individual vessels decrease and the walls become thinner. (*Figure 21–2*)
- 6. Atherosclerosis, a type of **arteriosclerosis**, is associated with changes in the endothelial lining of arteries. Fatty masses of tissue called **plaques** typically develop during atherosclerosis.
- 7. Capillaries are the only blood vessels whose walls are thin enough to permit an exchange between blood and interstitial fluid. Capillaries are **continuous** or **fenestrated**. **Sinusoids** have fenestrated walls and form elaborate networks that allow very slow blood flow. Sinusoids are located in the liver and in various endocrine organs. (*Figure 21–3*)
- 8. Capillaries form interconnected networks called **capillary beds (capillary plexuses)**. A band of smooth muscle, the **precapillary sphincter**, adjusts the blood flow into each capillary. Blood flow in a capillary changes as **vasomotion** occurs. The entire capillary bed may be bypassed by blood flow through **arteriovenous anastomoses**. (*Figure 21–4*)
- Venules collect blood from the capillaries and merge into medium-sized veins and then large veins. The arterial

system is a high-pressure system; blood pressure in veins is much lower. **Valves** in veins prevent the backflow of blood. (*Figures 21–1, 21–2, 21–5*)

Peripheral venoconstriction helps maintain adequate blood volume in the arterial system after a hemorrhage. The venous reserve normally accounts for about 20 percent of total blood volume. (*Figure 21–6*)

21-2 Pressure and resistance determine blood flow and affect rates of capillary exchange p. 734

- **11.** Cardiovascular regulation involves the manipulation of blood pressure and resistance to control the rates of blood flow and capillary exchange.
- 12. Blood flows from an area of higher pressure to one of lower pressure, and blood flow is proportional to the pressure gradient. The *circulatory pressure* is the pressure gradient across the systemic circuit. It is reported as three values: arterial **blood pressure (BP)**, capillary hydrostatic pressure (CHP), and venous pressure.
- **13.** The **resistance (R)** determines the rate of blood flow through the systemic circuit. The major determinant of blood flow rate is the **peripheral resistance**—the resistance of the arterial system. Neural and hormonal control mechanisms regulate blood pressure and peripheral resistance.
- **14. Vascular resistance** is the resistance of blood vessels. It is the largest component of peripheral resistance and depends on vessel length and vessel diameter. (*Figure 21–7*)
- **15. Viscosity** and **turbulence** also contribute to peripheral resistance. (*Table 21–1*)
- **16.** The high arterial pressures overcome peripheral resistance and maintain blood flow through peripheral tissues. Capillary pressures are normally low, and small changes in capillary pressure determine the rate of movement of fluid into or out of the bloodstream. Venous pressure, normally low, determines *venous return* and affects cardiac output and peripheral blood flow. (*Figures 21–8, 21–9; Table 21–1*)
- 17. Arterial blood pressure rises during ventricular systole and falls during ventricular diastole. The difference between these two blood pressures is the **pulse pressure**. Blood pressure is measured at the brachial artery with the use of a sphygmomanometer. (*Figures 21–8, 21–9*)
- **18.** Valves, muscular compression, and the **respiratory pump** help the relatively low venous pressures propel blood toward the heart. (*Figures 21–5, 21–8*)
- **19.** At the capillaries, blood pressure forces water and solutes out of the plasma, across capillary walls. Water moves out of the capillaries, through the peripheral tissues, and back to the bloodstream by way of the lymphatic system. Water movement across capillary walls is determined by the interplay between osmotic pressures and hydrostatic pressures. (*Figure 21–10*)
- **20. Osmotic pressure (OP)** is a measure of the pressure that must be applied to prevent osmotic movement across a membrane. Osmotic water movement continues until either solute concentrations are equalized or the movement is prevented by an opposing hydrostatic pressure.

21. The rates of filtration and reabsorption gradually change as blood passes along the length of a capillary, as determined by the **net filtration pressure** (the difference between the net hydrostatic pressure and the net osmotic pressure). (*Figure 21–11*)

21-3 Cardiovascular regulatory mechanisms involve autoregulation, neural mechanisms, and endocrine responses p. 742

- 22. Homeostatic mechanisms ensure that **tissue perfusion** (blood flow) delivers adequate oxygen and nutrients.
- 23. Autoregulation, neural mechanisms, and endocrine mechanisms influence the coordinated regulation of cardiovascular function. Autoregulation involves local factors changing the pattern of blood flow within capillary beds in response to chemical changes in interstitial fluids. Neural mechanisms respond to changes in arterial pressure or blood gas levels. Hormones can assist in short-term adjustments (changes in cardiac output and peripheral resistance) and long-term adjustments (changes in blood volume that affect cardiac output and gas transport). (*Figure 21–12*)
- 24. Peripheral resistance is adjusted at the tissues by local factors that result in the dilation or constriction of precapillary sphincters. (*Figure 21–4*)
- 25. **Cardiovascular (CV) centers** of the medulla oblongata are responsible for adjusting cardiac output and peripheral resistance to maintain adequate blood flow. The vasomotor center contains one group of neurons responsible for controlling vasoconstriction, and another group responsible for controlling vasodilation.
- **26. Baroreceptor reflexes** monitor the degree of stretch within expandable organs. Baroreceptors are located in the **carotid sinuses**, the **aortic sinuses**, and the right atrium. (*Figure 21–13*)
- 27. Chemoreceptor reflexes respond to changes in the oxygen or CO₂ levels in the blood. They are triggered by sensory neurons located in the carotid bodies and the aortic bodies. (*Figure 21–14*)
 - 28. The endocrine system provides short-term regulation of cardiac output and peripheral resistance with epinephrine and norepinephrine from the adrenal medullae. Hormones involved in the long-term regulation of blood pressure and volume are *antidiuretic hormone (ADH), angiotensin II, erythropoietin (EPO),* and *natriuretic peptides (ANP* and *BNP). (Figure 21–15)*
 - 21-4 The cardiovascular system adapts to physiological stress and maintains a special vascular supply to the brain, heart, and lungs p. 749
 - 29. During exercise, blood flow to skeletal muscles increases at the expense of blood flow to nonessential organs, and cardiac output rises. Cardiovascular performance improves with training. Athletes have larger stroke volumes, slower resting heart rates, and larger cardiac reserves than do nonathletes. (*Tables 21–2, 21–3*)
 - **30.** Blood loss lowers blood volume and venous return and decreases cardiac output. Compensatory mechanisms include an increase in cardiac output, mobilization of venous reserves, peripheral vasoconstriction, and the release of hormones that promote the retention of fluids and the manufacture of erythrocytes. (*Figure 21–16*)

- **31.** The blood–brain barrier, the coronary circulation, and the circulation to alveolar capillaries in the lungs are examples of special circulations, in which cardiovascular dynamics and regulatory mechanisms differ from those in other tissues.
- 21-5 The pulmonary and systemic circuits of the cardiovascular system exhibit three general functional patterns p. 753
- **32.** The peripheral distributions of arteries and veins are generally identical on both sides of the body, except near the heart. *(Figure 21–17)*
- 21-6 In the pulmonary circuit, deoxygenated blood enters the lungs in arteries, and oxygenated blood leaves the lungs by veins p. 754
- **33.** The pulmonary circuit includes the pulmonary trunk, the **left** and **right pulmonary arteries**, and the **pulmonary veins**, which empty into the left atrium. (*Figure 21–18*)
- 21-7 The systemic circuit carries oxygenated blood from the left ventricle to tissues and organs other than the pulmonary exchange surfaces, and returns deoxygenated blood to the right atrium p. 755
- 34. The **ascending aorta** gives rise to the coronary circulation. The **aortic arch** communicates with the **descending aorta**. (*Figures 21–19 to 21–25*)
- **35.** Three elastic arteries originate along the aortic arch: the **left common carotid artery**, the **left subclavian artery**, and the **brachiocephalic trunk**. (*Figures 21–20 to 21–22*)
- **36.** The remaining major arteries of the body originate from the **descending aorta**. (*Figures 21–23 to 21–25*)
- **37.** Arteries in the neck and limbs are deep beneath the skin; in contrast, there are generally two sets of peripheral veins, one superficial and one deep. This dual venous drainage is important for controlling body temperature. (*Figure 21–26*)
- **38.** The **superior vena cava** receives blood from the head, neck, chest, shoulders, and arms. (*Figures 21–26 to 21–29*)
- **39.** The **inferior vena cava** collects most of the venous blood from organs inferior to the diaphragm. (*Figures 21–28 to 21–30*)
- **40.** The **hepatic portal system** directs blood from the other digestive organs to the liver before the blood returns to the heart. (*Figure 21–31*)
- 21-8 Modifications of fetal and maternal cardiovascular systems promote the exchange of materials, and independence occurs at birth p. 772
- 41. Blood flows to the placenta in a pair of **umbilical** arteries and from the placenta in a single **umbilical vein**. (*Figure 21–32*)
- **42.** The interatrial partition remains functionally incomplete until birth. The **foramen ovale** allows blood to flow freely from the right to the left atrium, and the **ductus arteriosus** short-circuits the pulmonary trunk.
- 43. The foramen ovale closes, leaving the fossa ovalis. The ductus arteriosus constricts, leaving the ligamentum arteriosum. (*Figure 21–32*)
- 44. Congenital cardiovascular problems generally reflect abnormalities of the heart or of interconnections between the heart and great vessels. (*Spotlight Figure 21–33*)

21-9 Aging affects the blood, heart, and blood vessels p. 775

- 45. Age-related changes in the blood include (1) a decreased hematocrit, (2) constriction or blockage of peripheral veins by a *thrombus* (stationary blood clot), and (3) pooling of blood in the veins of the legs because valves are not working effectively.
- 46. Age-related changes in the heart include (1) a reduction in the maximum cardiac output, (2) changes in the activities of nodal and conducting cells, (3) a reduction in the elasticity of the cardiac skeleton, (4) progressive atherosclerosis that can restrict coronary circulation, and (5) the replacement of damaged cardiac muscle cells by scar tissue.

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the major arteries in the following diagram.

(a)	 (b)	
(c)	 (d)	
(e)	 (f)	
(g)	(h)	
(0)	()	

(i)

- The blood vessels that play the most important role in regulating blood pressure and blood flow to a tissue are the (a) arteries, (b) arterioles, (c) veins, (d) venules, (e) capillaries.
- Cardiovascular function is regulated by all of the following *except*
 (a) local factors, (b) neural factors, (c) endocrine factors, (d) venous return, (e) conscious control.
- 4. Baroreceptors that function in the regulation of blood pressure are located in the (a) left ventricle, (b) brain stem, (c) carotid sinus, (d) common iliac artery, (e) pulmonary trunk.

- 47. Age-related changes in blood vessels, commonly related to arteriosclerosis, include (1) a weakening in the walls of arteries, potentially leading to the formation of an *aneurysm*, (2) deposition of calcium salts on weakened vascular walls, increasing the risk of a stroke or myocardial infarction, (3) lipid deposits in the tunica media associated with damaged endothelial lining and calcium salts forming atherosclerotic plaques, and (4) the formation of a thrombus at atherosclerotic plaques.
- **48.** The cardiovascular system is anatomically and functionally connected to all other body systems. (*Figure 21–34*)

See the blue Answers tab at the back of the book.

- 5. The two-way exchange of substances between blood and body cells occurs only through (a) arterioles, (b) capillaries, (c) venules, (d) a, b, and c.
- Large molecules such as peptides and proteins move into and out of the bloodstream by way of (a) continuous capillaries, (b) fenestrated capillaries, (c) thoroughfare channels, (d) metarterioles.
- The local control of blood flow due to the action of precapillary sphincters is (a) vasomotion, (b) autoregulation, (c) selective resistance, (d) turbulence.
- Blood is transported through the venous system by means of (a) muscular contractions, (b) increasing blood pressure, (c) the respiratory pump, (d) a and c.
- 9. Identify the major veins in the following diagram.

(a)

(c)

(e)

(g)

(i)

- The most important factor in vascular resistance is (a) the viscosity of the blood, (b) the diameter of the lumen of blood vessels, (c) turbulence due to irregular surfaces of blood vessels, (d) the length of the blood vessels.
- 11. Net hydrostatic pressure forces water ______ a capillary; net osmotic pressure forces water ______ a capillary. (a) into, out of, (b) out of, into, (c) out of, out of, (d) into, into.
- 12. The two arteries formed by the division of the brachiocephalic trunk are the (a) aorta and internal carotid, (b) axillary and brachial, (c) external and internal carotid, (d) common carotid and subclavian.
- 13. The unpaired arteries supplying blood to the visceral organs include(a) the adrenal, renal, and lumbar arteries, (b) the iliac, gonadal, and femoral arteries, (c) the celiac and superior and inferior mesenteric arteries, (d) a, b, and c.
- 14. The paired arteries supplying blood to the body wall and other structures outside the abdominopelvic cavity include the (a) left gastric, hepatic, splenic, and phrenic arteries, (b) adrenal, colic, lumbar, and gonadal arteries, (c) iliac, femoral, and lumbar arteries, (d) celiac, left gastric, and superior and inferior mesenteric arteries.
- 15. The vein that drains the dural sinuses of the brain is the (a) cephalic vein, (b) great saphenous vein, (c) internal jugular vein, (d) superior vena cava.
- 16. The vein that collects most of the venous blood inferior to the diaphragm is the (a) superior vena cava, (b) great saphenous vein, (c) inferior vena cava, (d) azygos vein.
- 17. What are the primary forces that cause fluid to move (a) out of a capillary at its arterial end and into the interstitial fluid, (b) into a capillary at its venous end from the interstitial fluid?
- 18. What cardiovascular changes occur at birth?

LEVEL 2 Reviewing Concepts

A major difference between the arterial and venous systems is that

 (a) arteries are usually more superficial than veins,
 (b) in the limbs there is dual venous drainage,
 (c) veins are usually less branched compared to arteries,
 (d) veins exhibit a much more orderly pattern of branching in the limbs,
 (e) veins are not found in the abdominal cavity.

- 20. Which of the following conditions would have the *greatest* effect on peripheral resistance? (a) doubling the length of a vessel, (b) doubling the diameter of a vessel, (c) doubling the viscosity of the blood, (d) doubling the turbulence of the blood, (e) doubling the number of white cells in the blood.
- Which of the following is *greater*? (a) the osmotic pressure of the interstitial fluid during inflammation, (b) the osmotic pressure of the interstitial fluid during normal conditions, (c) neither is greater.
- **22.** Relate the anatomical differences between arteries and veins to their functions.
- **23.** Why do capillaries permit the diffusion of materials, whereas arteries and veins do not?
- 24. How is blood pressure maintained in veins to counter the force of gravity?
- **25.** How do pressure and resistance affect cardiac output and peripheral blood flow?
- 26. Why is blood flow to the brain relatively continuous and constant?
- **27.** Compare the effects of the cardioacceleratory and cardioinhibitory centers on cardiac output and blood pressure.

LEVEL 3 Critical Thinking and Clinical Applications

- 28. Bob is sitting outside on a warm day and is sweating profusely. Mary wants to practice taking blood pressures, and he agrees to play the patient. Mary finds that Bob's blood pressure is elevated, even though he is resting and has lost fluid from sweating. (She reasons that fluid loss should lower blood volume and, thus, blood pressure.) Why is Bob's blood pressure high instead of low?
- **29.** People with allergies commonly take antihistamines with decongestants to relieve their symptoms. The container warns that individuals who are being treated for high blood pressure should not take the medication. Why not?
- **30.** Jolene awakens suddenly to the sound of her alarm clock. Realizing that she is late for class, she jumps to her feet, feels light-headed, and falls back on her bed. What probably caused this reaction? Why doesn't this happen all the time?

CLINICAL CASE

Did Ancient Mummies Have Atherosclerosis?

The majority of American men and women today have atherosclerotic plaques in their arteries by the age of 50. The disease is usually thought of as a modern one, the result of too many cheeseburgers and hours spent in front of flat-screen TVs. But what could account for its incidence in the ancient mummies?

The degree of atherosclerosis discovered in the mummies turns out to be correlated with their age at death. The mean age at death for mummies without visible atherosclerosis is only 32. Among the mummies of people over age 40 that were examined, 50 percent had atherosclerosis.

Atherosclerosis is a vascular disease that progresses over many years. It is influenced by both genetics and environment. The most important risk factor, however, seems to be increasing age. Sex, diet, high level of cholesterol in the blood, smoking, hypertension, and obesity are additional risk factors.

Wrap-Up

The prevalence of atherosclerosis in varied, preindustrial popula-

tions raises the possibility of a basic, human predisposition to the disease. Atherosclerosis doesn't seem to be a purely modern health problem, caused exclusively by poor diet and lifestyle choices. It appears to have been stalking humans for millennia.

- 1. Why does the finding of calcium, which is easily seen on a CT scan, within systemic arteries indicate the presence of atherosclerosis?
- 2. Why do you think atherosclerosis is never seen in veins?

See the blue Answers tab at the back of the book.

The Lymphatic System and Immunity

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **22-1** Distinguish between innate (nonspecific) and adaptive (specific) defenses, and explain the role of lymphocytes in the immune response.
- **22-2** Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes.
- **22-3** List the body's innate (nonspecific) defenses, and describe the components, mechanisms, and functions of each.
- **22-4** Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.
- **22-5** Discuss the types of T cells and their roles in the immune response, and describe the mechanisms of T cell activation and differentiation.
- **22-6** Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure.
- **22-7** Describe the development of immunocompetence, list and explain examples of immune disorders and allergies, and discuss the effects of stress on immune function.
- **22-8** Describe the effects of aging on the lymphatic system and the immune response.
- **22-9** Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response.

SPOTLIGHT

- Graft Rejection and Immunosuppression p. 806
- AIDS p. 819

CLINICAL CASE

Isn't There a Vaccine for That?

Baby Ruthie is standing and holding on to a play table when her mother arrives to pick her up from day care. Ruthie is 11 months old and not yet walking. She hasn't had an appetite since yesterday, and last night she had a fever. When her mother gives Ruthie a hug, she notices a small blister near the corner of Ruthie's mouth. She also notices that Ruthie seems feverish again.

"Ruthie didn't do much today," reports the day care attendant. "Did you notice this little blister on her face?" asks Ruthie's mother. "No. It must have just appeared," the attendant replies. "Tommy, one of our older kids, had a little blister like that on his cheek just last week. He hasn't been back since." That night, Ruthie's fever worsens. She won't eat and seems to have a sore throat when trying to swallow. She is listless. When her mother undresses her for bed, she notices more small blisters on Ruthie's face, abdomen, and back. She takes her straight to the Urgent Care Center.

"This looks like chickenpox,"

says the doctor. "Thanks to vaccines, we don't see this disease very often any more." **Ruthie's mother is certain that Ruthie is current on all her vaccinations. How could Ruthie have come down with chickenpox? To find out, turn to the Clinical Case Wrap-Up on p. 829.**

An Introduction to the Lymphatic System and Immunity

Many organs and systems work together to keep us alive and healthy. The lymphatic system plays a central role in the ongoing struggle to maintain health. In this chapter we discuss the components of the lymphatic system and the ways those components interact.

The world is not always kind to the human body. Accidental bumps, cuts, and scrapes; chemical and thermal burns; extreme cold; and ultraviolet radiation are just a few of the hazards in our physical environment. Making matters worse, the world around us contains an assortment of viruses, bacteria, fungi, and parasites capable of not only surviving but thriving inside our bodies-and potentially causing us great harm. These disease-causing organisms, called pathogens, are responsible for many diseases in humans. Each pathogen has a different lifestyle and attacks the body in a specific way. For example, viruses spend most of their time hidden within cells, which they often eventually destroy. Some of the largest parasites actually burrow through internal organs. Many bacteria multiply in interstitial fluids, where they release foreign proteins-enzymes or toxins-that can damage cells, tissues, even entire organ systems. And as if that were not enough, we are constantly at risk from renegade body cells that have the potential to produce lethal cancers. $\bigcirc p$. 106

22–1 Surface barriers and internal defenses make up innate defenses, and lymphocytes provide adaptive defenses

Learning Outcome Distinguish between innate (nonspecific) and adaptive (specific) defenses, and explain the role of lymphocytes in the immune response.

The **lymphatic system** includes the cells, tissues, and organs responsible for defending the body. This system acts both against environmental hazards, such as various pathogens, and against internal threats, such as cancer cells. We introduced *lymphocytes*, the primary cells of the lymphatic system, in Chapters 4 and 19. **pp. 133, 671** These cells are vital to the body's ability to resist or overcome infection and disease. Lymphocytes respond to invading pathogens (such as bacteria or viruses), abnormal body cells (such as virus-infected cells or cancer cells), and foreign proteins (such as the toxins released by some bacteria). They act to eliminate these threats or render them harmless through a combination of physical and chemical attacks.

The ability to resist infection and disease is called immunity. We have two forms of defense systems that work independently or together to provide immunity. These forms are innate (nonspecific) defenses and adaptive (specific) defenses. Surface barriers prevent or slow the entry of infectious organisms, or attack them if they do enter. These defenses are called innate because you are born with them and nonspecific because they do not distinguish one potential threat from another. In contrast, lymphocytes respond specifically. If a bacterial pathogen invades peripheral tissues, lymphocytes organize a defense against that particular type of bacterium. For this reason, we say that lymphocytes provide an *adaptive* defense. Defense against specific antigens is known as the immune response. All the cells and tissues involved in producing immunity are considered part of the immune system. The immune system includes parts of the integumentary, skeletal, lymphatic, cardiovascular, respiratory, and digestive systems.

We begin this chapter by examining the organization of the lymphatic system. We then consider the body's two forms of defenses. Finally, we will see how the lymphatic system interacts with cells and tissues of other systems to defend the body against infection and disease.

782

- 1. Define pathogen.
- 2. Explain the difference between nonspecific defense and specific defense.

See the blue Answers tab at the back of the book.

22-2 Lymphatic vessels, lymphocytes, lymphoid tissues, and lymphoid organs function in body defenses

Learning Outcome Identify the major components of the lymphatic system, describe the structure and functions of each component, and discuss the importance of lymphocytes.

The lymphatic system consists of (1) **lymph**, a fluid that resembles plasma but contains a much lower concentration of suspended proteins; (2) a network of **lymphatic vessels**, often called **lymphatics**, which begin in peripheral tissues and connect to veins; (3) an array of **lymphoid tissues** and **lymphoid organs** scattered throughout the body; and (4) lymphocytes and smaller numbers of phagocytes and other cells.

Primary lymphoid tissues and organs are sites where lymphocytes are formed and mature. They include red bone marrow and the thymus gland. Recall that red bone marrow is also where other defense cells, the monocytes and macrophages, are also formed. Secondary lymphoid tissues and organs are where lymphocytes are activated and cloned (production of identical cellular copies). These structures include the appendix, spleen, lymph nodes, tonsils, and MALT. Figure 22-1 provides a general overview of the primary vessels, tissues, and organs of this system.

Functions of the Lymphatic System

The primary function of the lymphatic system is to produce, maintain, and distribute lymphocytes that provide defense against infections and other environmental hazards.

To provide an effective defense, lymphocytes must detect problems, and they must be able to reach the site of injury or infection. Lymphocytes, macrophages, and microphages circulate within the blood. They are able to enter or leave the capillaries that supply most of the tissues of the body. As noted in Chapter 21, capillaries normally deliver more fluid to peripheral tissues than they carry away. $\supset p$. 740 The excess fluid returns to the bloodstream through lymphatic vessels. This continuous circulation of extracellular fluid helps transport lymphocytes and other defense cells from one organ to another. In the process, it maintains normal blood volume. It also eliminates local variations in the composition of the interstitial fluid by distributing hormones, nutrients, and wastes from their tissues of origin to the general circulation.

Lymphatic Vessels

Lymphatic vessels carry lymph from peripheral tissues to the venous system. The smallest lymphatic vessels are called *lymphatic capillaries*.

Lymphatic Capillaries

The lymphatic network begins with **lymphatic capillaries**, or *terminal lymphatics*, which branch through peripheral tissues. Lymphatic capillaries differ from blood capillaries in several ways. They (1) originate as pockets rather than forming continuous tubes, (2) have larger diameters, (3) have thinner walls, and (4) typically have a flattened or irregular outline in sectional view (Figure 22–2).

Lymphatic capillaries are lined by endothelial cells, but the basement membrane is incomplete or absent. The endothelial cells of a lymphatic capillary are not bound tightly together, but they do overlap. The region of overlap acts as a one-way valve. It permits fluids and solutes (including those as large as proteins) to enter, along with viruses, bacteria, and cell debris, but it prevents them from returning to the intercellular spaces.

Lymphatic capillaries are present in almost every tissue and organ in the body. Prominent lymphatic capillaries in the small intestine called *lacteals* are important in the transport of lipids absorbed by the digestive tract. Lymphatic capillaries are absent in areas that lack a blood supply, such as the cornea of the eye. The red bone marrow and the central nervous system also lack lymphatic vessels.

Small Lymphatic Vessels

From the lymphatic capillaries, lymph flows into larger lymphatic vessels that lead toward the body's trunk. The walls

Figure 22–2 Lymphatic Capillaries.

 The interwoven network formed by blood capillaries and lymphatic capillaries. Arrows indicate the movement of fluid out of blood capillaries and the net flow of interstitial fluid and lymph.

b A sectional view indicating the movement of fluid from the plasma, through the tissues as interstitial fluid, and into the lymphatic system as lymph.

of these vessels contain layers comparable to those of veins. Like veins, the larger lymphatic vessels also contain valves (Figure 22–3). The valves are quite close together, and produce

Figure 22–3 Lymphatic Vessels and Valves.

noticeable bulges. As a result, large lymphatic vessels have a beaded appearance (Figure 22–3a). The valves prevent the backflow of lymph within lymphatic vessels, especially in the limbs. Pressures within the lymphatic system are minimal, and the valves are essential to maintaining normal lymph flow toward the thoracic cavity. Contractions of skeletal muscles surrounding the lymphatic vessels aid the flow of lymph.

Lymphatic vessels are often associated with blood vessels (Figure 22–3a). Differences in size, general appearance, and branching pattern distinguish lymphatic vessels from arteries and veins. We can see characteristic color differences in living tissues. Most arteries are bright red, veins are dark red (although usually illustrated as blue to distinguish them from arteries), and lymphatic vessels are a pale golden color. In general, a tissue contains many more lymphatic vessels than veins, but the lymphatic vessels are much smaller.

Major Lymph-Collecting Vessels

Two sets of lymphatic vessels collect lymph from the lymphatic capillaries: superficial lymphatics and deep lymphatics.

Superficial lymphatics are located in the subcutaneous layer deep to the skin; in the areolar tissues of the mucous membranes lining the digestive, respiratory, urinary, and reproductive tracts; and in the areolar tissues of the serous membranes lining the pleural, pericardial, and peritoneal cavities. **Deep lymphatics** are larger lymphatic vessels that accompany deep arteries and veins supplying skeletal muscles and other organs of the neck, limbs, and trunk, and the walls of visceral organs.

Superficial and deep lymphatics converge to form even larger vessels called **lymphatic trunks**. The trunks in turn empty into two large collecting vessels: the thoracic duct and the right lymphatic duct. The **thoracic duct** collects lymph from the body inferior to the diaphragm and from the left side of the body superior to the diaphragm. The smaller **right lymphatic duct** collects lymph from the right side of the body superior to the diaphragm (**Figure 22–4a**).

The thoracic duct begins inferior to the diaphragm at the level of vertebra L_2 (Figure 22–4b). The base of the thoracic duct is an expanded, saclike chamber called the **cisterna chyli**

(KĪ-lī; *chylos*, juice). The cisterna chyli receives lymph from the inferior part of the abdomen, the pelvis, and the lower limbs by way of the *right* and *left lumbar trunks* and the *intestinal trunk*.

The inferior segment of the thoracic duct lies anterior to the vertebral column. From the second lumbar vertebra, it passes posterior to the diaphragm alongside the aorta. It then ascends along the left side of the vertebral column to the level of the left clavicle. It collects lymph from the *left bronchomediastinal trunk*, the *left subclavian trunk*, and the *left jugular trunk*, and then empties into the left subclavian vein near the left internal jugular vein (Figure 22–4b). In this way, lymph re-enters the venous circulation from the left side of the head, neck, and thorax, as well as from the entire body inferior to the diaphragm.

The *right lymphatic duct* is formed by the merging of the *right jugular, right subclavian,* and *right bronchomediastinal trunks* in the area near the right clavicle. This duct empties into the right subclavian vein, delivering lymph from the right side of the body superior to the diaphragm.

Blockage of the lymphatic drainage from a limb produces **lymphedema** (limf-e-DĒ-muh). In this condition, interstitial fluids accumulate and the limb gradually becomes swollen and grossly distended. If the condition persists, the connective tissues lose their elasticity and the swelling becomes permanent.

Lymphedema by itself does not pose a major threat to life. The danger comes from the constant risk that an uncontrolled infection will develop in the affected area. Because the interstitial fluids are essentially stagnant, toxins and pathogens can accumulate and overwhelm local defenses without fully activating the immune system.

Lymphocytes

Lymphocytes account for 20–40 percent of circulating leukocytes. However, circulating lymphocytes are only a small fraction of the total lymphocyte population. The body contains some 10^{12} lymphocytes, with a combined weight of more than a kilogram (2.2 lb).

Types of Lymphocytes

Three classes of lymphocytes circulate in blood: (1) **T** (thymusdependent) **cells**, (2) **B** (bone marrow–derived) **cells**, and (3) **NK** (**n**atural **k**iller) **cells**. Each type has distinctive biochemical and functional characteristics (Figure 22–5).

Most lymphocytes are T cells, and the primary types of T cells include cytotoxic T (T_C) cells, helper T (T_H) cells, suppressor T (T_S) cells, and memory T cells. Cytotoxic T cells are involved in direct cellular attack. These lymphocytes are the primary cells involved in the production of *cell-mediated immunity*, or *cellular immunity*. The interplay between helper T cells and suppressor T cells helps establish and control the sensitivity of the immune response. For this reason, these cells are also known as *regulatory T cells*.

We will examine these T cells throughout this chapter. Other types of T cells also take part in the immune response. For example, *inflammatory T cells* stimulate regional inflammation and local defenses in an injured tissue. *Suppressor/inducer T cells* suppress B cell activity but stimulate other T cells.

Under proper stimulation, B cells differentiate into **plasma cells** that secrete antibodies. These antibodies are soluble

22

proteins, also known as *immunoglobulins*. **D** p. 657 B cells are responsible for *antibody-mediated immunity*, which is also known as *humoral* ("liquid") *immunity* because antibodies are found in body fluids.

Antibodies bind to specific chemical targets called **antigens**, which stimulate the immune response. Most antigens are pathogens, parts or products of pathogens, or other foreign substances. Antigens are usually proteins, but some lipids, polysaccharides, and nucleic acids are also antigens. The binding of an antibody to its target antigen starts a chain reaction leading to the destruction of the target compound or organism.

Natural killer cells are also known as **large granular lym-phocytes**. NK cells provide innate (nonspecific) immunity. They attack foreign cells, cells infected with viruses, and cancer cells that appear in normal tissues. Their continuous "policing" of peripheral tissues has been called *immune surveillance* (Figure 22–5).

Life Span and Circulation of Lymphocytes

The various types of lymphocytes are not evenly distributed in the blood, bone marrow, spleen, thymus, and peripheral lymphoid tissues. The ratio of B cells to T cells varies among tissues and organs. For example, B cells are seldom found in the thymus, but T cells outnumber B cells in blood by a ratio of 8:1.

The lymphocytes in these organs are visitors, not residents. All types of lymphocytes move throughout the body. They wander through tissues and then enter blood vessels or lymphatic vessels for transport.

T cells move quickly. For example, a wandering T cell may spend about 30 minutes in the blood, 5–6 hours in the spleen, and 15–20 hours in a lymph node. B cells, which are responsible for antibody production, move more slowly. A typical

Cancer and the Lymphatic System Metastasizing cancer cells commonly spread within lymphatic vessels. These vessels occur in almost all portions of the body except the central nervous system, and lymphatic capillaries offer little resistance to the passage of cancer cells. As a result, the lymph nodes serve as "way stations" for migrating cancer cells. For this reason, an analysis of lymph nodes can provide information on the spread of cancer cells. Such information helps determine the appropriate therapies. *Lymphomas* are one group of cancers originating in the cells of the lymphatic system.

B cell spends about 30 hours in a lymph node, a small lymphfiltering structure, before moving on.

Lymphocytes have relatively long life spans. About 80 percent survive 4 years, and some last 20 years or more. Throughout your life, you maintain normal lymphocyte populations by producing new lymphocytes in your red bone marrow and lymphoid tissues.

Lymphocyte Production

In Chapter 19, we discussed *hemopoiesis*—the formation of the cellular elements of blood. \bigcirc pp. 656, 661, 672 In adults, red blood cell formation, or *erythropoiesis*, is normally confined to red bone marrow. In contrast, lymphocyte production, or **lymphopoiesis** (lim-fō-poy-Ē-sis), involves the red bone marrow, thymus, and peripheral lymphoid tissues (Figure 22–6).

Red bone marrow plays the primary role in maintaining normal lymphocyte populations. Hemocytoblasts divide in the bone marrow of adults to generate the lymphoid stem cells that produce all types of lymphocytes. The red bone marrow produces two distinct populations of lymphoid stem cells.

One group of lymphoid stem cells remains in the red bone marrow and the other group migrates to the thymus (Figure 22–6). Lymphoid stem cells in the red bone marrow divide to produce immature B cells and NK cells. B cell development involves intimate contact with large **stromal** (*stroma*, a bed) **cells** in the red bone marrow. The cytoplasmic extensions of stromal cells contact or even wrap around the developing B cells. Stromal cells produce an immune system hormone, or *cytokine*, called *interleukin-7*. It promotes the differentiation of B cells. (We consider cytokines and their varied effects in a later section.)

As they mature, B cells and NK cells enter the bloodstream and migrate to peripheral tissues (Figure 22–6). Most of the B cells move into lymph nodes, the spleen, or other lymphoid tissues. The NK cells patrol the body, moving through peripheral tissues in search of abnormal cells.

The second group of lymphoid stem cells migrates to the thymus (Figure 22–6). These stem cells and their descendants develop and mature in an environment that is isolated from the general circulation by the **blood-thymus barrier**. Under the influence of thymic hormones, the lymphoid stem cells divide repeatedly, producing the various kinds of T cells. These T cells undergo a selection process to ensure that they will not react to the body's own healthy cells and cellular products. During this process up to 98 percent of developing T cells are deselected and undergo apoptosis. When the development of the surviving T cells nears completion, they re-enter the blood-stream and travel to peripheral tissues, including lymphoid tissues and organs, such as the spleen (Figure 22–6).

Figure 22–6 The Origin and Distribution of Lymphocytes.

The T cells and B cells that migrate from their sites of origin retain the ability to divide, producing daughter cells of the same type. For example, a dividing B cell produces other B cells, not T cells or NK cells. As we will see, the ability of specific types of lymphocytes to increase in number is crucial to the success of the immune response.

Lymphoid Tissues

Lymphoid tissues are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, or *lymphatic nodule*, the lymphocytes are densely packed in an area of areolar tissue. In many areas, lymphoid nodules form large clusters (Figure 22–7). Lymphoid nodules occur in the connective tissue deep to the epithelia lining the respiratory tract, where they are known as *tonsils*, and along the digestive, respiratory, urinary, and reproductive tracts. They are also found within more complex lymphoid organs, such as lymph nodes or the spleen.

A single nodule averages about a millimeter in diameter. Its boundaries are not distinct, because no fibrous capsule surrounds it. Each nodule often has a central zone called a **germinal center**, which contains dividing lymphocytes (Figure 22–7a,b).

Tonsils

The **tonsils** are large lymphoid nodules in the walls of the pharynx (Figure 22–7a). Most people have five tonsils. A single **pharyngeal tonsil**, often called the *adenoid*, lies in the posterior superior wall of the nasopharynx. Left and right **palatine tonsils** are located at the posterior, inferior margin of the oral cavity, along the boundary with the pharynx. A pair of **lingual tonsils** lie deep to the mucous epithelium covering the base (pharyngeal portion) of the tongue. Because of their location, the lingual tonsils are usually not visible unless they become infected and swollen. **Tonsillitis** is an inflammation of the tonsils (especially the palatines) although the other tonsils may also be affected. Tonsils reach their largest size by puberty and then begin to atrophy.

MALT

The collection of lymphoid tissues that protect the epithelia of the digestive, respiratory, urinary, and reproductive systems is called the **mucosa-associated lymphoid tissue (MALT)**. Clusters of lymphoid nodules deep to the epithelial lining of the intestine are known as **aggregated lymphoid nodules**, or *Peyer's patches* (Figure 22–7b). Other examples of MALT include the appendix and the tonsils.

The *appendix*, or *vermiform* ("worm-shaped") *appendix*, is a blind pouch that originates near the junction between the small and large intestines. Its walls contain a mass of fused lymphoid nodules.

Lymphoid Organs

A fibrous connective tissue capsule separates lymphoid organs—the *lymph nodes*, the *thymus*, and the *spleen*—from surrounding tissues.

Lymph Nodes

Lymph nodes are small lymphoid organs ranging in diameter from 1 mm to 25 mm (to about 1 in.). The greatest number of lymph nodes is located in the neck, armpits, and groin, where they defend us against bacteria and other invaders. **Figure 22–1** shows the general pattern of lymph node distribution in the body.

A dense connective tissue capsule covers each lymph node (Figure 22–8). Bundles of collagen fibers extend from the capsule into the interior of the node. These fibrous partitions are called **trabeculae** (*trabecula*, a beam).

The typical lymph node is shaped like a kidney bean (Figure 22–8). Blood vessels and nerves reach the lymph node at a shallow indentation called the **hilum**. Two sets of lymphatic vessels, afferent lymphatics and efferent lymphatics, are connected to each lymph node. **Afferent** (*afferens*, to bring to) **lymphatics** bring lymph to the lymph node from peripheral tissues. The afferent lymphatics penetrate the capsule of the lymph node on the side opposite the hilum. **Efferent** (*efferens*, to bring out) **lymphatics** leave the lymph node at the hilum. These vessels carry lymph away from the lymph node and toward the venous circulation.

Lymph Flow. Lymph from the afferent lymphatics flows through the lymph node within a network of sinuses, open passageways with incomplete walls (**Figure 22–8**). Lymph first enters a *subcapsular space* (formerly called the *subcapsular sinus*). It contains a meshwork of branching reticular fibers, macrophages, and dendritic cells. **Dendritic cells** are involved in starting an immune response. (We consider their role in a later section.) Lymph passes through the subcapsular space and then flows through the **outer cortex** of the node. The outer cortex contains B cells within germinal centers similar to those of lymphoid nodules.

Lymph then continues through lymph sinuses in the **deep cortex** (*paracortical area*), which is dominated by T cells. Here lymphocytes leave the bloodstream and enter the lymph node by crossing the walls of blood vessels.

After flowing through the sinuses of the deep cortex, lymph continues into the core, or **medulla**, of the lymph node. The medulla contains B cells and plasma cells organized into elongate masses known as **medullary cords**. Lymph passes through a network of sinuses in the medulla and then enters the efferent lymphatics at the hilum.

Lymph Node Function. A lymph node functions like a kitchen water filter. It purifies lymph before it reaches the veins. As

lymph flows through a lymph node, at least 99 percent of the antigens in the lymph are removed. Fixed macrophages in the walls of the lymphatic sinuses engulf debris or pathogens in lymph as it flows past. Antigens removed in this way are then processed by the macrophages and "presented" to nearby lymphocytes. Other antigens bind to receptors on the surfaces of dendritic cells, where they can stimulate lymphocyte activity. This process—*antigen presentation*—is generally the first step in the activation of the immune response.

TIPS&TRICKS

Helper T cells "help" translate the message from the antigenpresenting cells of the nonspecific response to the cells of the specific immune responses.

In addition to filtering, lymph nodes function as an earlywarning system. Any infection or other abnormality in a peripheral tissue puts antigens into the interstitial fluid, and thus into the lymph leaving the area. These antigens then

Figure 22–7 Lymphoid Nodules.

22

nodes.

To protect a house against intruders, you might guard all the entrances and exits or place traps by the windows and doors. The distribution of lymphoid tissues and lymph nodes follows such a pattern. The largest lymph nodes are located where peripheral lymphatics connect with the trunk, such as in the groin, the axillae, and the base of the neck. These nodes are often called lymph glands. Because lymph is monitored in these nodes, potential problems can be detected and dealt with before they affect the vital organs of the trunk. The mesenteries of the gut also have aggregations of lymph nodes, located near the trachea and passageways leading to the lungs, and in association with the thoracic duct. These lymph nodes protect against pathogens and other antigens within the digestive and respiratory systems.

A minor injury commonly produces a slight enlargement of the nodes along the lymphatic vessels draining the region. This sign is often called "swollen glands." It typically indicates inflammation in peripheral structures. The enlargement generally results from an increase in the number of lymphocytes

and phagocytes in the node in response to a minor, localized infection. Chronic or excessive enlargement of lymph nodes is lymphadenopathy (lim-fad-e-NOP-a-the). This condition may occur in response to bacterial or viral infections, endocrine disorders, or cancer.

The Thymus

The **thymus** is a pink, grainy organ located in the mediastinum, generally just posterior to the sternum (Figure 22-9a,b). In newborn infants and young children, the thymus is relatively large. It commonly extends from the base of the neck to the superior border of the heart. The thymus reaches its greatest size relative to body size in the first year or two after birth. (The organ continues to increase in mass throughout childhood, but the body as a whole grows even faster, so the size of the thymus relative to that of the other organs in the mediastinum gradually decreases.)

The thymus reaches its maximum absolute size, at a weight of about 40 g (1.4 oz), just before puberty. After puberty, it gradually diminishes in size and becomes increasingly fibrous, a process called *involution*. By the time a person reaches age 50, the thymus may weigh less than 12 g (0.3 oz). The gradual decrease in the size of functional tissue and secretory abilities of the thymus may make elderly people more susceptible to disease.

The capsule that covers the thymus divides it into two **thymic lobes** (Figure 22–9b). Fibrous partitions called **septa**

(singular, *septum*) originate at the capsule and divide the lobes into **lobules** averaging 2 mm in diameter (Figure 22–9b,c). Each lobule consists of a densely packed outer thymic **cortex** and a paler, central **medulla**. The cortex contains actively dividing lymphocytes (T cells). As the T cells mature, they migrate into the medulla. After about three weeks, these T cells leave the thymus by entering one of the medullary blood vessels.

Lymphocytes in the cortex are arranged in clusters that are completely surrounded by **thymic epithelial cells (TECs)**. Thymic epithelial cells regulate T cell development and function.

Figure 22–9 The Thymus. ATLAS: Plate 47a

Epithelial cells also encircle the blood vessels of the cortex. These cells maintain the blood-thymus barrier.

Maturing T cells leave the cortex and enter the medulla of the thymus. The medulla has no blood-thymus barrier. The thymic epithelial cells in the medulla cluster together in concentric layers, forming distinctive structures known as **thymic (Hassall's) corpuscles (Figure 22–9d)**. Despite their imposing appearance, the function of thymic corpuscles remains unknown. T cells in the medulla can enter or leave the bloodstream across the walls of blood vessels in this region or within one of the efferent lymphatics that collect lymph from the thymus.

The thymus produces several hormones that are important to the development and maintenance of normal immunological defenses. *Thymosin* (THĪ-mō-sin) is the name originally given to an extract from the thymus that promotes the development and maturation of lymphocytes. This extract actually contains several complementary hormones. They include *thymosin-a, thymosin-b, thymosin V, thymopoietin, thymulin,* and others. The plural term, *thymosins,* is now sometimes used to refer to all thymic hormones.

The Spleen

The adult **spleen** contains the largest collection of lymphoid tissue in the body. In essence, the spleen performs the same functions for blood that lymph nodes perform for lymph. Functions of the spleen can be summarized as (1) removing abnormal blood cells and other blood components by phagocytosis, (2) storing iron recycled from red blood cells, and (3) initiating immune responses by B cells and T cells in response to antigens in circulating blood.

Anatomy of the Spleen. The spleen is about 12 cm (5 in.) long and weighs, on average, nearly 160 g (5.6 oz). In gross dissection, the spleen is deep red, due to the blood it contains. The spleen lies along the curving lateral border of the stomach, extending between the 9th and 11th ribs on the left side. It is attached to the lateral border of the stomach by the **gastrosplenic ligament**, a broad band of mesentery (Figure 22–10a).

The spleen has a soft texture, so its shape primarily reflects the shapes of the structures around it. The spleen is in contact with the muscular diaphragm, the stomach, and the left kidney. The *diaphragmatic surface* is smooth and convex, conforming to the shape of the diaphragm and body wall. The *visceral surface* contains indentations that conform to the shape of the stomach (the *gastric area*) and the kidney (the *renal area*) (Figure 22–10b). Splenic blood vessels (the *splenic artery* and *splenic vein*) and lymphatic vessels communicate with the spleen on the visceral surface at the **hilum**, a groove marking the border between the gastric and renal areas. **Histology of the Spleen.** The spleen is surrounded by a capsule containing collagen and elastic fibers.¹ The cellular components within make up the **pulp** of the spleen (Figure 22–10c). **Red pulp** contains large quantities of red blood cells, and **white pulp** resembles lymphoid nodules.

The splenic artery enters at the hilum and branches to produce a number of arteries that radiate outward toward the capsule. These **trabecular arteries** in turn branch extensively, and their finer branches are surrounded by areas of white pulp. Capillaries then discharge the blood into the red pulp.

The cell population of the red pulp includes all the normal components of circulating blood, plus fixed and free macrophages. The structural framework of the red pulp consists of a network of reticular fibers. The blood passes through this meshwork and enters large sinusoids, also lined by fixed macrophages. The sinusoids empty into small veins, which ultimately collect into **trabecular veins** that continue toward the hilum.

This circulatory arrangement gives the phagocytes in the spleen an opportunity to identify and engulf damaged or infected cells in circulating blood. Lymphocytes are scattered throughout the red pulp, and the area surrounding the white pulp has a high concentration of macrophages and dendritic cells. For this reason, any microorganism or other antigen in the blood quickly comes to the attention of lymphocytes.

The spleen tears so easily that a seemingly minor hit to the left side of the abdomen can rupture the capsule. The result is serious internal bleeding and eventual circulatory shock. Such an injury is a known risk of contact sports (such as football, hockey, and rugby) and of more individual athletic activities, such as skiing and sledding.

Because the spleen is so fragile, it is very difficult to repair surgically. (Sutures typically tear out before they have been tensed enough to stop the bleeding.) A severely ruptured spleen is removed, a process called a **splenectomy** (splē-NEK-tō-mē). A person can survive without a spleen but lives with an increased risk of bacterial infection (particularly involving pneumococcal bacteria).

The Lymphatic System and Body Defenses

As we have noted, the human body has multiple defense mechanisms. Together they provide *resistance*—the natural or acquired ability to maintain immunity. We can sort body defenses into two general categories:

1. **Innate (nonspecific) immunity** does not distinguish one type of threat from another. Their response is the same, regardless of the type of invader. These innate defenses

¹The spleens of dogs, cats, and other mammals of the order *Carnivora* have extensive layers of smooth muscle that can contract to eject blood into the bloodstream. The human spleen lacks those muscle layers and cannot contract.

showing major anatomical landmarks.

darkly. Red pulp contains a large number of red blood cells.

are present at birth. They include *physical barriers*, *phagocytic cells*, *immune surveillance*, *interferons*, *complement*, *inflammation*, and *fever*. They provide a defensive capability known as **nonspecific resistance**.

2. Adaptive (specific) immunity protects against particular threats. For example, an adaptive defense may protect against one type of bacterium, but not other bacteria and viruses. Many specific defenses develop after birth as a result of accidental or deliberate exposure to environmental hazards. *Adaptive defenses depend on the activities of specific lymphocytes*. B cells and T cells are part of our adaptive defenses, which provides protection known as **specific resistance**. Innate and adaptive defenses work together. Both must function normally to provide adequate resistance to infection and disease.

CHECKPOINT

- 3. List the components of the lymphatic system.
- 4. How would blockage of the thoracic duct affect lymph circulation?
- 5. If the thymus failed to produce thymic hormones, which population of lymphocytes would be affected?
- 6. Why do lymph nodes enlarge during some infections?
- See the blue Answers tab at the back of the book.

22-3 Innate (nonspecific) defenses do not discriminate between potential threats and respond the same regardless of the invader

Learning Outcome List the body's innate (nonspecific) defenses, and describe the components, mechanisms, and functions of each.

Innate (nonspecific) defenses prevent the approach, deny the entry, or limit the spread of microorganisms or other environmental hazards. Seven major categories of innate defenses are summarized in Figure 22–11.

Physical Barriers

To cause trouble, an antigenic substance or a pathogen must enter body tissues. In other words, it must cross an epithelium—either at the skin or across a mucous membrane. The epithelial covering of the skin has multiple layers, a keratin coating, and a network of desmosomes that lock adjacent cells together. \bigcirc pp. 116–117, 153–155 These barriers are very effective in protecting underlying tissues. Even along the more delicate internal passageways of the respiratory, digestive, urinary, and reproductive tracts, epithelial cells are tied together by tight junctions. These cells generally are supported by a dense and fibrous basement membrane.

In addition, specialized accessory structures and secretions protect most epithelia. The hairs on most areas of your body provide some protection against mechanical abrasion, especially on the scalp. They often prevent hazardous materials or insects from contacting your skin. The epidermal surface also receives the secretions of sebaceous and sweat glands. These secretions flush the surface and wash away microorganisms and chemicals. Such secretions may also contain chemicals that kill bacteria, destructive enzymes called *lysozymes*, and antibodies.

The epithelia lining the digestive, respiratory, urinary, and reproductive tracts are more delicate, but they are equally well defended. Mucus bathes most surfaces of your digestive tract. Your stomach contains a powerful acid that can destroy many pathogens. Mucus moves across the respiratory tract lining, urine flushes the urinary passages, and glandular secretions do the same for the reproductive tract. Special enzymes, antibodies, and an acidic pH add to the effectiveness of these secretions.

Phagocytes

Phagocytes serve as janitors and police in peripheral tissues. They remove cellular debris and respond to invasion by foreign substances or pathogens. Phagocytes are the "first line of cellular defense" against pathogenic invasion. Many phagocytes attack and remove microorganisms even before lymphocytes detect them. The human body has two general classes of phagocytic cells: *microphages* and *macrophages*.

Microphages

Microphages are the neutrophils and eosinophils that normally circulate in the blood. These phagocytic cells leave the bloodstream and enter peripheral tissues that have been subjected to injury or infection. As noted in Chapter 19, neutrophils are abundant, mobile, and quick to phagocytize cellular debris or invading bacteria. \bigcirc p. 670 Eosinophils are less abundant. They target foreign substances or pathogens that have been coated with antibodies.

Macrophages

Macrophages are large, actively phagocytic cells. Your body contains several types of macrophages. Most are derived from the monocytes of the circulating blood. Typically, macrophages are either fixed in position or freely mobile. As a result they are usually classified as fixed macrophages or free macrophages, but the distinction is not absolute. During an infection, fixed macrophages may lose their attachments and begin roaming around the damaged tissue.

No organs or tissues are dominated by phagocytes, but almost every tissue in the body shelters resident or visiting macrophages. This relatively diffuse collection of phagocytes has been called the **monocyte–macrophage system**, or the *reticuloendothelial system*.

How does an activated macrophage respond to a pathogen? It may:

- engulf a pathogen or other foreign object and destroy it with lysosomal enzymes.
- bind to or remove a pathogen from the interstitial fluid, but be unable to destroy the invader until assisted by other cells.
- destroy its target by releasing toxic chemicals, such as *tumor* necrosis factor, nitric oxide, or hydrogen peroxide, into the interstitial fluid.

We consider these responses further in a later section.

Fixed Macrophages. Fixed macrophages, or *histiocytes*, reside in specific tissues and organs. These cells are normally incapable of movement, so their targets must diffuse or otherwise move through the surrounding tissue until they are within range. Fixed macrophages are scattered among connective tissues, usually in close association with collagen or reticular fibers. They are found in the papillary and reticular layers of the dermis, in the subarachnoid space of the meninges, and in bone marrow. In some organs, the fixed macrophages have special names. **Microglia** are macrophages in the central nervous system, and **Kupffer cells** are macrophages located in and around the liver sinusoids. **Figure 22–11 Innate Defenses.** Innate (nonspecific) defenses deny pathogens access to the body or destroy them without distinguishing among specific types.

Innate Defenses				
Physical barriers keep hazardous organisms and materials outside the body.	Duct of eccrine sweat gland Hair Secretions Epithelium			
Phagocytes engulf pathogens and cell debris.	Fixed nacrophage Neutrophil Monocyte			
Immune surveillance

Fever	100_			
is an elevation of body temperature that accelerates tissue metabolism and body defenses.	Body temperature rises above 37.2 °C in response to pyrogens			

Free Macrophages. Free macrophages, or *wandering macrophages*, travel throughout the body. They arrive at the site of an injury by migrating through adjacent tissues or by leaving the circulating blood. Some tissues contain free macrophages. For

example, **alveolar macrophages**, also known as *phagocytic dust cells*, monitor the exchange surfaces of the lungs for respiratory pathogens.

Movement and Phagocytosis

Free macrophages and microphages function in similar ways:

- Both can move through capillary walls by squeezing between adjacent endothelial cells. This process is known as *emigration*, or *diapedesis*. D p. 667 The endothelial cells in an injured area develop membrane "markers" that signal passing blood cells that something is wrong. The phagocytic cells then attach to the endothelial lining and migrate into the surrounding tissues.
- Both may be attracted to or repelled by chemicals in the surrounding fluids, a phenomenon called **chemotaxis**. They are particularly sensitive to cytokines released by other body cells and to chemicals released by pathogens.
- For both, phagocytosis begins with **adhesion**, the attachment of the phagocyte to its target. In adhesion, receptors on the plasma membrane of the phagocyte bind to the surface of the target. Adhesion is followed by the formation of a vesicle containing the bound target (Figure 3–21, p. 97). The contents of the vesicle are digested once the vesicle fuses with lysosomes or peroxisomes.

All phagocytic cells function in much the same way, although their targets may differ. The life span of an actively phagocytic cell can be rather brief. For example, most neutrophils die before they have engulfed more than 25 bacteria, and during an infection a neutrophil may attack that many in an hour.

2 TIPS & TRICKS

Membrane markers and chemotaxis are like putting up the flag on your mailbox: They signal the need for action.

Immune Surveillance

The immune system generally ignores the body's own cells unless they become abnormal in some way. Natural killer (NK) cells are lymphocytes responsible for recognizing and destroying abnormal cells when they appear in peripheral tissues. The constant monitoring of normal tissues by NK cells is called **immune surveillance**.

The plasma membrane of an abnormal cell generally contains antigens that are not found on the membranes of normal cells. NK cells recognize an abnormal cell by detecting those antigens. NK cells are much less selective about their targets than are other lymphocytes: They respond to a *variety* of abnormal antigens that may appear anywhere on a plasma membrane. They also attack *any* membrane containing abnormal antigens. As a result, NK cells are highly versatile. A single NK cell can attack bacteria in the interstitial fluid, body cells infected with viruses, or cancer cells.

NK cells respond much more rapidly than T cells or B cells. The activation of T cells and B cells involves a complex and time-consuming sequence of events. NK cells respond immediately on contact with an abnormal cell.

NK Cell Activation

Activated NK cells react in a predictable way (Figure 22–12):

1 *Recognition and adhesion* If a cell has unusual components in its plasma membrane, an NK cell recognizes that cell as abnormal. This recognition activates the NK cell, which then adheres to its target cell.

2 *Realignment of Golgi apparatus* The Golgi apparatus moves around the nucleus until the maturing face points directly toward the abnormal cell. The process might be compared to the rotation of a tank turret to point the cannon toward the enemy. The Golgi apparatus then produces a flood of secretory vesicles that contain proteins called **perforins**. These vesicles move through the cytosol toward the cell surface.

Secretion of perforin The perforins are released at the NK cell surface by exocytosis and diffuse across the narrow gap between the NK cell and its target.

4 *Lysis of abnormal cell* On reaching the opposing plasma membrane, perforin molecules interact with one another and with the membrane to create a network of pores in it. These pores are large enough to allow the free passage of ions, proteins, and other intracellular materials. As a result, the target cell can no longer maintain its internal environment, and it quickly disintegrates.

TIPS&TRICKS

Perforin gets its name because it perforates the target cell.

Why doesn't perforin affect the plasma membrane of the NK cell? The answer is not clear, but NK cell membranes contain a second protein, called *protectin*. It may bind and inactivate perforin.

NK cells attack cancer cells and body cells infected with viruses. Cancer cells probably appear throughout life, but their plasma membranes generally contain unusual proteins called **tumor-specific antigens**, which NK cells recognize as abnormal. The NK cells then destroy the cancer cells, preserving tissue integrity. Unfortunately, some cancer cells avoid detection, perhaps because they lack tumor-specific antigens or because these antigens are covered in some way. Other cancer cells are able to destroy the NK cells that detect them. This process of avoiding detection or neutralizing body defenses is called **immunological escape**. Once immunological escape has occurred, cancer cells can multiply and spread without interference by NK cells.

In viral infections, the viruses replicate inside cells, beyond the reach of circulating antibodies. However, infected cells incorporate viral antigens into their plasma membranes,

Figure 22–12 How Natural Killer Cells Kill Cellular Targets.

Interferons (in-ter-FER-onz) **(IFNs)** are small proteins released by activated lymphocytes and macrophages, and by tissue cells infected with viruses. An interferon binds to surface receptors on the membrane of a normal cell and, by second messengers, triggers the production of **antiviral proteins** in the cytoplasm. Antiviral proteins do not prevent viruses from entering the cell. Instead, they interfere with viral replication inside the cell. In addition to slowing the spread of viral infections, IFNs stimulate the activities of macrophages and NK cells.

At least three types of interferons exist: **interferon alpha** (α), **interferon beta** (β), and **interferon gamma** (γ) (Figure 22–13). Most cells other than lymphocytes and macrophages respond to viral infection by secreting interferon beta.

Interferons are examples of **cytokines** (SI-tō-kīnz), which are chemical messengers that tissue cells release to coordinate local activities. Most cells produce cytokines only for paracrine communication—that is, cell-to-cell communication within one tissue. However, defense cells release cytokines that also act as hormones, affecting cells and tissues throughout the body. We discuss their role in regulating adaptive (specific) defenses in a later section.

Complement System

Plasma contains over 30 special **complement (C) proteins** that form the **complement system**. The term *complement* refers to the fact that this system complements the action of antibodies.

Figure 22–13 Interferons.

The complement proteins interact with one another in chain reactions, or *cascades*, reminiscent of those of the clotting system. Figure 22–14 provides an overview of the complement system.
The **classical pathway** activates the complement system most rapidly and effectively. It begins with the binding of complement protein C1 to two nearby antibodies already attached to

its specific antigen, such as a bacterial cell wall. In the absence

of antibody molecules, the alternative pathway, or properdin

pathway, activates the complement system. The alternative

pathway is slower and less effective than the classical pathway. It begins when several complement proteins—including **properdin** (*factor P*), *factor B*, and *factor D*—interact in the plasma. Exposure to foreign materials, such as the cell wall

of a bacterium, can trigger this interaction. Like the classical pathway, the alternative pathway ends with the conversion of inactive C3 protein to the activated C3b protein. Complement activation brings about the following effects: pore formation, enhanced phagocytosis, and histamine release. Figure 22–14 shows the pathways of complement activation and its effects.

Inflammation

Inflammation, or the *inflammatory response*, is a localized tissue response to injury. \supset **p**. 144 Inflammation produces local redness (*rubor*), swelling (*tumor*), heat (*calor*), and pain (*dolor*). These are known as the so-called *cardinal signs and symptoms of inflammation*. Sometimes a fifth is included: lost function (*functio laesa*).

Many stimuli can produce inflammation. They include impact, abrasion, distortion, chemical irritation, infection by pathogens, and extreme temperatures (hot or cold). Each of these stimuli kills cells, damages connective tissue fibers, or injures the tissue in some other way. The changes alter the chemical composition of the interstitial fluid. Damaged cells release prostaglandins, proteins, and potassium ions. The injury itself may have introduced foreign proteins or pathogens. These changes in the interstitial environment trigger the complex process of inflammation.

Inflammation has several effects:

- The injury is temporarily repaired, and additional pathogens are prevented from entering the wound.
- The spread of pathogens away from the injury is slowed.
- Local, regional, and systemic defenses are mobilized to overcome the pathogens and facilitate permanent repairs. This repair process is called *regeneration*.

The Response to Injury

Mast cells play a pivotal role in the inflammatory response. Figure 22–15 summarizes the events of inflammation in the skin. Comparable events take place in almost any tissue subjected to physical damage or infection.

When stimulated by mechanical stress or chemical changes in the local environment, mast cells release histamine, heparin, prostaglandins, and other chemicals into interstitial fluid. The histamine makes capillaries more permeable and speeds up blood flow through the area. The combination of abnormal tissue conditions and chemicals released by mast cells stimulates local sensory neurons, producing sensations of pain. The person then may take steps to limit the damage, such as removing a splinter or cleaning a wound.

The increased blood flow reddens the area and raises the local temperature. These changes increase the rate of enzymatic reactions and accelerate the activity of phagocytes. The rise in

temperature may also denature foreign proteins or vital enzymes of invading microorganisms.

Because vessel permeability has increased, clotting factors and complement proteins can leave the bloodstream and enter the injured or infected area. Clotting does not take place at the actual site of injury, due to the presence of heparin. However, a clot soon forms around the damaged area, both isolating the region and slowing the spread of the chemical or pathogen into healthy tissues. Meanwhile, complement activation through the alternative pathway breaks down bacterial cell walls and attracts phagocytes.

Neutrophils are drawn to the area by chemotaxis, where they attack debris and bacteria. As neutrophils circulate through a blood vessel in an injured area, they undergo *activation*. In this process (1) they stick to the side of the vessel and move into the tissue by diapedesis; (2) their metabolic rate goes up dramatically, and while this *respiratory burst* continues, they generate reactive compounds, such as nitric oxide and hydrogen peroxide, that can destroy engulfed pathogens; and (3) they secrete cytokines that attract other neutrophils and macrophages to the area. As inflammation proceeds, the foreign proteins, toxins, microorganisms, and active phagocytes in the area activate the body's specific defenses.

Fixed and free macrophages engulf pathogens and cell debris. At first, neutrophils outnumber these cells. Then, as the macrophages and neutrophils continue to secrete cytokines, the number of macrophages increases rapidly. Eosinophils may get involved if antibodies coat the foreign materials.

The cytokines released by active phagocytes stimulate fibroblasts in the area. The fibroblasts then begin forming scar tissue that reinforces the clot and slows the invasion of adjacent tissues. Over time, the clot is broken down and the injured tissues are either repaired or replaced by scar tissue. The process is essentially complete, although subsequent remodeling may take place over a period of years.

After an injury, tissue conditions generally become even more abnormal before they begin to improve. The tissue destruction that occurs after cells have been injured or destroyed is called **necrosis** (ne-KRŌ-sis). The destruction begins several hours after the initial event, and the damage is due to lysosomal enzymes. Lysosomes break down by autolysis, releasing digestive enzymes that first destroy the injured cells and then attack surrounding tissues. **D** p. 76 As local inflammation continues, debris, fluid, dead and dying cells, and necrotic tissue components accumulate at the injury site. This viscous fluid mixture is known as **pus**. An accumulation of pus in an enclosed tissue space is called an **abscess**.

Fever

Fever is a body temperature greater than 37.2 °C (99 °F). Recall from Chapter 14 that the preoptic area of the hypothalamus

contains the temperature-regulating center. **D p**. **480** Circulating proteins called **pyrogens** (PĪ-rō-jen*z; pyro-*, fever or heat + *-gen*, substance) can reset this thermostat and raise body temperature.

A variety of stimuli either act as pyrogens themselves or stimulate macrophages to release pyrogens. These stimuli include pathogens, bacterial toxins, and antigen–antibody complexes. Active macrophages release a cytokine called **tumor necrosis factor (TNF)**, which directly causes fever or stimulates the release of **endogenous pyrogen**, or **interleukin-1** (in-ter-LOO-kin), abbreviated **IL-1**.

Within limits, a fever can be beneficial. High body temperatures may inhibit some viruses and bacteria. The most likely beneficial effect is on body metabolism. For each 1 °C rise in body temperature, metabolic rate increases by 10 percent. Cells can move faster, and enzymatic reactions take place more quickly. As a result, tissue defenses can be mobilized more rapidly and the repair process speeds up.

CHECKPOINT

- 7. List the body's innate (nonspecific) defenses.
- 8. What types of cells would be affected by a decrease in the number of monocyte-forming cells in red bone marrow?
- 9. A rise in the level of interferon in the body suggests what kind of infection?
- 10. What effects do pyrogens have in the body?
- See the blue Answers tab at the back of the book.

22-4 Adaptive (specific) defenses respond to individual threats and are either cell-mediated or antibody-mediated

Learning Outcome Define adaptive (specific) defenses, identify the forms and properties of immunity, and distinguish between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.

Adaptive (specific) defenses result from the coordinated activities of T cells and B cells. These cells respond to the presence of specific antigens. In general, T cells bring about **cell-mediated immunity**, or *cellular immunity*, which defends against abnormal cells and pathogens inside cells. B cells provide **antibodymediated immunity**, or *humoral immunity*, which defends against antigens and pathogens in body fluids.

Both kinds of immunity are important because they come into play under different circumstances. Activated T cells do not respond to antigens in solution, and antibodies (produced by activated B cells) cannot cross plasma membranes. Moreover, helper T cells play a crucial role in antibody-mediated immunity by stimulating the activity of B cells.

Figure 22–16 Forms of Immunity.

Forms of Immunity

We can classify immunity as either innate or adaptive. (Figure 22–16). As we stated earlier, **innate immunity** is genetically determined. It is present at birth and is not related to previous exposures to a particular antigen. For example, people do not get the same diseases that goldfish do. Innate immunity breaks down only in the case of AIDS or other conditions that depress all aspects of specific resistance.

Adaptive immunity is not present at birth. Instead, you develop immunity to a specific antigen only when you have been exposed to that antigen. Adaptive immunity can be *ac-tive* or *passive*. These forms of immunity can be either naturally acquired or artificially induced.

Active immunity develops after exposure to an antigen. It is a consequence of the immune response. In active immunity, the body responds to an antigen by making its own antibody. The immune system is *capable* of defending against a huge number of antigens. However, the appropriate defenses are mounted only after you encounter a particular antigen. Active immunity can result from natural exposure to an antigen in the environment (*naturally acquired active immunity*) or from deliberate exposure to an antigen (*artificially induced active immunity*).

- Naturally acquired active immunity normally begins to develop after birth. It continues to build as you encounter "new" pathogens or other antigens. You might compare this process to the development of a child's vocabulary: The child begins with a few basic common words and learns new ones as they are encountered.
- Artificially induced active immunity stimulates the body to produce antibodies under controlled conditions so that you will be able to overcome natural exposure to the pathogen in the future. This is the basic principle behind *immunization*, or *vaccination*, to prevent disease. A **vaccine** is a preparation designed to induce an immune response. It contains either a dead or an inactive pathogen, or antigens derived from that pathogen.

Passive immunity is produced by transferring antibodies from another source.

- In naturally acquired passive immunity, a baby receives antibodies from the mother, either during gestation (by crossing the placenta) or in early infancy (through breast milk).
- In artificially induced passive immunity, a person receives antibodies to fight infection or prevent disease. For example, someone who has been bitten by a rabid animal gets injections containing antibodies against the rabies virus.

Properties of Adaptive Immunity

Regardless of the form, adaptive immunity has four general properties: (1) *specificity*, (2) *versatility*, (3) *memory*, and (4) *tolerance*.

Specificity

A specific defense is activated by a specific antigen, and the immune response targets that particular antigen and no others. **Specificity** results from the activation of appropriate lymphocytes and the production of antibodies with targeted effects. Specificity occurs because T cells and B cells respond to the molecular structure of an antigen. The shape and size of the antigen determine which lymphocytes will respond to it. Each T cell or B cell has receptors that will bind to one specific antigen, ignoring all others. The response of an activated T cell or B cell is equally specific. Either lymphocyte will destroy or inactivate that antigen without affecting other antigens or normal tissues.

Versatility

Millions of antigens in the environment can pose a threat to health. Over a normal lifetime, you encounter only a fraction of that number—perhaps tens of thousands of antigens. Your immune system, however, has no way of anticipating which antigens it will encounter. It must be ready to confront *any* antigen at *any* time. **Versatility** results in part from the large diversity of lymphocytes present in the body, and in part from variability in the structure of synthesized antibodies.

During development, cells in the lymphatic system differentiate to produce a huge number of lymphocytes with varied antigen sensitivities. The trillion or more T cells and B cells in your body include millions of different lymphocyte populations, distributed throughout the body. Each population contains several thousand cells with receptors in their membranes that differ from the receptors of other lymphocyte populations. As a result, each population of lymphocytes responds to a different antigen.

Several thousand lymphocytes are not enough to overcome a pathogenic invasion. However, when activated by an appropriate antigen, a lymphocyte begins to divide, producing more lymphocytes with the same specificity. All the cells produced by these divisions make up a **clone**, and all the members of that clone are sensitive to the same specific antigen. To understand how this system works, think about running a commercial kitchen with only samples on display. You can display a wide selection because the samples don't take up much space, and you don't have to expend energy now preparing food that might never be eaten. When a customer selects one of your samples and places an order for several dozen, you prepare them on the spot.

The same principle applies to the lymphatic system. Your body contains a small number of many different kinds of lymphocytes. When an antigen arrives, lymphocytes sensitive to it are "selected." These lymphocytes divide to generate a large number of additional lymphocytes of the same type.

Memory

As we just saw, during the initial response to an antigen, lymphocytes that are sensitive to it undergo repeated cycles of cell division. Immunologic **memory** exists because those cell divisions produce two groups of cells. One group attacks the invader immediately. Another group remains inactive unless it meets the same antigen at a later date. This inactive group is made up of *memory cells* that enable your immune system to "remember" an antigen it has previously encountered, and to launch a faster, stronger, and longer-lasting counterattack if such an antigen appears again.

Tolerance

The immune system does not respond to all antigens. All cells and tissues in the body, for example, contain antigens that normally do not stimulate an immune response. We say that the immune system exhibits **tolerance** toward such antigens.

The immune response targets foreign cells and compounds, but it generally ignores normal tissues. During their differentiation in the red bone marrow (B cells) and thymus (T cells), any cells that react to antigens that are normally present in the body are destroyed. As a result, mature B cells and T cells ignore normal antigens, also called *self-antigens*, but attack foreign antigens, or *nonself antigens*. Tolerance can also develop over time in response to chronic exposure to an antigen in the environment. Such tolerance lasts only as long as the exposure continues.

An Introduction to the Immune Response

Figure 22–17 provides an overview of the immune response. When an antigen triggers an immune response, it usually activates both T cells and B cells. The activation of T cells generally occurs first, but only after phagocytes have been exposed to the antigen. Once activated, T cells attack the antigen and stimulate the activation of B cells. Activated B cells mature into cells that produce antibodies. Antibodies in the bloodstream then bind to and attack the antigen. We examine these processes more closely in the sections that follow.

CHECKPOINT

- Explain the difference between cell-mediated (cellular) immunity and antibody-mediated (humoral) immunity.
- 12. Identify the two forms of active immunity and the two forms of passive immunity.
- 13. List the four general properties of adaptive immunity.

See the blue Answers tab at the back of the book.

22-5 T cells play a role in initiating, maintaining, and controlling the immune response

Learning Outcome Discuss the types of T cells and their roles in the immune response, and describe the mechanisms of T cell activation and differentiation.

The role of T cells in the immune response is varied and important in resisting pathogens. We have already noted four major types of T cells:

- 1. *Cytotoxic T* (T_c) *cells* are responsible for cell-mediated immunity. These cells enter peripheral tissues and directly attack antigens physically and chemically.
- **2.** *Memory T cells* respond to antigens they have already encountered by cloning more lymphocytes to ward off the invader.
- 3. Helper T (T_H) cells stimulate the responses of both T cells and B cells. Helper T cells are absolutely vital to the

immune response, because they must activate B cells before the B cells can produce antibodies. The reduction in the helper T cell population that occurs in AIDS is largely responsible for the loss of immunity. (We discuss AIDS on p. 819.)

4. Suppressor $T(T_s)$ cells inhibit T cell and B cell activities and moderate the immune response.

Before an immune response can begin, T cells must be activated by exposure to an antigen. This activation seldom occurs through direct interaction between a T cell and the antigen. Foreign substances or pathogens entering a tissue commonly fail to stimulate an immediate immune response.

Antigen Presentation

For T cells to recognize an antigen, the antigen must be bound to glycoproteins in the plasma membranes of another cell. Recall that glycoproteins are integral membrane components. ⊃ p. 70 Antigen presentation occurs when an antigenglycoprotein combination capable of activating T cells appears in a plasma membrane.

The structure of these glycoproteins is genetically determined. The genes controlling their synthesis are located along one portion of chromosome 6, in a region called the **major histocompatibility complex (MHC)**. These membrane glycoproteins are called **MHC proteins**, or *human leukocyte antigens* (*HLAs*).

The amino acid sequences and the shapes of MHC proteins differ among individuals. Each MHC molecule has a

Clinical Note

Graft Rejection and Immunosuppression Organ transplant may be a treatment option for patients with severe disorders of the bone marrow, kidneys, liver, heart, lungs, or pancreas. Finding a suitable donor is the first major problem. In the United States, each day many people die while waiting for an organ transplant, and dozens are added to the transplant waiting list.

After transplant surgery, the major problem is **graft rejection**. In graft rejection, T cells are activated by contact with MHC proteins on plasma membranes in the donated tissues. The cytotoxic T cells that develop then attack and destroy the foreign cells.

Transplant success can be improved by *immunosuppression*, a reduction in the sensitivity of the immune system. Until recently, the drugs used to produce immunosuppression did not selectively target the immune response. For example, **prednisone** (PRED-ni-sōn), a corticosteroid, was used because it has anti-inflammatory effects that reduce the number of circulating white blood cells and depress the immune response. Unfortunately, corticosteroid use also causes undesirable side effects in systems other than the immune system.

An understanding of the communication among T cells, macrophages, and B cells has now led to the development of drugs with more selective effects. **Cyclosporin A**, a compound derived from a fungus, was the most important *immunosuppressive drug* developed in the 1980s. This compound suppresses all aspects of the immune response. It acts primarily by suppressing helper T cell activity while leaving suppressor T cells relatively unaffected. Even more narrowly focused drugs are available. These include monoclonal antibodies that prevent antigen recognition by T cell receptors.

distinct three-dimensional shape with a relatively narrow central groove. An antigen that fits into this groove can be held in position by hydrogen bonding.

Two major classes of MHC proteins are known: *Class I* and *Class II*. An antigen bound to a Class I MHC protein acts like a red flag that in effect tells the immune system "Hey, I'm an abnormal cell—kill me!" An antigen bound to a Class II MHC protein tells the immune system "Hey, this antigen is dangerous—get rid of it!"

Class I MHC proteins are in the plasma membranes of all nucleated cells. These proteins are continuously synthesized and exported to the plasma membrane in vesicles created at the Golgi apparatus. As they form, Class I proteins pick up small peptides from the surrounding cytoplasm and carry them to the cell surface. If the cell is healthy and the peptides are normal, T cells ignore them. If the cytoplasm contains abnormal

(nonself) peptides or viral proteins (Figure 22–18a), they soon appear in the plasma membrane, and T cells will recognize them as foreign and be activated. Ultimately, their activation leads to the destruction of the abnormal cells. This is the primary reason that donated organs are commonly rejected by the recipient. Despite preliminary cross-match testing, the recipient's T cells recognize the transplanted tissue as foreign.

Class II MHC proteins are present only in the plasma membranes of antigen-presenting cells and lymphocytes. **Antigen-presenting cells (APCs)** are specialized cells responsible for activating T cell defenses against foreign cells (including bacteria) and foreign proteins. Antigen-presenting cells include all the phagocytic cells of the monocyte–macrophage group discussed in other chapters, including (1) free and fixed macrophages in connective tissues, (2) the Kupffer cells of the liver, and (3) the microglia in the central nervous system (Chapter 12). \bigcirc pp. 127, 397 The dendritic (Langerhans) cells of the skin and the dendritic cells of the lymph nodes and spleen are APCs that are not phagocytic. \bigcirc p. 153

Phagocytic APCs engulf and break down pathogens or foreign antigens. This **antigen processing** creates fragments of the antigen, which are then bound to Class II MHC proteins and inserted into the plasma membrane (Figure 22–18b,c). *Class II MHC proteins appear in the plasma membrane only when the cell is processing antigens*. Exposure to an APC membrane containing a processed antigen can stimulate appropriate T cells.

The dendritic cells remove antigenic materials from their surroundings by pinocytosis rather than phagocytosis. However, their plasma membranes still present antigens bound to Class II MHC proteins. More important is that, unlike macrophages that do not migrate very far from an infection site, dendritic cells travel with their foreign antigens to lymphocytepacked lymph nodes.

Antigen Recognition

How do T cells recognize antigens? Inactive T cells have receptors that can bind either Class I or Class II MHC proteins. These receptors also have binding sites for a specific target antigen. If an MHC protein contains any antigen other than the specific target of a particular kind of T cell, the T cell remains inactive. If the MHC protein contains the antigen that the T cell is programmed to detect, binding occurs. This process is called **antigen recognition**, because the T cell recognizes that it has found an appropriate target.

Some T cells can recognize antigens bound to Class I MHC proteins, whereas others can recognize antigens bound to Class II MHC proteins. Whether a T cell responds to antigens held by one class or the other depends on a type of protein in the T cell's own plasma membrane. The membrane proteins involved are members of a larger group of proteins called **CD** (*cluster of differentiation*) **markers**.

Figure 22–18 Antigens and MHC Proteins.

c Phagocytic antigen-presenting cell.

Lymphocytes, macrophages, and other related cells have CD markers. More than 70 types of CD markers exist, and each type is designated by a number. All T cells have a **CD3 receptor complex** in their plasma membranes, and this complex ultimately activates the T cell. Either of two other CD markers may be bound to the CD3 receptor complex, and these two CD markers are especially important in specific groups of T cells: 1. **CD8** markers are found on cytotoxic T cells and suppressor T cells, which together are often called *CD8 T cells* or *CD8* + *T cells*. CD8 T cells respond to antigens presented by Class I MHC proteins.

22

2. CD4 markers are found on helper T cells, often called *CD4* T *cells* or *CD4* + T *cells*. CD4 T cells respond to antigens presented by Class II MHC proteins.

22

T cells are not usually activated upon their first encounter with the antigen. Antigen recognition simply prepares the cell for activation.

Costimulation

In order to proceed from recognition to activation, a T cell must also bind to the stimulating cell at a second site. This vital secondary binding process, called *costimulation*, essentially confirms the initial activation signal.

Costimulation is like the safety on a gun: It helps prevent T cells from mistakenly attacking normal (self) tissues. If a cell displays an unusual antigen but does not display the "I am an active phagocyte" or "I am infected" signal, T cell activation will not occur. Costimulation is important only in determining whether a T cell will become activated. Once activation has occurred, the "safety" is off and the T cell will attack any cells that carry the target antigens.

Activation of CD8 T Cells

Two different types of CD8 T cells are activated by exposure to antigens bound to Class I MHC proteins. One type responds quickly, giving rise to large numbers of *cytotoxic T cells* and

memory T cells (Figure 22–19). The other type responds more slowly and produces relatively small numbers of *suppressor T* cells.

Cytotoxic T Cells

Cytotoxic T (T_C) cells seek out and destroy abnormal and infected cells. They are highly mobile cells that roam throughout injured tissues. When a cytotoxic T cell encounters its target antigen bound to Class I MHC proteins, it immediately destroys the target cell (Figure 22–19). The T cell may (1) release perforin to destroy the target cell's plasma membrane, (2) secrete a poisonous **lymphotoxin** (lim-fō-TOK-sin) to kill the target cell, or (3) activate genes in the target cell's nucleus that tell that cell to die. (We introduced genetically programmed cell death, called *apoptosis*, in Chapter 3.) \supset p. 101

The entire sequence of events, from the appearance of the antigen in a tissue to cell destruction by cytotoxic T cells, takes a significant amount of time. After the first exposure to an antigen, two days or more may pass before the concentration of cytotoxic T cells reaches effective levels at the site of injury or infection. Over this period, the damage or infection may spread, making it more difficult to control.

Memory T_c Cells

The same cell divisions that produce cytotoxic T cells also produce thousands of **memory** \mathbf{T}_{C} **cells**. These cells do not differentiate further the first time the antigen triggers an immune response. However, if the same antigen appears a second time, memory T cells *immediately* differentiate into cytotoxic T cells. They produce a prompt, effective cellular response that can overwhelm the invader before it becomes well established in the tissues.

Suppressor T Cells

Suppressor T (T_s) cells suppress the responses of other T cells and of B cells by secreting inhibitory cytokines called *suppression factors*. Suppression does not take place right away, because activation takes much longer for suppressor T cells than for other types of T cells. In addition, upon activation, most of the CD8 T cells in the bloodstream produce cytotoxic T cells rather than suppressor T cells. As a result, suppressor T cells act *after* the initial immune response. In effect, these cells limit the degree of immune system activation from a single stimulus.

Activation of CD4 T Cells

Upon activation, helper T cells (T_H cells) with CD4 markers undergo a series of divisions that produce both active helper T cells and **memory helper T cells**, also called **memory T_H cells** (Figure 22–20). The memory helper T cells remain in reserve. The active helper T cells secrete a variety of cytokines that coordinate specific and nonspecific defenses and stimulate cellmediated and antibody-mediated immunities. These cytokines do the following:

- stimulate the T cell divisions that produce memory helper T cells and speed the maturation of cytotoxic T cells;
- 2. enhance nonspecific defenses by attracting macrophages to the affected area, preventing their departure, and stimulating their phagocytic activity and effectiveness;
- **3.** attract and stimulate the activity of cytotoxic T cells, providing another means of destroying abnormal cells and pathogens; and
- 4. promote the activation of B cells, leading ultimately to antibody production.

Figure 22–21 provides a review of the methods of antigen presentation and T cell stimulation. The plasma membranes of infected or otherwise abnormal cells trigger an immune response when CD8 T cells recognize antigens bound to Class I MHC proteins. Extracellular pathogens or foreign proteins trigger an immune response when CD4 T cells recognize antigens displayed by Class II MHC proteins. In the next section, we will see how the helper T cells derived from activated CD4 T cells **Figure 22–20** Antigen Recognition and Activation of Helper T Cells. Inactive CD4 T cells (T_H cells) must be exposed to appropriate antigens bound to Class II MHC proteins. The T_H cells then undergo activation, dividing to produce active T_H cells and memory T_H cells.

in turn activate B cells that are sensitive to the same specific antigen.

CHECKPOINT

- 14. Identify the four major types of T cells.
- **15**. How can the presence of an abnormal peptide in the cytoplasm of a cell initiate an immune response?
- **16**. A decrease in the number of cytotoxic T cells would affect which type of immunity?
- **17**. How would a lack of helper T cells affect the antibodymediated immune response?

810 UNIT 4 Fluids and Transport

Figure 22–21 A Summary of the Pathways of T Cell Activation.

22-6 B cells respond to antigens by producing specific antibodies

Learning Outcome Discuss the mechanisms of B cell activation and differentiation, describe the structure and function of antibodies, and explain the primary and secondary responses to antigen exposure.

B cells are responsible for launching a chemical attack on antigens. They produce appropriate specific *antibodies*.

B Cell Sensitization and Activation

As noted earlier, the body has millions of B cell populations. Each B cell carries its own particular type of antibody molecules in its plasma membrane. If corresponding antigens appear in the interstitial fluid, they interact with these superficial antibodies. When binding occurs, the B cell prepares to undergo activation. This preparatory process is called **sensitization** (Figure 22–22). Because B cells migrate throughout the body, pausing briefly in one lymphoid tissue or another, sensitization typically takes place within the lymph node nearest the site of infection or injury.

Recall that B cell plasma membranes contain Class II MHC proteins. During sensitization, antigens are brought into the cell by endocytosis. The antigens subsequently appear on the surface of the B cell, bound to Class II MHC proteins. (The mechanism is comparable to that shown in Figure 22–18b). The sensitized B cell is then on "standby" but generally does

not undergo activation unless it receives the "OK" from a helper T cell. The need for activation by a helper T cell helps prevent inappropriate activation, the same way that costimulation acts as a "safety" in cell-mediated immunity.

What happens when a sensitized B cell meets a helper T cell that has already been activated by antigen presentation? The helper T cell binds to the B cell's MHC complex, recognizes the antigen, and begins secreting cytokines that promote B cell activation (Figure 22–22). After activation of the B cell, these same cytokines stimulate B cell division, speed plasma cell formation, and enhance antibody production.

The activated B cell typically divides several times, producing daughter cells that differentiate into plasma cells and *memory B cells* (Figure 22–22). The plasma cells begin synthesizing and secreting large quantities of antibodies into the interstitial fluid. These antibodies have the same target as the antibodies on the surface of the sensitized B cell. When stimulated by cytokines from helper T cells, a plasma cell can secrete up to 100 million antibody molecules each hour.

Memory B cells perform the same role in antibodymediated immunity that memory T cells perform in cellmediated immunity. Memory B cells do not respond to a threat on first exposure. Instead, they remain in reserve to deal with subsequent injuries or infections that involve the same antigens. On subsequent exposure, the memory B cells divide and differentiate into plasma cells that secrete antibodies in massive quantities. **Figure 22–22** The Sensitization and Activation of B Cells. A B cell is sensitized by exposure to antigens. Once antigens are bound to antibodies in the B cell plasma membrane, the B cell displays those antigens on Class II MHC proteins in its plasma membrane. Activated helper T cells encountering the antigens release cytokines that costimulate the sensitized B cell and trigger its activation. The activated B cell then divides, producing memory B cells and plasma cells that secrete antibodies.

Antibody Structure

A Y-shaped antibody molecule consists of two pairs of polypeptide chains: one pair of **heavy chains** and one pair of **light chains (Figure 22–23)**. Each chain contains both *constant segments* and *variable segments*.

The constant segments of the heavy chains form the base of the antibody molecule (Figure 22–23a,b). B cells produce only five types of constant segments. These are the basis of a classification scheme that identifies antibodies as *IgG*, *IgE*, *IgD*, *IgM*, or *IgA*, as we discuss in the next section. The structure of the constant segments of the heavy chains determines the way the antibody is secreted and how it is distributed within the body. For example, antibodies in one class circulate in body fluids, whereas those of another class bind to the membranes of basophils and mast cells.

The heavy-chain constant segments, which are bound to constant segments of the light chains, also contain binding sites that can activate the complement system. These binding sites are covered when the antibody is secreted but become exposed when the antibody binds to an antigen. The specificity of an antibody molecule depends on the amino acid sequence of the variable segments of the light and heavy chains. The free tips of the two variable segments form the **antigen binding sites** of the antibody molecule (Figure 22–23a). These sites can interact with an antigen in the same way that the active site of an enzyme interacts with a substrate molecule. \bigcirc p. 54

Small differences in the structure of the variable segments affect the precise shape of the antigen binding site. These differences make antibodies specific for different antigens. The distinctions are the result of minor genetic variations that occur during the production, division, and differentiation of B cells. A normal adult body contains roughly 10 trillion B cells, which can produce an estimated 100 million types of antibodies, each with a different specificity.

The Antigen–Antibody Complex

An **antigen–antibody complex** forms when an antibody molecule binds to its corresponding antigen molecule. Once the two molecules are in position, hydrogen bonding and other weak chemical forces lock them together.

Figure 22–23 Antibody Structure and Function.

Antibodies do not bind to the entire antigen. Instead, they bind to specific portions of its exposed surface—regions called **antigenic determinant sites**, or **epitopes** (Figure 22–23c). The specificity of the binding depends initially on the threedimensional "fit" between the variable segments of the antibody molecule and the corresponding antigenic determinant sites. A **complete antigen** has at least two antigenic determinant sites, one for each of the antigen binding sites on an antibody molecule. Exposure to a complete antigen can lead to B cell sensitization and a subsequent immune response. Most environmental antigens have multiple antigenic determinant sites, and entire microorganisms may have thousands.

Haptens, or *partial antigens*, do not ordinarily cause B cell activation and antibody production. Haptens include short peptide chains, steroids and other lipids, and several drugs, including antibiotics such as *penicillin*. However, haptens may

become attached to carrier molecules, forming combinations that can function as complete antigens (Figure 22–23d). In some cases, the carrier contributes an antigenic determinant site. Antibodies will then attack both the hapten and the carrier molecule. If the carrier molecule is normally present in the tissues, the antibodies may begin attacking and destroying normal cells. This process is the basis for several drug reactions, including allergies to penicillin.

Classes and Actions of Antibodies

Body fluids may contain five classes of antibodies, or **immunoglobulins (Igs)**: *IgG*, *IgE*, *IgD*, *IgM*, and *IgA* (Table 22–1). The classes are determined by differences in the structure of the heavy-chain constant segments. For this reason, the classes have no effect on the antibody's specificity, which is determined by the antigen binding sites.

Table 22–1 Classes of Antibodies

IgG is the largest and most diverse class of antibodies. They account for 80 percent of all antibodies. IgG antibodies are responsible for resistance against many viruses, bacteria, and bacterial toxins. These antibodies can cross the placenta, and maternal IgG provides passive immunity to the fetus during embryological development. However, the anti-Rh antibodies produced by Rh-negative mothers are also IgG antibodies and produce hemolytic disease of the newborn.

IgE attaches as an individual molecule to the exposed surfaces of basophils and mast cells. When a suitable antigen is bound by IgE molecules, the cell is stimulated to release histamine and other chemicals that accelerate inflammation in the immediate area. IgE is also important in the allergic response. **IgD** is an individual molecule on the surfaces of B cells, where it can bind antigens in the extracellular fluid. This binding can play a role in the sensitization of the B cell involved.

IgM is the first class of antibody secreted after an antigen is encountered. IgM concentration declines as IgG production accelerates. Although plasma cells secrete individual IgM molecules, IgM circulates as a five-antibody starburst. The anti-A and anti-B antibodies responsible for the agglutination of incompatible blood types are IgM antibodies. IgM antibodies may also attack bacteria that are insensitive to IgG.

IgA is found primarily in glandular secretions such as mucus, tears, saliva, and semen. These antibodies attack pathogens before they gain access to internal tissues. IgA antibodies circulate in blood as individual molecules or in pairs. Epithelial cells absorb them from the blood and attach a *secretory piece*, which confers solubility, before secreting the IgA molecules onto the epithelial surface.

The formation of an antigen–antibody complex may cause the elimination of the antigen in seven ways:

- 1. *Neutralization*. Both viruses and bacterial toxins have specific sites that must bind to target regions on body cells before they can enter or injure those cells. Antibodies may bind to those sites, making the virus or toxin incapable of attaching itself to a cell. This mechanism is known as **neutralization**.
- 2. Precipitation and Agglutination. Each antibody molecule has two antigen binding sites, and most antigens have many antigenic determinant sites. If individual antigens (such as macromolecules or bacterial cells) are far apart, an antibody molecule will necessarily bind to two antigenic sites on the same antigen. However, if antigens are close together, an antibody can bind to antigenic determinant sites on two separate antigens. In this way, antibodies can link large numbers of antigens together. The three-dimensional structure created by such binding is known as an immune complex. When the antigen is a soluble molecule, such as a toxin, this process may create complexes that are too large to remain in solution. The formation of insoluble immune complexes is called **precipitation**. When the target antigen is on the surface of a cell or virus, the formation of large complexes is called **agglutination**. For example, the clumping of erythrocytes that takes place when incompatible blood types are mixed is an agglutination reaction. \bigcirc p. 666
- **3.** Activation of the Complement System. When an antibody molecule binds to an antigen, portions of the antibody

molecule change shape. This change exposes areas that bind complement proteins. The bound complement molecules then activate the complement system, which destroys the antigen (as discussed previously).

- 4. *Attraction of Phagocytes*. Antigens covered with antibodies attract eosinophils, neutrophils, and macrophages. These cells phagocytize pathogens and destroy foreign or abnormal plasma membranes.
- 5. Opsonization. A coating of antibodies and complement proteins increases the effectiveness of phagocytosis. This effect is called *opsonization*. Some bacteria have slick plasma membranes or capsules, but opsonization makes it easier for phagocytes to hold onto their prey before they engulf it. Phagocytes can bind more easily to antibodies and complement proteins than they can to the bare surface of a pathogen.
- 6. *Stimulation of Inflammation*. Antibodies may promote inflammation by stimulating basophils and mast cells.
- 7. *Prevention of Bacterial and Viral Adhesion.* Antibodies dissolved in saliva, mucus, and perspiration coat epithelia, adding an additional layer of defense. A covering of antibodies makes it difficult for pathogens to attach to and penetrate body surfaces.

TIPS&TRICKS

The classes of immunoglobulins—lg*M*,lg*A*, lg*D*, lg*G*, lg*E*—spell *MADGE*.

Primary and Secondary Responses to Antigen Exposure

The initial immune response to an antigen is called the **primary response**. When the antigen appears again, it triggers a more extensive and prolonged **secondary response**. This response is due to the presence of large numbers of memory cells that are primed for the arrival of the antigen. Primary and secondary responses occur in both cell-mediated and antibodymediated immunities. Let's look at the pattern of antibody production over time to see the differences between the primary and secondary responses.

The Primary Response

The primary response takes time to develop because the antigen must activate the appropriate B cells. These cells must then differentiate into plasma cells. As plasma cells differentiate and begin secreting, the concentration of circulating antibodies makes a gradual, sustained rise (Figure 22–24a).

During the primary response, the **antibody titer**, or level of antibodies in the plasma, does not peak until one to two weeks after the initial exposure. If the individual is no longer exposed to the antigen, the antibody concentration then declines. The antibody titer declines because (1) plasma cells have very high metabolic rates and survive for only a short time, and (2) suppressor T cells release suppression factors that inhibit further production of plasma cells. However, suppressor T cell activity does not begin immediately after exposure to the antigen. Also, under normal conditions helper T cells outnumber suppressor T cells by more than 3 to 1. As a result, many B cells are activated before suppressor T cell activity has a noticeable effect. Activated B cells start dividing immediately. At each cycle of division, some of the daughter cells differentiate into plasma cells, while others continue to divide. Molecules of *immunoglobulin M*, or *IgM*, are the first to appear in the bloodstream. The plasma cells that produce IgM differentiate after only a few cycles of B cell division. Levels of *immunoglobulin G*, or *IgG*, rise more slowly, because the plasma cells responsible differentiate only after repeated cell divisions that also generate large numbers of memory B cells. In general, IgM is less effective as a defense than IgG. However, IgM provides an immediate defense that can fight the infection until massive quantities of IgG can be produced.

The Secondary Response

Unless memory B cells are exposed to the same antigen a second time, they do not differentiate into plasma cells. If and when that exposure occurs, the memory B cells respond right away faster than the B cells stimulated during the initial exposure. This response is immediate in part because memory B cells are activated at relatively low antigen concentrations. In addition, these cells synthesize more effective and destructive antibodies. Activated memory B cells divide and differentiate into plasma cells that secrete these antibodies in massive quantities. This secretion is the secondary response to antigen exposure.

During the secondary response, antibody concentrations and titers increase more rapidly and reach levels many times higher than they did in the primary response (Figure 22–24b). The secondary response appears even if the second exposure occurs years after the first. The reason is that memory cells may survive for 20 years or more.

The primary response develops slowly and does not produce antibodies in massive quantities. For these reasons, it

Figure 22–24 The Primary and Secondary Responses in Antibody-Mediated Immunity.

a The primary response takes about two weeks to develop peak antibody levels (titers). IgM and IgG antibody levels do not remain elevated.

may not prevent an infection the first time a pathogen appears in the body. However, a person who survives the first infection will probably be resistant to that pathogen in the future, thanks to a rapid and overwhelming secondary response. The effectiveness of the secondary response is one of the basic principles behind the use of immunization to prevent disease.

TIPS&TRICKS

The antibody response is like ordering a custom suit. The first suit (the primary antibody response) takes time to make because the tailor (an activated B cell) must first make a pattern (a clone of memory cells). Subsequent suits (secondary responses) are made much more quickly because the pattern already exists.

Summary of the Immune Response

We have now examined the basic cellular and chemical interactions that follow the appearance of a foreign antigen in the body. Table 22–2 reviews the cells that participate in tissue defenses and Figure 22–25 gives a timeline for their appearance at the site of a bacterial infection.

In the early stages of infection, neutrophils and NK cells migrate into the threatened area and destroy bacteria. Over time, cytokines draw increasing numbers of phagocytes into the region. Cytotoxic T cells appear as arriving T cells are activated by antigen presentation. Last of all, the population of plasma cells rises as activated B cells differentiate. This rise is followed **Figure 22–25** The Course of the Body's Response to a Bacterial Infection. The basic sequence of events begins with the appearance of bacteria in peripheral tissues at time 0.

by a gradual, sustained increase in the activity (titer) of circulating antibodies.

Figure 22–26 provides an integrated review of the relationship between innate and adaptive immunity. The basic sequence of events is similar when a viral infection occurs. The initial steps are different, however, because cytotoxic T cells provide an adaptive defense and NK cells provide an innate defense. **Figure 22–27** contrasts the events involved in defending against bacterial infection with those involved in defending against viral infection.

Table 22–2	Cells That Participate in Tissue Defenses	
Cell		Functions
Neutrophils		Phagocytosis; stimulation of inflammation
Eosinophils		Phagocytosis of antigen–antibody complexes; suppression of inflammation; participation in allergic response
Mast cells and basophils		Stimulation and coordination of inflammation by release of histamine, heparin, leukotrienes, prostaglandins
ANTIGEN-PRESENTING CELLS		
Macrophages (free and fixed macrophages, Kupffer cells, microglia, etc.)		Phagocytosis; antigen processing; antigen presentation with Class II MHC proteins; secretion of cytokines, especially interleukins and interferons
Dendritic cells		Pinocytosis; antigen processing; antigen presentation bound to Class II MHC proteins
LYMPHOCYTES		
NK cells		Destruction of plasma membranes containing abnormal antigens
Cytotoxic T cells (T _c , CD8 marker)		Lysis of plasma membranes containing antigens bound to Class I MHC proteins; secretion of perforins, defensins, lymphotoxins, and other cytokines
Helper T cells (T _H , CD4 marker)		Secretion of cytokines that stimulate cell-mediated and antibody-mediated immunity; activation of sensitized B cells
B cells		Differentiation into plasma cells, which secrete antibodies and provide antibody-mediated immunity
Suppressor T cells (T _s , CD8 marker)		Secretion of suppression factors that inhibit the immune response
Memory cells (T _s , T _H , B)		Produced during the activation of T cells and B cells; remain in tissues awaiting rearrival of antigens

CHECKPOINT

- **18**. Define sensitization.
- **19**. A sample of lymph contains an elevated number of plasma cells. Would you expect the number of antibodies in the blood to be increasing or decreasing? Why?
- **20**. Describe the structure of an antibody.
- 21. Which would be more negatively affected—the primary response or the secondary response—by a lack of memory B cells for a particular antigen?

See the blue Answers tab at the back of the book.

22-7 I Immunocompetence enables a normal immune response; abnormal responses result in immune disorders

Learning Outcome Describe the development of immunocompetence, list and explain examples of immune disorders and allergies, and discuss the effects of stress on immune function.

We begin this section by exploring **immunocompetence**, the ability to produce an immune response after exposure to an antigen. Then we consider some of the disorders that result when immune responses go wrong. Finally, we examine the role of stress in immune responses.

The Development of Immunocompetence

Cell-mediated immunity can be demonstrated as early as the third month of fetal development. Active antibody-mediated immunity follows about one month later.

The first cells that leave the fetal thymus migrate to the skin and into the epithelia lining the mouth, the digestive tract, and the uterus and vagina in females. These cells take up residence in these tissues as antigen-presenting cells, such as the dendritic cells of the skin, whose primary function will be to help activate T cells. T cells that leave the thymus later in development populate lymphoid organs throughout the body.

The plasma membranes of the first B cells produced in the liver and bone marrow carry IgM antibodies. Sometime after the fourth month the fetus may produce IgM antibodies if exposed to specific pathogens. It is uncommon for the fetus to produce antibodies, however, because the developing fetus has naturally acquired passive immunity due to IgG antibodies from the mother's bloodstream. These are the only antibodies that can cross the placenta. They include the antibodies responsible for the clinical problems due to Rh incompatibility, discussed in Chapter 19. December 19. Chapter 19. Chap

The natural immunity provided by maternal IgG may not be enough to protect the fetus if the maternal defenses are overwhelmed by a bacterial or viral infection. For example, the microorganisms responsible for syphilis and rubella ("German measles") can cross from the maternal to the fetal bloodstream, producing a congenital infection that leads to the production of fetal antibodies. IgM provides only a partial defense, and these infections can result in severe developmental problems for the fetus.

Delivery eliminates the maternal supply of IgG. Although the mother provides IgA antibodies in breast milk, the infant gradually loses its passive immunity. The amount of maternal IgG in the infant's bloodstream declines rapidly over the first two months after birth. During this period, the infant becomes vulnerable to infection by bacteria or viruses that were previously overcome by maternal antibodies. The infant's immune system begins to respond to infections, environmental antigens, and vaccinations. As a result, the infant begins producing its own IgG. It has been estimated that, from birth to age 12, children encounter a "new" antigen every six weeks. (This fact explains why most parents, who were exposed to the same antigens when they were children, remain healthy while their children develop runny noses and colds.) Over this period, the concentration of circulating antibodies gradually rises toward normal adult levels. Populations of memory B cells and T cells also increase.

Skin tests are sometimes used to determine whether an individual has been exposed to a particular antigen. In these procedures, small quantities of antigen are injected into the skin, generally on the anterior surface of the forearm. If resistance has developed, the region becomes inflamed over the next two to four days. Many states require a tuberculosis test, called a *tuberculin skin test*, before children enter public school. If the test is positive, further tests must then be performed to determine whether an infection is currently under way. Skin tests are also used to check for allergies to environmental antigens.

Cytokines of the Immune System

Cytokines are chemical messengers involved in cellular immunity. They include hormones and paracrine-like glycoproteins important to the immune response. Interferons, interleukins, and tumor necrosis factors are examples of cytokines (Spotlight Figure 22–28).

Immune Disorders

Because the immune response is so complex, many opportunities exist for things to go wrong. A variety of clinical conditions result from disorders of the immune function. **Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues. In an **immunodeficiency disease**, either the immune system fails to develop normally or the immune response is blocked in some way. Autoimmune disorders and immunodeficiency diseases are fairly rare—clear evidence of the effectiveness of the immune system's control mechanisms. A far more common (and generally far less dangerous) class of immune disorders is **allergies**. Next we consider examples of each type of immune disorder.

Autoimmune Disorders

Autoimmune disorders affect an estimated 5 percent of adults in North America and Europe. In previous chapters we have cited many examples of the effects of autoimmune disorders on the function of major systems.

The immune system usually recognizes but ignores antigens normally found in the body—self-antigens. When the recognition system does not work correctly, however, activated B cells make antibodies against other body cells and tissues.

Clinical Note

AIDS Acquired immunodeficiency syndrome (AIDS), or *late-stage HIV disease*, is caused by the **human immunodeficiency** virus (HIV). This virus is a *retrovirus*: It carries its genetic information in RNA rather than in DNA. The virus enters human leukocytes by receptor-mediated endocytosis. ⊃ p. 97 Specifically, the virus binds to CD4 T cells. HIV also infects several types of antigen-presenting cells, including those of the monocyte–macrophage line. It is the infection of helper T cells that leads to clinical problems.

Once the virus is inside a cell, the viral enzyme *reverse transcriptase* synthesizes a complementary strand of DNA. This strand is then incorporated into the cell's genetic material. When these inserted viral genes are activated, the infected cell begins synthesizing viral proteins. In effect, the viral genes take over the cell's synthetic machinery and force the cell to produce additional viruses. These new viruses are then shed at the cell surface.

Cells infected with HIV are ultimately destroyed by (1) formation of pores in the plasma membrane as the viruses are shed, (2) interruption of cell maintenance due to the continuing synthesis of viral components, (3) autolysis, or (4) stimulation of programmed cell death (apoptosis).

The gradual destruction of helper T cells impairs the immune response, because these cells play a central role in coordinating cell-mediated and antibody-mediated responses to antigens. To make matters worse, suppressor T cells are relatively unaffected by the virus. Over time the excess of suppressing factors "turns off" the normal immune response. Circulating antibody levels decline and cell-mediated immunity is reduced. The body is left with impaired defenses against a wide variety of microbial invaders. Microorganisms that would ordinarily be harmless can now initiate lethal *opportunistic infections*. The risk of cancer also increases because immune surveillance is depressed.

Infection with HIV occurs through intimate contact with the body fluids of infected individuals. The major routes of transmission involve contact with blood, semen, or vaginal secretions, although all body fluids may contain the virus. Worldwide, most individuals with AIDS become infected through sexual contact with an HIV-infected person (who may *not* necessarily show clinical signs of AIDS). The next largest group of infected individuals is intravenous drug users who shared contaminated needles. Relatively few individuals have become infected with the virus after receiving a transfusion of contaminated blood or blood products. Finally, an increasing number of infants are born with AIDS acquired from infected mothers.

AIDS continues to be a public health problem of massive proportions. Current statistics from the Centers for Disease Control and Prevention (CDC) show that more than 1.1 million people in the United States are infected with HIV. Moreover, nearly 1 in 5 people are not aware that they are infected.

The most effective ways to prevent HIV infection include abstinence, mutual monogamy of uninfected partners, male circumcision (to reduce the risk of transmission), and the avoidance of needle sharing. Circumcised men are up to 70 percent less likely to become infected than uncircumcised men. They are also less likely to infect their female partners. The use of latex condoms labeled "for the prevention of disease" has been shown to prevent the passage of HIV as well as the hepatitis and herpes viruses. Natural condoms, also called lambskin condoms, are made from the intestinal membrane of a lamb. They are not effective against disease transmission because infectious agents can pass through the naturally occurring pores. (The pores are too small for sperm to pass through, so they are effective as a contraceptive.) Synthetic condoms, usually made of polyurethane, are considered to offer similar protection as latex, but differences in their manufacture cause variable reliability.

Clinical signs and symptoms of AIDS may not appear until 5–10 years or more after infection. When they do appear, they are commonly mild, consisting of swollen lymph nodes and chronic, but nonfatal, infections. So far as is known, however, AIDS is almost always fatal. Most people who carry the virus eventually die from complications of the disease. (A handful of infected individuals have been able to tolerate the virus without apparent illness for many years.)

Despite intensive efforts, a vaccine has yet to be developed that prevents HIV infection in an uninfected person exposed to the virus. The survival rate for AIDS patients has been steadily increasing. That is, more people are living longer before dying of AIDS or its complications. New drugs and drug combinations slow the progression of the disease, and improved antibiotic therapies help combat secondary infections.

HIV (green) budding from an infected T_H cell (blue)

SPOTLIGHT Figure 22–28 Cytokines of the Immune System

Innate (nonspecific) immunity and adaptive (specific) immunity are coordinated by both physical interactions and the release of chemical messengers.

> **Physical** Interactions

The Immune System is coordinated by

> Chemical Messengers

An example of the release of chemical messengers is the secretion of cytokines by many cell types involved in the immune response. The six groups of cytokines shown here merit special attention.

Interleukins

Interleukins may be the most diverse and important chemical messengers in the immune system. Nearly 20 types of interleukins have been identified. Lymphocytes and macrophages are the primary sources of interleukins, but endothelial cells, fibroblasts, and astrocytes also produce certain interleukins, such as interleukin-1 (IL-1).

The functions of interleukins include the following:

- 1. Increasing T Cell Sensitivity to Antigens Exposed on Macrophage Membranes. Heightened sensitivity speeds up the production of cytotoxic and regulatory T cells.
- 2. Stimulating B Cell Activity, Plasma Cell Formation, and Antibody Production. These events promote the production of antibodies and the development of antibody-mediated immunity.
- 3. Enhancing Innate (Nonspecific) Immunity. Known effects of interleukin production include (a) stimulation of inflammation, (b) formation of scar tissue by fibroblasts, (c) increasing body temperature by the preoptic nucleus of the hypothalamus, (d) stimulation of mast cell formation, and (e) promotion of adrenocorticotropic hormone (ACTH) secretion by the anterior lobe of the pituitary gland.
- 4. Moderating the Immune Response. Some interleukins help suppress immune function and shorten the immune response.

Two interleukins, IL-1 and IL-2, are important in stimulating and maintaining the immune response. When released by activated macrophages and lymphocytes, these cytokines stimulate the activities of other immune cells and of the secreting cell. The result is a positive feedback loop that helps to recruit additional immune cells.

Although mechanisms exist to control the degree of stimulation, the regulatory process sometimes breaks down. Massive production of interleukins can cause problems at least as severe as those of the primary infection. For example, in Lyme disease, activated macrophages release IL-1 in response to a localized bacterial infection. This release produces fever, pain, skin rash, and arthritis throughout the entire body.

Some interleukins enhance the immune response, while others suppress it. The quantities secreted at any moment affect the nature and intensity of the response to an antigen. During a typical infection, the pattern of interleukin secretion changes constantly. Whether stimulatory interleukins or suppressive interleukins predominate plays a part in determining whether the individual overcomes the infection. For this reason, interleukins and their interactions are now the focus of intensive research.

macrophage

Interferons

Interferons (IFNs) make the cell that synthesizes them, and that cell's neighbors, resistant to viral infection. In this way, IFNs slow the spread of a virus. They may have other beneficial effects as well. For example, interferon alpha (α) and interferon gamma (γ) attract and stimulate NK cells. Interferon beta (β) slows the progress of inflammation associated with viral infection. Interferon gamma also stimulates macrophages, making them more effective at killing bacterial or fungal pathogens.

Because they stimulate NK cell activity, interferons can be used to fight some cancers. For example, interferon alpha has been used to treat malignant melanoma, bladder cancer, ovarian cancer, and some forms of leukemia. Interferon alpha or gamma may be used to treat Kaposi's sarcoma, a cancer that typically develops in patients with AIDS.

Tumor Necrosis Factors

Tumor necrosis factors (TNFs) slow the growth of a tumor and kill sensitive tumor cells. Activated macrophages secrete one type of TNF and carry the molecules in their plasma membranes. Cytotoxic T cells produce a different type of TNF. In addition to their effects on tumor cells, TNFs stimulate granular leukocyte production, promote eosinophil activity, act as pyrogens and cause fever, and increase T cell sensitivity to interleukins.

Phagocyte-Activating Chemicals

Several cytokines coordinate immune defenses by adjusting the activities of phagocytic cells. These cytokines include factors that attract free macrophages and microphages and prevent their premature departure from the site of an iniurv.

Colony-Stimulating Factors

Colony-stimulating factors (CSFs) were introduced in Chapter 19. **p. 674** These factors are produced by active T cells, cells of the monocyte-macrophage system, endothelial cells, and fibroblasts. CSFs stimulate the production of blood cells in red bone marrow and lymphocytes in lymphoid tissues and organs.

Miscellaneous Cytokines

This general category includes many chemicals discussed in earlier chapters. Examples include leukotrienes, lymphotoxins, perforin, hemopoiesis-stimulating factor, and suppression factors.

NOTE: Cytokines are often classified according to their origins. For example, lymphokines are produced by lymphocytes. Monokines are secreted by active monocytes, macrophages, and other antigen-presenting cells. These terms are misleading, however, because lymphocytes and macrophages may secrete the same cytokines. In addition, cells involved in adaptive immunity and tissue repair can also secrete cytokines.

These "misguided" antibodies are called **autoantibodies**. The trigger may be a reduction in suppressor T cell activity, the excessive stimulation of helper T cells, tissue damage that releases large quantities of antigenic fragments, haptens bound to compounds normally ignored, viral or bacterial toxins, or a combination of factors.

The resulting condition depends on the antigen that the autoantibodies attack. For example:

- The inflammation of *thyroiditis* is due to autoantibodies against thyroglobulin.
- *Rheumatoid arthritis* occurs when autoantibodies form immune complexes in connective tissues around the joints.
- Type 1 diabetes develops when autoantibodies attack cells in the pancreatic islets.

Many autoimmune disorders appear to be cases of mistaken identity. For example, proteins associated with the measles, Epstein–Barr, influenza, and other viruses contain amino acid sequences that are similar to those of myelin proteins. As a result, antibodies that target these viruses may also attack myelin sheaths. This accounts for the neurological complications that sometimes follow a vaccination or a viral infection. It also may be responsible for *multiple sclerosis*.

For unknown reasons, the risk of autoimmune problems increases if an individual has an unusual type of MHC protein. At least 50 clinical conditions have been linked to specific variations in MHC structure.

Immunodeficiency Diseases

Immunodeficiency diseases result from (1) problems with the embryonic development of lymphoid organs and tissues; (2) an infection with a virus, such as HIV, that depresses immune function; or (3) treatment with, or exposure to, immunosuppressive agents, such as radiation or drugs.

Individuals born with **severe combined immunodeficiency disease (SCID)** fail to develop either cell-mediated or antibody-mediated immunity. Their lymphocyte populations are low, and normal B cells and T cells are absent. Such infants cannot produce an immune response, so even a mild infection can prove fatal. Total isolation offers protection but at great cost—extreme restrictions on lifestyle. Bone marrow transplants from a compatible donor, normally a close relative, have been used to colonize lymphoid tissues with functional lymphocytes. Gene-splicing techniques have led to therapies that can treat at least one form of SCID.

AIDS is an immunodeficiency disease that results from a viral infection that targets helper T cells. As the number of T cells declines, normal immune control breaks down. When a subsequent infection occurs, suppressor factors from suppressor T cells inhibit an immune response before the few surviving helper T cells can stimulate the formation of cytotoxic T cells or plasma cells in adequate numbers. We discussed AIDS in the Clinical Note (p. 819).

Immunosuppressive drugs have been used for many years to prevent graft rejection after transplant surgery. Unfortunately, immunosuppressive agents can destroy stem cells and lymphocytes and lead to a complete failure of the immune response.

Allergies

Allergies are inappropriate or excessive immune responses to antigens. The sudden increase in cellular activity or antibody titers can have several unpleasant side effects. For example, neutrophils or cytotoxic T cells may destroy normal cells while they are attacking an antigen. Or the antigen–antibody complex may trigger massive inflammation. Antigens that set off allergic reactions are often called **allergens**.

There are several types of allergies. A complete classification has four categories. They include *immediate hypersensitivity* (*Type I*), *cytotoxic reactions* (*Type II*), *immune complex disorders* (*Type III*), and *delayed hypersensitivity* (*Type IV*). In Chapter 19 we discussed one example of a cytotoxic (Type II) reaction: the cross-reaction that follows the transfusion of an incompatible blood type. **D p**. 666 Here we focus on immediate (Type I) hypersensitivity. It is probably the most common type of allergy.

Immediate hypersensitivity is a rapid and especially severe response to an antigen. One form, *allergic rhinitis*, includes hay fever and environmental allergies. This form may affect 15 percent of the U.S. population. Sensitization to an allergen during the initial exposure leads to the production of large quantities of IgE. Genes may determine a person's tendency to produce IgE in response to particular allergens.

Due to the lag time needed to activate B cells, produce plasma cells, and synthesize antibodies, the first exposure to an allergen does not produce signs and symptoms. Instead, it sets the stage for the next encounter. After sensitization, the IgE molecules become attached to basophils and mast cells throughout the body. When the individual meets the same allergen again, the bound antibodies stimulate these cells to release histamine, heparin, several cytokines, prostaglandins, and other chemicals into the surrounding tissues. This results in a sudden, massive inflammation of the affected tissues.

The cytokines and other mast cell secretions draw basophils, eosinophils, T cells, and macrophages into the area. These cells release their own chemicals, extending and intensifying the responses initiated by mast cells. The severity of the allergic reaction depends on the individual's sensitivity and on the location involved. If allergen exposure occurs at the body surface, the response may be restricted to that area. If the allergen enters the bloodstream, the response could be lethal.

In **anaphylaxis** (an-a-fi-LAK-sis; *ana-*, again + *phylaxis*, protection), a circulating allergen affects mast cells throughout

the body (Figure 22–29). (In drug reactions, such as allergies to penicillin, IgE antibodies are produced in response to a hapten [partial antigen] bound to a larger molecule that is widely distributed within the body because the combination acts as an allergen.) A wide range of signs and symptoms can develop within minutes. Changes in capillary permeabilities produce swelling and edema in the dermis, and raised welts, or *hives*, appear on the skin. Smooth muscles along the respiratory passageways contract, and the narrowed passages make breathing extremely difficult. In severe cases, an extensive peripheral vasodilation occurs, producing a drop in blood pressure that can lead to a circulatory collapse. This response is **anaphylactic shock**.

The prompt administration of drugs that block the action of histamine, known as **antihistamines** (an-tē-HISta-mēnz), can prevent many of the signs and symptoms of immediate hypersensitivity. *Benadryl* (*diphenhydramine hydrochloride*) is a popular antihistamine that is available over the counter. Severe anaphylaxis is treated with injections of antihistamines, corticosteroids, and epinephrine.

Stress and the Immune Response

One of the normal effects of interleukin-1 secretion is the stimulation of adrenocorticotropic hormone (ACTH) production by the anterior lobe of the pituitary gland. This hormone in turn prompts the secretion of glucocorticoids by the adrenal cortex. \bigcirc p. 632 The anti-inflammatory effects of the glucocorticoids may help control the extent of the immune response.

It is clear, however, that chronic stress depresses the immune system and can be a serious threat to health. The longterm secretion of glucocorticoids, as in the resistance phase of the *stress response*, can inhibit the immune response and lower a person's resistance to disease. \bigcirc p. 645 The effects of glucocorticoids that alter the effectiveness of innate and adaptive defenses include the following:

- Depression of Inflammation. Glucocorticoids inhibit mast cells and make capillaries less permeable. Inflammation becomes less likely. When it does occur, the reduced permeability of the capillaries slows the entry of fibrinogen, complement proteins, and cellular defenders into tissues.
- Reduction in the Abundance and Activity of Phagocytes in Peripheral Tissues. This reduction further impairs innate defense mechanisms. It also interferes with the processing and presentation of antigens to lymphocytes.
- Inhibition of Interleukin Secretion. A reduction in interleukin production depresses the response of lymphocytes, even to antigens bound to MHC proteins.

Figure 22–29 The Mechanism of Anaphylaxis.

The mechanisms that bring about these changes are still under investigation.

CHECKPOINT

- 22. Which kind of immunity protects a developing fetus, and how is that immunity produced?
- 23. Define autoimmune disorder.
- 24. How does increased stress reduce the effectiveness of the immune response?

See the blue Answers tab at the back of the book.

Page 1010

Figure 22–30 diagrams the functional relationships between the lymphatic system and the other body systems we have studied so far.

22-8 The immune response diminishes as we age

Learning Outcome Describe the effects of aging on the lymphatic system and the immune response.

As we age, the immune system becomes less effective at combating disease. T cells become less responsive to antigens, so fewer cytotoxic T cells respond to an infection. This effect may be due to the gradual shrinking of the thymus and to lower circulating levels of thymic hormones. Because the number of helper T cells is also reduced, B cells are less responsive, so antibody levels do not rise as quickly after antigen exposure. The net result is an increased susceptibility to viral and bacterial infections. For this reason, vaccinations for acute viral diseases such as the flu (influenza), and for pneumococcal pneumonia, are strongly recommended for elderly individuals. The increased incidence of cancer in elderly people reflects the fact that immune surveillance declines, so tumor cells are not eliminated as effectively.

CHECKPOINT

- **25**. Why are elderly people more susceptible to viral and bacterial infections?
- 26. What may account for the increased incidence of cancer among elderly people?
- See the blue Answers tab at the back of the book.

22-9 The nervous and endocrine systems influence the immune response

Learning Outcome Give examples of interactions between the lymphatic system and other organ systems we have studied so far and explain how the nervous and endocrine systems influence the immune response.

Figure 22–30 summarizes the interactions between the lymphatic system and other physiological systems we have studied so far. Interactions among elements of the immune response and the nervous and endocrine systems are now the focus of intense research. For example,

- The thymus secretes oxytocin, ADH, and endorphins as well as thymic hormones. The effects on the CNS are not known, but removal of the thymus lowers brain endorphin levels.
- Both thymic hormones and cytokines help establish the normal levels of CRH and TRH produced by the hypothalamus.
- Other thymic hormones affect the anterior lobe of the pituitary gland directly, stimulating the secretion of prolactin and GH.

Conversely, the nervous system can apparently adjust the sensitivity of the immune response:

- The PNS innervates dendritic cells in the lymph nodes, spleen, skin, and other antigen-presenting cells. The nerve endings release neurotransmitters that heighten local immune responses. For this reason, some skin conditions, such as *psoriasis*, worsen when a person is under stress.
- Neuroglia in the CNS produce cytokines that promote an immune response.
- A sudden decline in immune function can occur after even a brief period of emotional distress.

CHECKPOINT

- 27. What is the relationship between the endocrine system and the lymphatic system?
- **28**. Identify the role of the lymphatic system for all body systems.
- See the blue Answers tab at the back of the book.

22

Related Clinical Terms

- adenitis: Inflammation of the adenoid (pharyngeal tonsil).
- **allograft:** Transplant between compatible recipient and donor of the same species.
- **anamnestic response:** An immune response that is initiated by memory cells.
- **autograft:** A transplant of tissue that is taken from the same person.

Burkitt's lymphoma: A malignant cancer of B lymphocytes.

- **chronic fatigue syndrome:** A complicated disorder most often characterized by extreme fatigue that does not improve with rest, and which may worsen with physical activity.
- **congenital thymic aplasia:** Congenital (present at birth) absence of the thymus and parathyroid glands and a deficiency of immunity.
- **Coombs test:** A medical test to detect antibodies or complement in the blood.
- **dermatomyositis:** An autoimmune disease characterized by inflammation of the skin and muscles.
- **eczema:** A genetic inflammatory skin disorder, often with crusts, papules, and leaky eruptions.
- **Hodgkin's lymphoma:** A malignant lymphoma affecting lymph nodes and lymph organs.

- **host versus graft disease:** A pathological condition in which cells from the transplanted tissue of a donor initiate an immunological response, attacking the cells and tissue of the recipient.
- **hybridoma:** A tissue culture composed of cancer cells fused to lymphocytes to mass-produce a specific antibody.
- **immunology:** Branch of biomedicine concerned with the structure and function of the immune system.
- **infectious mononucleosis:** An acute disease caused by the Epstein– Barr virus, producing fever, swelling of the lymph nodes, sore throat, and increased lymphocytes in the bloodstream.
- **latex allergy:** Hypersensitivity to products made of the sap of the rubber plant.

- **polymyositis:** An autoimmune disease characterized by inflammation and atrophy of muscles.
- **sentinel node:** The first lymph node to receive drainage from a tumor. It is used to determine if there is lymphatic metastasis in some types of cancer.

splenomegaly: Enlargement of the spleen.

- **systemic lupus erythematosus (SLE):** An autoimmune disease in which a person's immune system attacks and injures its own organs and tissues in virtually every system of the body.
- **xenograft:** A transplant that is made between two different species.

- 22-1 Surface barriers and internal defenses make up innate defenses, and lymphocytes provide adaptive defenses p. 782
 - 1. The cells, tissues, and organs of the **lymphatic system** play a central role in the body's defenses against a variety of **patho-***gens*, or disease-causing organisms.
- 2. *Lymphocytes*, the primary cells of the lymphatic system, are central to an **immune response** against specific threats to the body. **Immunity** is the ability to resist infection and disease.
- 22-2 Lymphatic vessels, lymphocytes, lymphoid tissues, and lymphoid organs function in body defenses p. 783
- 3. The lymphatic system includes a network of **lymphatic** vessels, or **lymphatics**, that carry **lymph** (a fluid similar to plasma, but with a lower concentration of proteins). **Primary lymphoid tissues and organs** are sites where lymphocytes are formed and mature. Secondary lymphoid tissues and organs are where lymphocytes are activated and cloned. An array of lymphoid tissues and lymphoid organs is connected to lymphatics. (*Figure 22–1*)
- 4. The lymphatic system produces, maintains, and distributes lymphocytes (which attack invading organisms, abnormal cells, and foreign proteins); it also helps maintain blood volume and eliminate local variations in the composition of interstitial fluid.
- 5. Lymph flows along a network of lymphatic vessels, the smallest of which are the **lymphatic capillaries** (*terminal lymphatics*). The lymphatic vessels empty into the **thoracic duct** and the **right lymphatic duct**. (*Figures 22–2 to 22–4*)
- The three classes of lymphocytes are T (thymus-dependent) cells, B (bone marrow-derived) cells, and NK (natural killer) cells. (*Figure 22–5*)

- Cytotoxic T cells attack foreign cells or body cells infected by viruses and provide cell-mediated (cellular) immunity. *Regulatory T cells* (helper T cells and suppressor T cells) regulate and coordinate the immune response.
- 8. B cells can differentiate into **plasma cells**, which produce and secrete *antibodies* that react with specific chemical targets called **antigens**. Antibodies in body fluids are called *immunoglobulins*. B cells are responsible for **antibody-mediated** (humoral) immunity.
- **9.** NK cells (also called **large granular lymphocytes**) attack foreign cells, normal cells infected with viruses, and cancer cells. NK cells provide *immune surveillance*.
- 10. Lymphocytes continuously migrate into and out of the blood through the lymphoid tissues and organs. Lymphopoiesis (lymphocyte production) involves the red bone marrow, thymus, and peripheral lymphoid tissues. (*Figure 22–6*)
- 11. Lymphoid tissues are connective tissues dominated by lymphocytes. In a **lymphoid nodule**, the lymphocytes are densely packed in an area of areolar tissue. The lymphoid tissue that protects the epithelia of the digestive, respiratory, urinary, and reproductive tracts is called **mucosa-associated lymphoid** tissue (MALT). (*Figure 22–7*)
- 12. Important lymphoid organs include the **lymph nodes**, the **thymus**, and the **spleen**. Lymphoid tissues and organs are distributed in areas that are especially vulnerable to injury or invasion.
- **13.** Lymph nodes are encapsulated masses of lymphoid tissue. The **deep cortex** is dominated by T cells; the **outer cortex** and **medulla** contain B cells. (*Figure 22–8*)
- **14.** The thymus lies behind the sternum, in the anterior mediastinum. **Thymic epithelial cells (TECs)** regulate T cell development and function. (*Figure 22–9*)
- 15. The adult spleen contains the largest mass of lymphoid tissue in the body. The cellular components form the **pulp** of the spleen. **Red pulp** contains large numbers of red blood cells, and **white pulp** resembles lymphoid nodules. (*Figure 22–10*)
- 16. The lymphatic system is a major component of the body's defenses, which are classified as either (1) innate (nonspecific) immunity, which protects without distinguishing one threat from another, or (2) adaptive (specific) immunity, which protects against particular threats only.

22-3 Innate (nonspecific) defenses do not discriminate between potential threats and respond the same regardless of the invader p. 796

- Innate (nonspecific) defenses prevent the approach, deny the entry, or limit the spread of living or nonliving hazards. (*Figure 22–11*)
- **18.** Physical barriers include skin, mucous membranes, hair, epithelia, and various secretions of the integumentary and digestive systems.
- **19.** The two types of phagocytic cells are **microphages** and **macrophages** (cells of the **monocyte–macrophage system**). Microphages are neutrophils and eosinophils in circulating blood.
- 20. **Phagocytes** leave the bloodstream by *emigration*, or *diapedesis* (migration between adjacent endothelial cells), and exhibit **chemotaxis** (sensitivity and orientation to chemical stimuli).
- **21. Immune surveillance** involves constant monitoring of normal tissues by NK cells that are sensitive to abnormal antigens on the surfaces of otherwise normal cells. NK cells kill cancer cells that have **tumor-specific antigens** on their surfaces. (*Figure 22–12*)
- 22. Interferons (IFNs)—small proteins released by cells infected with viruses—trigger the production of **antiviral proteins**, which interfere with viral replication inside the cell. IFNs are **cytokines**, which are chemical messengers released by tissue cells to coordinate local activities. (*Figure 22–13*)
- **23.** At least 30 **complement proteins** make up the **complement system**. These proteins interact with each other in cascades to destroy target plasma membranes, stimulate inflammation, attract phagocytes, or enhance phagocytosis. The complement system can be activated by either the **classical pathway** or the **alternative pathway**. (*Figure 22–14*)
- 24. **Inflammation** is a localized tissue response to injury. (*Figure 22–15*)
- **25.** A **fever** (body temperature greater than 37.2 °C [99 °F]) can inhibit pathogens and accelerate metabolic processes. **Pyrogens** can reset the body's thermostat and raise the temperature.
- 22-4 Adaptive (specific) defenses respond to individual threats and are either cell-mediated or antibodymediated p. 802
- 26. T cells are responsible for **cell-mediated (cellular) immunity**. B cells provide **antibody-mediated (humoral) immunity**.
- 27. Forms of immunity include **innate immunity** (genetically determined and present at birth) or **adaptive immunity** (produced by prior exposure to an antigen or antibody production). The two types of adaptive immunity are **active immunity** (which appears after exposure to an antigen) and **passive immunity** (produced by the transfer of antibodies from another source). (*Figure 22–16*)
- 28. Immunity exhibits four general properties: specificity, versatility, memory, and tolerance. *Memory cells* enable the immune system to "remember" previous target antigens. Tolerance is the ability of the immune system to ignore some antigens, such as those of normal body cells.
- **29.** The immune response is triggered by the presence of an antigen and includes cell-mediated and antibody-mediated defenses. (*Figure 22–17*)
- **22-5** T cells play a role in initiating, maintaining, and controlling the immune response **p.** 805
- **30. Antigen presentation** occurs when an antigen–glycoprotein combination appears in a plasma membrane (typically of a

macrophage or dendritic cell). T cells sensitive to this combination are activated if they contact the membrane of the antigen-presenting cell.

- 31. All body cells have plasma membrane glycoproteins. The genes controlling their synthesis make up a chromosomal region called the major histocompatibility complex (MHC). The membrane glycoproteins are called MHC proteins.
 APCs (antigen-presenting cells) are involved in antigen stimulation.
- 32. Lymphocytes are not activated by free antigens, but respond instead to an antigen bound to either a Class I or a Class II MHC protein in a process called antigen recognition. (*Figure 22–18*)
- **33.** Class I MHC proteins are in all nucleated body cells. Class II MHC proteins are only in antigen-presenting cells (APCs) and lymphocytes.
- 34. Whether a T cell responds to antigens held in Class I or Class II MHC proteins depends on the structure of the T cell plasma membrane. T cell plasma membranes contain proteins called CD (*cluster of differentiation*) markers. CD3 markers are present on all T cells. CD8 markers are on cytotoxic and suppressor T cells. CD4 markers are on all helper T cells.
- **35.** One type of CD8 cell responds quickly to a Class I MHCbound antigen, giving rise to large numbers of cytotoxic T cells and memory T cells. The other type of CD8 cell responds more slowly, giving rise to small numbers of suppressor T cells.
- **36.** Cytotoxic T cells seek out and destroy abnormal and infected cells, using three different methods, including the secretion of **lymphotoxin**. (*Figure 22–19*)
- **37.** Cell-mediated immunity (cellular immunity) results from the activation of CD8 T cells by antigens bound to Class I MHCs. When activated, most of these T cells divide to generate cytotoxic T cells and **memory** T_{C} **cells**, which remain in reserve to guard against future such attacks. Suppressor T cells depress the responses of other T cells and of B cells. (*Figures 22–19*, 22–21)
- **38.** Helper, or CD4, T cells respond to antigens presented by Class II MHC proteins. When activated, helper T cells secrete cytokines that aid in coordinating adaptive and innate defenses, and regulate cell-mediated and antibody-mediated immunity. (*Figures 22–20, 22–21*)

22-6 B cells respond to antigens by producing specific antibodies p. 810

- **39.** B cells become **sensitized** when antibody molecules in their membranes bind antigens. The antigens are then displayed on the Class II MHC proteins of the B cells, which become activated by helper T cells activated by the same antigen. (*Figure 22–22*)
- **40.** An active B cell may differentiate into a plasma cell or produce daughter cells that differentiate into plasma cells and **memory B cells**. Antibodies are produced by plasma cells. (*Figure 22–22*)
- **41.** A Y-shaped antibody molecule consists of two parallel pairs of polypeptide chains containing *constant* and *variable segments*. (*Figure 22–23*)
- 42. When antibody molecules bind to an antigen, they form an antigen–antibody complex. Effects that appear after binding include neutralization (antibody binding that prevents viruses or bacterial toxins from binding to body cells); precipitation (formation of an insoluble immune complex) and agglutination (formation of large complexes); opsonization (coating of pathogens with antibodies and complement

proteins to enhance phagocytosis); stimulation of inflammation; and prevention of bacterial or viral adhesion. (*Figure* 22–23)

- 43. The five classes of antibodies (immunoglobulins, Ig) in body fluids are (1) IgG, responsible for resistance against many viruses, bacteria, and bacterial toxins; (2) IgE, which releases chemicals that accelerate local inflammation; (3) IgD, located on the surfaces of B cells; (4) IgM, the first type of antibody secreted after an antigen arrives; and (5) IgA, found in glandular secretions. (*Table 22–1*)
- 44. In humoral immunity, the antibodies first produced by plasma cells are the agents of the **primary response**. The maximum antibody level and **antibody titer** appears during the **secondary response** to antigen exposure. (*Figure 22–24*)
- 45. The initial steps in the immune responses to viral and bacterial infections differ. (*Figures 22–25 to 22–27; Table 22–2*)
- **46.** Cytokines are chemical messengers coordinated by the immune system. **Interleukins** increase T cell sensitivity to antigens exposed on macrophage membranes; stimulate B cell activity, plasma cell formation, and antibody production; enhance innate defenses; and moderate the immune response. (*Spotlight Figure 22–28*)
- 47. Interferons (IFNs) slow the spread of a virus by making the synthesizing cell and its neighbors resistant to viral infections. (*Spotlight Figure 22–28*)
- **48. Tumor necrosis factors (TNFs)** slow tumor growth and kill tumor cells, and act as a pyrogen. (*Spotlight Figure 22–28*)
- 49. Several cytokines adjust the activities of phagocytic cells to coordinate innate and adaptive defenses. (*Spotlight Figure 22–28*)
- **50. Colony-stimulating factors (CSFs)** are factors produced by active T cells, cells of the monocyte–macrophage group, endo-thelial cells, and fibroblasts. (*Spotlight Figure 22–28*)

22-7 Immunocompetence enables a normal immune response; abnormal responses result in immune disorders p. 818

- **51. Immunocompetence** is the ability to produce an immune response after exposure to an antigen. A developing fetus receives passive immunity from the maternal bloodstream. After delivery, the infant begins developing active immunity following exposure to environmental antigens.
- **52. Autoimmune disorders** develop when the immune response inappropriately targets normal body cells and tissues.
- **53.** In an **immunodeficiency disease**, either the immune system does not develop normally or the immune response is blocked.
- 54. **Allergies** are inappropriate or excessive immune responses to **allergens** (antigens that trigger allergic reactions). The four types of allergies are *immediate hypersensitivity* (*Type I*), *cytotoxic reactions* (*Type II*), *immune complex disorders* (*Type III*), and *delayed hypersensitivity* (*Type IV*).
- 55. In **anaphylaxis**, a circulating allergen affects mast cells throughout the body. (*Figure 22–29*)
- **56.** Interleukin-1 released by active macrophages triggers the release of ACTH by the anterior pituitary gland. Glucocorticoids produced by the adrenal cortex moderate the immune response, but their long-term secretion can lower a person's resistance to disease.

22-8 The immune response diminishes as we age p. 825

- 57. With aging, the immune system becomes less effective at combating disease.
- **22-9** The nervous and endocrine systems influence the immune response p. 825
- **58.** The lymphatic system has extensive interactions with the nervous and endocrine systems. (*Figure 22–30*).

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the lymphatic system in the following diagram.

Lymph from the right arm, the right half of the head, and the right chest is received by the (a) cisterna chyli, (b) right lymphatic duct,

See the blue Answers tab at the back of the book.

- (c) right thoracic duct, (d) aorta.3. Anatomically, lymphatic vessels resemble (a) elastic arteries, (b) mus-
- cular arteries, (c) arterioles, (d) medium veins, (e) the venae cavae.
 4. The specificity of an antibody is determined by the (a) fixed segment, (b) antigenic determinants, (c) variable region, (d) size of the antibody, (e) antibody class.
- 5. The major histocompatibility complex (MHC) (a) is responsible for forming lymphocytes, (b) produces antibodies in lymph glands, (c) is a group of genes that codes for human leukocyte antigens, (d) is a membrane protein that can recognize foreign antigens, (e) is the antigen found on bacteria that stimulates an immune response.
- 6. Red blood cells that are damaged or defective are removed from the bloodstream by the (a) thymus, (b) lymph nodes, (c) spleen, (d) tonsils.
- 7. Phagocytes move through capillary walls by squeezing between adjacent endothelial cells, a process known as (a) diapedesis, (b) chemotaxis, (c) adhesion, (d) perforation.
- 8. Perforins are proteins associated with the activity of (a) T cells,(b) B cells, (c) NK cells, (d) plasma cells.
- **9.** Complement activation **(a)** stimulates inflammation, **(b)** attracts phagocytes, **(c)** enhances phagocytosis, **(d)** achieves a, b, and c.
- The most beneficial effect of fever is that it (a) inhibits the spread of some bacteria and viruses, (b) increases the metabolic rate by up to 10 percent, (c) stimulates the release of pyrogens, (d) achieves a and b.
- 11. CD4 markers are associated with (a) cytotoxic T cells, (b) suppressor T cells, (c) helper T cells, (d) a, b, and c.

- **12.** List the specific functions of each of the body's primary and secondary lymphoid tissues and organs.
- 13. Give a function for each of the following: (a) cytotoxic T cells,
 (b) helper T cells, (c) suppressor T cells, (d) plasma cells, (e) NK cells,
 (f) stromal cells, (g) thymic epithelial cells, (h) interferons, (i) pyrogens, (j) T cells, (k) B cells, (l) interleukins, (m) tumor necrosis factor, (n) colony-stimulating factors.
- 14. What are the three classes of lymphocytes, and where does each class originate?
- **15.** What seven defenses, present at birth, provide the body with the defensive capability known as innate (nonspecific) resistance?

LEVEL 2 Reviewing Concepts

- 16. Compared with innate defenses, adaptive defenses (a) do not distinguish between one threat and another, (b) are always present at birth, (c) protect against threats on an individual basis, (d) deny the entry of pathogens to the body.
- Blocking the antigen receptors on the surface of lymphocytes would interfere with (a) phagocytosis of the antigen, (b) that lymphocyte's ability to produce antibodies, (c) antigen recognition, (d) the ability of the lymphocyte to present antigen, (e) opsonization of the antigen.
- 18. A *decrease* in which population of lymphocytes would impair all aspects of an immune response? (a) cytotoxic T cells, (b) helper T cells, (c) suppressor T cells, (d) B cells, (e) plasma cells.
- 19. Skin tests are used to determine if a person (a) has an active infection, (b) has been exposed to a particular antigen, (c) carries a particular antigen, (d) has measles, (e) can produce antibodies.
- **20.** Compare and contrast the effects of complement with those of interferon.
- **21.** How does a cytotoxic T cell destroy another cell displaying antigens bound to Class I MHC proteins?
- **22.** How does the formation of an antigen–antibody complex cause the elimination of an antigen?

- **23.** Give one example of each type of immunity: innate immunity, naturally acquired active immunity, artificially induced active immunity, artificially induced passive immunity, and naturally acquired passive immunity.
- 24. An anesthesia technician is advised that she should be vaccinated against hepatitis B, which is caused by a virus. She is given one injection and is told to come back for a second injection in a month and a third injection after six months. Why is this series of injections necessary?

LEVEL 3 Critical Thinking and Clinical Applications

- **25.** An investigator at a crime scene discovers some body fluid on the victim's clothing. The investigator carefully takes a sample and sends it to the crime lab for analysis. On the basis of the analysis of antibodies, could the crime lab determine whether the sample is blood plasma or semen? Explain.
- **26.** Ted finds out that he has been exposed to measles. He is concerned that he might have contracted the disease, so he goes to see his physician. The physician takes a blood sample and sends it to a lab for antibody levels and titers. The results show an elevated level and activity of IgM antibodies to rubella (measles) virus but very few IgG antibodies to the virus. Has Ted contracted the disease?
- 27. While walking along the street, you and your friend see an elderly woman whose left arm appears to be swollen to several times its normal size. Your friend wonders aloud what might be its cause. You say that it may be likely that the woman had a radical mastectomy (the removal of a breast because of cancer). Explain the rationale behind your answer.
- **28.** Paula's grandfather is diagnosed as having lung cancer. His physician takes biopsies of several lymph nodes from neighboring regions of the body, and Paula wonders why, since his cancer is in the lungs. What would you tell her?
- **29.** Willy is allergic to ragweed pollen and tells you that he read about a medication that can help his condition by blocking certain antibodies. Do you think that this treatment could help Willy? Explain.

CLINICAL CASE Wrap-Up

Isn't There a Vaccine for That?

Immunizations against infectious diseases are one of the most successful medical advancements in the history of public health. A vaccine, containing weakened or dead forms of the infecting microbe (antigen), is administered orally, intranasally, subcutaneously, or intramuscularly. The antigens are not virulent enough to cause the disease, but they provoke the adaptive immune response in the body. This immune response involves B cells that mature into plasma cells and make antibodies. It also involves cytotoxic (killer) T cells and helper (defensive) T cells. Suppressor T cells are the regulators. Memory T cells and memory B cells help the body remember the antigen so when the protected person is exposed to the real disease, a strong secondary immune response occurs.

Immunizations are as varied as the diseases they protect against. Some are given as live, attenuated (greatly weakened) forms of a virus. Others are given as inactivated antigens, made from small pieces of killed bacteria. Some vaccines require repeat doses (booster shots) to boost the secondary immune response

and keep immune memory alive. Baby Ruthie is due for her chickenpox vaccination next

month, at her 12-month checkup. She is not yet immune to the varicella-zoster virus (VZV) that causes chickenpox. Disease control in babies not yet immunized depends on the rest of the population being immunized. This is known as "herd" immunity. Ruthie's day care classmate, Tommy, had never been vaccinated and was spreading chickenpox to other unprotected children in the class.

- 1. Is immunity to chickenpox, developed after an immunization, innate immunity or adaptive immunity? Why?
- Does baby Ruthie still need her chickenpox vaccination at her 12-month checkup?

See the blue Answers tab at the back of the book.

22

The Respiratory System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **23-1** Describe the primary functions of the respiratory system, and explain how the delicate respiratory exchange surfaces are protected from pathogens, debris, and other hazards.
- **23-2** Identify the organs of the upper respiratory system, and describe their functions.
- **23-3** Describe the structure of the larynx, and discuss its roles in normal breathing and in sound production.
- **23-4** Discuss the structures of the extrapulmonary airways.
- **23-5** Describe the superficial anatomy of the lungs, the structure of a pulmonary lobule, and the functional anatomy of alveoli.
- **23-6** Define and compare the processes of external respiration and internal respiration.
- **23-7** Summarize the physical principles controlling the movement of air into and out of the lungs, and describe the origins and actions of the muscles responsible for respiratory movements.
- **23-8** Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues.
- **23-9** Describe the structure and function of hemoglobin, and the transport of oxygen and carbon dioxide in the blood.
- **23–10** List the factors that influence respiration rate, and discuss reflex respiratory activity and the brain centers involved in the control of respiration.
- **23-11** Describe age-related changes in the respiratory system.
- **23-12** Give examples of interactions between the respiratory system and other organ systems studied so far.

CLINICAL CASE

How Long Should a Cough Last?

Andrea is in her A&P lab dissecting a cadaver when one of her lab partners suddenly sneezes. With Andrea's next breath, she inhales droplets from the sneeze, which contains rhinovirus one of the viruses that cause the common cold. The virus quickly spreads across her respiratory mucosa, overtakes the innate immunity of her respiratory epithelium, and enters the epithelial cells of her pharynx and trachea. Once inside the respiratory epithelial cells, the virus begins to multiply.

Three days later, the infected respiratory cells burst, releasing rhinovirus to infect other cells throughout Andrea's body. Andrea feels terrible. She has a fever of 101°F, a runny nose, sore throat, general fatigue, and an unrelenting cough. After a few days, her cough becomes productive with thick, yellow mucus.

After a week, Andrea is still coughing. She makes an appointment to see her family doctor. She insists she needs a prescription for antibiotics because her cough is lasting longer than a week. The last time she had a bad cough, a doctor prescribed antibiotics, and her cough finally

subsided after a second week. Is a cough lasting longer than a week cause for concern? To find out, turn to the Clinical Case Wrap-Up on p. 879.

An Introduction to the Respiratory System

When we think of the respiratory system, we generally think of breathing—pulling air into and out of our bodies. However, an efficient respiratory system must do more than merely move air. Cells need energy for maintenance, growth, defense, and division. Our cells obtain that energy mainly through aerobic mechanisms that require oxygen and produce carbon dioxide.

Many aquatic organisms can obtain oxygen and excrete carbon dioxide by diffusion across the surface of the skin or specialized structures, such as the gills of a fish. But such arrangements are poorly suited for life on land. The exchange surfaces must be very thin to permit rapid diffusion. In air, these exposed membranes collapse, evaporation and dehydration reduce blood volume, and the delicate surfaces become vulnerable to attack by pathogens. The respiratory exchange surfaces of humans are just as thin and delicate as those of an aquatic organism, but they are confined to the inside of the *lungs*—a warm, moist, protected environment. Under these conditions, diffusion can take place between the air and the blood.

The cardiovascular system is the link between your interstitial fluids and the exchange surfaces of your lungs. Circulating blood carries oxygen from the lungs to peripheral tissues. Your blood also accepts and transports the carbon dioxide generated by those tissues, delivering it to the lungs. In this chapter we describe how air enters the lungs as a result of the actions of respiratory muscles, and how oxygen and carbon dioxide are exchanged across delicate epithelial surfaces within the lungs.

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, has several basic functions

Learning Outcome Describe the primary functions of the respiratory system, and explain how the delicate respiratory exchange surfaces are protected from pathogens, debris, and other hazards.

The **respiratory system** is composed of structures involved in ventilation (providing air) and gas exchange. In this section we consider this body system's functions and structural organization.

Functions of the Respiratory System

The respiratory system has five basic functions:

- 1. Providing an extensive surface area for gas exchange between air and circulating blood.
- **2.** Moving air to and from the exchange surfaces of the lungs along the respiratory passageways.
- **3.** Protecting respiratory surfaces from dehydration, temperature changes, or other environmental variations, and defending the respiratory system and other tissues from invasion by pathogens.
- 4. Producing sounds for speaking, singing, and other forms of communication.
- 5. Facilitating the detection of odors by olfactory receptors in the superior portions of the nasal cavity.

In addition, the capillaries of the lungs indirectly help to regulate blood volume and blood pressure. They do so through the conversion of angiotensin I to angiotensin II. \bigcirc p. 640

23

Organization of the Respiratory System

We can organize the respiratory system from either an anatomical or a functional perspective. Anatomically, we can divide the system into an upper respiratory system and a lower respiratory system (Figure 23–1). The **upper respiratory system** consists of the nose, nasal cavity, paranasal sinuses, and pharynx (throat). These passageways filter, warm, and humidify incoming air, protecting the more delicate surfaces of the lower respiratory system. They also reabsorb heat and water from the outgoing air. The **lower respiratory system** includes the larynx (voice box), trachea (windpipe), bronchi, bronchioles, and alveoli of the lungs.

TIPS&TRICKS

To recall the boundary between the upper and lower respiratory systems, remember that the *l*ower respiratory system begins at the *l*arynx. The term **respiratory tract** refers to the passageways that carry air to and from the exchange surfaces of the lungs. The *conducting portion* of the respiratory tract begins at the entrance to the nasal cavity and extends through the pharynx, larynx, trachea, bronchi, and larger bronchioles. The *respiratory portion* of the tract includes the smallest, thinnest *bronchioles* and the associated **alveoli** (al-VĒ-ō-lī), air-filled pockets within the lungs where all gas exchange between air and blood takes place.

Gas exchange can take place quickly and efficiently because the distance between the blood in an alveolar capillary and the air inside an alveolus is generally less than 1 μ m. In some cases this distance is as short as 0.1 μ m. To meet the metabolic requirements of peripheral tissues, the surface area for gas exchange in the lungs must be very large. It is about 35 times the surface area of your body. Estimates of the surface area involved in gas exchange range from 70 m² to 140 m² (753 ft² to 1506 ft²).

Filtering, warming, and humidifying inhaled air begin at the entrance to the respiratory tract and continue as air

Figure 23–1 The Structures of the Respiratory System. Only the conducting portion of the respiratory tract is shown; the smaller bronchioles and alveoli have been omitted. ATLAS: Plates 47a,b

passes along the conducting portion. By the time air reaches the alveoli, most foreign particles and pathogens have been removed, and the humidity and temperature are within acceptable limits. The success of this "conditioning process" is due to the respiratory mucosa.

The Respiratory Mucosa

The **respiratory mucosa** (mū-KŌ-suh) lines the conducting portion of the respiratory system. A *mucosa* is a *mucous membrane*, one of the four types of membranes introduced in Chapter 4. It consists of an epithelium and an underlying layer of areolar tissue. \bigcirc p. 137 The **lamina propria** (LAM-i-nuh PRŌ-prē-uh) is the underlying layer of areolar tissue that supports the respiratory epithelium. In the upper respiratory system, trachea, and bronchi, the lamina propria contains mucous glands that discharge their secretions onto the epithelial surface (Figure 23–2). The lamina propria in the conducting portions of the lower respiratory system contains bundles of smooth muscle cells. At the bronchioles, the smooth muscles form thick bands that encircle or spiral around the lumen.

Figure 23–2 The Respiratory Epithelium of the Nasal Cavity and Conducting System.

lium of the trachea, showing the direction of mucus transport inferior to the pharynx.

c A sectional view of the respiratory epithelium, a pseudostratified ciliated columnar epithelium.

The structure of the respiratory epithelium changes along the respiratory tract. A pseudostratified ciliated columnar epithelium with numerous mucous cells lines the nasal cavity and the superior portion of the pharynx. D p. 123 The epithelium lining inferior portions of the pharynx is a stratified squamous epithelium similar to that of the oral cavity. These portions of the pharynx conduct air to the larynx and also convey food to the esophagus. The pharyngeal epithelium must therefore protect against abrasion and chemical attack.

A pseudostratified ciliated columnar epithelium, comparable to that of the nasal cavity, lines the superior portion of the lower respiratory system. The smaller bronchioles have a cuboidal epithelium with scattered cilia. The exchange surfaces of the alveoli are lined by a very delicate simple squamous epithelium. Other, more specialized cells are scattered among the squamous cells and together they form the *alveolar epithelium*.

The Respiratory Defense System

Debris or pathogens in inhaled air can severely damage the delicate exchange surfaces of the respiratory system. A series of filtration mechanisms that make up the **respiratory defense system** prevent such contamination.

Along much of the respiratory tract, mucous cells in the epithelium and mucous glands in the lamina propria produce a sticky mucus that bathes exposed surfaces. In the nasal cavity, cilia sweep that mucus and any trapped debris or microorganisms toward the pharynx. There it is swallowed and exposed to the acids and enzymes of the stomach. In the lower respiratory system, the cilia beat toward the pharynx, moving a carpet of mucus in that direction and cleaning the respiratory surfaces. This process is often called a *mucus escalator* (Figure 23–2b,c).

TIPS&TRICKS

The mucus layer of the respiratory epithelium functions like sticky flypaper, but instead of flies, it traps particles and debris from the air that moves past it.

Filtration in the nasal cavity removes virtually all particles larger than about 10 μ m from the inhaled air. Smaller particles may be trapped by the mucus of the nasopharynx or by secretions of the pharynx. The rate of mucus production in the nasal cavity and paranasal sinuses speeds up upon exposure to unpleasant stimuli, such as noxious vapors, large quantities of dust and debris, allergens, or pathogens. (The familiar signs and symptoms of the "common cold" appear when any of more than 200 types of viruses invades the respiratory epithelium.)

Most particles $1-5 \ \mu m$ in diameter are trapped in the mucus coating the respiratory bronchioles or in the liquid covering the alveolar surfaces. These areas are outside of the mucus escalator, but the foreign particles can be engulfed by alveolar macrophages. Most particles smaller than about 0.5 μm remain suspended in the air.

Clinical Note

Breakdown of the Respiratory Defense System Large quantities of airborne particles may overload the respiratory defenses and produce a variety of illnesses. For example, irritants in the lining of the conducting passageways can provoke the formation of mucus plugs that block airflow and reduce pulmonary function. Damage to the epithelium in the affected area may allow irritants to enter the surrounding tissues of the lung. The irritants then produce local inflammation. Airborne irritants—such as those in cigarette smoke—are known to promote the development of lung cancer (p. 875).

Aggressive pathogens can also overwhelm respiratory defenses. **Tuberculosis** (tū-ber-kū-LŌ-sis), or **TB**, results from an infection of the lungs by the bacterium *Mycobac-terium tuberculosis*. Other organs may be invaded as well. Bacteria may colonize the respiratory passageways, the interstitial spaces, the alveoli, or a combination of the three. Signs and symptoms are variable. They generally include coughing and chest pain, plus fever, night sweats, fatigue, and weight loss. In 1900, TB, then known as "consumption," was the leading cause of death. It remains among the most common and serious infectious diseases. An estimated one-third of the world's population is infected with TB. According to the Centers for Disease Control and Prevention (CDC), there are nearly 2 million TB-related deaths worldwide each year.

The respiratory defense system can also fail due to inherited congenital defects affecting mucus production or transport. For example, **cystic fibrosis (CF)** is the most common lethal inherited disease in individuals of Northern European descent. It occurs in 1 birth in 2500. The respiratory mucosa in these individuals produces dense, viscous mucus that cannot be transported by the respiratory defense system. The mucus escalator stops working, leading to frequent infections. Mucus also blocks the smaller respiratory passageways, making breathing difficult. For people who have CF and live in the United States, the median predicted age of survival is the mid-30s. Death generally results from heart failure associated with a massive chronic bacterial infection of the lungs.

CHECKPOINT

- 1. Identify several functions of the respiratory system.
- 2. List the two anatomical divisions of the respiratory system.
- 3. What membrane lines the conducting portion of the respiratory tract?

See the blue Answers tab at the back of the book.

23-2 Located outside the thoracic cavity, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx

Learning Outcome Identify the organs of the upper respiratory system, and describe their functions.

As we have noted, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx (Figures 23–1 and 23–3).

The Nose, Nasal Cavity, and Paranasal Sinuses

The nose is the primary passageway for air entering the respiratory system. Air normally enters through the paired **external nares** (NĀ-res), or *nostrils* (Figure 23–3a), which open into the *nasal cavity*. The **nasal vestibule** is the space contained within the flexible tissues of the nose (Figure 23–3c). The epithelium of the vestibule contains coarse hairs that extend across the external nares. Large airborne particles, such as sand, sawdust, or even insects, are trapped in these hairs and prevented from entering the nasal cavity.

The **nasal septum** divides the nasal cavity into left and right portions (Figure 23–3b). The bony portion of the nasal septum is formed by the fusion of the perpendicular plate of the ethmoid bone and the plate of the vomer (Figure 7–3d, p. 211). The anterior portion of the nasal septum is formed of hyaline cartilage. This cartilaginous plate supports the *dorsum nasi* (DOR-sum NĀ-zī), or bridge, and *apex* (tip) of the nose.

The maxillary, nasal, frontal, ethmoid, and sphenoid bones form the lateral and superior walls of the nasal cavity. The mucous secretions produced in the *paranasal sinuses* (sinuses of the frontal, sphenoid, ethmoid, and paired maxillary and palatine bones) help keep the surfaces of the nasal cavity moist and clean (Figure 7–15, p. 224). The tears draining through the nasolacrimal ducts do so as well.

The *olfactory region* is the superior portion of the nasal cavity. It includes the areas lined by olfactory epithelium: (1) the inferior surface of the cribriform plate, (2) the superior portion of the nasal septum, and (3) the superior nasal conchae. Receptors in the olfactory epithelium provide your sense of smell. \bigcirc p. 565

The *superior*, *middle*, and *inferior nasal conchae* project toward the nasal septum from the lateral walls of the nasal cavity. (Some references use the terms *superior*, *middle*, and *inferior*, *turbinates*.) ⊃ pp. 218, 221 To pass from the vestibule to the internal nares, air tends to flow between adjacent conchae, through the **superior**, **middle**, and **inferior meatuses** (mē-Ā-tus-ez; *meatus*, a passage) (Figure 23–3b). These are narrow grooves rather than open passageways. The incoming air bounces off the conchal surfaces and churns like a stream flowing over rocks. This turbulence serves several purposes. As the air swirls, small airborne particles are likely to come into contact with the mucus that coats the lining of the nasal cavity. In addition, the turbulence provides extra time for warming and humidifying incoming air. It also creates circular air currents that bring olfactory stimuli to the olfactory receptors.

The bony **hard palate** is made up of portions of the maxillary and palatine bones. The hard palate forms the floor of the nasal cavity and separates it from the oral cavity. A fleshy **soft palate** extends posterior to the hard palate, marking the boundary between the superior *nasopharynx* (nā-zō-FAR-ingks) and the rest of the pharynx. The nasal cavity opens into the nasopharynx through a connection known as the **internal nares**.

The Nasal Mucosa

The mucosa of the nasal cavity prepares inhaled air for arrival at the lower respiratory system. Throughout much of the nasal cavity, the lamina propria contains an abundance of arteries, veins, and capillaries that bring nutrients and water to the secretory cells. The lamina propria of the nasal conchae also contains an extensive network of highly expandable veins. This vascularization warms and humidifies the incoming air (and cools and dehumidifies the outgoing air as well). As cool, dry air passes inward over the exposed surfaces of the nasal cavity, the warm epithelium radiates heat, and water in the mucus evaporates. In this way, air moving from your nasal cavity to your lungs is heated almost to body temperature. It is also nearly saturated with water vapor. These changes protect more delicate respiratory surfaces from chilling or drying out-two potentially disastrous events. If you breathe through your mouth, you eliminate much of this preliminary filtration, heating, and humidifying of the inhaled air. To avoid alveolar damage, patients breathing on a respirator (mechanical ventilator), which utilizes a tube to conduct air directly into the trachea, must receive air that has been externally filtered and humidified.

As air moves out of the respiratory tract, it again passes over the epithelium of the nasal cavity. This air is warmer and more humid than the air that enters. It warms the nasal mucosa, and moisture condenses on the epithelial surfaces. In this way, breathing through your nose helps prevent heat loss and water loss.

The extensive vascularization of the nasal cavity and the vulnerable position of the nose make a nosebleed, or *epistaxis* (ep-i-STAK-sis), a fairly common event. (The leading cause of epistaxis in children is nose-picking.) This bleeding generally involves vessels of the mucosa covering the cartilaginous portion of the septum. Possible causes include trauma (such as a punch in the nose), drying, infections, allergies, or clotting disorders. Hypertension can also bring on a nosebleed by rupturing small vessels of the lamina propria.

nasal septum removed

The Pharynx

The **pharynx** (FAR-ingks), or throat, is a chamber shared by the digestive and respiratory systems. It extends between the internal nares and the entrances to the larynx and esophagus. The curving superior and posterior walls of the pharynx are closely bound to the axial skeleton, but the lateral walls are flexible and muscular.

We can divide the pharynx into the nasopharynx, the oropharynx, and the laryngopharynx (Figure 23–3c):

- 1. The **nasopharynx** is the superior portion of the pharynx. It is connected to the posterior portion of the nasal cavity through the internal nares. The soft palate separates it from the oral cavity. The nasopharynx is lined by the same pseudostratified ciliated columnar epithelium as in the nasal cavity. The *pharyngeal tonsil* is located on the posterior wall of the nasopharynx. Each auditory tube opens into the nasopharynx at the **nasopharyngeal meatus** on either side of this tonsil. ⊃ pp. 591, 790
- 2. The **oropharynx** (*oris*, mouth) extends between the soft palate and the base of the tongue at the level of the hyoid bone. The posterior portion of the oral cavity communicates directly with the oropharynx, as does the posterior inferior portion of the nasopharynx. At the boundary between the nasopharynx and the oropharynx, the epithelium changes from pseudostratified columnar epithelium to stratified squamous epithelium.
- **3.** The narrow **laryngopharynx** (la-rin-gō-FAR-ingks) is the inferior part of the pharynx. It includes that portion of the pharynx between the hyoid bone and the entrance to the larynx and esophagus. Like the oropharynx, the laryngopharynx is lined with a stratified squamous epithelium that resists abrasion, chemical attack, and invasion by pathogens.

CHECKPOINT

- 4. Name the structures of the upper respiratory system.
- 5. Why is the vascularization of the nasal cavity important?
- 6. Why is the lining of the nasopharynx different from that of the oropharynx and the laryngopharynx?

See the blue Answers tab at the back of the book.

23-3 Composed of cartilages, ligaments, and muscles, the larynx produces sound

Learning Outcome Describe the structure of the larynx, and discuss its roles in normal breathing and in sound production.

Inhaled air leaves the pharynx and enters the larynx through a narrow opening of the *glottis*. The glottis is the vocal apparatus, or "voice box," of the larynx. The **larynx** (LAR-ingks) is a cartilaginous tube that surrounds and protects the glottis. The larynx begins at the level of vertebra C_4 or C_5 and ends at the level of vertebra C_6 . Essentially a cylinder, the larynx has incomplete cartilaginous walls that are stabilized by ligaments and skeletal muscles (Figure 23–4).

Cartilages and Ligaments of the Larynx

Three large, unpaired cartilages form the larynx: (1) the thyroid cartilage, (2) the cricoid cartilage, and (3) the epiglottis (Figure 23–4). The **thyroid cartilage** (*thyroid*, shield shaped) is the largest laryngeal cartilage. Made of hyaline cartilage, it forms most of the anterior and lateral walls of the larynx. In section, this cartilage is U-shaped, and posteriorly, it is incomplete. You can easily see and feel the prominent anterior surface of the thyroid cartilage, called the *laryngeal prominence* or *Adam's apple*. The inferior surface articulates with the cricoid cartilage. The superior surface has ligamentous attachments to the hyoid bone and to the epiglottis and smaller laryngeal cartilages.

The thyroid cartilage sits superior to the **cricoid** (KRIkoyd; ring shaped) **cartilage**, another hyaline cartilage. The posterior portion of the cricoid is greatly expanded, providing support in the absence of the thyroid cartilage. The cricoid and thyroid cartilages protect the glottis and the entrance to the trachea. Their broad surfaces provide sites for the attachment of important laryngeal muscles and ligaments. Ligaments attach the inferior surface of the cricoid cartilage to the first tracheal cartilage. The superior surface of the cricoid cartilage articulates with the small, paired *arytenoid cartilages*.

The shoehorn-shaped **epiglottis** (ep-i-GLOT-is) projects superior to the glottis and forms a lid over it. The epiglottis is composed of elastic cartilage. It has ligamentous attachments to the anterior and superior borders of the thyroid cartilage and the hyoid bone. During swallowing, the larynx is elevated and the epiglottis folds back over the glottis, preventing both liquids and solid food from entering the respiratory tract.

The larynx also contains three pairs of smaller hyaline cartilages: (1) The **arytenoid** (ar-i-TĒ-noyd; ladle shaped) **cartilages** articulate with the superior border of the enlarged portion of the cricoid cartilage. (2) The **corniculate** (kor-NIK- \bar{u} -lāt; horn shaped) **cartilages** articulate with the arytenoid cartilages. The corniculate and arytenoid cartilages function in the opening and closing of the glottis and the production of sound. (3) Elongated, curving **cuneiform** (k \bar{u} -N \bar{E} -i-form; wedge shaped) **cartilages** lie within folds of tissue (the *ary-epiglottic folds*) that extend between the lateral surface of each arytenoid cartilage and the epiglottis (Figures 23–4c and 23–5).

Ligaments bind together the various laryngeal cartilages. Additional ligaments attach the thyroid cartilage to the hyoid bone, and the cricoid cartilage to the trachea (cricotracheal ligament) (Figure 23–4a,b). The median cricothyroid ligament attaches the thyroid cartilage to the cricoid cartilage. Because it has easily identifiable landmarks and is clear of the thyroid gland,

Figure 23–4 The Anatomy of the Larynx.

this ligament is a common placement site for an emergency tracheostomy, a tracheal incision to bypass an airway obstruction. The **vestibular ligaments** and the **vocal ligaments** extend between the thyroid cartilage and the arytenoid cartilages.

The vestibular and vocal ligaments are covered by folds of laryngeal epithelium. The vestibular ligaments lie within the superior pair of folds, known as the **vestibular folds** (Figure 23–5). These folds are fairly inelastic and lie laterally to the glottis. The **glottis** (GLOT-is) is made up of the **vocal folds** and the space between them, called the *rima glottidis* (Figure 23–5). The vestibular folds help prevent foreign objects from entering the open glottis. They also protect the more inferior, delicate vocal folds of the glottis.

The vocal folds are highly elastic, because the vocal ligaments consist of elastic tissue. The vocal folds are involved with the production of sound. For this reason they are known as the **vocal cords**.

Sound Production

How do you produce sounds? Air passing through your open glottis vibrates its vocal folds and produces sound waves. The pitch of the sound depends on the diameter, length, and tension in your vocal folds. The diameter and length are directly related to the size of your larynx. You control the tension by contracting voluntary muscles that reposition the arytenoid cartilages relative to the thyroid cartilage. When the distance increases, your vocal folds tense and the pitch rises. When the distance decreases, your vocal folds relax and the pitch falls.

Children have slender, short vocal folds, so their voices tend to be high-pitched. At puberty, the larynx of males enlarges much more than does that of females. The vocal cords of an adult male are thicker and longer. They produce lower tones than those of an adult female.

Sound production at the larynx is called *phonation* (fō-NĀshun; *phone*, voice). Phonation is one part of speech production. Clear speech also requires *articulation*, the modification of those sounds by other structures, such as the tongue, teeth, and lips to form words. In a stringed instrument, such as a guitar, the quality of the sound produced does not depend solely on the nature of the vibrating string. Rather, the entire instrument becomes involved as the walls vibrate and the composite sound echoes within the hollow body. Similar amplification and resonance take place within your pharynx, oral cavity, nasal cavity, and paranasal sinuses. The combination gives you the particular and distinctive sound of your voice. That sound changes when you have a sinus infection and your nasal cavity and paranasal sinuses are filled with mucus rather than air.

Figure 23–5 The Glottis and Surrounding Structures.

TIPS&TRICKS

Intelligible sound requires both phonation and articulation. Saying "ahhhh" while your tongue is depressed during a tonsil examination is an example of phonation. Saying "hot" adds articulation to that sound.

The final production of distinct words depends further on voluntary movements of your tongue, lips, and cheeks. An infection or inflammation of the larynx is known as *laryngitis* (lar-in-JĪ-tis). It commonly affects the vibrational qualities of the vocal folds. Hoarseness is the most familiar result. Mild cases are temporary and seldom serious. However, bacterial or viral infections of the epiglottis can be very dangerous. The resulting swelling may close the glottis and cause suffocation. This condition, *acute epiglottitis* (ep-i-glot-TĪ-tis), can develop rapidly after a bacterial infection of the throat. Young children are most likely to be affected.

The Laryngeal Musculature

The larynx is associated with two sets of muscles. They include (1) muscles of the neck and pharynx, which position and stabilize the larynx (\bigcirc pp. 348–350), and (2) smaller intrinsic muscles that control tension in the glottal vocal folds or open and close the glottis. These smaller muscles insert on the thyroid, arytenoid, and corniculate cartilages. The opening or closing of the glottis involves rotational movements of the arytenoid cartilages.

When you swallow, both sets of muscles work together to prevent food or drink from entering the glottis. Food is crushed and chewed into a pasty mass, known as a *bolus*, before being swallowed. Muscles of the neck and pharynx then elevate the larynx, bending the epiglottis over the glottis, so that the bolus can glide across the epiglottis rather than falling into the larynx. While this movement is under way, the glottis is closed.

Food or liquids that touch the vestibular folds or glottis trigger the *coughing reflex*. In a cough, the glottis is kept closed while the chest and abdominal muscles contract, compressing the lungs. When the glottis is opened suddenly, a blast of air from the trachea ejects material that blocks the entrance to the glottis.

CHECKPOINT

- 7. Identify the paired and unpaired cartilages associated with the larynx.
- 8. What are the highly elastic vocal folds of the glottis better known as?
- 9. When the tension in your vocal folds increases, what happens to the pitch of your voice?

See the blue Answers tab at the back of the book.

23-4 The trachea and primary bronchi convey air to and from the lungs

Learning Outcome Discuss the structures of the extrapulmonary airways.

Three large, extrapulmonary airways are associated with the lungs: the trachea and the right and left primary bronchi.

The Trachea

The **trachea** (TRĀ-kē-uh), or windpipe, is a tough, flexible tube with a diameter of about 2.5 cm (1 in.) and a length of about 11 cm (4.33 in.) (Figure 23–6). The trachea begins anterior to vertebra C_6 in a ligamentous attachment to the cricoid cartilage. It ends in the mediastinum, at the level of vertebra T_5 , where it branches to form the *right* and *left primary bronchi*. Figure 23–6 The Anatomy of the Trachea. ATLAS: Plates 42b,c

EFT LUNG

a A diagrammatic anterior view showing the plane of section for part (b)

Secondary bronchi

The epithelium of the trachea is continuous with that of the larynx. The mucosa of the trachea resembles that of the nasal cavity and nasopharynx (Figure 23–2a). The submucosa (sub-mū-KO-suh), a thick layer of connective tissue, surrounds the mucosa. The submucosa contains mucous glands that communicate with the epithelial surface through a number of secretory ducts. The trachea contains 15-20 tracheal cartilages, which serve to stiffen the tracheal walls and protect the airway (Figure 23-6a). They also prevent it from collapsing or overexpanding as pressures change in the respiratory system.

Each tracheal cartilage is C-shaped. The closed portion of the C protects the anterior and lateral surfaces of the trachea. The open portion of the C faces posteriorly, toward the esophagus (Figure 23-6b). Because these cartilages are not continuous, the posterior tracheal wall can easily distort when you swallow, allowing large masses of food to pass through the esophagus.

An elastic ligament and the trachealis muscle, a band of smooth muscle, connect the ends of each tracheal cartilage (Figure 23–6b). Contraction of the trachealis muscle reduces the

sympathetic division of the ANS. Sympathetic stimulation increases the diameter of the trachea and makes it easier to move large volumes of air along the respiratory passageways.

The Primary Bronchi

The trachea branches within the mediastinum into the **right** and left primary bronchi (BRONG-kī; singular, bronchus). An internal ridge called the carina (ka-RI-nuh) separates the two bronchi (Figure 23–6a). Like the trachea, the primary bronchi have C-shaped rings, but the ends of the C overlap. The right primary bronchus supplies the right lung, and the left supplies the left lung. The right primary bronchus is larger in diameter than the left, and descends toward the lung at a steeper angle. For these reasons, most foreign objects that enter the trachea find their way into the right bronchus rather than the left.

Before branching further, each primary bronchus travels to a groove along the medial surface of its lung. This groove, the hilum of the lung, also provides access for entry to pulmonary vessels, nerves, and lymphatics (Figure 23-7c). The entire array is firmly anchored in a meshwork of dense connective tissue. This complex is the root of the lung (Figure 23–6a). The root attaches to the mediastinum and fixes the positions of the major nerves, blood vessels, and lymphatic vessels. The roots of the lungs are anterior to vertebrae T_5 (right) and T_6 (left).

RIGHT LUNG

CHECKPOINT

- 10. List functions of the trachea.
- 11. Why are the cartilages that reinforce the trachea C-shaped?
- **12**. If food accidentally enters the bronchi, in which bronchus is it more likely to lodge? Why?

- See the blue Answers tab at the back of the book.

23-5 Enclosed by pleural cavities, the lungs are paired organs containing alveoli, which permit gaseous exchange

Learning Outcome Describe the superficial anatomy of the lungs, the structure of a pulmonary lobule, and the functional anatomy of alveoli.

The left and right lungs are surrounded by the left and right pleural cavities, respectively (Figure 23–7). Each lung is a blunt cone. Its tip, or apex, points superiorly. The apex on each side extends superior to the first rib. The broad concave inferior portion, or base, of each lung rests on the superior surface of the diaphragm.

Lobes and Surfaces of the Lungs

The lungs have distinct **lobes** that are separated by deep fissures (Figure 23–7). The right lung has three lobes—*superior*, *middle*, and *inferior*—separated by the *horizontal* and *oblique fissures*. The left lung has only two lobes—*superior* and *inferior*—separated by the *oblique fissure*. The right lung is broader than the left, because most of the heart and great vessels project into the left thoracic cavity. However, the left lung is longer than the right lung, because the diaphragm rises on the right side to accommodate the mass of the liver. The lateral and medial lung surfaces are shown in Figure 23–7b,c.

The heart is located to the left of the midline, so its corresponding impression is larger in the left lung than in the right. In anterior view, the medial edge of the right lung forms a vertical line, but the medial margin of the left lung is indented at the **cardiac notch** (Figure 23–7). Figure 23–8 shows the relationship between the heart and the lungs.

The Bronchi

The primary bronchi and their branches form the **bronchial tree**. Because the left and right primary bronchi are outside the lungs, they are called *extrapulmonary bronchi*. As the primary bronchi enter the lungs, they divide to form smaller passage-ways (Figure 23–6a). The branches within the lungs are collectively called the *intrapulmonary bronchi*.

Each primary bronchus divides to form **secondary bronchi**, also known as *lobar bronchi*. In each lung, one secondary

bronchus goes to each lobe, so the right lung has three secondary bronchi, and the left lung has two.

Figure 23–9 depicts the branching pattern of the left primary bronchus as it enters the lung. (The number of branches has been reduced for clarity.) In each lung, the secondary bronchi branch to form **tertiary bronchi**, or *segmental bronchi*. The branching pattern differs between the two lungs, but each tertiary bronchus ultimately supplies air to a single **bronchopulmonary segment**, a specific region of one lung (**Figure 23–9a**). The right lung has 10 bronchopulmonary segments. During development, the left lung also has 10 segments, but adjacent tertiary bronchi fuse, generally reducing the number to 8 or 9.

The walls of the primary, secondary, and tertiary bronchi contain progressively less cartilage. In the secondary and tertiary bronchi, the cartilages form plates arranged around the lumen. These cartilages serve the same structural purpose as the rings of cartilage in the trachea and primary bronchi. As the amount of cartilage decreases, the amount of smooth muscle increases. With less cartilaginous support, the amount of tension in those smooth muscles has a greater effect on bronchial diameter and the resistance to airflow. During a respiratory infection, the bronchi and bronchioles can become inflamed and constricted, increasing resistance. In this condition, called **bronchitis**, the individual has difficulty breathing.

The Bronchioles

Each tertiary bronchus branches several times within a bronchopulmonary segment, forming many **bronchioles**. These bronchioles then branch into the finest conducting branches, called **terminal bronchioles**. Nearly 6500 terminal bronchioles arise from each tertiary bronchus. The lumen of each terminal bronchiole has a diameter of 0.3–0.5 mm.

The walls of bronchioles lack cartilage but are dominated by smooth muscle tissue (Figure 23–9c). In functional terms, bronchioles are to the respiratory system what arterioles are to the cardiovascular system. Changes in the diameter of the bronchioles control the resistance to airflow and the distribution of air in the lungs.

The autonomic nervous system controls the diameter of the bronchioles. It does so by regulating the activity in the smooth muscle layer. Sympathetic activation leads to **bronchodilation**, the enlargement of the diameter of the airway. Parasympathetic stimulation leads to **bronchoconstriction**, a reduction in the diameter of the airway. Bronchoconstriction also takes place during allergic reactions such as anaphylaxis, in response to histamine released by activated mast cells and basophils. $\supset p. 823$

Bronchodilation and bronchoconstriction are ways of adjusting the resistance to airflow. These actions direct airflow toward or away from specific portions of the respiratory exchange

surfaces. Tension in the smooth muscles commonly causes the bronchiole mucosa to form a series of folds that limits airflow. Excessive stimulation, as in **asthma** (AZ-muh), can almost completely prevent airflow along the terminal bronchioles.

Pulmonary Lobules

The connective tissues of the root of each lung extend into the lung's *parenchyma*, or functional cells. These fibrous partitions, or *trabeculae*, contain elastic fibers, smooth muscles, and lymphatic vessels. The trabeculae branch repeatedly, dividing the lobes into ever-smaller compartments. The branches of the conducting passageways, pulmonary vessels, and nerves of the lungs follow these trabeculae.

The finest partitions, or **interlobular septa** (*septum*, a wall), divide the lung into **pulmonary lobules** (LOB-ūlz). Branches of the pulmonary arteries, pulmonary veins, and respiratory passageways supply each lobule (Figure 23–9c). The connective tissues of the septa are, in turn, continuous with those of the *visceral pleura*, the serous membrane covering the lungs.

Each terminal bronchiole delivers air to a single pulmonary lobule. Within the lobule, the terminal bronchiole branches to form several **respiratory bronchioles**. The respiratory bronchioles are the thinnest and most delicate branches of the bronchial tree. They deliver air to the gas exchange surfaces of the lungs.

Before incoming air moves beyond the terminal bronchioles, it has been filtered and humidified. A cuboidal epithelium lines the terminal bronchioles and respiratory bronchioles. There are only scattered cilia and no mucous cells or underlying mucous glands. If particulates or pathogens reach this part of the respiratory tract, there is little to prevent them from damaging the delicate exchange surfaces of the lungs.

Alveolar Ducts and Alveoli

Respiratory bronchioles are connected to individual alveoli and to multiple alveoli along regions called **alveolar ducts**. Alveolar ducts end at **alveolar sacs**, common chambers connected to multiple individual alveoli. Each lung contains about 150 million alveoli. They give the lungs an open, spongy appearance (Figures 23–9c,d and 23–10a,b).

Each alveolus is associated with an extensive network of capillaries (Figure 23–10a). A network of elastic fibers surrounds the capillaries. These fibers help maintain the relative positions of the alveoli and respiratory bronchioles. When these fibers recoil during exhalation, they reduce the size of the alveoli and help push air out of the lungs.

The alveolar epithelium consists mainly of simple squamous epithelium (Figure 23–10c). The squamous epithelial cells, called **type I pneumocytes** (or *type I alveolar cells*), are unusually thin and are the sites of gas diffusion. Roaming **alveolar macrophages**, or *dust cells*, patrol the epithelial surface. They phagocytize any particles that have eluded other defenses. Large **type II pneumocytes**, also called *type II alveolar cells*, are scattered among the squamous cells. Type II pneumocytes produce **surfactant** (sur-FAK-tant), an oily secretion containing phospholipids and proteins. They secrete surfactant onto the alveolar surfaces, where it forms a superficial coating over a thin layer of water.

Figure 23–9 The Bronchi, Lobules, and Alveoli of the Lung. ATLAS: Plates 42b,c; 47b-d

 The structure of a single pulmonary lobule, part of a bronchopulmonary segment **d** SEM of lung tissue showing the appearance and organization of the alveoli

 A diagrammatic view of alveolar structure. A single capillary may be involved in gas exchange with several alveoli simultaneously.

Surfactant plays a key role in keeping the alveoli open. It reduces surface tension in the liquid coating the alveolar surface. Recall from Chapter 2 that *surface tension* results from the attraction between water molecules at an air–water boundary. \bigcirc **p. 35** Surface tension creates a barrier that keeps small objects from entering the water, but it also tends to collapse small

air bubbles. Without surfactant, the surface tension would collapse the alveoli in much the same way. Surfactant forms a thin

TIPS&TRICKS

The term *surfactant* is derived from its purpose as a *surf*ace **act**ive **a**gent.

surface layer that interacts with the water molecules, reducing the surface tension and keeping the alveoli open.

If type II pneumocytes produce inadequate amounts of surfactant due to injury or genetic abnormalities, respiration becomes difficult. The alveoli collapse after each exhalation. With each breath, the inhalation must be forceful enough to pop open the alveoli. A person without enough surfactant is soon exhausted by the effort of inflating and deflating the lungs. This condition is called *respiratory distress syndrome*.

Gas exchange occurs across the **respiratory membrane** of the alveoli. The respiratory membrane has three layers (Figure 23–10d). It contains (1) the squamous epithelial cells lining the alveolus, (2) the endothelial cells lining an adjacent capillary, and (3) the fused basement membranes that lie between the alveolar and endothelial cells.

At the respiratory membrane, only a very short distance separates alveolar air from blood. The total distance can be as little as 0.1 μ m, but averages about 0.5 μ m. Diffusion proceeds very rapidly across the respiratory membrane because the distance is short and both oxygen and carbon dioxide are small, lipid-soluble molecules. The plasma membranes of the epithelial and endothelial cells do not prevent oxygen and carbon dioxide from moving between blood and alveolar air.

Certain diseases can compromise the function of the respiratory membrane. **Pneumonia** (nū-MŌ-nē-uh) develops from an infection or any other stimulus that causes inflammation of the lobules of the lung. As inflammation occurs, fluids leak into the alveoli. The respiratory bronchioles swell, narrowing passageways and restricting the passage of air. Respiratory function deteriorates as a result. When bacteria are involved, they are generally types that normally inhabit the mouth and pharynx but have managed to evade the respiratory defenses.

Pneumonia becomes more likely when the respiratory defenses have already been compromised by other factors. Such factors include epithelial damage from smoking and the breakdown of the immune system in AIDS. The respiratory defenses of healthy individuals prevent infection and tissue damage, but the breakdown of those defenses in AIDS can lead to a massive, potentially fatal lung infection. The most common pneumonia that develops in individuals with AIDS results from infection by the fungus *Pneumocystis jiroveci* (formerly known as *Pneumocystis carini*).

The Blood Supply to the Lungs

Two circuits nourish lung tissue. One supplies the *respiratory* portion of the lungs. The other perfuses the *conducting* portion.

The respiratory exchange surfaces receive blood from arteries of the pulmonary circuit. The pulmonary arteries carry deoxygenated blood. They enter the lungs at the hilum and branch with the bronchi as they approach the lobules. Each lobule receives an arteriole and a venule, and a network of capillaries surrounds each alveolus as part of the respiratory membrane. Oxygen-rich blood from the alveolar capillaries passes through the pulmonary venules and then enters the pulmonary veins, which deliver the blood to the left atrium.

In addition to providing for gas exchange, the endothelial cells of the alveolar capillaries are the primary source of *angiotensin-converting enzyme (ACE)*, which converts circulating angiotensin I to angiotensin II. This enzyme plays an important role in regulating blood volume and blood pressure. **D** p. 747

The tissues of conducting passageways of your lungs receive oxygen and nutrients from capillaries supplied by the bronchial arteries, which branch from the thoracic aorta. \bigcirc p. 761 The venous blood from these bronchial capillaries may return to the heart by either the systemic or pulmonary circuit. About oneeighth of the venous blood drains into bronchial veins, passes through the azygos, hemiazygos, or highest intercostal vein, and enters the superior vena cava. The larger fraction of the venous blood enters anastomoses and drains into the pulmonary veins. This venous blood dilutes the oxygenated alveolar blood within the pulmonary veins.

Blood pressure in the pulmonary circuit is usually low. Systemic pressures in the pulmonary circuit are 30 mm Hg or less. With such pressures, pulmonary vessels can easily become blocked by small blood clots, fat masses, or air bubbles in the pulmonary arteries. Because the lungs receive the entire cardiac output, any such objects drifting in blood are likely to be trapped in the pulmonary arterial or capillary networks. Very small blood clots occasionally form in the venous system. These are usually trapped in the pulmonary capillary network, where they soon dissolve. Larger emboli are much more dangerous. The blockage of a branch of a pulmonary artery stops blood flow to a group of lobules or alveoli. This condition is called **pulmonary embolism**. If a pulmonary embolism is in place for several hours, the alveoli will permanently collapse. If the blockage occurs in a major pulmonary vessel rather than a minor branch, pulmonary resistance increases. The resistance places extra strain on the right ventricle, which may be unable to maintain cardiac output, and congestive heart failure can result.

The Pleural Cavities and Pleural Membranes

The thoracic cavity has the shape of a broad cone. Its walls are the rib cage, and the muscular diaphragm forms its floor. The two **pleural cavities** are separated by the mediastinum (Figure 23–8). Each lung is surrounded by a single pleural cavity, which is lined by a serous membrane called the **pleura** (PLOOR-uh; plural, *pleurae*). The pleura consists of two layers: the parietal pleura and the visceral pleura. The **parietal pleura** covers the inner surface of the thoracic wall and extends over the diaphragm and mediastinum. The **visceral pleura** covers the outer surfaces of the lungs, extending into the fissures between the lobes. Each pleural cavity actually represents a

potential space rather than an open chamber, because the parietal and visceral pleurae are usually in close contact.

Both pleurae secrete a small amount of **pleural fluid**. Pleural fluid forms a moist, slippery coating that provides lubrication. It reduces friction between the parietal and visceral surfaces as you breathe. Samples of pleural fluid, obtained through a long needle inserted between the ribs, are sometimes needed for diagnostic purposes. This sampling procedure is called *thoracentesis* (thōr-a-sen-TĒ-sis; *thora-*, thoracic + *centesis*, puncture). The extracted fluid is examined for bacteria, blood cells, or other abnormal components.

In some diseases, the normal coating of pleural fluid does not prevent friction between the pleural surfaces. The result is pain and pleural inflammation, a condition called *pleurisy*. When pleurisy develops, the secretion of pleural fluid may be excessive, or the inflamed pleurae may adhere to one another, limiting movement. In either case, breathing becomes difficult, and prompt medical attention is required.

CHECKPOINT

- 13. What would happen to the alveoli if surfactant were not produced?
- 14. Trace the path air takes in flowing from the glottis to the respiratory membrane.
- **15**. Which arteries supply blood to the gas exchange surfaces and conducting portions of the respiratory system?
- 16. List the functions of the pleura.

See the blue Answers tab at the back of the book.

Figure 23–11 An Overview of the Key Steps in Respiration.

23-6 External respiration and internal respiration allow gaseous exchange within the body

Learning Outcome Define and compare the processes of external respiration and internal respiration.

The general term *respiration* includes two integrated processes: *external respiration* and *internal respiration*. The definitions of these terms vary among references. In our discussion, **external respiration** includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. The purpose of external respiration, and the primary function of the respiratory system, is to meet the respiratory demands of cells. **Internal respiration** is the absorption of oxygen and the release of carbon dioxide by those cells. We consider the biochemical pathways responsible for oxygen consumption and for the generation of carbon dioxide by mitochondria—pathways known collectively as *cellular respiration*—in Chapter 25.

Our discussion here focuses on three integrated steps in external respiration (Figure 23–11):

- 1. *Pulmonary ventilation*, or breathing, physically moves air into and out of the lungs.
- **2.** *Gas diffusion* across the respiratory membrane between alveolar air spaces and alveolar capillaries, and across capillary walls between blood and other tissues.
- **3.** *Transport of oxygen and carbon dioxide* between alveolar capillaries and capillary beds in other tissues.

Abnormalities affecting any of the steps involved in external respiration ultimately affect the concentrations of gases in interstitial fluids, and thus cellular activities as well. If the oxygen level declines, the affected tissues will become starved for oxygen. **Hypoxia**, or low tissue oxygen levels, places severe limits on the metabolic activities of the affected area. For example, the effects of coronary ischemia result from chronic hypoxia affecting cardiac muscle cells. \bigcirc **p.** 698 If the oxygen supply is cut off completely, the condition called **anoxia** (an-OK-sē-uh; *an-*, without + *oxy-*, oxygen) results. Anoxia kills cells very quickly. Much of the damage from strokes and heart attacks results from local anoxia.

In the sections that follow, we examine each of the processes involved in external respiration in greater detail.

CHECKPOINT

- 17. Define external respiration and internal respiration.
- 18. Name the integrated steps involved in external respiration.

See the blue Answers tab at the back of the book.

23-7 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs—involves pressure changes, muscle movement, and respiratory rates and volumes

Learning Outcome Summarize the physical principles controlling the movement of air into and out of the lungs, and describe the origins and actions of the muscles responsible for respiratory movements.

Pulmonary ventilation is the physical movement of air into and out of the respiratory tract. Its primary function is to maintain adequate *alveolar ventilation*—movement of air into and out of the alveoli. Alveolar ventilation prevents the buildup of carbon dioxide in the alveoli. It also ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream.

The Movement of Air

Some basic physical principles govern the movement of air. One of the most basic is that the weight of Earth's atmosphere compresses our bodies and everything around us. This **atmospheric pressure (atm)** has several important physiological effects. For example, air moves into and out of the respiratory tract as the air pressure in the lungs cycles between below atmospheric pressure and above atmospheric pressure.

Gas Pressure and Volume (Boyle's Law)

The primary differences between liquids and gases reflect the interactions among individual molecules. The molecules in a liquid are in constant motion, but they are held closely together

by weak interactions, such as the hydrogen bonding between adjacent water molecules. \bigcirc p. 35 Yet because the electrons of adjacent atoms tend to repel one another, liquids tend to resist compression. If you squeeze a balloon filled with water, it will change into a different shape, but the volumes of the two shapes will be the same.

In a gas, such as air, the molecules bounce around as independent objects. At normal atmospheric pressures, gas molecules are much farther apart than the molecules in a liquid. The forces acting between gas molecules are minimal because the molecules are too far apart for weak interactions to take place, so an applied pressure can push them closer together. Consider a sealed container of air at atmospheric pressure. The pressure exerted by the gas inside results from gas molecules bumping into the walls of the container. The greater the number of collisions, the higher the pressure.

You can change the gas pressure within a sealed container by changing the volume of the container, giving the gas molecules more or less room in which to bounce around. If you decrease the volume of the container, pressure increases (Figure 23–12a). If you increase the volume of the container, pressure decreases (Figure 23–12b).

Figure 23–12 The Relationship between Gas Pressure and Volume.

For a gas in a closed container and at a constant temperature, pressure (*P*) is inversely proportional to volume (*V*). That is, *if you decrease the volume of a gas, its pressure will increase. If you increase the volume of a gas, its pressure will decrease.* In particular, the relationship between pressure and volume is reciprocal: If you double the external pressure on a flexible container, its volume will drop by half, and if you reduce the external pressure by half, the volume of the container will double. This relationship, P = 1/V, is called **Boyle's law** because it was first recognized by Robert Boyle in the 1600s.

Pressure and Airflow to the Lungs

Air flows from an area of higher pressure to an area of lower pressure. This tendency for directed airflow, plus the pressurevolume relationship of Boyle's law, provides the basis for pulmonary ventilation. A single respiratory cycle consists of an *inspiration*, or inhalation, and an *expiration*, or exhalation. Inhalation and exhalation involve changes in the volume of the lungs. These volume changes create pressure gradients that move air into or out of the respiratory tract.

Each lung is surrounded by a pleural cavity. The parietal and visceral pleurae are separated by only a thin film of pleural fluid. The two membranes can slide across one another, but they are held together by that fluid film. You can see the same principle when you set a wet glass on a smooth tabletop. You can slide the glass easily, but when you try to lift it, you feel considerable resistance. As you pull the glass away from the tabletop, you create a powerful suction. The only way to overcome it is to tilt the glass so that air is pulled between the glass and the table, breaking the fluid bond.

A comparable fluid bond exists between the parietal pleura and the visceral pleura covering the lungs. For this reason, the surface of each lung sticks to the inner wall of the chest and to the superior surface of the diaphragm. Movements of the diaphragm or rib cage that change the volume of the thoracic cavity also change the volume of the lungs (Figure 23–13a):

- The diaphragm forms the floor of the thoracic cavity. The relaxed diaphragm has the shape of a dome that projects superiorly into the thoracic cavity. When the diaphragm contracts, it tenses and moves inferiorly. This movement increases the volume of the thoracic cavity, decreasing the pressure within it. When the diaphragm relaxes, it returns to its original position, and the volume of the thoracic cavity decreases.
- Due to the nature of the articulations between the ribs and the vertebrae, superior movement of the rib cage increases the depth and width of the thoracic cavity, increasing its volume. Inferior movement of the rib cage reverses the process, decreasing the volume of the thoracic cavity.

At rest just prior to inhalation, pressures inside and outside the thoracic cavity are identical, and no air moves into or out of the lungs (Figure 23–13b). When the thoracic cavity enlarges, the lungs expand to fill the additional space (Figure 23–13c). This increase in volume decreases the pressure inside the lungs. Air then enters the respiratory passageways, because the pressure inside the lungs (P_{inside}) is lower than atmospheric pressure ($P_{outside}$). Air continues to enter the lungs until their volume stops increasing and the internal pressure is the same as that outside. When the thoracic cavity decreases in volume, pressures increase inside the lungs, forcing air out of the respiratory tract (Figure 23–13d).

Compliance

The **compliance** of the lungs is an indication of their expandability, or how easily the lungs expand. The lower the compliance, the greater the force required to fill the lungs. The greater the compliance, the easier it is to fill the lungs. Factors affecting compliance include the following:

- *The Connective Tissue of the Lungs.* The loss of supporting tissues due to alveolar damage, as in *emphysema*, increases compliance. This loss results in the alveoli increasing beyond their normal size, making the lungs easier to fill.
- *The Level of Surfactant Production.* On exhalation, the collapse of alveoli due to inadequate surfactant, as in respiratory distress syndrome, reduces compliance.
- *The Mobility of the Thoracic Cage.* Arthritis or other skeletal disorders that affect the articulations of the ribs or spinal column also reduce compliance.

At rest, the muscular activity involved in pulmonary ventilation accounts for 3–5 percent of the resting energy demand. If compliance is reduced, that figure climbs dramatically. An individual may become exhausted simply trying to continue breathing.

Pressure Changes during Inhalation and Exhalation

To understand the mechanics of respiration and the principles of gas exchange, we must know the pressures inside and outside the respiratory tract. We can report pressure readings in several ways (Table 23–1). In this text, we use millimeters of mercury (mm Hg), as we did for blood pressure. Atmospheric pressure is also measured in *atmospheres*. At sea level, one atmosphere of pressure (1 atm) is equivalent to 760 mm Hg.

The Intrapulmonary Pressure

The direction of airflow is determined by the relationship between atmospheric pressure and intrapulmonary pressure. **Intrapulmonary** (in-tra-PUL-mo-nār-ē) **pressure**, or **intra-alveolar** (in-tra-al-VĒ-ō-lar) **pressure**, is the pressure inside the respiratory tract, at the alveoli.

cavity decreases, and air flows into the lungs.

When you are relaxed and breathing quietly, the difference between atmospheric pressure and intrapulmonary pressure is relatively small. On inhalation, your lungs expand, and the intrapulmonary pressure drops to about 759 mm Hg. Because the intrapulmonary pressure is 1 mm Hg below atmospheric pressure, it is generally reported as -1 mm Hg. On exhalation, your lungs recoil, and intrapulmonary pressure rises to 761 mm Hg, or +1 mm Hg (Figure 23–14a).

The size of the pressure gradient increases when you breathe heavily. When a trained athlete breathes at maximum capacity, the pressure differentials can reach -30 mm Hg during inhalation and +100 mm Hg if the individual is straining with the glottis kept closed. This is one reason you are told to exhale while lifting weights. Exhaling keeps your intrapulmonary

Table 23–1The Four Most Common Methods
of Reporting Gas Pressures

increases, and air moves out of the lungs.

millimeters of mercury (mm Hg): This is the most common method of reporting blood pressure and gas pressures. Normal atmospheric pressure is approximately 760 mm Hg.

torr: This unit of measurement is preferred by many respiratory therapists; it is also commonly used in Europe and in some technical journals. One torr is equivalent to 1 mm Hg; in other words, normal atmospheric pressure is equal to 760 torr.

centimeters of water (cm H₂O): In a hospital setting, anesthetic gas pressures and oxygen pressures are commonly measured in centimeters of water. One cm H₂O is equivalent to 0.735 mm Hg; normal atmospheric pressure is 1033.6 cm H₂O.

pounds per square inch (psi): Pressures in compressed gas cylinders and other industrial applications are generally reported in psi. Normal atmospheric pressure at sea level is approximately 15 psi. pressures and peritoneal pressure from increasing so high that an alveolar rupture or hernia could occur.

The Intrapleural Pressure

Intrapleural pressure is the pressure in the pleural cavity, between the parietal and visceral pleurae. Intrapleural pressure averages about -4 mm Hg (Figure 23–14b). During a powerful inhalation, it can reach -18 mm Hg. This pressure is below atmospheric pressure, due to the relationship between the lungs and the body wall. Earlier, we noted that the lungs are highly elastic. In fact, they would collapse to about 5 percent of their normal resting volume if their elastic fibers could recoil completely. The elastic fibers cannot recoil so much, however. The reason is that they are not strong enough to overcome the fluid bond between the parietal and visceral pleurae.

The elastic fibers continuously oppose that fluid bond and pull the lungs away from the chest wall and diaphragm, lowering the intrapleural pressure slightly. The elastic fibers remain stretched even after a full exhalation. For this reason, intrapleural pressure remains below atmospheric pressure throughout normal cycles of inhalation and exhalation. The cyclical changes in the intrapleural pressure create the *respiratory pump* that assists the venous return to the heart. \bigcirc p. 739

The Respiratory Cycle

A **respiratory cycle** is a single cycle of inhalation and exhalation. The curves in **Figure 23–14a**,**b** show the intrapulmonary and intrapleural pressures during a single respiratory cycle of an individual at rest. The graph in **Figure 23–14c** plots the **tidal volume**, the amount of air you move into or out of your lungs during a single respiratory cycle.

TIPS&TRICKS

Tidal volume floods and ebbs like the ocean tides.

At the start of the respiratory cycle, the intrapulmonary and atmospheric pressures are equal, and no air is moving. Inhalation begins with the fall of intrapleural pressure that takes place when the thoracic cavity expands. This pressure gradually falls to approximately -6 mm Hg. Over the period, intrapulmonary pressure drops to just under -1 mm Hg. It then begins to rise as air flows into the lungs.

23

When exhalation begins, intrapleural and intrapulmonary pressures rise rapidly, forcing air out of the lungs. At the end of exhalation, air again stops moving when the difference between intrapulmonary and atmospheric pressures has been eliminated. The amount of air moved into the lungs during inhalation equals the amount moved out of the lungs during exhalation. That amount is the tidal volume.

The Mechanics of Breathing

As we have just seen, you move air into and out of the respiratory system by changing the volume of the lungs. Those changes alter the pressure relationships, producing air movement. The changes of volume in the lungs take place through the contraction of skeletal muscles—specifically, those that insert on the rib cage—and the *diaphragm*, which separates the thoracic and abdominopelvic cavities. Because of the nature of their articulations with the vertebrae, when the ribs are elevated they swing outward, increasing the depth of the thoracic cavity. \bigcirc p. 236 We can compare this movement to raising the handle of a bucket. Respiratory muscles and pulmonary ventilation are featured in **Spotlight Figure 23–15**.

The Respiratory Muscles

We introduced the skeletal muscles involved in respiratory movements in Chapter 11. Of those muscles, the most important are the *diaphragm* and the *external intercostal muscles*. \bigcirc pp. 354–355

Muscles Used in Inhalation. Inhalation is an active process. It involves one or more of the following actions:

- Contraction of the diaphragm flattens the floor of the thoracic cavity, increasing its volume and drawing air into the lungs. Contraction of the diaphragm brings about 75 percent of the air movement in normal breathing at rest.
- Contraction of the external intercostal muscles assists in inhalation by raising the ribs. This action contributes approximately 25 percent of the volume of air in the lungs at rest.
- Contraction of accessory muscles, including the sternocleidomastoid, serratus anterior, pectoralis minor, and scalene muscles, can assist the external intercostal muscles in elevating the ribs. These muscles increase the speed and amount of rib movement.

Muscles Used in Exhalation. Exhalation is either passive or active, depending on the level of respiratory activity. When exhalation is active, it may involve one or more of the following actions:

• The internal intercostal and transversus thoracic muscles depress the ribs. This action reduces the width and depth of the thoracic cavity.

Clinical Note

Pneumothorax Air can enter the pleural cavity due to an injury to the chest wall that penetrates the parietal pleura, or a rupture of the alveoli that breaks through the visceral pleura. This condition, called **pneumothorax** (noo-mō-THOR-aks; *pneumo-*, air), breaks the fluid bond between the pleurae and allows the elastic fibers to recoil, resulting in a "collapsed lung," or **atelectasis** (at-e-LEK-ta-sis; *ateles*, incomplete + *ektasis*, extension). The opposite lung is not affected due to compartmentalization. The treatment for a collapsed lung involves removing as much of the air as possible from the affected pleural cavity and then sealing the opening. This treatment lowers the intrapleural pressure and reinflates the lung.

• The abdominal muscles, including the external and internal oblique, transversus abdominis, and rectus abdominis muscles, can assist the internal intercostal muscles in exhalation by compressing the abdomen. This action forces the diaphragm upward.

Modes of Breathing

We use the respiratory muscles in various combinations, depending on the volume of air that must be moved into or out of the system. We usually classify respiratory movements as *quiet breathing* or *forced breathing* according to the pattern of muscle activity during a single respiratory cycle.

Quiet Breathing. In **quiet breathing**, or **eupnea** ($\overline{U}P$ -n \overline{e} -uh; *eu*-, normal + *-pnea*, breath), inhalation involves muscular contractions, but exhalation is a passive process. Inhalation usually involves contracting both the diaphragm and the external intercostal muscles. The relative contributions of these muscles can vary:

- During diaphragmatic breathing, or deep breathing, contraction of the diaphragm provides the necessary change in thoracic volume. Air is drawn into the lungs as the diaphragm contracts. Air is exhaled passively when the diaphragm relaxes.
- In **costal breathing**, or **shallow breathing**, the thoracic volume changes because the rib cage alters its shape. Inhalation takes place when contractions of the external intercostal muscles raise the ribs and enlarge the thoracic cavity. Exhalation takes place passively when these muscles relax.

During quiet breathing, expansion of the lungs stretches their elastic fibers. In addition, elevation of the rib cage stretches

SPOTLIGHT Figure 23–15 Respiratory Muscles and Pulmonary Ventilation

The Respiratory Muscles

The most important skeletal muscles involved in respiratory movements are the diaphragm and the external intercostals. These muscles are the **primary respiratory muscles** and are active during normal breathing at rest. The accessory respiratory muscles become active when the depth and frequency of respiration must be increased markedly.

The Mechanics of Breathing

Pulmonary ventilation, air movement into and out of the respiratory system, occurs by changing the volume of the lungs. The changes in volume take place through the contraction of sleketal

muscles. As the ribs are elevated or the diaphragm is depressed, the volume of the thoracic cavity increases and air moves into the lungs. The outward movement of the ribs as they are elevated resembles the outward swing of a raised bucket handle.

Diaphragm contracts

Ribs and

sternum

elevate

Respiratory Movements

Respiratory muscles may be used in various combinations, depending on the volume of air that must be moved in or out of the lungs. In quiet breathing, inhalation involves muscular contractions, but exhalation is a passive process. Forced breathing calls upon the accessory muscles to assist with inhalation, and exhalation involves contraction by the transversus thoracis, internal intercostal, and rectus abdominis muscles.

Inhalation

Inhalation is an active process. It primarily involves the diaphragm and the external intercostal muscles, with assistance from the accessorv respiratory muscles as needed

Exhalation

= Muscle contraction

During forced Accessorv exhalation, the Respiratory tranversus thoracis **Muscles** and internal (Exhalation) intercostal muscles actively depress Transversus the ribs, and thoracis the abdominal muscle muscles (external and internal obligues, transversus Internal abdominis, and intercostal rectus abdominis) muscles compress the Rectus abdomen and push abdominis the diaphragm up. = Movement of rib cage = Movement of diaphragm

opposing skeletal muscles and elastic fibers in the connective tissues of the body wall. When the muscles of inhalation relax, these elastic components recoil, returning the diaphragm, the rib cage, or both to their original positions. This action is called **elastic rebound**.

We typically use diaphragmatic breathing at minimal levels of activity. As we need increased volumes of air, our inspiratory movements become larger and the contribution of rib movement increases. Even when we are at rest, costal breathing can predominate when abdominal pressures, fluids, or masses restrict diaphragmatic movements. For example, pregnant women rely more and more on costal breathing as the enlarging uterus pushes the abdominal organs against the diaphragm.

Forced Breathing. Forced breathing, or **hyperpnea** (hī-PERP-nē-uh), involves active inspiratory and expiratory movements. In forced breathing, our accessory muscles assist with inhalation, and exhalation involves contraction of the internal intercostal muscles. At absolute maximum levels of forced breathing, our abdominal muscles take part in exhalation. Their contraction compresses the abdominal contents, pushing them up against the diaphragm. This action further reduces the volume of the thoracic cavity.

Respiratory Rates and Volumes

The respiratory system is extremely adaptable. You can be breathing slowly and quietly one moment, rapidly and deeply the next. The respiratory system adapts to meet the oxygen demands of the body by varying both the number of breaths per minute and the amount of air moved per breath. When you exercise at peak levels, the amount of air moving into and out of the respiratory tract can be 50 times the amount moved at rest.

Respiratory Rate

Your **respiratory rate** is the number of breaths you take each minute. As you read this, you are probably breathing quietly, with a low respiratory rate. The normal respiratory rate of a resting adult ranges from 12 to 18 breaths each minute, roughly one for every four heartbeats. Children breathe more rapidly, at rates of about 18–20 breaths per minute.

The Respiratory Minute Volume

We can calculate the amount of air moved each minute, symbolized \dot{V}_{E} , by multiplying the respiratory rate f by the tidal volume V_{T} . This value is called the **respiratory minute volume**. The respiratory rate at rest averages 12 breaths per minute, and the tidal volume at rest averages around 500 mL per breath. On that basis, we calculate the respiratory minute volume as follows:

In other words, the respiratory minute volume at rest is approximately 6 liters (1.6 gallons) per minute.

Alveolar Ventilation

The respiratory minute volume measures pulmonary ventilation. It provides an indication of how much air is moving into and out of the respiratory tract. However, only some of the inhaled air reaches the alveolar exchange surfaces. A typical inhalation pulls about 500 mL of air into the respiratory system. The first 350 mL of inhaled air travels along the conducting passageways and enters the alveolar spaces. The last 150 mL of inhaled air never gets that far. It stays in the conducting passageways and thus does not participate in gas exchange with blood. The volume of air in the conducting passages is known as the **anatomic dead space**, denoted $V_{\rm D}$.

Alveolar ventilation, symbolized \dot{V}_A , is the amount of air reaching the alveoli each minute. The alveolar ventilation is less than the respiratory minute volume, because some of the air never reaches the alveoli, but instead remains in the dead space of the lungs. We can calculate alveolar ventilation by subtracting the dead space from the tidal volume:

At rest, alveolar ventilation rates are approximately 4.2 liters per minute (12 per minute \times 350 mL). However, the gas arriving in the alveoli is significantly different from the surrounding atmosphere. The reason is that inhaled air always mixes with "used" air in the conducting passageways (the anatomic dead space) on its way in. The air in alveoli thus contains less oxygen and more carbon dioxide than does atmospheric air.

Relationships among $V_{\rm T}$, $\dot{V}_{\rm E}$, and $\dot{V}_{\rm A}$

The respiratory minute volume can be increased by increasing either the tidal volume or the respiratory rate. In other words, you can breathe more deeply or more quickly or both. Under maximum stimulation, the tidal volume can increase to roughly 4.8 liters. At peak respiratory rates of 40–50 breaths per minute and maximum cycles of inhalation and exhalation, the respiratory minute volume can approach 200 liters (about 55 gal) per minute. In functional terms, the alveolar ventilation rate is more important than the respiratory minute volume, because it determines the rate of delivery of oxygen to the alveoli. The respiratory rate and the tidal volume together determine the alveolar ventilation rate:

- For a given respiratory rate, increasing the tidal volume (breathing more deeply) increases the alveolar ventilation rate.
- For a given tidal volume, increasing the respiratory rate (breathing more quickly) increases the alveolar ventilation rate.

The alveolar ventilation rate can change independently of the respiratory minute volume. In our previous example, the respiratory minute volume at rest was 6 liters and the alveolar ventilation rate was 4.2 L/min. If the respiratory rate rises to 20 breaths per minute, but the tidal volume drops to 300 mL, the respiratory minute volume remains the same $(20 \times 300 = 6000)$. However, the alveolar ventilation rate drops to only 3 L/min $(20 \times [300 - 150] = 3000)$. For this reason, whenever the demand for oxygen increases, both the tidal volume *and* the respiratory rate must be regulated closely. (We focus on the mechanisms involved in a later section.)

Respiratory Performance and Volume Relationships

We exchange only a small proportion of the air in our lungs during a single quiet respiratory cycle. We can increase the tidal volume by inhaling more vigorously and exhaling more completely.

We can divide the total volume of the lungs into a series of *volumes* and *capacities* (each the sum of various volumes), as indicated in Figure 23–16. These measurements are obtained by an instrument called a **spirometer**. Spirometry values are useful in diagnosing problems with pulmonary ventilation. Adult females, on average, have smaller bodies and thus smaller lung volumes than do males. As a result, there are sex-related differences in respiratory volumes and capacities. The table in the figure shows representative values for both sexes.

Pulmonary volumes include the following:

- The tidal volume (V_T) is the amount of air you move into or out of your lungs during a single respiratory cycle. The tidal volume averages about 500 mL in both males and females.
- The **expiratory reserve volume (ERV)** is the amount of air that you can voluntarily expel after you have completed a normal, quiet respiratory cycle. As an example, with maximum use of the accessory muscles, males can expel an additional 1000 mL of air, on average. Female expiratory reserve volume averages 700 mL.

Figure 23–16 Pulmonary Volumes and Capacities. The red line indicates the volume of air within the lungs during breathing.

- The **residual volume** is the amount of air that remains in your lungs even after a maximal exhalation—typically about 1200 mL in males and 1100 mL in females. The **minimal volume**, a component of the residual volume, is the amount of air that would remain in your lungs if they were allowed to collapse. The minimal volume ranges from 30 to 120 mL. Unlike other volumes, it cannot be measured in a healthy person. The minimal volume and the residual volume are very different, because the fluid bond between the lungs and the chest wall normally prevents the recoil of the elastic fibers in the lungs. Some air remains in the lungs, even at minimal volume, because the surfactant coating the alveolar surfaces prevents their collapse.
- The **inspiratory reserve volume (IRV)** is the amount of air that you can take in over and above the tidal volume. On average, the lungs of males are larger than those of females. For this reason, the inspiratory reserve volume of males averages 3300 mL, compared with 1900 mL in females.

We can calculate respiratory capacities by adding the values of various volumes. Examples include the following:

- The **inspiratory capacity** is the amount of air that you can draw into your lungs after you have completed a quiet respiratory cycle. The inspiratory capacity is the sum of the tidal volume and the inspiratory reserve volume.
- The **functional residual capacity (FRC)** is the amount of air remaining in your lungs after you have completed a quiet respiratory cycle. The FRC is the sum of the expiratory reserve volume and the residual volume.
- The **vital capacity** is the maximum amount of air that you can move into or out of your lungs in a single respiratory cycle. The vital capacity is the sum of the expiratory reserve volume, the tidal volume, and the inspiratory reserve volume. It averages around 4800 mL in males and 3400 mL in females.

The total lung capacity is the total volume of your lungs. We calculate it by adding the vital capacity and the residual volume. The total lung capacity averages around 6000 mL in males and 4200 mL in females.

Pulmonary function tests monitor several aspects of respiratory function by measuring rates and volumes of air movement.

CHECKPOINT

- 19. Define compliance and identify the factors that affect it.
- 20. Name the various measurable pulmonary volumes.
- 21. Mark breaks a rib that punctures the chest wall on his left side. What do you expect will happen to his left lung as a result?
- 22. In pneumonia, fluid accumulates in the alveoli of the lungs. How would this accumulation affect vital capacity?

See the blue Answers tab at the back of the book.

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of molecules

Learning Outcome Summarize the physical principles governing the diffusion of gases into and out of the blood and body tissues.

Pulmonary ventilation ensures both that your alveoli are supplied with oxygen and that the carbon dioxide arriving from your bloodstream is removed. The actual process of gas exchange takes place between blood and alveolar air across the respiratory membrane. To understand these events, let's first consider (1) the *partial pressures* of the gases involved and (2) the diffusion of molecules between a gas and a liquid. Then we can discuss the movement of oxygen and carbon dioxide across the respiratory membrane.

The Gas Laws

Gases are exchanged between the alveolar air and the blood through diffusion, which takes place in response to concentration gradients. As we saw in Chapter 3, the rate of diffusion varies in response to a variety of factors, including the size of the concentration gradient and the temperature. \bigcirc p. 91 The principles that govern the movement and diffusion of gas molecules, such as those in the atmosphere, are relatively straightforward. These principles, known as *gas laws*, have been understood for about 250 years. You have already heard about Boyle's law, which determines the direction of air movement in pulmonary ventilation. In this section, you will learn about gas laws and other factors that determine the rate of oxygen and carbon dioxide diffusion across the respiratory membrane.

Dalton's Law and Partial Pressures

The air we breathe is a mixture of gases. Nitrogen molecules (N_2) are the most abundant, accounting for about 78.6 percent of atmospheric gas molecules. Oxygen molecules (O_2) , the second most abundant, make up roughly 20.9 percent of air. Most of the remaining 0.5 percent consists of water molecules, with carbon dioxide (CO_2) contributing a mere 0.04 percent.

Atmospheric pressure, 760 mm Hg, represents the combined effects of collisions involving each type of molecule in air. At any moment, 78.6 percent of those collisions involve nitrogen molecules, 20.9 percent oxygen molecules, and so on. Thus, each of the gases contributes to the total pressure in proportion to its relative abundance. This relationship is known as **Dalton's law**.

The **partial pressure** of a gas is the pressure contributed by a single gas in a mixture of gases. The partial pressure is abbreviated by the symbol P or p. A subscript shows the gas in question. For example, the partial pressure of oxygen is abbreviated $P_{\Omega_{a}}$.

All the partial pressures added together equal the total pressure exerted by a gas mixture. For the atmosphere, this relationship can be summarized as follows:

$$P_{N_2} + P_{O_2} + P_{H_2O} + P_{CO_2} = 760 \text{ mm Hg}$$

We can easily calculate the partial pressure of each gas because we know the individual percentages of each gas in air. For example, the partial pressure of oxygen, P_{O_2} , is 20.9 percent of 760 mm Hg, or roughly 159 mm Hg. Table 23–2 includes the partial pressures of other atmospheric gases.

Diffusion between Liquids and Gases (Henry's Law)

Differences in pressure, which move gas molecules from one place to another, also affect the movement of gas molecules into and out of solution. At a given temperature, the amount of a particular gas in solution is directly proportional to the partial pressure of that gas. This principle is known as **Henry's law**.

When a gas under pressure contacts a liquid, the pressure tends to force gas molecules into solution. At a given pressure, the number of dissolved gas molecules rises until an equilibrium is established. At equilibrium, gas molecules diffuse out of the liquid as quickly as they enter it, so the total number of gas molecules in solution remains constant. If the partial pressure increases, more gas molecules go into solution. If the partial pressure decreases, gas molecules come out of solution. You see Henry's law in action whenever you open a can of soda. The soda was put into the can under pressure, and the gas (carbon dioxide) is in solution (Figure 23–17a). When you open the can, the pressure decreases and the gas molecules begin coming out of solution (Figure 23–17b). Theoretically, the process will continue until an equilibrium develops between the surrounding air and the gas in solution. In fact, the volume of the can is so small, and the volume of the atmosphere so great, that within a half hour or so virtually all the carbon dioxide comes out of solution. You are left with "flat" soda.

The actual *amount* of a gas in solution at a given partial pressure and temperature depends on the solubility of the gas in that particular liquid. In body fluids, carbon dioxide is highly soluble, and oxygen is somewhat less soluble. Nitrogen has very limited solubility. The dissolved gas content is usually reported in milliliters of gas per 100 mL (1 dL) of solution. To see the differences in relative solubility of these three gases, we can compare the gas content of blood in the pulmonary veins with the partial pressure of each gas in the alveoli. In

Table 23–2	Partial Pressures (mm Hg) and Normal Gas Concentrations (%) in Air				
Source of Sample		Nitrogen (N ₂)	Oxygen (O ₂)	Carbon Dioxide (CO ₂)	Water Vapor (H ₂ O)
Inhaled air (dry)		597 (78.6%)	159 (20.9%)	0.3 (0.04%)	3.7 (0.5%)
Alveolar air (saturated)		573 (75.4%)	100 (13.2%)	40 (5.2%)	47 (6.2%)
Exhaled air (saturated)		569 (74.8%)	116 (15.3%)	28 (3.7%)	47 (6.2%)
			,	(/	

Figure 23–17 Henry's Law and the Relationship between Solubility and Pressure.

Clinical Note

Decompression Sickness Decompression sickness is a painful condition that develops when a person is exposed to a sudden drop in atmospheric pressure. Nitrogen is the gas responsible for the problems experienced, due to its high partial pressure in air. When the pressure drops, nitrogen comes out of solution, forming bubbles like those in a shaken can of soda. The bubbles may form in joint cavities, in the bloodstream, and in the cerebrospinal fluid. Individuals with decompression sickness typically curl up from the pain in affected joints. This reaction accounts for the condition's common name: *the bends*.

Decompression sickness most commonly affects scuba divers who return to the surface too quickly after breathing air under greaterthan-normal pressure while submerged. It can also develop in airline passengers subject to sudden losses of cabin pressure.

a pulmonary vein, plasma generally contains 2.62 mL/dL of dissolved CO₂ ($P_{CO_2} = 40 \text{ mm Hg}$), 0.29 mL/dL of dissolved O₂ ($P_{O_2} = 100 \text{ mm Hg}$), and 1.25 mL/dL of dissolved N₂ ($P_{N_2} = 573 \text{ mm Hg}$). Thus even though the partial pressure of carbon dioxide is less than one-tenth the partial pressure of nitrogen, the plasma contains more than twice as much carbon dioxide as nitrogen in solution.

Diffusion and Respiratory Function

The gas laws apply to the diffusion of oxygen, carbon dioxide, and nitrogen between a gas and a liquid. We will now consider how differing partial pressures and solubilities determine the direction and rate of diffusion across the respiratory membrane that separates the air within the alveoli from the blood in alveolar capillaries.

The Composition of Alveolar Air

As soon as air enters the respiratory tract, its characteristics begin to change. In passing through the nasal cavity, inhaled air becomes warmer, and the amount of water vapor increases. Humidification and filtration continue as the air travels through the pharynx, trachea, and bronchial passageways. On reaching the alveoli, the incoming air mixes with air remaining in the alveoli from the previous respiratory cycle. For this reason, alveolar air contains more carbon dioxide and less oxygen than does atmospheric air.

The last 150 mL of inhaled air never gets farther than the conducting passageways. It remains in the anatomic dead space of the lungs. During the next exhalation, the departing alveolar air mixes with air in the dead space, producing yet another mixture that differs from both atmospheric and alveolar samples. The differences in composition between atmospheric (inhaled) and alveolar air are given in Table 23–2.

Efficiency of Diffusion at the Respiratory Membrane

Gas exchange at the respiratory membrane is efficient for the following five reasons:

- 1. The differences in partial pressure across the respiratory membrane are substantial. This fact is important, because the greater the difference in partial pressure, the faster the rate of gas diffusion. Conversely, if P_{O_2} in alveoli decreases, the rate of oxygen diffusion into blood drops. This is why many people feel light-headed at altitudes of 3000 m or more. The partial pressure of oxygen in their alveoli has dropped so low that the rate of oxygen absorption is significantly reduced.
- 2. The distances involved in gas exchange are short. The fusion of capillary and alveolar basement membranes reduces the distance for gas exchange to an average of $0.5 \ \mu$ m. Inflammation of the lung tissue or a buildup of fluid in alveoli increases the diffusion distance and impairs alveolar gas exchange.
- **3.** *The gases are lipid soluble.* Both oxygen and carbon dioxide diffuse readily through the surfactant layer and the alveolar and endothelial plasma membranes.
- 4. The total surface area is large. The combined alveolar surface area at peak inhalation may approach 140 m² (1506 ft²). This area is slightly bigger than half of a tennis court. Damage to alveolar surfaces, which occurs in emphysema, reduces the available surface area and the efficiency of gas transfer.
- 5. *Blood flow and airflow are coordinated.* This close coordination makes both pulmonary ventilation and pulmonary circulation more efficient. For example, blood flow is greatest around alveoli with the highest P_{O2} values, where oxygen uptake can proceed with maximum efficiency. If

Figure 23–18 An Overview of Respiratory Processes and Partial Pressures in Respiration.

the normal blood flow is impaired (as it is in *pulmonary embolism*), or if the normal airflow is interrupted (as it is in various forms of *pulmonary obstruction*), this coordination is lost and respiratory efficiency decreases.

Partial Pressures in Alveolar Air and Alveolar Capillaries

Figure 23–18 illustrates the partial pressures of oxygen and carbon dioxide in the pulmonary and systemic circuits. Notice that blood arriving from the pulmonary arteries has a lower P_{O_2} and a higher P_{CO_2} than does alveolar air (**Figure 23–18a**). Diffusion between the alveolar gas mixture and the alveolar capillaries then increases the P_{O_2} of blood and decreases its P_{CO_2} . By the time the blood enters the pulmonary venules, it has reached equilibrium with the alveolar air. Blood departs the alveoli with a P_{O_2} of about 100 mm Hg and a P_{CO_2} of roughly 40 mm Hg.

Diffusion between alveolar air and blood in the alveolar capillaries occurs very rapidly. When you are at rest, a red blood cell moves through one of your alveolar capillaries in about 0.75 second. When you exercise, the passage takes less than 0.3

23

second. This amount of time is usually sufficient to reach an equilibrium between the alveolar air and the blood.

Partial Pressures in the Systemic Circuit

Oxygenated blood leaves the alveolar capillaries to return to the heart, to be pumped into the systemic circuit. As this blood enters the pulmonary veins, it mixes with blood that flowed through capillaries around conducting passageways. Because gas exchange in the lungs occurs only at alveoli, the blood leaving the conducting passageways carries relatively little oxygen. The partial pressure of oxygen in the pulmonary veins therefore

Clinical Note

Blood Gas Analysis Blood samples can be analyzed to determine their concentrations of dissolved gases. The usual tests include the determination of pH, $P_{CO_2'}$ and P_{O_2} in an arterial sample. Such samples provide information about the degree of oxygenation in peripheral tissues. For example, if the arterial P_{CO_2} is very high and the P_{O_2} is very low, tissues are not receiving adequate oxygen. This problem may be solved by giving the patient a gas mixture that has a high P_{O_2} (or even pure oxygen, with a P_{O_2} of 760 mm Hg).

Blood gas measurements also provide information on the efficiency of gas exchange at the lungs. If the arterial P_{O_2} remains low despite the administration of oxygen, or if the P_{CO_2} is very high, pulmonary exchange problems may exist. Such problems may include pulmonary edema, asthma, or pneumonia.

drops to about 95 mm Hg. This is the P_{O_2} in the blood that enters the systemic circuit. No further changes in partial pressure occur until the blood reaches the systemic capillaries (Figure 23–18b).

Normal interstitial fluid has a P_{O_2} of 40 mm Hg. As a result, oxygen diffuses out of the capillaries until the capillary partial pressure is the same as that in the adjacent tissues. Inactive peripheral tissues normally have a P_{CO_2} of about 45 mm Hg, whereas blood entering peripheral capillaries normally has a P_{CO_2} of 40 mm Hg. As a result, carbon dioxide diffuses into the blood as oxygen diffuses out (Figure 23–18b).

23-9 Most oxygen is transported bound to hemoglobin; and carbon dioxide is transported in three ways: as carbonic acid, bound to hemoglobin, or dissolved in plasma

Learning Outcome Describe the structure and function of hemoglobin, and the transport of oxygen and carbon dioxide in the blood.

Oxygen and carbon dioxide have limited solubilities in blood plasma. For example, at the normal P_{O_2} of alveoli, 100 mL of plasma absorbs only about 0.3 mL of oxygen. The limited solubilities of these gases are a problem. The peripheral tissues need more oxygen and generate more carbon dioxide than the plasma alone can absorb and transport.

Red blood cells (RBCs) solve this problem. They remove dissolved oxygen and CO_2 molecules from plasma and bind them (in the case of oxygen) or use them to manufacture soluble compounds (in the case of carbon dioxide). As these reactions remove dissolved gases from blood plasma, these gases continue to diffuse into the blood, but never reach equilibrium.

The important thing about these reactions is that they are both temporary and completely reversible. When oxygen or carbon dioxide concentrations in blood plasma are high, RBCs remove the excess molecules. When plasma concentrations are falling, the RBCs release their stored reserves.

Oxygen Transport

Each 100 mL of blood leaving the alveolar capillaries carries away about 20 mL of oxygen. Only 1.5 percent (about 0.3 mL) of this amount is oxygen molecules in solution. The rest of the oxygen molecules are bound to *hemoglobin (Hb) molecules*. Recall that the hemoglobin molecule consists of four globular protein subunits, each containing a heme unit. The oxygen molecules bind to the iron ions in the center of heme units. \bigcirc p. 659 Thus, each hemoglobin molecule can bind four molecules of oxygen, forming **oxyhemoglobin (HbO₂)**. This reaction is reversible. We can summarize it as

$$Hb + O_2 \Longrightarrow HbO_2.$$

This reversible reaction allows hemoglobin to pick up oxygen in the lungs and then release it to body tissues elsewhere.

Each red blood cell has approximately 280 million molecules of hemoglobin. With four heme units per hemoglobin molecule, each RBC potentially can carry more than a billion molecules of oxygen.

The percentage of heme units containing bound oxygen at any given moment is called the **hemoglobin saturation**. If all the Hb molecules in the blood are fully loaded with oxygen, saturation is 100 percent. If, on average, each Hb molecule carries two O_2 molecules, saturation is 50 percent.

In Chapter 2, we saw that the shape and functional properties of a protein change in response to changes in its environment. \bigcirc p. 54 Hemoglobin is no exception. Any changes in shape can affect oxygen binding. Under normal conditions, the most important environmental factors affecting hemoglobin are (1) the P_{O2} of blood, (2) blood pH, (3) temperature, and (4) ongoing metabolic activity within RBCs.

Hemoglobin and P_{0_2}

Hemoglobin in RBCs carries most of the oxygen in the bloodstream and releases it in response to changes in the partial pressure of oxygen in the surrounding plasma. If the P_{O_2} increases, hemoglobin binds oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen. An **oxygen–hemoglobin saturation curve**, or *oxygen–hemoglobin dissociation curve*, is a graph that relates the hemoglobin saturation to the partial pressure of oxygen (Figure 23–19). The binding and dissociation, or release, of oxygen to hemoglobin is a typical reversible reaction. At equilibrium, oxygen molecules bind to heme at the same rate that other oxygen molecules are being released. If the P_{O_2} increases, then more oxygen molecules bind to hemoglobin, and fewer are released. Referring to the equation given in the previous section, we say that the reaction shifts to the right. If the P_{O_2} decreases, more oxygen molecules are released from hemoglobin, while fewer oxygen molecules bind. In this case, we say that the reaction shifts to the left.

Notice that the graph of this relationship between P_{O_2} and hemoglobin saturation is a curve rather than a straight line. It is a curve because the shape of the hemoglobin molecule changes slightly each time it binds an oxygen molecule. This change in shape enhances the ability of hemoglobin to bind *another* oxygen molecule. In other words, the binding of the first oxygen molecule makes it easier to bind the second; binding the second promotes binding of the third; and binding the third enhances binding of the fourth.

Because each arriving oxygen molecule makes it easier for hemoglobin to bind the *next* oxygen molecule, the saturation curve takes the form shown in Figure 23–19. Once the first oxygen molecule binds to the hemoglobin, the slope rises rapidly until it levels off near 100 percent saturation. Where the slope is steep, a very small change in plasma P_{O_2} results in a

Figure 23–19 An Oxygen–Hemoglobin Saturation Curve. The saturation characteristics of hemoglobin at various partial pressures of oxygen under normal conditions (body temperature of 37°C and blood pH of 7.4).

large change in the amount of oxygen bound to Hb or released from HbO₂. Notice that hemoglobin will be more than 90 percent saturated if exposed to an alveolar P_{O_2} above 60 mm Hg. Thus, near-normal oxygen transport can continue even when the oxygen content of alveolar air decreases below normal, or $P_{O_2} = 100$ mm Hg. Without this ability, you could not survive at high altitudes. Conditions that significantly reduce pulmonary ventilation would be immediately fatal.

At normal alveolar pressures ($P_{O_2} = 100 \text{ mm Hg}$) the hemoglobin saturation is very high (97.5 percent), but complete saturation does not occur until the P_{O_2} reaches excessively high levels (about 250 mm Hg). In functional terms, the maximum saturation is not as important as the ability of hemoglobin to provide oxygen over the normal P_{O_2} range in body tissues. Over that range—from 100 mm Hg at the alveoli to perhaps 15 mm Hg in active tissues—the saturation drops from 97.5 percent to less than 20 percent, and a small change in P_{O_2} makes a big difference in terms of the amount of oxygen bound to hemoglobin.

Note that the relationship between P_{O_2} and hemoglobin saturation remains valid whether the P_{O_2} is rising or falling. If the P_{O_2} increases, the saturation goes up and hemoglobin stores oxygen. If the P_{O_2} decreases, hemoglobin releases oxygen into its surroundings. When oxygenated blood arrives in the peripheral capillaries, the blood P_{O_2} declines rapidly due to gas exchange with the interstitial fluid. As the P_{O_2} falls, hemoglobin gives up its oxygen.

The relationship between the P_{O_2} and hemoglobin saturation provides a mechanism for automatic regulation of oxygen delivery. Inactive tissues have little demand for oxygen, and the local P_{O_2} is usually about 40 mm Hg. Under these conditions, hemoglobin does not release much oxygen. As it passes through the capillaries, it goes from 97 percent saturation ($P_{O_2} = 95 \text{ mm Hg}$) to 75 percent saturation ($P_{O_2} = 40 \text{ mm Hg}$). Because hemoglobin still retains three-quarters of its oxygen, venous blood has a relatively large oxygen reserve. This reserve is important, because it can be mobilized if tissue oxygen demands increase.

Active tissues use oxygen at an accelerated rate, so their P_{O_2} may drop to 15–20 mm Hg. Hemoglobin passing through these capillaries goes from 97 percent saturation to about 20 percent saturation. In practical terms, this means that as blood circulates through peripheral capillaries, active tissues receive 3.5 times as much oxygen as do inactive tissues.

Hemoglobin and pH

At a given $P_{O_{2'}}$ hemoglobin releases additional oxygen if the pH decreases. The oxygen-hemoglobin saturation curve in **Figure 23–19** was determined in normal blood, with a pH of 7.4 and a temperature of 37 °C. In addition to consuming oxygen, active tissues generate acids that lower the pH of the interstitial fluid. When the pH decreases, the shape of hemoglobin molecules changes. As a result of this change,

the molecules release their oxygen reserves more readily, so the slope of the hemoglobin saturation curve changes (Figure 23–20a). In other words, as pH drops, the saturation declines. At a tissue P_{O_2} of 40 mm Hg, for example, you can see in Figure 23–20a that a pH decrease from 7.4 to 7.2 changes hemoglobin saturation from 75 percent to 60 percent. This means that hemoglobin molecules release 20 percent more oxygen in peripheral tissues at a pH of 7.2 than they do at a pH of 7.4. This effect of pH on the hemoglobin saturation curve is called the **Bohr effect**.

Carbon dioxide is the primary compound responsible for the Bohr effect. When CO_2 diffuses into the blood, it rapidly diffuses into red blood cells. There, an enzyme called **carbonic anhydrase** catalyzes the reaction of CO_2 with water molecules:

$$CO_2 + H_2O \xrightarrow{\text{carbonic anhydrase}} H_2CO_3 \xrightarrow{\leftarrow} H^+ + HCO_3^-$$

The product of this enzymatic reaction, H_2CO_3 , is called *carbonic acid*, because it dissociates into a hydrogen ion (H^+) and a bicarbonate ion (HCO_3^-). The rate of carbonic acid formation depends on the amount of carbon dioxide in solution, which, as noted earlier, depends on the P_{CO_2} . When the P_{CO_2} rises, the rate of carbonic acid formation accelerates and the reaction proceeds from left to right. The hydrogen ions that are generated diffuse out of the RBCs, and the pH of the plasma drops. When the P_{CO_2} declines, hydrogen ions diffuse out of the plasma and into the RBCs. As a result, the pH of the plasma increases as the reaction proceeds from right to left.

Hemoglobin and Temperature

At a given P_{CO_2} , hemoglobin releases additional oxygen if the temperature increases. Changes in temperature affect the slope of the hemoglobin saturation curve (Figure 23–20b). As the temperature increases, hemoglobin releases more oxygen. As the temperature decreases, hemoglobin holds oxygen more tightly. Temperature effects are significant only in active tissues that are generating large amounts of heat. For example, active skeletal muscles generate heat, and the heat warms blood that flows through these organs. As the blood warms, the Hb molecules release more oxygen than can be used by the active muscle fibers.

Hemoglobin and BPG

Red blood cells lack mitochondria. These cells produce ATP only by glycolysis. As a result, lactic acid is formed, as we saw in Chapter 10. ⊃ p. 318 The metabolic pathways involved in glycolysis in an RBC also generate the compound **2,3-bisphos-phoglycerate** (biz-fos-fō-GLIS-er-āt), or **BPG**. This compound has a direct effect on oxygen binding and release. For any partial pressure of oxygen, the higher the concentration of BPG, the greater the release of oxygen by Hb molecules. Normal RBCs always contain BPG.

Both BPG synthesis and the Bohr effect improve oxygen delivery when the pH changes: BPG levels rise when the pH increases, and the Bohr effect appears when the pH decreases. The concentration of BPG can be increased by high blood pH, thyroid hormones, growth hormone, epinephrine, and androgens. When plasma P_{O_1}

Figure 23–20 The Effects of pH and Temperature on Hemoglobin Saturation.

a Effect of pH. When the pH decreases below normal levels, more oxygen is released; the oxygen-hemoglobin saturation curve shifts to the right. When the pH increases, less oxygen is released; the curve shifts to the left.

Clinical Note

Carbon Monoxide Poisoning The exhaust from automobiles and other petroleum-burning engines, oil lamps, and fuel-fired space heaters contains *carbon monoxide* (CO). Each winter entire families die from **carbon monoxide poisoning**. Carbon monoxide competes with oxygen molecules for the binding sites on heme units. Unfortunately, the carbon monoxide usually wins the competition. The reason is that at very low partial pressures it has a much stronger affinity for hemoglobin than does oxygen. The bond formed between CO and heme is extremely durable. As a result, the attachment of a CO molecule essentially makes that heme unit inactive for respiratory purposes.

If CO molecules make up just 0.1 percent of inhaled air, enough hemoglobin is affected that human survival becomes impossible without medical assistance. Treatment includes (1) preventing further CO exposure; (2) administering pure oxygen, because at sufficiently high partial pressures, the oxygen molecules gradually replace CO at the hemoglobin molecules; and if necessary, (3) transfusing compatible red blood cells.

levels are low for an extended time, red blood cells generate more BPG. These factors improve oxygen delivery to the tissues, because when BPG levels are elevated, hemoglobin releases about 10 percent more oxygen at a given P_{O_2} than it would do otherwise.

The production of BPG decreases as RBCs age. For this reason, the level of BPG can determine how long a blood bank can store fresh whole blood. When BPG levels get too low, hemoglobin becomes firmly bound to the available oxygen. The blood is then useless for transfusions, because the RBCs will no longer release oxygen to peripheral tissues, even at a disastrously low P_O.

Fetal Hemoglobin

The RBCs of a developing fetus contain **fetal hemoglobin**. The structure of fetal hemoglobin differs from that of adult hemoglobin, giving it a much higher affinity for oxygen. At the same $P_{O_{2'}}$ fetal hemoglobin binds more oxygen than does adult hemoglobin (Figure 23–21). This trait is key to transferring oxygen across the placenta.

A fetus obtains oxygen from the maternal bloodstream. At the placenta, maternal blood has a relatively low P_{O_2} , ranging from 35 to 50 mm Hg. If maternal blood arrives at the placenta with a P_{O_2} of 40 mm Hg, hemoglobin saturation is roughly 75 percent. The fetal blood arriving at the placenta has a P_{O_2} close to 20 mm Hg. However, because fetal hemoglobin has a higher affinity for oxygen, it is still 58 percent saturated. As diffusion takes place between fetal blood and maternal blood, oxygen enters the fetal bloodstream until the P_{O_2} reaches equilibrium at 30 mm Hg. At this $P_{O_2'}$ the maternal hemoglobin is less than 60 percent saturated, but the fetal hemoglobin is over 80 percent saturated, as you can see on Figure 23–21. The steep slope of the saturation curve for fetal hemoglobin means that when fetal RBCs reach peripheral tissues of the fetus, the Hb molecules release a large amount of oxygen in response to a very small change in P_{O_2} .

Carbon Dioxide Transport

Carbon dioxide is generated by aerobic metabolism in peripheral tissues. Carbon dioxide travels in the bloodstream in three different ways. After entering the blood, a CO₂ molecule either (1) is converted to a molecule of carbonic acid, (2) binds to hemoglobin within red blood cells, or (3) dissolves in plasma. All three reactions are completely reversible, allowing carbon dioxide to be picked up from body tissues and then delivered to the alveoli. Let's consider the events that take place as blood enters peripheral tissues in which the P_{CO_2} is 45 mm Hg.

Carbonic Acid Formation

Roughly 70 percent of the carbon dioxide absorbed by blood is transported as molecules of carbonic acid. Carbon dioxide is converted to carbonic acid through the activity of the enzyme carbonic anhydrase in RBCs. The carbonic acid molecules immediately dissociate into a hydrogen ion and a bicarbonate ion, as described earlier (p. 862). We can ignore the intermediate steps in this sequence and summarize the reaction as

$$CO_2 + H_2O \xrightarrow{carbonic anhydrase} H^+ + HCO_3^-$$

This reaction is completely reversible. In peripheral capillaries, it proceeds vigorously, tying up large numbers of CO_2 molecules. The reaction continues as carbon dioxide diffuses out of the interstitial fluids.

The hydrogen ions and bicarbonate ions have different fates. Most of the hydrogen ions bind to hemoglobin molecules, forming HbH⁺. The Hb molecules function as pH buffers, tying up the released hydrogen ions before the ions can leave the RBCs and lower the pH of the plasma. The bicarbonate ions move into the plasma with the aid of a countertransport mechanism that exchanges intracellular bicarbonate ions (HCO₃⁻) for extracellular chloride ions (Cl⁻). This exchange trades one anion for another and does not require ATP. The result is a mass movement of chloride ions into the RBCs, an event known as the **chloride shift**.

CO₂ Binding to Hemoglobin

About 23 percent of the carbon dioxide carried by blood is bound to the protein portions of Hb molecules inside RBCs. These CO_2 molecules are attached to exposed amino groups $(-NH_2)$ of the Hb molecules. The resulting compound is called **carbaminohemoglobin** (kar-BAM-i-nō-hē-mō-glōbin), HbCO₂. We can summarize the reversible reaction as follows:

 $CO_2 + HbNH_2 \implies HbNHCOOH$

We can abbreviate this reaction without the amino groups as

$$CO_2 + Hb \Longrightarrow HbCO_2$$

Transport in Plasma

Plasma becomes saturated with carbon dioxide quite rapidly. Only about 7 percent of the carbon dioxide absorbed at peripheral capillaries is transported as dissolved gas molecules. RBCs absorb the rest and convert it using carbonic anhydrase or store it as carbaminohemoglobin.

Figure 23–22 summarizes carbon dioxide transport.

Summary: Gas Transport

Figure 23–23 summarizes the transport of oxygen and carbon dioxide in the respiratory and cardiovascular systems. Note that the bottom portion of the figure shows the carbon dioxide being delivered to the alveoli. The reactions we have just discussed then proceed in the reverse direction.

Gas transport is a dynamic process. It is capable of varying its responses to meet changing circumstances. Some of the responses are automatic and result from the basic chemistry of the transport mechanisms. Other responses require coordinated adjustments in the activities of the cardiovascular and

respiratory systems. We consider those levels of control and regulation next.

23-10 Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration

Learning Outcome List the factors that influence respiration rate, and discuss reflex respiratory activity and the brain centers involved in the control of respiration.

Figure 23–23 A Summary of the Primary Gas Transport Mechanisms.

Peripheral cells continuously absorb oxygen and generate carbon dioxide. Under normal conditions, the cellular rates of absorption and generation are matched by the capillary rates of delivery and removal. Both rates are identical to those of oxygen absorption and carbon dioxide excretion at the lungs.

If diffusion rates at the peripheral and alveolar capillaries become unbalanced, homeostatic mechanisms intervene to restore equilibrium. Such mechanisms involve (1) changes in blood flow and oxygen delivery that are regulated at the local level and (2) changes in the depth and rate of respiration under the control of the brain's respiratory centers. The activities of the respiratory centers are coordinated with changes in cardiovascular function, such as fluctuations in blood pressure and cardiac output.

Local Regulation of Gas Transport and Alveolar Function

The rate of oxygen delivery in each tissue and the efficiency of oxygen pickup at the lungs are largely regulated at the local level. For example, when a peripheral tissue becomes more active, the interstitial P_{O_2} falls and the P_{CO_2} rises. This change increases the difference between the partial pressures in the tissues and in the arriving blood. As a result, more oxygen is delivered and more carbon dioxide is carried away. In addition, the rising P_{CO_2} levels cause the relaxation of smooth muscles in the walls of arterioles and capillaries in the area, increasing local blood flow.

At the lungs, local factors coordinate (1) *lung perfusion*, or blood flow to the alveoli, with (2) *alveolar ventilation*, or airflow. This local coordination takes place over a wide range

of conditions and activity levels. As blood flows toward the alveolar capillaries, it is directed toward lobules with a relatively high P_{O_2} . This movement takes place because alveolar capillaries constrict when the local P_{O_2} is low. (This response is the opposite of that seen in peripheral tissues, as we noted in Chapter 21. \bigcirc p. 752)

Also in the lungs, smooth muscles in the walls of bronchioles are sensitive to the P_{CO_2} of the air they contain. When the P_{CO_2} goes up, the bronchioles increase in diameter (bronchodilation). When the P_{CO_2} declines, the bronchioles constrict (bronchoconstriction). Airflow is therefore directed to lobules with a high P_{CO_2} . These lobules get their carbon dioxide from blood and are actively engaged in gas exchange. The response of the bronchioles to P_{CO_2} is especially important, because improvements in airflow to functional alveoli can at least partially compensate for damage to pulmonary lobules.

Local adjustments improve the efficiency of gas transport by directing blood flow to alveoli with low CO_2 levels and increasing airflow to alveoli with high CO_2 levels. These adjustments in alveolar blood flow and bronchiole diameter take place automatically. When activity levels increase and the demand for oxygen rises, the cardiac output and respiratory rates increase under neural control.

The Respiratory Centers of the Brain

Respiratory control has both involuntary and voluntary components. Your brain's involuntary centers regulate the activities of the respiratory muscles. These centers control the respiratory minute volume by adjusting the frequency and depth of pulmonary ventilation. They make these adjustments in response to sensory information arriving from your lungs and other parts of the respiratory tract, as well as from a variety of other sites.

The voluntary control of respiration reflects activity in the cerebral cortex. This activity affects the output of either the respiratory centers in the medulla oblongata and pons or motor neurons in the spinal cord that control respiratory muscles. The **respiratory centers** are three pairs of nuclei in the reticular formation of the medulla oblongata and pons. The motor neurons in the spinal cord are generally controlled by *respiratory reflexes*, but they can also be controlled voluntarily through commands delivered by the corticospinal pathway. \bigcirc **p.** 524

Respiratory Centers in the Medulla Oblongata

We introduced the paired *respiratory rhythmicity centers* of the medulla oblongata in Chapter 14; these centers play a key role in establishing the pace of respiration. \bigcirc **p**. 470 Each respiratory rhythmicity center can be subdivided into a *dorsal respiratory group (DRG)* and a *ventral respiratory group (VRG)*. The DRG is chiefly concerned with inspiration whereas the VRG is primarily associated with expiration.

The DRG functions in every respiratory cycle, whether quiet or forced. The DRG's *inspiratory center* contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm.

The VRG functions only during forced breathing. It has an *expiratory center* consisting of neurons that innervate lower motor neurons controlling accessory respiratory muscles involved in active exhalation. Its *inspiratory center* contains neurons involved in maximal inhalation, such as gasping.

Reciprocal inhibition takes place between the neurons involved with inhalation and exhalation. **D p**. 455 When the inspiratory neurons are active, the expiratory neurons are inhibited, and vice versa. The pattern of interaction between these groups differs between quiet breathing and forced breathing. During quiet breathing (Figure 23–24a):

- Activity in the DRG increases over a period of about 2 seconds, stimulating the inspiratory muscles. Over this period, inhalation takes place.
- After 2 seconds, the DRG neurons become inactive. They remain quiet for the next 3 seconds and allow the inspiratory muscles to relax. Over this period, passive exhalation takes place.

During forced breathing (Figure 23-24b):

- Increases in the level of activity in the DRG stimulate neurons of the VRG that activate the accessory muscles involved in inhalation.
- After each inhalation, active exhalation takes place as the neurons of the expiratory center stimulate the appropriate accessory muscles.

The basic pattern of respiration thus reflects a cyclic interaction between the DRG and the VRG. However, the timing of this interaction is highly variable, and current research suggests that respiratory rate and rhythm cannot be attributed to a single area. The nuclei involved in respiratory control form a complex network that includes (1) the rhythmicity centers, (2) centers in the pons that are modulated by peripheral and higher central inputs, and (3) an area in the ventrolateral medulla, known as the central pattern generator or the pre-Bötzinger complex, that is essential to all forms of breathing. There are reciprocal pathways between all these nuclei and deciphering the communication is extremely difficult and the patterns change with different situations. Central nervous system stimulants, such as amphetamines or even caffeine, increase the respiratory rate by facilitating the respiratory centers. These actions are opposed by CNS depressants, such as barbiturates or opiates.

Respiratory control is an area of intense study and our understanding of the interactions and mechanisms remains incomplete. Due to the brain stem locations, it is nearly impossible to study this mechanism in humans, and much of the work has been done in cats and newborn rodents.

Figure 23–24 Basic Regulatory Patterns of Respiration.

The Apneustic and Pneumotaxic Centers of the Pons

The apneustic centers and pneumotaxic centers of the pons regulate the depth and rate of respiration in response to sensory stimuli or input from other centers in the brain. Each apneustic center provides continuous stimulation to the DRG on that side of the brain stem. During quiet breathing, stimulation from the apneustic center helps increase the intensity of inhalation over the next 2 seconds. Under normal conditions, after 2 seconds the apneustic center is inhibited by signals from the pneumotaxic center on that side. During forced breathing, the apneustic centers also respond to sensory input from the vagus nerves regarding the amount of lung inflation.

The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. Centers in the hypothalamus and cerebrum can alter the activity of the pneumotaxic centers, as well as the respiratory rate and depth. However, essentially normal respiratory cycles continue even if the brain stem superior to the pons has been severely damaged.

In some cases, the inhibitory output of the pneumotaxic centers is cut off by a stroke or other damage to the brain stem, or sensory innervation from the lungs is eliminated due to damage to the vagus nerves. In these cases, the person inhales to maximum capacity and maintains that state for 10–20 seconds

at a time. Intervening exhalations are brief, and little pulmonary ventilation occurs.

The CNS regions involved with respiratory control are diagrammed in **Spotlight Figure 23–25**. Interactions between the DRG and the VRG establish the basic pace and depth of respiration. The pneumotaxic centers modify that pace: An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation. A decrease in pneumotaxic output slows the respiratory pace, but increases the depth of respiration, because the apneustic centers are more active.

Sudden infant death syndrome (SIDS), also known as *crib death*, is the leading cause of death for babies 1–12 months old and kills an estimated 2250 infants each year in the United States alone. Most crib deaths occur between midnight and 9:00 a.m., in the late fall or winter, and involve infants two to four months old. Eyewitness accounts indicate that the sleeping infant suddenly stops breathing, turns blue, and relaxes. Genetic factors appear to be involved, but controversy remains as to the relative importance of other factors. The age at the time of death corresponds with a period when the pacemaker complex and respiratory centers are establishing connections with other portions of the brain. It has been suggested that SIDS results from a problem in the interconnection process that disrupts the reflexive respiratory pattern.

SPOTLIGHT Figure 23–25 Control of Respiration

Respiratory control involves multiple levels of regulation. Most of the regulatory activities occur outside of our awareness.

Apneustic and Pneumotaxic Centers

Respiratory

The **apneustic** (ap-NŪ-stik) **centers** and the **pneumotaxic** (nū-mō-TAKS-ik) **centers** of the pons are paired nuclei that adjust the output of the respiratory rhythmicity centers. The pneumotaxic centers inhibit the apneustic centers and promote passive or active exhalation. An increase in pneumotaxic output quickens the pace of respiration by shortening the duration of each inhalation. A decrease in pneumotaxic output slows the respiratory pace but increases the depth of respiration, because the apneustic centers are more active.

The apneustic centers promote inhalation by stimulating the DRG. During forced breathing, the apneustic centers adjust the degree of stimulation in response to sensory information from N X (the vagus nerve) concerning the amount of lung inflation.

Rhythmicity CentersThe most basic level of respiratory control
involves pacemaker cells in the medulla
oblongata. These neurons generate cycles
of contraction and relaxation in the
diaphragm. The respiratory rhythmicity
centers set the pace of respiration by
adjusting the activities of these pace-
makers and coordinating the activities
of additional respiratory muscles. Each
rhythmicity center can be subdivided into
a dorsal respiratory group (DRG) and a
ventral respiratory group (VRG). The
DRG is mainly concerned with inspirationTo diaphragm
To diaphragm

DRG is mainly concerned with inspiration and the VRG is primarily associated with expiration. The DRG modifies its activities in response to input from chemoreceptors and baroreceptors that monitor O_2 , CO_2 , and pH in the blood and CSF and from stretch receptors that monitor the degree of stretching in the walls of the lungs.

Pons

Medulla oblongata

Respiratory Centers and Reflex Controls

Respiratory Reflexes

The activities of the respiratory centers are modified by sensory information from several sources:

- Chemoreceptors sensitive to the P_{CO2} pH, or P_{O2} of the blood or cerebrospinal fluid.
- Baroreceptors in the aortic or carotid sinuses sensitive to changes in blood pressure.
- Stretch receptors that respond to changes in the volume of the lungs.
- Irritating physical or chemical stimuli in the nasal cavity, larynx, or bronchial tree.
- Other sensations, including pain, changes in body temperature, and abnormal visceral sensations.

Information from these receptors alters the pattern of respiration. The induced changes have been called *respiratory reflexes*.

The Chemoreceptor Reflexes

The respiratory centers are strongly influenced by chemoreceptor inputs from cranial nerves IX and X, and from receptors that monitor the composition of the cerebrospinal fluid (CSF):

- The glossopharyngeal nerves (N IX) carry chemoreceptive information from the carotid bodies, adjacent to the carotid sinus. ⁽⁾ pp. 517, 755 The carotid bodies are stimulated by a decrease in the pH or P_{O2} of blood. Because changes in P_{CO2} affect pH, an increase in the P_{CO2} indirectly stimulates these receptors.
- The vagus nerves (N X) monitor chemoreceptors in the aortic bodies, near the aortic arch. > pp. 517, 755 These receptors are sensitive to the same stimuli as the carotid bodies. Carotid and aortic body receptors are often called *peripheral chemoreceptors*.
- Chemoreceptors are located on the ventrolateral surface of the medulla oblongata in a region known as the *chemosensitive area*. The neurons in that area respond only to P_{CO2} the and pH of the CSF. They are often called *central chemoreceptors*.

We discussed chemoreceptors and their effects on cardiovascular function in Chapters 15 and 21. \bigcirc pp. 517, 746–747 Stimulation of these chemoreceptors leads to an increase in the depth and rate of respiration. Under normal conditions, a drop in arterial P_{O2} has little effect on the respiratory centers, until the arterial P_{O2} drops by about 40 percent, to below 60 mm Hg. If the P_{O2} of arterial blood drops to 40 mm Hg (the level in peripheral tissues), the respiratory rate increases by only 50–70 percent. In contrast, a rise of just 10 percent in the arterial P_{CO2} causes the respiratory rate to double, even if the P_{O2} remains completely normal. Carbon dioxide levels are therefore responsible for regulating respiratory activity under normal conditions.

Although the receptors monitoring CO_2 levels are more sensitive, oxygen and carbon dioxide receptors work together in a crisis. Carbon dioxide is generated during oxygen consumption, so when oxygen concentrations are falling rapidly, CO_2 levels are usually increasing. This cooperation breaks down only under unusual circumstances. For example, you can hold your breath longer than normal by taking deep, full breaths, but the practice is very dangerous. The danger lies in the fact that the increased ability is due not to extra oxygen, but to less carbon dioxide. If the P_{CO_2} is driven down far enough, your ability to hold your breath can increase to the point at which you become unconscious from oxygen starvation in the brain without ever feeling the urge to breathe.

The chemoreceptors are subject to adaptation—a decrease in sensitivity after chronic stimulation—if the P_{O_2} or P_{CO_2} remains abnormal for an extended period. This adaptation can complicate the treatment of chronic respiratory disorders. For example, if the P_{O_2} remains low for an extended period while the P_{CO_2} remains chronically elevated, the chemoreceptors will reset to those values. They will then oppose any attempts to return the partial pressures to the proper range.

Any condition altering the pH of blood or CSF affects respiratory performance because the chemoreceptors monitoring CO_2 levels are also sensitive to pH. The increase in lactic acid levels after exercise, for example, causes a decrease in pH that helps stimulate respiratory activity.

Hypercapnia and Hypocapnia. Hypercapnia is an increase in the P_{CO_2} of arterial blood. Figure 23–26a diagrams the central response to hypercapnia. Stimulation of chemoreceptors in the carotid and aortic bodies triggers this response. It is reinforced by the stimulation of CNS chemoreceptors. Carbon dioxide crosses the blood–brain barrier quite rapidly. For this reason, a rise in arterial P_{CO_2} almost immediately increases CO₂ levels in the CSF, decreasing the pH of the CSF and stimulating the chemoreceptive neurons of the medulla oblongata.

These chemoreceptors stimulate the respiratory centers to increase the rate and depth of respiration. Your breathing becomes more rapid, and more air moves into and out of your lungs with each breath. Because more air moves into and out of the alveoli each minute, alveolar concentrations of carbon dioxide decline, accelerating the diffusion of carbon dioxide out of alveolar capillaries. In this way, homeostasis is restored.

The most common cause of hypercapnia is hypoventilation. In **hypoventilation**, the respiratory rate remains abnormally low and cannot meet the demands for normal oxygen delivery and carbon dioxide removal. Carbon dioxide then accumulates in the blood.

If the rate and depth of respiration exceed the demands for oxygen delivery and carbon dioxide removal, the condition called **hyperventilation** exists. Hyperventilation gradually leads to **hypocapnia**, an abnormally low P_{CO_2} . If the arterial P_{CO_2} drops below normal levels, chemoreceptor activity decreases and the respiratory rate falls (Figure 23–26b). This situation continues until the P_{CO_2} returns to normal and homeostasis is restored.

The Baroreceptor Reflexes

We described the effects of carotid and aortic baroreceptor stimulation on systemic blood pressure in Chapter 21. \bigcirc pp. 744–745 The output from these baroreceptors also affects the respiratory centers. When blood pressure falls, the respiratory rate increases. When blood pressure rises, the respiratory rate decreases. These adjustments result from the stimulation or inhibition of the respiratory centers by sensory fibers in the glossopharyngeal (N IX) and vagus (N X) nerves.

The Hering–Breuer Reflexes

The **Hering–Breuer reflexes** are named after the physiologists who described them in 1865. The sensory information from these reflexes goes to the apneustic centers and the ventral respiratory group. The Hering–Breuer reflexes are not involved
in normal quiet breathing (eupnea) or in tidal volumes under 1000 mL. There are two such reflexes:

- 1. The **inflation reflex** prevents overexpansion of the lungs during forced breathing. Lung expansion stimulates stretch receptors in the smooth muscle tissue around bronchioles. Sensory fibers from the stretch receptors of each lung reach the respiratory rhythmicity center on the same side by the vagus nerve. As lung volume increases, the dorsal respiratory group is gradually inhibited, and the expiratory center of the VRG is stimulated. Inhalation stops as the lungs near maximum volume. Active exhalation then begins.
- 2. The **deflation reflex** normally functions only during forced exhalation, when both the inspiratory and expiratory centers are active. This reflex inhibits the expiratory centers and stimulates the inspiratory centers when the lungs are deflating. These receptors are distinct from those of the inflation reflex. They are located in the alveolar wall near the alveolar capillary network. The smaller the volume of the lungs, the greater the degree of inhibition. Finally, exhalation stops and inhalation begins.

Protective Reflexes

Protective reflexes operate when you are exposed to toxic vapors, chemical irritants, or mechanical stimulation of the respiratory tract. The receptors involved are located in the epithelium of the respiratory tract. Examples of protective reflexes include sneezing, coughing, and laryngeal spasms.

Sneezing is triggered by an irritation of the nasal cavity wall. Coughing is triggered by an irritation of the larynx, trachea, or bronchi. Both reflexes involve **apnea** (AP-nē-uh), a period in which respiration is suspended. A forceful expulsion of air usually follows to remove the offending stimulus. The glottis is forcibly closed while the lungs are still relatively full. The abdominal and internal intercostal muscles then contract suddenly, creating pressures that blast air out of the respiratory passageways when the glottis reopens. Air leaving the larynx can travel at 160 kph (99 mph), carrying mucus, foreign particles, and irritating gases out of the respiratory tract via the nose or mouth.

Laryngeal spasms result when chemical irritants, foreign objects, or fluids enter the area around the glottis. This reflex generally closes the airway temporarily. A very strong stimulus, such as a toxic gas, could close the glottis so powerfully that you could lose consciousness and die without taking another breath. Fine chicken bones or fish bones that pierce the laryngeal walls can also stimulate laryngeal spasms, swelling, or both, restricting the airway.

Voluntary Control of Respiration

Activity of the cerebral cortex has an indirect effect on the respiratory centers, as the following examples show:

- Conscious thought processes tied to strong emotions, such as rage or fear, affect the respiratory rate by stimulating centers in the hypothalamus.
- Emotional states can affect respiration by activating the sympathetic or parasympathetic division of the autonomic nervous system. Sympathetic activation causes bronchodilation and increases the respiratory rate. Parasympathetic stimulation has the opposite effect.
- An anticipation of strenuous exercise can trigger an automatic increase in the respiratory rate, along with increased cardiac output, by sympathetic stimulation.

Conscious control over respiratory activities may bypass the respiratory centers completely, using pyramidal fibers that innervate the same lower motor neurons that are controlled by the DRG and VRG. This control mechanism is an essential part of speaking, singing, and swimming, when respiratory activities must be precisely timed. Higher centers can also have an inhibitory effect on the apneustic centers and on the DRG and VRG. This effect is important when you hold your breath.

Your abilities to override the respiratory centers have limits, however. The chemoreceptor reflexes are extremely powerful in stimulating respiration, and you cannot consciously suppress them. For example, you cannot kill yourself by holding your breath "till you turn blue." Once the P_{CO_2} increases to critical levels, you are forced to take a breath.

Changes in the Respiratory System at Birth

The respiratory systems of fetuses and newborns differ in several important ways. Before delivery, pulmonary arterial resistance is high, because the pulmonary vessels are collapsed. The rib cage is compressed, and the lungs and conducting passageways contain only small amounts of fluid and no air. During delivery, the lungs are compressed further. As the placental connection is lost, blood oxygen levels fall and carbon dioxide levels climb rapidly.

At birth, the newborn infant takes a truly heroic first breath through powerful contractions of the diaphragmatic and external intercostal muscles. The inhaled air must enter the respiratory passageways with enough force to overcome surface tension and inflate the bronchial tree and most of the alveoli. The same drop in pressure that pulls air into the lungs also pulls blood into the pulmonary circulation. The changes in blood flow and rise in oxygen levels lead to the closure of the *foramen ovale*, an interatrial connection, and the *ductus arteriosus*, the fetal connection between the pulmonary trunk and the aorta. \bigcirc pp. 772–773 ATLAS: Embryology Summary 18: The Development of the Respiratory System

The exhalation that follows does not empty the lungs completely, because the rib cage does not return to its former, fully compressed state. Cartilages and connective tissues keep the conducting passageways open, and surfactant covering the alveolar surfaces prevents their collapse. The next breaths complete the inflation of the alveoli.

Pathologists sometimes use these physical changes to determine whether a newborn infant died before delivery or shortly thereafter. Before the first breath, the lungs are completely filled with amniotic fluid, and extracted lungs will sink if placed in water. After the infant's first breath, even the collapsed lungs contain enough air to keep them afloat.

CHECKPOINT

- **28**. What effect does exciting the pneumotaxic centers have on respiration?
- 29. Are peripheral chemoreceptors more or less sensitive to levels of carbon dioxide than they are to levels of oxygen? Why?
- **30**. Little Johnny is angry with his mother, so he tells her that he will hold his breath until he turns blue and dies. Should Johnny's mother worry that this will happen?

See the blue Answers tab at the back of the book.

23-11 Respiratory performance declines with age

Learning Outcome Describe age-related changes in the respiratory system.

Many factors interact to reduce the efficiency of the respiratory system in elderly individuals. Here are three examples:

- 1. With age, elastic tissue deteriorates throughout the body. These changes reduce the compliance of the lungs and lower vital capacity.
- 2. Chest movements are restricted by arthritic changes in the rib articulations and by decreased flexibility at the costal cartilages. Along with elastic tissue deterioration, the stiffening and reduction in chest movement effectively limit the respiratory minute volume. This restriction contributes to the reduction in exercise performance and capabilities with increasing age.
- 3. Some degree of emphysema is normal in individuals over age 50. However, the extent varies widely with the life-time exposure to cigarette smoke and other respiratory irritants. Figure 23–27 compares the respiratory performance of individuals who have never smoked with individuals who have smoked for various periods of time. The message is quite clear: Some decrease in respiratory performance is inevitable, but you can prevent serious respiratory deterioration by stopping smoking or never starting.

Figure 23–27 Decline in Respiratory Performance with Age and Smoking. The relative respiratory performances of people who have never smoked, people who quit smoking at age 45, people who quit smoking at age 65, and lifelong smokers.

CHECKPOINT

31. Name several age-related factors that affect the respiratory system.

See the blue Answers tab at the back of the book.

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems

Learning Outcome Give examples of interactions between the respiratory system and other organ systems studied so far.

The goal of respiratory activity is to maintain homeostatic oxygen and carbon dioxide levels in peripheral tissues. Changes in respiratory activity alone are seldom enough to accomplish this. Coordinated changes in cardiovascular activity must also take place.

Consider these examples of the integration between the respiratory and cardiovascular systems:

- At the local level, changes in lung perfusion in response to changes in alveolar P_{O2} improve the efficiency of gas exchange within or among lobules.
- Chemoreceptor stimulation not only increases the respiratory drive, but it also causes blood pressure to rise and cardiac output to increase.
- The stimulation of baroreceptors in the lungs has secondary effects on cardiovascular function. For example, the stimulation of airway stretch receptors not only triggers the inflation reflex, but also increases heart rate. Thus, as

. Page 1010

Figure 23–28 diagrams the functional relationships between the respiratory system and the other body systems we have studied so far.

Clinical Note

Emphysema and Lung Cancer Emphysema and lung cancer are two relatively common disorders. Both are often associated with cigarette smoking. Emphysema (em-fi-ZEmuh) is a chronic, progressive condition. It is characterized by shortness of breath and an inability to tolerate physical exertion. The underlying problem is the destruction of alveolar surfaces and inadequate surface area for oxygen and carbon dioxide exchange. In essence, respiratory bronchioles and alveoli no longer function. The alveoli gradually expand, and adjacent alveoli merge to form larger air spaces supported by fibrous tissue without alveolar capillary networks. As connective tissues are eliminated, compliance increases, so air moves into and out of the lungs more easily than before. But the loss of respiratory surface area restricts oxygen absorption, so the individual becomes short of breath.

Emphysema has been linked to breathing air that contains fine particles or toxic vapors, such as those in cigarette smoke. Genetic factors also predispose individuals to the condition. Some degree of emphysema is a normal consequence of aging. An estimated 66 percent of adult males and 25 percent of adult females have detectable areas of emphysema in their lungs.

Lung cancer, or *bronchopulmonary carcinoma*, is an aggressive class of malignancies originating in the bronchial passageways or alveoli. These cancers affect the epithelial cells that line conducting passageways, mucous glands, or alveoli. Signs and symptoms generally do not appear until tumors restrict airflow or compress adjacent structures. Chest pain, shortness of breath, a cough or a wheeze, and weight loss are common. Treatment varies with the cellular organization of the tumor and whether metastasis (cancer cell migration) has occurred. Surgery, radiation, or chemotherapy may be involved.

According to the CDC, more people die from lung cancer than any other type of cancer. In 2009, lung cancer affected an estimated 110,000 men and 96,000 women in the United States, and accounted for 12.6 percent of new cancer cases in both men and women. the lungs fill, cardiac output rises and more blood flows through the alveolar capillaries.

The adaptations that take place at high altitudes are an excellent example of the functional interplay between the respiratory and cardiovascular systems. Atmospheric pressure decreases with increasing altitude, and so do the partial pressures of the component gases, including oxygen. People living in Denver or Mexico City function normally with alveolar oxygen pressures in the 80–90 mm Hg range. At higher elevations, alveolar P_{O_2} is even lower. At 3300 meters (10,826 ft), an altitude many hikers and skiers have experienced, alveolar P_{O_2} is about 60 mm Hg.

Despite the low alveolar $P_{O_2'}$ millions of people live and work at altitudes this high or higher. Important physiological adjustments include increased respiratory rate, increased heart rate, increased BPG levels, and elevated hematocrit. Thus, even though the hemoglobin is not fully saturated, the bloodstream holds more of it, and the round trip between the lungs and the peripheral tissues takes less time. However, most of these adaptations take days to weeks to develop. As a result, athletes planning to compete in events at high altitude must begin training under such conditions well in advance.

The respiratory system is functionally linked to all other body systems as well. **Figure 23–28** illustrates these interrelationships with the systems studied so far.

CHECKPOINT

- **32**. Identify the functional relationship between the respiratory system and all other organ systems.
- **33**. Describe the functional relationship between the respiratory system and the lymphatic system.

See the blue Answers tab at the back of the book.

Related Clinical Terms

- **asbestosis:** Pneumoconiosis, disease of the lungs, caused by the inhalation of asbestos particles over time.
- **asphyxia:** Impaired oxygen–carbon dioxide exchange that results in suffocation.
- **aspirate:** Drawing fluid from the body by suction; foreign material accidentally sucked into the lungs.
- **bronchography:** A procedure in which radiopaque materials are introduced into the airways to improve x-ray imaging of the bronchial tree.
- **bronchoscope:** A fiber-optic bundle small enough to be inserted into the trachea and finer airways; the procedure is called *bronchoscopy*.
- **cardiopulmonary resuscitation (CPR):** The application of cycles of compression to the rib cage and mouth-to-mouth breathing to restore cardiovascular and respiratory function.
- **Cheyne-Stokes breathing:** Hyperpnea (deep, fast breathing) alternating with apnea (absence of breathing).

chronic obstructive pulmonary disease (COPD): A general term describing temporary or permanent lung disease of the bronchial tree.

dyspnea: The condition of labored breathing.

- **endotracheal tube:** Tube that is passed through the mouth or nose to the trachea.
- **Heimlich maneuver, or** *abdominal thrust*: Sudden compression applied to the abdomen just inferior to the diaphragm, to force air out of the lungs to clear a blocked trachea or larynx.

hemoptysis: Coughing up blood or bloody mucus.

- **hemothorax:** The condition of having blood in the pleural cavity. **hyperbaric oxygenation:** Therapy to force more oxygen into the blood by use of a pressure chamber.
- **nasal polyps:** Benign growths on the mucous lining of the nasal cavity.
- **orthopnea:** Condition in which one has breathing difficulty except when in an upright position.

otorhinolaryngology: Branch of medicine dealing with disease and treatment of the ear, nose, and throat.

rales: Abnormal hissing or other respiratory sounds.

rhinitis: Inflammation of the nasal cavity.

rhinoplasty: Plastic surgery of the nose.

- **severe acute respiratory syndrome (SARS):** A harsh viral respiratory illness caused by a coronavirus that typically progresses to pneumonia.
- **sputum:** A mixture of saliva and mucus coughed up from the respiratory tract, often as the result of an infection.
- **stridor:** Harsh vibrating breathing sound caused by an obstruction in the windpipe or larynx.
- **stuttering:** To speak with a continued involuntary repetition of sounds.

tachypnea: Rapid rate of breathing.

tussis: A cough.

wheeze: An audible whistling sound when breathing.

An introduction to the respiratory system p. 831

1. Body cells must obtain oxygen and eliminate carbon dioxide. Gas exchange takes place at respiratory surfaces inside the lungs.

23-1 The respiratory system, organized into an upper respiratory system and a lower respiratory system, has several basic functions p. 831

- 2. The functions of the **respiratory system** include (1) providing an area for gas exchange between air and circulating blood; (2) moving air to and from exchange surfaces; (3) protecting respiratory surfaces from environmental variations and defending the respiratory system and other tissues from invasion by pathogens; (4) producing sounds; and (5) facilitating the detection of olfactory stimuli.
- 3. The respiratory system includes the **upper respiratory system**, composed of the nose, nasal cavity, paranasal sinuses, and pharynx, and the **lower respiratory system**, which includes the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. (*Figure 23–1*)
- 4. The **respiratory tract** consists of the conducting airways that carry air to and from the **alveoli**. The passageways of the upper respiratory tract filter and humidify incoming air. The lower respiratory tract includes delicate conduction passages and the exchange surfaces of the alveoli.
- 5. The **respiratory mucosa** (respiratory epithelium and underlying connective tissue) lines the conducting portion of the respiratory tract.

- 6. The respiratory epithelium changes in structure along the respiratory tract. It is supported by the **lamina propria**, a layer of areolar tissue. (*Figure 23–2*)
- 7. Contamination of the respiratory system is prevented by the mucus and cilia of the **respiratory defense system**. (*Figure 23–2*)
- 23-2 Located outside the thoracic cavity, the upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx p. 835
- 8. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. (*Figures* 23–1, 23–3)
- 9. Air normally enters the respiratory system through the **external nares**, which open into the *nasal cavity*. The **nasal vestibule** (entryway) is guarded by hairs that screen out large particles. (*Figure 23–3*)
- **10.** Incoming air flows through the **superior**, **middle**, and **inferior meatuses** (narrow grooves) and bounces off the conchal surfaces. (*Figure 23–3*)
- 11. The **hard palate** separates the oral and nasal cavities. The **soft palate** separates the superior nasopharynx from the rest of the pharynx. The connections between the nasal cavity and nasopharynx are the **internal nares**.
- **12.** The nasal mucosa traps particles, warms and humidifies incoming air, and cools and dehumidifies outgoing air.
- **13.** The **pharynx**, or throat, is a chamber shared by the digestive and respiratory systems. The **nasopharynx** is the superior part of the pharynx. The **oropharynx** is continuous with the oral cavity. The **laryngopharynx** includes the narrow zone between the hyoid bone and the entrance to the esophagus. (*Figure 23–3*)

23-3 Composed of cartilages, ligaments, and muscles, the larynx produces sound p. 837

- Inhaled air passes through the glottis en route to the lungs; the larynx surrounds and protects the glottis, or vocal apparatus. (*Figure 23–4*)
- **15.** The cylindrical larynx is composed of three large cartilages (the **thyroid cartilage**, **cricoid cartilage**, and **epiglottis**) and three smaller pairs of cartilages (the **arytenoid**, **corniculate**, and **cuneiform cartilages**). The epiglottis projects into the pharynx. (*Figures 23–4, 23–5*)

- **16.** A pair of inelastic **vestibular folds** surround the glottis. The **glottis** includes the elastic **vocal folds** and the space between them, the *rima glottidis*. (*Figure 23–5*)
- 17. Air passing through the open glottis vibrates its vocal folds, producing sound. The pitch of the sound depends on the diameter, length, and tension of the vocal folds.
- **18.** The muscles of the neck and pharynx position and stabilize the larynx. The smaller intrinsic muscles regulate tension in the vocal folds or open and close the glottis. During swallowing, both sets of muscles help prevent particles from entering the glottis.

23-4 The trachea and primary bronchi convey air to and from the lungs p. 839

- **19.** The **trachea** extends from the sixth cervical vertebra to the fifth thoracic vertebra. The **submucosa** contains C-shaped **tracheal cartilages**, which stiffen the tracheal walls and protect the airway. The posterior tracheal wall can distort to permit large masses of food to pass through the esophagus. (*Figure 23–6*)
- 20. The trachea branches within the mediastinum to form the **right** and **left primary bronchi**. Each bronchus enters a lung at the **hilum** (a groove). The **root of the lung** is a connective tissue mass that includes the bronchus, pulmonary vessels, and nerves. (*Figures 23–6, 23–7*)
- 23-5 Enclosed by pleural cavities, the lungs are paired organs containing alveoli, which permit gaseous exchange p. 841
- **21.** The **lobes** of the lungs are separated by fissures. The right lung has three lobes, the left lung two. (*Figure 23–7*)
- **22.** The anterior and lateral surfaces of the lungs follow the inner contours of the rib cage. The concavity of the medial surface of the left lung is the **cardiac notch**, which conforms to the shape of the pericardium. (*Figures 23–7, 23–8*)
- **23.** The primary bronchi and their branches form the **bronchial tree**. The **secondary** and **tertiary bronchi** are branches within the lungs. As they branch, the amount of cartilage in their walls decreases and the amount of smooth muscle increases. (*Figure 23–9*)
- 24. Each tertiary bronchus supplies air to a single **bronchopulmonary segment**. (*Figure 23–9*)
- **25. Bronchioles** within the bronchopulmonary segments ultimately branch into **terminal bronchioles**. Each terminal bronchiole delivers air to a single **pulmonary lobule** in which the terminal bronchiole branches into **respiratory bronchioles**. The connective tissues of the root of the lung extend into the parenchyma of the lung as a series of *trabeculae* (partitions) that branch to form **interlobular septa**, which divide the lung into lobules. (*Figure 23–9*)
- **26.** The respiratory bronchioles open into **alveolar ducts**, where many alveoli are interconnected. The respiratory exchange surfaces are extensively connected to the circulatory system by the capillaries of the pulmonary circuit. (*Figure 23–9*)
- 27. The **respiratory membrane** consists of a simple squamous epithelium, the endothelial cell lining an adjacent capillary, and their fused basement membranes. **Type II pneumocytes** (type II alveolar cells) scattered in the respiratory membrane produce **surfactant** that reduces surface tension and keeps the alveoli from collapsing. **Alveolar macrophages** patrol the epithelium and engulf foreign particles. (*Figure 23–10*)
- **28.** The conducting portions of the respiratory tract receive blood from the external carotid arteries, the thyrocervical trunks, and the bronchial arteries. Venous blood flows into the pulmonary

veins, bypassing the rest of the systemic circuit and diluting the oxygenated blood leaving the alveoli.

29. Each lung is surrounded by a single **pleural cavity** lined by a **pleura** (serous membrane). The two types of pleurae are the **parietal pleura**, covering the inner surface of the thoracic wall, and the **visceral pleura**, covering the lungs.

23-6 External respiration and internal respiration allow gaseous exchange within the body p. 847

- 30. Respiratory physiology focuses on a series of integrated processes. External respiration is the exchange of oxygen and carbon dioxide between interstitial fluid and the external environment and includes pulmonary ventilation (breathing). Internal respiration is the exchange of oxygen and carbon dioxide between interstitial fluid and cells. If the oxygen content declines, the affected tissues suffer from hypoxia; if the oxygen supply is completely shut off, anoxia and tissue death result. (*Figure 23–11*)
- 23-7 Pulmonary ventilation—the exchange of air between the atmosphere and the lungs—involves pressure changes, muscle movement, and respiratory rates and volumes p. 848
- **31. Pulmonary ventilation** is the physical movement of air into and out of the respiratory tract.
- **32.** As pressure on a gas decreases, its volume expands; as pressure increases, gas volume contracts. This inverse relationship is **Boyle's law**. (*Figure 23–12; Table 23–1*)
- **33.** Movement of the diaphragm and ribs changes lung volume.
- 34. The relationship between intrapulmonary pressure (the pressure inside the respiratory tract) and atmospheric pressure (atm) determines the direction of airflow. Intrapleural pressure is the pressure in the potential space between the parietal and visceral pleurae. (*Figures 23–13, 23–14*)
- **35.** A **respiratory cycle** is a single cycle of inhalation and exhalation. The amount of air moved in one respiratory cycle is the **tidal volume**. A **spirometer** is an instrument used to measure the capacity of the lungs. (*Figure 23–14*)
- 36. The diaphragm and the external and internal intercostal muscles are involved in normal quiet breathing, or eupnea. Accessory muscles become active during the active inspiratory and expiratory movements of forced breathing, or hyperpnea. (Spotlight Figure 23–15)
- **37. Alveolar ventilation** is the amount of air reaching the alveoli each minute. The **vital capacity** includes the **tidal volume** plus the **expiratory** and **inspiratory reserve volumes**. The air left in the lungs at the end of maximum exhalation is the **residual volume**. (*Figure 23–16*)

23-8 Gas exchange depends on the partial pressures of gases and the diffusion of molecules p. 856

- **38.** In a mixed gas, the individual gases exert a pressure proportional to their abundance in the mixture (**Dalton's law**). The pressure contributed by a single gas is its **partial pressure**. (*Table 23–2*)
- **39.** The amount of a gas in solution is directly proportional to the partial pressure of that gas (**Henry's law**). (*Figure 23–17*)
- **40.** Alveolar air and atmospheric air differ in composition. Gas exchange across the respiratory membrane is efficient due to differences in partial pressures, the short diffusion distance, lipid-soluble gases, the large surface area of all the alveoli combined, and the coordination of blood flow and airflow. (*Figure 23–18*)

- 23-9 Most oxygen is transported bound to hemoglobin; and carbon dioxide is transported in three ways: as carbonic acid, bound to hemoglobin, or dissolved in plasma p. 860
- 41. Blood entering peripheral capillaries delivers oxygen and absorbs carbon dioxide. The transport of oxygen and carbon dioxide in blood involves reactions that are completely reversible.
- **42.** Oxygen is carried mainly by RBCs, reversibly bound to hemoglobin. At alveolar $P_{O_{2'}}$ hemoglobin is almost fully saturated; at the P_{O_2} of peripheral tissues, it releases oxygen but still retains a substantial oxygen reserve. The effect of pH on the hemoglobin saturation curve is called the **Bohr effect**. When low plasma P_{O_2} continues for extended periods, red blood cells generate more **2,3-bisphosphoglycerate (BPG)**, which reduces hemoglobin's affinity for oxygen. (*Figures 23–19, 23–20*)
- **43. Fetal hemoglobin** has a stronger affinity for oxygen than does adult hemoglobin, aiding the removal of oxygen from maternal blood. (*Figure 23–21*)
- 44. Aerobic metabolism in peripheral tissues generates CO₂. About 7 percent of the CO₂ transported in blood is dissolved in the plasma, 23 percent is bound as **carbaminohemoglobin**, and 70 percent is converted to carbonic acid, which dissociates into H⁺ and HCO₃⁻. (*Figure 23–22*)
- **45.** Driven by differences in partial pressure, oxygen enters the blood at the lungs and leaves it in peripheral tissues; similar forces drive carbon dioxide into the blood at the tissues and into the alveoli at the lungs. (*Figure 23–23*)
- 23-10 Neurons in the medulla oblongata and pons, along with respiratory reflexes, control respiration p. 864
- **46.** Normally, the cellular rates of gas absorption and generation are matched by the capillary rates of delivery and removal and are identical to the rates of oxygen absorption and carbon dioxide removal at the lungs. When these rates are unbalanced, homeostatic mechanisms restore equilibrium.

- **47.** Local factors regulate alveolar blood flow (*lung perfusion*) and airflow (*alveolar ventilation*). Alveolar capillaries constrict under conditions of low oxygen, and bronchioles dilate under conditions of high carbon dioxide.
- 48. The **respiratory centers** include three pairs of nuclei in the reticular formation of the pons and medulla oblongata. The *respiratory rhythmicity centers* set the pace for respiration; the **apneustic centers** cause strong, sustained inspiratory movements; and the **pneumotaxic centers** inhibit the apneustic centers and promote exhalation. (*Figure 23–24, Spotlight Figure 23–25*)
- **49.** Stimulation of the chemoreceptor reflexes is based on the level of carbon dioxide in the blood and CSF. (*Spotlight Figure 23–25, Figure 23–26*)
- **50.** The **inflation reflex** prevents overexpansion of the lungs during forced breathing. The **deflation reflex** stimulates inhalation when the lungs are collapsing.
- **51.** Conscious and unconscious thought processes can affect respiration by affecting the respiratory centers.
- **52.** Before delivery, the fetal lungs are filled with body fluids and are collapsed. At the first breath, the lungs inflate and do not collapse completely thereafter.
- 23-11 Respiratory performance declines with age p. 873
- **53.** The respiratory system is generally less efficient in the elderly because (1) elastic tissue deteriorates, lowering compliance and the vital capacity of the lungs; (2) movements of the chest are restricted by arthritic changes and decreased flexibility of costal cartilages; and (3) some degree of emphysema is generally present. (*Figure 23–27*)

23-12 The respiratory system provides oxygen to, and eliminates carbon dioxide from, other organ systems p. 873

54. The respiratory system has extensive anatomical and physiological connections to the cardiovascular system. (*Figure 23–28*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- 1. Surfactant (a) protects the surface of the lungs, (b) phagocytizes small particulates, (c) replaces mucus in the alveoli, (d) helps prevent the alveoli from collapsing, (e) is not found in healthy lung tissue.
- The hard palate separates the (a) nasal cavity from the larynx, (b) left and right sides of the nasal cavity, (c) nasal cavity and the oral cavity, (d) external nares from the internal nares, (e) soft palate from the nasal cavity.
- 3. Air moves into the lungs because (a) the gas pressure in the lungs is less than atmospheric pressure, (b) the volume of the lungs decreases with inspiration, (c) the thorax is muscular, (d) contraction of the diaphragm decreases the volume of the thoracic cavity, (e) the respiratory control center initiates active expansion of the thorax.
- 4. The glottis closes partway through an exhalation. The abdominal and internal intercostal muscles then contract suddenly, creating pressure that blasts the air out of the respiratory passages. This describes a
 (a) sneeze, (b) hiccough, (c) cough, (d) laryngeal spasm, (e) gag.
- When the diaphragm and external intercostal muscles contract,
 (a) exhalation occurs, (b) intrapulmonary pressure increases,
 (c) intrapleural pressure decreases, (d) the volume of the lungs decreases, (e) the size of the thoracic cavity increases.

See the blue Answers tab at the back of the book.

6. Identify the structures of the respiratory system in the figure at left:

(a)	
(b)	
(c)	
(d)	
(e)	
(f)	
(g)	
(h)	
(i)	

3

- 8. Distinguish the structures of the upper respiratory system from those of the lower respiratory system.
- 9. Name the three regions of the pharynx. Where is each region located?
- **10.** List the cartilages of the larynx. What are the functions of each?
- 11. What three integrated steps are involved in external respiration?
- **12.** What important physiological differences exist between fetal hemoglobin and maternal hemoglobin?
- 13. By what three ways is carbon dioxide transported in the bloodstream?

LEVEL 2 Reviewing Concepts

- 14. Which of the following does *not* occur in internal respiration?(a) Oxygen diffuses from the blood to the interstitial spaces,(b) Carbon dioxide diffuses from the interstitial spaces to the blood, (c) Hemoglobin binds more oxygen, (d) Bicarbonate ions are formed in red blood cells, (e) Chloride ions diffuse into red blood cells as bicarbonate ions diffuse out.
- 15. Gas exchange at the respiratory membrane is efficient because(a) the differences in partial pressure are substantial, (b) the gases are lipid soluble, (c) the total surface area is large, (d) of a, b, and c.
- 16. For any partial pressure of oxygen, if the concentration of 2,3-bisphosphoglycerate (BPG) increases, (a) the amount of oxygen released by hemoglobin will decrease, (b) the oxygen levels in hemoglobin will be unaffected, (c) the amount of oxygen released by hemoglobin will increase, (d) the amount of carbon dioxide carried by hemoglobin will increase.
- 17. An increase in the partial pressure of carbon dioxide in arterial blood causes chemoreceptors to stimulate the respiratory centers, resulting in (a) a decreased respiratory rate, (b) an increased respiratory rate, (c) hypocapnia, (d) hypercapnia.
- **18.** Why is breathing through the nasal cavity more desirable than breathing through the mouth?

- **19.** How would you justify the statement "The bronchioles are to the respiratory system what the arterioles are to the cardiovascular system"?
- **20.** How are type II pneumocytes involved with keeping the alveoli from collapsing?
- **21.** How does pulmonary ventilation differ from alveolar ventilation, and what is the function of each type of ventilation?
- 22. What is the significance of (a) Boyle's law, (b) Dalton's law, and (c) Henry's law to the process of respiration?
- **23.** What happens to the process of respiration when a person is sneezing or coughing?
- 24. What are the differences between pulmonary volumes and respiratory capacities? How are pulmonary volumes and respiratory capacities determined?
- 25. What is the functional difference between the dorsal respiratory group (DRG) and the ventral respiratory group (VRG) of the medulla oblongata?

LEVEL 3 Critical Thinking and Clinical Applications

- **26.** Billy's normal alveolar ventilation rate (AVR) during mild exercise is 6.0 L/min. While at the beach on a warm summer day, he goes snorkeling. The snorkel has a volume of 50 mL. Assuming that the water is not too cold and that snorkeling is mild exercise for Billy, what would his respiratory rate have to be for him to maintain an AVR of 6.0 L/min while snorkeling? (Assume a constant tidal volume of 500 mL and an anatomic dead space of 150 mL.)
- 27. Mr. B. has had chronic advanced emphysema for 15 years. While hospitalized with a respiratory infection, he goes into respiratory distress. Without thinking, his nurse immediately administers pure oxygen, which causes Mr. B. to stop breathing. Why?
- **28.** Cary hyperventilates for several minutes before diving into a swimming pool. After he enters and begins swimming underwater, he blacks out and almost drowns. What caused this to happen?
- **29.** Why do individuals who are anemic generally not exhibit an increase in respiratory rate or tidal volume, even though their blood is not carrying enough oxygen?
- **30.** Doris has an obstruction of her right primary bronchus. As a result, how would you expect the oxygen–hemoglobin saturation curve for her right lung to compare with that for her left?

CLINICAL CASE Wrap-Up

How Long Should a Cough Last?

Andrea, like many people, thinks a typical cough should only last about a week. In reality, however, coughs caused by colds and flu tend to last about 18 days. Andrea thinks she got over her previous cough due to antibiotics, but antibiotics only work against bacteria. If her previous cough was caused by a virus, her body likely resolved the cough on its own during the normal course of the illness. It's worth noting that viruses cause 90 percent of acute cough illnesses.

Fever is the body's innate immunity at work. Excessive mucus production, leading to a productive cough and runny nose, indicates that the immune system is working. The excessive mucus produced by the respiratory mucosa builds up and irritates the trachea and bronchi. This causes parasympathetic reflexive coughing. The explosive ejection of air and mucus against a suddenly open glottis helps clear away cold viruses. It also helps spread these viruses to new hosts.

Andrea's doctor tells her to drink plenty of fluids, rest, and use a vaporizer and saline nasal spray. He will not

prescribe antibiotics because they are ineffective against cold viruses. He also advises Andrea to wear a mask to avoid spreading this virus to her lab partners for the duration of her cough.

- 1. Do you think Andrea should take medicine to suppress her acute, productive cough?
- **2.** What anatomical structures of Andrea's respiratory system are infected by the rhinovirus?

See the blue Answers tab at the back of the book.

23

The Digestive System

Learning Outcomes

24

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **24-1** Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion.
- **24-2** Discuss the anatomy of the oral cavity, and list the functions of its major structures and regions.
- **24-3** Describe the structure and functions of the pharynx.
- **24-4** Describe the structure and functions of the esophagus.
- **24-5** Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.
- **24-6** Describe the anatomy and histology of the small intestine, explain the functions and regulation of intestinal secretions, and describe the structure, functions, and regulation of the accessory digestive organs.
- **24-7** Describe the gross and histological structure of the large intestine, including its regional specializations and role in nutrient absorption.
- **24-8** List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients.
- **24-9** Summarize the effects of aging on the digestive system.
- **24-10** Give examples of interactions between the digestive system and other organ systems studied so far.

CLINICAL CASE

An Unusual Transplant

Mirasol has been in the hospital and on antibiotics for a stubborn case of pneumonia for over

a week. She desperately misses her grandchildren, and is feeling worse than ever. Her cough has resolved, but she has had watery diarrhea 10 times today. The last few times, there was blood in the stool. She has lost her appetite and feels crampy abdominal pain. She is dehydrated and unable to drink enough liquids to keep up with her fluid loss from diarrhea. She also has a fever and has lost weight.

Her doctor enters the room with results of recent tests performed on her stool. "I'm afraid the normal, helpful bacteria that live in your colon have been killed off by the antibiotics used to cure your pneumonia. Now, harmful bacteria have taken over and are causing your bloody diarrhea," reports the doctor. "Your colon is overgrown with *Clostridium difficile* bacteria. These bacteria are producing toxins that are causing your colitis (inflammation of the colon). The usual treatment for this condition is more antibiotics."

"Doctor," cries Mirasol, "I don't think I can take any more antibiotics. I feel worse now than when I arrived."

"Well, I have an idea that may work," the doctor replies. "A transplant, from one of your healthy, adult grandchildren. It's a little unusual, however. You need to keep an open mind." What kind of transplant can possibly help Mirasol? To find out, turn to the Clinical Case Wrap-Up on p. 934.

An Introduction to the Digestive System

The digestive system may not have the visibility of the integumentary system or the glamour of the reproductive system, but it is certainly just as important. All living organisms must get nutrients from their environment to sustain life. These nutrients are used as raw materials for synthesizing essential compounds (anabolism). They are also broken down to provide the energy that cells need to continue functioning (catabolism). ⁵ pp. 36–38, 317–318 Catabolic reactions require two essential ingredients: oxygen and organic molecules (such as carbohydrates, fats, or proteins) that can be broken down by enzymes inside cells. Obtaining oxygen and organic molecules can be straightforward for a single-celled organism like an amoeba. The process is much more complicated for animals as large and complex as humans. Along with increasing size and complexity come a division of labor within the body and the need to coordinate organ system activities.

In this chapter we discuss the structure and function of the digestive tract and several digestive glands, notably the liver and pancreas. We look at the process of digestion and how it breaks down large and complex organic molecules into smaller fragments that can be absorbed by the digestive epithelium. We also see how a few organic wastes are removed from the body.

24-1 The digestive system, consisting of the digestive tract and accessory organs, has overlapping food utilization functions

Learning Outcome Identify the organs of the digestive system, list their major functions, describe the histology of the digestive tract, and outline the mechanisms that regulate digestion.

In our bodies, the respiratory system works with the cardiovascular system to supply the oxygen needed for catabolism. The *digestive system*, working with the cardiovascular and lymphatic systems, provides the needed organic molecules. In effect, the digestive system supplies both the fuel that keeps all the body's cells running and the building blocks needed for cell growth and repair.

The **digestive system** consists of a muscular tube, the **digestive tract**, also called the *gastrointestinal (GI) tract* or *alimentary canal*, and various **accessory organs**. The *oral cavity* (mouth), *pharynx* (throat), *esophagus, stomach, small intestine*, and *large intestine* make up the digestive tract. Accessory digestive organs include the teeth, tongue, and various *glandular organs*, such as the salivary glands, liver, gallbladder, and pancreas. The glandular organs secrete their products into ducts that empty into the digestive tract. These secretions contain water, enzymes, buffers, and other substances. Food enters the digestive tract and passes along its length. Along the way, the secretions of the glandular

Figure 24–1 The Components of the Digestive System.

organs prepare organic and inorganic nutrients for absorption across the epithelium of the digestive tract.

Figure 24–1 shows the major parts of the digestive system. The digestive tract begins at the oral cavity. It continues through the pharynx, esophagus, stomach, small intestine, and large intestine, which opens to the exterior at the anus. These structures have overlapping functions, but each has certain areas of specialization and shows distinctive histological characteristics.

Functions of the Digestive System

We can regard digestive functions as a series of six integrated steps:

- 1. **Ingestion** takes place when materials enter the oral cavity of the digestive tract. Ingestion is an active process involving conscious choice and decision making.
- 2. **Mechanical processing** is crushing and shearing that makes materials easier to propel along the digestive tract.

It also increases their surface area, making them more susceptible to attack by enzymes. Mechanical processing may or may not be required before ingestion. You can swallow liquids immediately, but you must chew most solids first. Tearing and mashing with the teeth, followed by squashing and compacting by the tongue, are examples of preliminary mechanical processing. Swirling, mixing, and churning motions of the stomach and intestines provide mechanical processing after ingestion.

3. Digestion refers to the chemical breakdown of food into small organic fragments suitable for absorption by the digestive epithelium. Simple molecules in food, such as glucose, can be absorbed intact. However, epithelial cells have no way to absorb molecules with the size and complexity of proteins, polysaccharides, or triglycerides. Digestive enzymes must first disassemble these molecules. For example, the starches in a potato are of no nutritional value until enzymes have broken them down to simple sugars

that the digestive epithelium can absorb for distribution to body cells.

- 4. **Secretion** is the release of water, acids, enzymes, buffers, and salts by the epithelium of the digestive tract and by glandular organs.
- 5. **Absorption** is the movement of organic molecules, electrolytes (inorganic ions), vitamins, and water across the digestive epithelium and into the interstitial fluid of the digestive tract.
- 6. Excretion is the removal of wastes from the body. The digestive tract and glandular organs discharge wastes in secretions that enter the lumen of the tract. Most of these wastes mix with the indigestible residue of the digestive process and then leave the body. The process called **defecation** (def-e-KĀ-shun) ejects materials from the digestive tract, eliminating them as matter called **feces**.

The lining of the digestive tract also plays a protective role. It safeguards surrounding tissues against (1) the corrosive effects of digestive acids and enzymes; (2) mechanical stresses, such as abrasion; and (3) bacteria that either are swallowed with food or live in the digestive tract. The digestive epithelium and its secretions provide a nonspecific defense against these bacteria. When bacteria reach the underlying layer of areolar tissue, the *lamina propria*, macrophages and other cells of the immune system attack them.

We explore specific functions in more detail as we consider the individual regions and components of the system. First, however, let's look at several structural and functional characteristics of the system as a whole.

The Digestive Organs and the Peritoneum

The abdominopelvic cavity contains the *peritoneal cavity*, which is lined by a serous membrane. This membrane consists of a superficial mesothelium covering a layer of areolar tissue. > pp. 22, 137 We divide this serous membrane into two parts. The serosa or *visceral peritoneum* covers organs that project into the peritoneal cavity. The *parietal peritoneum* lines the inner surfaces of the body wall.

The serous membrane lining the peritoneal cavity continuously produces peritoneal fluid, which lubricates the surfaces. Because a thin layer of peritoneal fluid separates them, the parietal and visceral surfaces can slide without friction and resulting irritation. The membrane secretes and reabsorbs about 7 liters (7.4 quarts) of fluid each day, but the volume within the peritoneal cavity at any one time is very small. Liver disease, kidney disease, and heart failure can increase the rate at which fluids move into the peritoneal cavity. The buildup of fluid creates a characteristic abdominal swelling called **ascites** (a-SĪ-tēz). This fluid can distort internal organs and cause symptoms such as heartburn, indigestion, and lower back pain.

Mesenteries

Portions of the digestive tract are suspended within the peritoneal cavity by sheets of serous membrane that connect the parietal peritoneum with the visceral peritoneum. These **mesenteries** (MEZ-en-ter-ēz) are double sheets of peritoneal membrane. The areolar tissue between the mesothelial surfaces provides a route to and from the digestive tract for blood vessels, nerves, and lymphatic vessels. Mesenteries stabilize the positions of the attached organs. The mesenteries also prevent the intestines from becoming entangled during digestive movements or sudden changes in body position.

During embryonic development, the digestive tract and accessory organs are suspended within the peritoneal cavity by *dorsal* and *ventral mesenteries* (Figure 24–2a). The ventral mesentery later disappears along most of the digestive tract. It persists in adults in only two places: on the ventral surface of the stomach, between the stomach and the liver (the *lesser omentum*) (Figure 24–2b,d); and between the liver and the anterior abdominal wall (the *falciform ligament*) (Figure 24–2c,d). The **lesser omentum** (ō-MEN-tum; *omentum*, fat skin) stabilizes the position of the stomach and provides an access route for blood vessels and other structures entering or leaving the liver. The **falciform** (FAL-si-form; *falx*, sickle + *forma*, form) **ligament** helps stabilize the position of the liver relative to the diaphragm and abdominal wall. ATLAS: Embryology Summary 19: The Development of the Digestive System

As the digestive tract elongates, it twists and turns within the crowded peritoneal cavity. The dorsal mesentery of the stomach becomes greatly enlarged and forms an enormous pouch that extends inferiorly between the body wall and the anterior surface of the small intestine. This pouch is the **greater omentum** (Figure 24–2b,d). It hangs like an apron from the lateral and inferior borders of the stomach. Adipose tissue in the greater omentum conforms to the shapes of the surrounding

Clinical Note

Peritonitis An inflammation of the peritoneal membrane (peritoneum) is called **peritonitis** (per-i-tō-NĪ-tis). This painful condition interferes with the normal functions of the affected organs. Physical damage, chemical irritation, and bacterial invasion of the peritoneum can lead to severe cases of peritonitis. Such cases can even be fatal. In untreated appendicitis, the appendix may rupture and release bacteria into the peritoneal cavity. This event may cause peritonitis. Peritonitis can also be a complication of any surgery that opens the peritoneal cavity. There is also danger of peritonitis in any disease or injury that perforates the stomach or intestines.

Figure 24–2 Mesenteries.

a During embryonic development, the digestive tube is initially suspended by dorsal and ventral mesenteries. In adults, the ventral mesentery is lost, except where it connects the stomach to the liver (at the lesser omentum) and the liver to the anterior body wall and diaphragm (at the falciform ligament).

A diagrammatic view of the organization of mesenteries in an adult. As the digestive tract enlarges, mesenteries associated with the proximal portion of the small intestine, the pancreas, and the ascending and descending portions of the colon fuse to the body wall.

omentum

An anterior view of the empty peritoneal cavity, showing the attachment of mesenteries to the posterior body wall. Some visceral organs that were originally suspended within the peritoneal cavity are now retroperitoneal due to fusion of the serosa with the parietal peritoneum. d A sagittal section showing the mesenteries of an adult. Notice that the pancreas, duodenum, and rectum are retroperitoneal.

organs, providing padding and protection across the anterior and lateral surfaces of the abdomen. When an individual gains weight, this adipose tissue contributes to the characteristic "beer belly." The lipids in the adipose tissue are an important energy reserve. The greater omentum also insulates to reduce heat loss across the anterior abdominal wall.

All but the first 25 cm (10 in.) of the small intestine is suspended by the **mesentery proper**, a thick mesenterial sheet. It provides stability, but permits some independent movement. The mesentery associated with the initial portion of the small intestine (the *duodenum*) and the pancreas fuses with the posterior abdominal wall and locks those structures in place. Only their anterior surfaces remain covered by peritoneum. We describe these organs as **retroperitoneal** (*retro*, behind) because their mass lies posterior to, rather than surrounded by, the peritoneal cavity.

A **mesocolon** is a mesentery associated with a portion of the large intestine. During normal development, the mesocolon of the *ascending colon*, the *descending colon*, and the *rectum* of the large intestine fuse to the posterior body wall. These regions become locked in place. Thereafter, these organs are retroperitoneal. The visceral peritoneum covers only their anterior surfaces and portions of their lateral surfaces (**Figure 24–2b,c,d**). The **transverse mesocolon**, which supports the transverse colon, and the **sigmoid mesocolon**, which supports the sigmoid colon, are all that remain of the original embryonic mesocolon.

Histology of the Digestive Tract

The four major layers of the digestive tract are (1) the *mucosa*, (2) the *submucosa*, (3) the *muscularis externa*, and (4) the *serosa*. The structure of these layers varies by region. Figure 24–3 is a composite view. It most closely resembles the small intestine, the longest segment of the digestive tract.

The Mucosa

The inner lining, or **mucosa**, of the digestive tract is a *mucous membrane*. It consists of an epithelium, moistened by glandular secretions, and a *lamina propria* of areolar tissue.

The Digestive Epithelium. The mucosal epithelium is either simple or stratified, depending on its location and the stresses placed on it. Mechanical stresses are most severe in the oral cavity, pharynx, and esophagus. These structures are lined by a stratified squamous epithelium. In contrast, the stomach, the small intestine, and almost the entire length of the large intestine (where absorption occurs) have a simple columnar epithelium that contains mucous cells. Scattered among the columnar cells are **enteroendocrine cells**. They secrete hormones that coordinate the activities of the digestive tract and the accessory glands.

The lining of the digestive tract appears as longitudinal folds, which disappear as the tract fills. The lining also

Figure 24–3 The Structure of the Digestive Tract. A diagrammatic view of a representative portion of the digestive tract. The features illustrated are typical of those of the small intestine.

Clinical Note

Epithelial Renewal and Repair The life span of a typical epithelial cell varies from two to three days in the esophagus to six days in the large intestine. The divisions of epithelial stem cells continuously renew the lining of the entire digestive tract. These divisions normally keep pace with the rates of cell destruction and loss at epithelial surfaces. This high rate of cell division explains why radiation and anticancer drugs that inhibit mitosis have drastic effects on the digestive tract. Lost epithelial cells are no longer replaced. The cumulative damage to the epithelial lining quickly leads to problems in absorbing nutrients. In addition, the exposure of the lamina propria to digestive enzymes can cause internal bleeding and other serious problems.

has permanent transverse folds called *circular folds*, or *plicae* (PLĪ-sē; folds) *circulares* (Figure 24–3). The folding increases the surface area available for absorption. The secretions of gland cells in the mucosa and submucosa—or in accessory glandular organs—are carried to the epithelial surfaces by ducts.

The Lamina Propria. The lamina propria is a layer of areolar tissue that also contains blood vessels, sensory nerve endings, lymphatic vessels, smooth muscle cells, and scattered lymphatic tissue. In the oral cavity, pharynx, esophagus, stomach, and *duodenum* (the proximal portion of the small intestine), the lamina propria also contains the secretory cells of mucous glands.

In most areas of the digestive tract, the lamina propria contains a narrow sheet of smooth muscle and elastic fibers. This sheet is called the **muscularis** (mus-kū-LAIR-is) **muco-sae** (mū-KŌ-sē) (Figure 24–3). The smooth muscle cells in the muscularis mucosae are arranged in two concentric layers. The inner layer encircles the lumen (the *circular muscle*), and the outer layer contains muscle cells arranged parallel to the long axis of the tract (the *longitudinal layer*). Contractions in these layers alter the shape of the lumen and move the epithelial pleats and folds.

The Submucosa

The **submucosa** is a layer of dense irregular connective tissue that binds the mucosa to the muscularis externa (Figure 24–3). The submucosa has numerous blood vessels and lymphatic vessels. In some regions it also contains exocrine glands that secrete buffers and enzymes into the lumen of the digestive tract.

Along its outer margin, the submucosa contains a network of intrinsic nerve fibers and scattered neurons. This network is

the **submucosal plexus**, or *Meissner's plexus*. It contains sensory neurons, parasympathetic ganglionic neurons, and sympathetic postganglionic fibers that innervate the mucosa and submucosa.

The Muscularis Externa

The submucosal plexus lies along the inner border of the **muscularis externa**, also called the **muscularis**. Smooth muscle cells dominate this region. Like the smooth muscle cells in the muscularis mucosae, those in the muscularis externa are arranged in an inner circular layer and an outer longitudinal layer. These layers play an essential role in mechanical processing and in moving materials along the digestive tract.

The movements of the digestive tract are coordinated primarily by the sensory neurons, interneurons, and motor neurons of the enteric nervous system (ENS). \bigcirc p. 536 The ENS is primarily innervated by the parasympathetic division of the ANS. Sympathetic postganglionic fibers also synapse here. Many of these fibers continue onward to innervate the mucosa and the **myenteric** (mī-en-TER-ik) **plexus** (*mys*, muscle + *enteron*, intestine), or *Auerbach's plexus*. This plexus is a network of parasympathetic ganglia, sensory neurons, interneurons, and sympathetic postganglionic fibers. It lies sandwiched between the circular and longitudinal muscle layers. In general, parasympathetic stimulation *increases* muscle tone and activity.

TIPS&TRICKS

Because the parasympathetic nervous system plays a dominant role in the digestive process, it is often referred to as the "rest and digest" division.

The Serosa

A serous membrane known as the **serosa** covers the muscularis externa along most portions of the digestive tract inside the peritoneal cavity (Figure 24–3).

There is no serosa covering the muscularis externa of the oral cavity, pharynx, esophagus, and rectum. Instead, a dense network of collagen fibers firmly attaches the digestive tract to adjacent structures. This fibrous sheath is called an *adventitia* (ad-ven-TISH-uh).

The Movement of Digestive Materials

The muscular layers of the digestive tract consist of *visceral smooth muscle tissue*. We introduced this type of smooth muscle in Chapter 10. \bigcirc p. 327 The smooth muscle along the digestive tract has rhythmic cycles of activity due to *pacesetter cells*. These

smooth muscle cells undergo spontaneous depolarization, triggering a wave of contraction that spreads throughout the entire muscular sheet. Pacesetter cells are located in the muscularis mucosae and muscularis externa, which surround the lumen of the digestive tract. The coordinated contractions of the muscularis externa play a vital role in moving materials along the tract, through *peristalsis*, and in mechanical processing, through *segmentation*.

Peristalsis

The muscularis externa propels materials from one portion of the digestive tract to another by contractions known as **peristalsis** (per-i-STAL-sis). Peristalsis consists of waves of muscular contractions that move a **bolus** (BŌ-lus), or soft rounded ball of digestive contents, along the length of the digestive tract (Figure 24–4). During a peristaltic movement, the circular muscles contract behind the bolus while circular muscles ahead of the bolus relax. Longitudinal muscles ahead of the bolus then contract, shortening adjacent segments. A wave of contraction in the circular muscles then forces the bolus forward.

TIPS&TRICKS

Squeezing toothpaste out of a tube is similar to peristalsis: Your squeezing hand (contracting circular muscles) forces toothpaste (the bolus) along and out of the tube (the digestive tract).

Segmentation

Most areas of the small intestine and some portions of the large intestine undergo cycles of contraction that churn and fragment the bolus, mixing the contents with intestinal secretions. This activity, called **segmentation**, does not follow a set pattern. For this reason, segmentation does not push materials along the tract in any one direction.

Control of Digestive Functions

Local factors interact with neural and hormonal mechanisms to regulate the activities of the digestive system (Figure 24–5, p. 888).

Local Factors

The initial regulation of digestive function occurs at the local level (1). Local environmental factors such as the pH, volume, or chemical composition of the intestinal contents can have a direct effect on digestive activity in that segment of the digestive tract. Some of these local factors have a direct effect on local digestive activities; for example, stretching of the intestinal wall can stimulate localized contractions of smooth muscles. In other cases, the local factors stimulate the release of chemicals.

Figure 24–4 Peristalsis. Peristalsis propels materials along the length of the digestive tract.

Prostaglandins, histamine, and other chemicals released into interstitial fluid may affect adjacent cells within a small segment of the tract. For example, the release of histamine in the lamina propria of the stomach stimulates the secretion of acid by cells in the adjacent epithelium.

Neural Mechanisms

Neural mechanisms control digestive tract movement (2). For example, sensory receptors in the walls of the digestive tract trigger peristaltic movements that are limited to a few centimeters. The motor neurons that control smooth muscle contraction and glandular secretion are located in the myenteric plexus. These neurons are usually considered parasympathetic, because some of them are innervated by parasympathetic preganglionic fibers. However, the plexus also contains sensory neurons, motor neurons, and interneurons responsible for local reflexes that operate entirely outside the control of the central nervous system. As we noted in Chapter 16, local reflexes are called *short reflexes*. $\supset p. 549$

In general, short reflexes control localized activities that involve small segments of the digestive tract. For example, they may coordinate local peristalsis and trigger secretion by digestive glands in response to the arrival of a bolus. Many neurons are involved. The enteric nervous system has about as many neurons as the spinal cord, and as many neurotransmitters as the brain. The specific functions and interactions of these neurotransmitters in the enteric nervous system are unknown.

Sensory information from receptors in the digestive tract is also distributed to the CNS. There it can trigger *long reflexes*, which involve interneurons and motor neurons in the CNS. **D** p. 549

Hormonal Mechanisms

Digestive hormones can enhance or diminish the sensitivity of the smooth muscle cells to neural commands (3). These hormones, produced by enteroendocrine cells in the digestive tract, travel through the bloodstream to reach their target organs.

CHECKPOINT

- 1. Identify the organs of the digestive system.
- 2. List and define the six primary functions of the digestive system.
- 3. What is the importance of the mesenteries?
- 4. Name the layers of the gastrointestinal tract beginning at the surface of the lumen.
- 5. Which is more efficient in propelling intestinal contents from one place to another: peristalsis or segmentation?
- 6. What effect would a drug that blocks parasympathetic stimulation of the digestive tract have on peristalsis?

- See the blue Answers tab at the back of the book.

24–2 The oral cavity contains the tongue, salivary glands, and teeth, each with specific functions

Learning Outcome Discuss the anatomy of the oral cavity, and list the functions of its major structures and regions.

Let's continue our exploration of the digestive tract by following the path of ingested food. We begin at the **oral cavity** (mouth), or **buccal** (BUK-ul) **cavity** (Figure 24–6). The functions of the oral cavity include (1) *sensory analysis* of food before swallowing; (2) *mechanical processing* through the actions of the teeth, tongue, and palatal surfaces; (3) *lubrication* by mixing with mucus and saliva; and (4) limited *digestion* of carbohydrates and lipids.

The oral cavity is lined by the **oral mucosa**, which has a stratified squamous epithelium. A layer of keratinized cells covers regions exposed to severe abrasion, such as the superior surface of the tongue and the opposing surface of the hard palate (part of the roof of the mouth). The epithelial lining of the cheeks, lips, and inferior surface of the tongue is relatively thin and nonkeratinized. Nutrients are not absorbed in the oral cavity, but the mucosa inferior to the tongue is thin enough and vascular enough to permit the rapid absorption of lipid-soluble drugs. *Nitroglycerin* may be administered by this route to treat acute angina pectoris. \bigcirc **p**. 699

The mucosae of the **cheeks**, or lateral walls of the oral cavity, are supported by pads of fat and the buccinator muscles. Anteriorly, the mucosa of each cheek is continuous with that of the lips, or **labia** (LĀ-bē-uh; singular, *labium*). The **vestibule** is the space between the cheeks (or lips) and the teeth. The **gingivae** (JIN-ji-vē), or *gums*, are ridges of oral mucosa that surround the base of each tooth on the alveolar processes of the maxillary bones and mandible. In most regions, the gingivae are firmly bound to the periostea of the underlying bones. The *frenulum of lower lip* is a fold of mucosa that extends from the gingiva to the lower lip, attaching the lip to the gum.

The hard and soft palates form the roof of the oral cavity. The tongue dominates its floor (Figure 24–6b). The floor of the mouth inferior to the tongue gets extra support from the

Figure 24–6 The Oral Cavity. ATLAS: Plates 11a; 19

geniohyoid and mylohyoid muscles. \bigcirc p. 349 The palatine processes of the maxillary bones and the horizontal plates of the palatine bones form the *hard palate*. A prominent central ridge, or *raphe* (RĀ-fee), extends along the midline of the hard palate. The mucosa lateral and anterior to the raphe is thick, with complex ridges. When your tongue compresses food against the hard palate, these ridges provide traction. The *soft palate* lies posterior to the hard palate. A thinner and more delicate mucosa covers the posterior margin of the hard palate and extends onto the soft palate.

The posterior margin of the soft palate supports the **uvula** $(\overline{U}$ -v \overline{u} -luh), a dangling process that helps prevent food from entering the pharynx too soon (**Figure 24–6a**). On either side of the uvula are two pairs of muscular *pharyngeal arches* (**Figure 24–6b**). The more anterior **palatoglossal** (pal-a-t \overline{o} -GLOS-al) **arch** extends between the soft palate and the base of the tongue. A curving line that connects the palatoglossal arches and uvula forms the boundaries of the **fauces** (FAW-s $\overline{e}z$), the arched opening between the soft palate and the base of the tongue. The fauces serve as the passageway between the oral cavity and the oropharynx. The more posterior **palatopharyn-geal** (pal-a-t \overline{o} -fa-RIN-j \overline{e} -al) **arch** extends from the soft palate to the pharyngeal wall. A palatine tonsil lies between the palato-glossal and palatopharyngeal arches on either side.

The Tongue

The **tongue** (Figure 24–6) manipulates food inside the mouth and occasionally brings in foods (such as ice cream on a cone). The primary functions of the tongue are (1) mechanical processing by compression, abrasion, and distortion; (2) manipulation to assist in chewing and to prepare food for swallowing; (3) sensory analysis by touch, temperature, and taste receptors; and (4) secretion of mucins and the enzyme *lingual lipase*.

We can divide the tongue into an anterior **body**, or *oral portion*, and a posterior **root**, or *pharyngeal portion*. The superior surface, or *dorsum*, of the body contains a forest of fine projections, the *lingual papillae*. \bigcirc **p**. 568 The thickened epithelium covering each papilla assists the tongue in moving materials. A V-shaped line of vallate papillae roughly marks the boundary between the body and the root of the tongue, which is located in the oropharynx (Figure 24–6a).

The epithelium covering the inferior surface of the tongue is thinner and more delicate than that of the dorsum. Along the inferior midline is the **lingual frenulum** (FREN-ū-lum; *frenum*, bridle), a thin fold of mucous membrane that connects the body of the tongue to the mucosa covering the floor of the oral cavity (**Figure 24–6a**). Ducts from two pairs of salivary glands open on either side of the lingual frenulum, which serves to prevent extreme movements of the tongue. However, an overly restrictive lingual frenulum hinders normal eating or speech. Properly diagnosed, this condition, called *ankyloglossia* (ang-ki-lō-GLOS-ē-uh), can be corrected surgically.

The tongue's epithelium is flushed by the secretions of small glands that extend into the underlying lamina propria. These secretions contain water, mucins, and the enzyme **lingual lipase**. This enzyme works over a broad pH range (3.0–6.0), enabling it to start lipid digestion immediately. Because lingual lipase tolerates an acid environment, it can continue to break down lipids—specifically, triglycerides—for a considerable time after the food reaches the stomach.

The tongue contains two groups of skeletal muscles. The large **extrinsic tongue muscles** perform all gross movements of the tongue. **D p**. 348 The smaller **intrinsic tongue muscles** change the shape of the tongue and assist the extrinsic muscles during precise movements, as in speech. Both intrinsic and extrinsic tongue muscles are under the control of the hypoglossal cranial nerves (N XII).

Salivary Glands

Three pairs of salivary glands secrete into the oral cavity (Figure 24–7a). Each pair has a distinctive cellular organization and produces *saliva*, a mixture of glandular secretions, with slightly different properties:

1. The large **parotid** (pa-ROT-id) **salivary glands** lie inferior to the zygomatic arch deep to the skin covering the lateral and posterior surface of the mandible. Each gland has an irregular shape. It extends from the mastoid process of the temporal bone across the outer surface of the masseter muscle. The parotid salivary glands produce a serous secretion containing large amounts of *salivary amylase*. This enzyme breaks down starches (complex carbohydrates). The

Ca Clinical Note

Mumps The *mumps virus* most often targets the salivary glands, especially the parotid salivary glands, but other organs can also be infected. Infection typically occurs at 5–9 years of age. The first exposure stimulates the production of antibodies and, in most cases, confers permanent immunity. In postadolescent males, the mumps virus can also infect the testes and cause sterility. Infection of the pancreas by the mumps virus can produce temporary or permanent diabetes. Other organ systems, including the central nervous system, are affected in severe cases. A mumps vaccine effectively confers active immunity. Widespread administration of that vaccine has almost eliminated mumps in the United States.

Figure 24–7 The Salivary Glands. ATLAS: Plates 3c,d; 18a,b

secretions of each parotid gland are drained by a **parotid duct**, which empties into the vestibule at the second upper molar.

- 2. The **sublingual** (sub-LING-gwal) **salivary glands** are covered by the mucous membrane of the floor of the mouth. These glands produce a mucous secretion that acts as a buffer and lubricant. Numerous **sublingual ducts** open along either side of the lingual frenulum.
- 3. The submandibular salivary glands lie along the inner surfaces of the mandible within a depression called the *mandibular groove*. Cells of the submandibular glands (Figure 24–7b) secrete a mixture of buffers, glycoproteins called *mucins*, and salivary amylase. The submandibular ducts open into the mouth on either side of the lingual frenulum immediately posterior to the teeth (Figure 24–6b).

Saliva

The salivary glands produce 1.0-1.5 liters of saliva each day. Saliva is 99.4 percent water. The remaining 0.6 percent includes electrolytes (principally Na⁺, Cl⁻, and HCO₃⁻), buffers, glycoproteins, antibodies, enzymes, and waste products. The glycoproteins, called **mucins**, give saliva its lubricating action. About 70 percent of saliva comes from the submandibular salivary glands. Another 25 percent comes from the parotid glands, and 5 percent from the sublingual salivary glands.

Saliva continuously flushes the oral surfaces, helping to keep them clean. Buffers in the saliva keep the pH of your mouth near 7.0. They prevent the buildup of acids produced by bacteria. In addition, saliva contains antibodies (IgA) and *lysozyme*. Both help control populations of oral bacteria. A reduction in or elimination of salivary secretions—caused by radiation, emotional distress, certain drugs, sleep, or other factors—triggers a bacterial population explosion. This proliferation rapidly leads to recurring infections and progressive erosion of the teeth and gums.

The saliva produced when you eat has a variety of functions, including the following:

- Lubricating the mouth.
- Moistening and lubricating food in the mouth.
- Dissolving chemicals that can stimulate the taste buds and provide sensory information about the food.
- Beginning the digestion of complex carbohydrates before the food is swallowed. The enzyme involved is **salivary amylase**, also known as *ptyalin* or *alpha-amylase*. Saliva also contains a small amount of lingual lipase secreted by the glands of the tongue. The digestive process begins in the oral cavity, but it is not completed there. No absorption of nutrients takes place across the lining of the oral cavity.

Control of Salivary Secretions

The autonomic nervous system normally controls salivary secretions. Each salivary gland has parasympathetic and sympathetic innervation. The parasympathetic outflow originates in the **salivatory nuclei** of the medulla oblongata and synapses in the submandibular and otic ganglia. \bigcirc pp. 497, 499

Any object in your mouth can trigger a salivary reflex. It stimulates receptors monitored by the trigeminal nerve (N V) or taste buds innervated by cranial nerve VII, IX, or X. Parasympathetic stimulation speeds up secretion by all the salivary glands. As a result, you produce large amounts of saliva. The role of sympathetic innervation is unclear. Evidence suggests that it provokes the secretion of small amounts of very thick saliva.

The salivatory nuclei are also influenced by other brain stem nuclei, as well as by the activities of higher centers. For example, chewing with an empty mouth, smelling food, or even thinking about food begins an increase in salivary secretion rates. That is why chewing gum keeps your mouth moist. Irritating stimuli in the esophagus, stomach, or intestines also speed up production of saliva, as does nausea. Increased saliva production in response to unpleasant stimuli helps reduce the stimulus by dilution, by rinsing, or by buffering strong acids or bases.

The Teeth

Tongue movements are important in passing food across the opposing surfaces, or *occlusal surfaces*, of the **teeth**. These surfaces carry out chewing, or **mastication** (mas-ti-KĀ-shun), of food. Mastication breaks down tough connective tissues in meat and the plant fibers in vegetables. It also helps saturate the food with salivary secretions and enzymes.

Figure 24–8 Teeth.

Crown

Neck

Figure 24–8a is a sectional view through an adult tooth. The bulk of each tooth consists of a mineralized matrix similar to that of bone. This material, called **dentin**, differs from bone in that it does not contain cells. Instead, cytoplasmic processes extend into the dentin from cells in the central **pulp cavity**, an interior chamber. The pulp cavity receives blood vessels and nerves through the **root canal**, a narrow tunnel located at the **root**, or base, of the tooth. Blood vessels and nerves enter the root canal through an opening called the **apical foramen** to supply the pulp cavity.

The root of each tooth sits in a bony cavity or socket called the *tooth socket* or an *alveolus*. Collagen fibers of the **periodontal ligament** extend from the dentin of the root to the alveolar bone, creating a strong articulation known as a gomphosis. **D p**. 265 A layer of **cementum** (se-MEN-tum) covers the dentin of the root. Cementum protects and firmly anchors the periodontal ligament. Cementum is histologically similar to bone and is less resistant to erosion than is dentin.

The **neck** of the tooth marks the boundary between the root and the **crown**, the exposed portion of the tooth that projects beyond the soft tissue of the gingiva. A shallow groove called the **gingival sulcus** surrounds the neck of each tooth. The mucosa of the gingival sulcus is very thin and is not tightly bound to the periosteum. The epithelium is bound to the tooth at the base of the sulcus. This epithelial attachment prevents bacterial access to the lamina propria of the gingiva and the relatively soft cementum of the root. When you brush and massage your gums, you stimulate the epithelial cells and strengthen the attachment. A condition called *gingivitis*, an inflammation of the gingivae caused by bacterial infection, can occur if the attachment breaks down.

A layer of **enamel** covers the dentin of the crown. Enamel, which contains calcium phosphate in a crystalline form, is the hardest biologically manufactured substance. Adequate amounts of calcium, phosphates, and vitamin D_3 during

Enamel

Dentin

Gingiva Gingival

sulcus

Pulp cavity

childhood are essential if the enamel coating is to be complete and resistant to decay.

Tooth decay generally results from the action of bacteria that live in your mouth. Bacteria adhering to the surfaces of the teeth produce a sticky matrix that traps food particles and creates deposits known as *dental plaque*. Over time, this organic material can become calcified, forming a hard layer of *tartar*, or *dental calculus*, which can be difficult to remove. Tartar deposits most commonly develop at or near the gingival sulcus, where brushing cannot remove the soft plaque deposits.

Types of Teeth

The alveolar processes of the maxillae and the mandible form the *maxillary* and *mandibular arcades*, or upper and lower dental arches, respectively. These arcades contain four types of teeth, each with specific functions (Figure 24–8b):

- 1. **Incisors** (in-SĪ-zerz) are blade-shaped teeth located at the front of the mouth. Incisors are useful for clipping or cutting, as when you nip off the tip of a carrot stick. These teeth have a single root.
- 2. The **cuspids** (KUS-pidz), or *canines*, are conical, with a sharp ridgeline and a pointed tip. Also known as the "eyeteeth," because they lie directly under the eye, the cuspids are used for tearing or slashing. You might weaken a tough piece of celery using the clipping action of the incisors and then take advantage of the shearing action of the cuspids. Cuspids have a single root.
- **3. Bicuspids** (bī-KUS-pidz), or **premolars**, have flattened crowns with prominent ridges. They crush, mash, and grind. Bicuspids have one or two roots.
- 4. **Molars** have very large, flattened crowns with prominent ridges adapted for crushing and grinding. You can usually shift a tough nut to your bicuspids and molars for successful crunching. Molars in the upper jaw typically have three roots while those in the lower jaw usually have two roots.

Dental Succession

Two sets of teeth form during development. The first to appear are the **deciduous teeth** (de-SID-ū-us; *deciduus*, falling off), the temporary teeth of the **primary dentition**. Deciduous teeth are also called *primary teeth*, *milk teeth*, or *baby teeth*. Most children have 20 deciduous teeth (**Figure 24–9a**). On each side of the upper or lower jaw, the primary dentition consists of two incisors, one cuspid, and a pair of deciduous molars. These teeth are later replaced by the **secondary dentition**, or *permanent dentition* of the larger adult jaws (**Figure 24–9b**). Three additional molars appear on each side of the upper and lower jaws as the person ages. These molars extend the rows of teeth posteriorly and bring the permanent tooth count to 32.

TIPS&TRICKS

Here's how to remember the timing of dental succession: The deciduous (primary) teeth are present during the primary grades, and the secondary (permanent) teeth are present during and after the secondary grades.

As replacement proceeds, the periodontal ligaments and roots of the primary teeth erode. The deciduous teeth either fall out or are pushed aside by the **eruption**, or emergence, of the secondary teeth (Figure 24–9c). The adult premolars take the place of the deciduous molars. The adult molars extend the tooth rows as the jaw enlarges.

The third molars, or *wisdom teeth*, may not erupt before age 21. Wisdom teeth may not erupt because they develop in inappropriate positions or because there is not enough space. Any teeth that develop in locations that do not allow them to erupt are called *impacted teeth*. Impacted wisdom teeth can be surgically removed to prevent the formation of abscesses.

Mastication

The *muscles of mastication* close your jaws and slide or rock your lower jaw from side to side. **D p**. **344** Chewing is not a simple process. It can involve any combination of mandibular elevation/depression, protraction/retraction, and medial/lateral movement. (Try classifying the movements involved the next time you eat.)

During mastication, you force food from the oral cavity to the vestibule and back, crossing and recrossing the **occlusal** (biting) **surfaces**. This movement results in part from the action of the muscles of mastication. Control would be impossible, however, without help from the muscles of the cheeks, lips, and tongue. Once you have shredded or torn the food to a satisfactory consistency and have moistened it with salivary secretions, your tongue compacts the debris into a moist, cohesive bolus that is fairly easy to swallow.

CHECKPOINT

- 7. Name the structures associated with the oral cavity.
- 8. Which type of epithelium lines the oral cavity?
- 9. The digestion of which nutrient would be affected by damage to the parotid salivary glands?
- 10. Which type of tooth is most useful for chopping off bits of rigid food?
- 11. Where are the fauces located?
- See the blue Answers tab at the back of the book.

24-3 The pharynx is a passageway between the oral cavity and esophagus

Learning Outcome Describe the structure and functions of the pharynx.

The **pharynx** (FAR-ingks), or throat, is an anatomical space that serves as a common passageway for solid food, liquids, and air. We described the epithelial lining and regions of the pharynx nasopharynx, oropharynx, and laryngopharynx—in Chapter 23. **⊃ p.** 837 Food normally passes through the oropharynx and laryngopharynx on its way to the esophagus. These regions have a stratified squamous epithelium similar to that of the oral cavity. The lamina propria contains scattered mucous glands and the lymphatic tissue of the pharyngeal, palatal, and lingual tonsils. Deep to the lamina propria lies a dense layer of elastic fibers, bound to the underlying skeletal muscles.

We described the specific pharyngeal muscles involved in swallowing in Chapter 11. \bigcirc p. 348

- The *pharyngeal constrictor muscles* push the bolus toward and into the esophagus.
- The *palatopharyngeus* and *stylopharyngeus muscles* elevate the larynx.
- The *palatal muscles* elevate the soft palate and adjacent portions of the pharyngeal wall.

These muscles work with muscles of the oral cavity and esophagus to start swallowing, which pushes the bolus along the esophagus and into the stomach.

CHECKPOINT

12. Describe the structure and function of the pharynx.

13. Identify the muscles associated with the pharynx.

See the blue Answers tab at the back of the book.

24-4 The esophagus is a muscular tube that transports solids and liquids from the pharynx to the stomach

Learning Outcome Describe the structure and functions of the esophagus.

The **esophagus** (Figure 24–10) is a hollow muscular tube that conveys solid food and liquids to the stomach. Its length is approximately 25 cm (10 in.) and its diameter is about 2 cm (0.80 in.) at its widest point.

The esophagus begins posterior to the cricoid cartilage, at the level of vertebra C_6 . It is narrowest at this point. The esophagus descends toward the thoracic cavity posterior to the trachea, continuing inferiorly along the posterior wall of the mediastinum. It then enters the abdominopelvic cavity through the **esophageal hiatus** (hī-Ā-tus), an opening in the diaphragm. The esophagus empties into the stomach anterior to vertebra T_7 .

The esophagus is innervated by parasympathetic and sympathetic fibers from the esophageal plexus. \bigcirc p. 548 Resting muscle tone in the circular muscle layer in the superior 3 cm (1.2 in.) of the esophagus normally prevents air from entering

the esophagus. A comparable zone at the inferior end of the esophagus normally remains in a state of active contraction. This state prevents the backflow (reflux) of materials from the stomach into the esophagus. Neither region has a well-defined sphincter muscle. Nevertheless, we often use the terms *upper esophageal sphincter* and *lower esophageal sphincter (cardiac sphincter)* to describe these regions, which are similar in function to other sphincters.

TIPS&TRICKS

Just as security gates control the passage of people by opening and closing, sphincters control the passage of material through them by dilating and constricting.

Histology of the Esophagus

The wall of the esophagus contains mucosal, submucosal, and muscularis layers comparable to those shown in Figure 24–3. Distinctive features of the esophageal wall include the following (Figure 24–10):

- The mucosa of the esophagus contains a nonkeratinized, stratified squamous epithelium similar to that of the pharynx and oral cavity.
- The mucosa and submucosa are packed into large folds that extend the length of the esophagus. These folds allow for expansion during the passage of a large bolus. Muscle tone in the walls keeps the lumen closed, except when you swallow.

Figure 24–10 The Esophagus.

- The muscularis mucosae consists of an irregular layer of smooth muscle.
- The submucosa contains scattered *esophageal glands*. They produce mucus that reduces friction between the bolus and the esophageal lining.
- The muscularis externa has the usual inner circular and outer longitudinal layers. However, in the superior third of the esophagus, these layers contain skeletal muscle fibers. The middle third contains a mixture of skeletal and smooth muscle tissue. Along the inferior third, only smooth muscle occurs.
- There is no serosa, but an adventitia of connective tissue outside the muscularis externa anchors the esophagus to the posterior body wall. Over the 1–2 cm (0.4–0.8 in.) between the diaphragm and stomach, the esophagus is retroperitoneal. Peritoneum covers the anterior and left lateral surfaces.

Swallowing

Swallowing, or **deglutition** (de-glu-TISH-un), is a complex process that can be initiated voluntarily but proceeds automatically once it begins. You take conscious control over swallowing when you eat or drink, but swallowing is also controlled at the subconscious level. The swallowing reflex begins when tactile receptors on the palatal arches and uvula are stimulated by the passage of the bolus. The information is relayed to the swallowing center of the medulla oblongata over the trigeminal (N V) and glossopharyngeal (N IX) cranial nerves. Motor commands from this center then signal the pharyngeal musculature, producing a coordinated and stereotyped pattern of muscle contraction. It takes less than a second for the pharyngeal muscles to propel the bolus into the esophagus. During this period, the respiratory centers are inhibited and breathing stops. Swallowing takes place at regular intervals as saliva collects at the back of the mouth. Each day you swallow approximately 2400 times.

24

We divide swallowing into buccal, pharyngeal, and esophageal phases, detailed in Figure 24–11.

Primary peristaltic waves are peristaltic movements coordinated by afferent and efferent fibers in the glossopharyngeal (N IX) and vagus (N X) nerves. For a typical bolus, the entire trip along the esophagus takes about 9 seconds. Liquids may make the journey in a few seconds, flowing ahead of the peristaltic contractions with the assistance of gravity.

A dry or poorly lubricated bolus travels much more slowly. A series of *secondary peristaltic waves* may be required to push it all the way to the stomach. Secondary peristaltic waves are local reflexes triggered by the stimulation of sensory receptors in the esophageal walls. **Figure 24–11** The Swallowing Process. This sequence, based on a series of x-rays, shows the phases of swallowing and the movement of a bolus from the mouth to the stomach.

CHECKPOINT

- 14. Name the structure connecting the pharynx to the stomach.
- **15**. Compared to other segments of the digestive tract, what is unusual about the muscularis externa of the esophagus?
- **16**. What is occurring when the soft palate and larynx elevate and the glottis closes?

- See the blue Answers tab at the back of the book.

24–5 The stomach is a J-shaped organ that receives the bolus from the esophagus and aids in chemical and mechanical digestion

Learning Outcome Describe the anatomy of the stomach, including its histology, and discuss its roles in digestion and absorption.

The **stomach** has four major functions: (1) storage of ingested food; (2) mechanical breakdown of ingested food; (3) disruption of chemical bonds in food through the action of acid and enzymes; and (4) production of *intrinsic factor*, a glycoprotein needed for the absorption of vitamin B_{12} in the small intestine. Ingested substances combine with the secretions of the glands of the stomach, producing a viscous, highly acidic, soupy mixture of partially digested food called **chyme** (KĪM).

Anatomy of the Stomach

The stomach has the shape of an expanded J (Figure 24–12). A short **lesser curvature** forms the medial surface of the organ, and a long **greater curvature** forms the lateral surface. The anterior and posterior surfaces are smoothly rounded. The shape and size of the stomach can vary greatly from individual to individual and even from one meal to the next. In an "average" stomach, the lesser curvature is approximately 10 cm (4 in.) long, and the greater curvature measures about 40 cm (16 in.).

Clinical Note

Gastritis and Peptic Ulcers A superficial inflammation of the gastric mucosa is called *gastritis* (gas-TRĪ-tis). The condition can develop after a person has swallowed drugs, including beverage alcohol and aspirin. Gastritis is also associated with smoking, severe emotional or physical stress, bacterial infection of the gastric wall, or ingestion of strongly acidic or alkaline chemicals. Over time, gastritis can lead to the erosion of the stomach or duodenal lining, and a *peptic ulcer* may form. The stomach typically extends between the levels of vertebrae T_7 and $\mathrm{L}_3.$

We divide the stomach into four regions (Figure 24–12):

- 1. *The Cardia*. The **cardia** (KAR-dē-uh) is the smallest part of the stomach. It consists of the superior, medial portion of the stomach within 3 cm (1.2 in.) of the junction between the stomach and the esophagus. The cardia contains abundant mucous glands. Their secretions coat the connection with the esophagus and help protect that tube from the acid and enzymes of the stomach.
- 2. *The Fundus.* The **fundus** (FUN-dus) is the portion of the stomach that is superior to the junction between the stomach and the esophagus. The fundus contacts the inferior, posterior surface of the diaphragm (Figure 24–12a).
- **3.** *The Body.* The area of the stomach between the fundus and the curve of the J is the **body**, the largest region of the stomach. The body acts as a mixing tank for ingested food and secretions produced in the stomach. *Gastric (gaster, stomach) glands* in the fundus and body secrete most of the acid and enzymes involved in gastric digestion.
- 4. The Pylorus. The pylorus (pī-LOR-us) forms the sharp curve of the J. The pylorus is divided into a pyloric antrum (antron, cavity), which is connected to the body, and a pyloric canal, which empties into the duodenum, the proximal segment of the small intestine. As mixing movements take place during digestion, the pylorus frequently changes shape. A muscular pyloric sphincter regulates the release of chyme into the duodenum. Glands in the pylorus secrete mucus and important digestive hormones, including gastrin, a hormone that stimulates gastric glands.

TIPS&TRICKS

The stomach squeezes chyme into the small intestine just as you squeeze cake frosting out of a pastry bag.

The stomach's volume increases while you eat and then decreases as chyme enters the small intestine. When the stomach is relaxed (empty), the mucosa has prominent folds called **rugae** (ROO- $g\bar{e}$; wrinkles). These temporary features let the gastric lumen expand (**Figure 24–12b**). The stomach can stretch up to 50 times its empty size. As the stomach fills, the rugae gradually flatten out until, at maximum distension, they almost disappear. (The world record, set in 2013, for eating hot dogs with buns in 10 minutes is 69!) When empty, the stomach resembles a muscular tube with a narrow, constricted lumen. When full, it can contain 1–1.5 liters of material.

The muscularis mucosae and muscularis externa of the stomach contain extra layers of smooth muscle cells in addition to the usual circular and longitudinal layers. The muscularis mucosae generally contain an outer, circular layer of muscle cells.

Figure 24–12 The Stomach. ATLAS: Plates 49a–c; 50a–c

Pyloric antrum

The muscularis externa has an inner, **oblique layer** of smooth muscle (Figure 24–12b). The extra layers of smooth muscle strengthen the stomach wall and assist in the mixing and churning essential to the formation of chyme.

TIPS&TRICKS

Both circular folds and rugae allow a large surface area to fit within a small volume, just as crumpling a sheet of paper rearranges its surface area so that it occupies a smaller space. When the stomach fills, its rugae allow its volume to expand, so that the stomach's lining can hold a larger volume of chyme.

Histology of the Stomach

Simple columnar epithelium lines all portions of the stomach (Figure 24–13a). The epithelium is a *secretory sheet*, which

Figure 24–13 The Stomach Lining.

produces a carpet of mucus that covers the interior surface of the stomach. The alkaline mucous layer protects epithelial cells against the acid and enzymes in the gastric lumen.

Shallow depressions called **gastric pits** open onto the gastric surface (Figure 24–13b). The mucous cells at the base, or *neck*, of each gastric pit actively divide, replacing superficial cells that are shed into the chyme. A typical gastric epithelial cell has a life span of three to seven days. Exposure to alcohol or other chemicals that damage or kill epithelial cells increases cell turnover.

Gastric Glands

In the fundus and body of the stomach, each gastric pit communicates with several **gastric glands**, which extend deep into the underlying lamina propria (Figure 24–13b). Gastric glands are dominated by two types of secretory cells: *parietal cells* and *chief cells*. Together, they secrete about 1500 mL (1.6 qt.) of **gastric juice** each day.

Parietal cells are especially common along the proximal portions of each gastric gland (Figure 24–13b). These cells secrete **intrinsic factor**. This glycoprotein helps absorb **vitamin B**₁₂ across the intestinal lining. (Recall from Chapter 19 that this vitamin is essential for normal erythropoiesis.) \supset p. 663

Parietal cells also secrete *hydrochloric acid* (HCl). They do not produce HCl in the cytoplasm, however. This acid is so strong that it would erode a secretory vesicle and destroy the cell. Instead, H^+ and Cl^- , the two ions that form HCl, are transported independently by different mechanisms (Figure 24–14).

The initial step in HCl production is the formation of carbonic acid within parietal cells. The dissociation of carbonic acid releases bicarbonate and hydrogen ions. The H^+ are actively transported into the lumen of the gastric gland. The bicarbonate ions are exchanged for chloride ions from the interstitial fluid. When gastric glands are actively secreting, enough bicarbonate ions diffuse into the bloodstream from the interstitial fluid to increase the pH of the blood significantly. This sudden influx of bicarbonate ions has been called the *alkaline tide*.

The secretions of the parietal cells can keep the stomach contents at pH 1.5–2.0. Although this highly acidic environment does not by itself digest chyme, it has four important functions:

- 1. The acidity of gastric juice kills most of the microorganisms ingested with food.
- **2.** The acidity denatures proteins and inactivates most of the enzymes in food.
- 3. The acidity helps break down plant cell walls and the connective tissues in meat.
- 4. An acidic environment is essential for the activation and function of *pepsin*, a protein-digesting enzyme secreted by chief cells.

Chief cells, also called *zymogenic cells*, are most abundant near the base of a gastric gland (**Figure 24–13b**). These cells secrete **pepsinogen** (pep-SIN-ō-jen), an inactive proenzyme. Acid in the gastric lumen converts pepsinogen to **pepsin**, an active *proteolytic*, or protein-digesting, enzyme. Pepsin functions most effectively at a strongly acidic pH of 1.5–2.0. In addition, the stomachs of newborn infants (but not of adults) produce **rennin**, also known as *chymosin*, and **gastric lipase**. These enzymes are important for the digestion of milk. Rennin coagulates milk proteins. Gastric lipase initiates the digestion of milk fats.

Pyloric Glands

Glands in the pylorus produce primarily a mucous secretion, rather than enzymes or acid. In addition, several types of enteroendocrine cells are scattered among the mucus-secreting cells. These enteroendocrine cells produce at least seven hormones, most notably **gastrin** (GAS-trin). Gastrin is produced by *G cells*, which are most abundant in the gastric pits of the pyloric antrum. Gastrin stimulates secretion by both parietal and chief cells, as well as contractions of the gastric wall that mix and stir the gastric contents.

The pyloric glands also contain *D cells*, which release **somatostatin**, a hormone that inhibits the release of gastrin. D cells continuously release their secretions into the interstitial fluid adjacent to the G cells. Neural and hormonal stimuli can override this inhibition of gastrin production when the stomach is preparing for digestion or is already engaged in digestion.

Several other hormones play a role in hunger and satiety (a feeling of not being hungry). Levels of *ghrelin*, a hormone

produced by *P*/*D1 cells* lining the fundic region of the stomach, increase before meals to initiate hunger. Ghrelin levels decrease shortly after eating to curb appetite. Ghrelin is also antagonistic to *leptin*, a hormone derived from fat tissue that induces satiety. Another hormone from the stomach and small intestine, *obestatin*, is thought to decrease appetite and inhibit thirst. The same gene encodes both ghrelin and obestatin.

Regulation of Gastric Activity

The production of acid and enzymes by the gastric mucosa can be (1) controlled by the CNS; (2) regulated by short reflexes of the enteric nervous system, coordinated in the wall of the stomach; and (3) regulated by hormones of the digestive tract. Gastric control proceeds in three overlapping phases. They are named according to the location of the control center: the *cephalic phase*, the *gastric phase*, and the *intestinal phase* (Spotlight Figure 24–15).

Digestion and Absorption in the Stomach

The stomach carries out preliminary digestion of proteins by pepsin. For a variable period, it allows the digestion of carbohydrates and lipids by salivary amylase and lingual lipase. These enzymes continue to work until the pH throughout the contents of the stomach falls below 4.5. They generally remain active one to two hours after a meal.

As the stomach contents become more fluid and the pH approaches 2.0, pepsin activity increases. Protein disassembly begins. Protein digestion is not completed in the stomach, because time is limited and pepsin attacks only specific types of peptide bonds, not all of them. However, pepsin generally has enough time to break down complex proteins into smaller peptide and polypeptide chains before the chyme enters the duodenum.

Although digestion takes place in the stomach, nutrients are not absorbed there. This is because: (1) The epithelial cells are covered by a blanket of alkaline mucus and are not directly exposed to chyme; (2) the epithelial cells lack the specialized transport mechanisms of cells that line the small intestine; (3) the gastric lining is somewhat impermeable to water; and (4) digestion has not been completed by the time chyme leaves the stomach. At this stage, most carbohydrates, lipids, and proteins are only partially broken down.

Some drugs can be absorbed in the stomach. For example, ethyl alcohol can diffuse through the mucous barrier and penetrate the lipid membranes of the epithelial cells. As a result, beverage alcohol is absorbed in your stomach before any nutrients in a meal reach the bloodstream. Meals containing large amounts of fat slow the rate of alcohol absorption. Why? The reason is that alcohol is lipid soluble, and some of it will be dissolved in fat droplets in the chyme. Aspirin is another lipid-soluble drug that can enter the bloodstream across the gastric mucosa. Such drugs alter the properties of the mucous layer and can promote epithelial damage by stomach acid and enzymes. Prolonged use of aspirin can cause gastric bleeding, so individuals with stomach ulcers usually avoid aspirin.

- CHECKPOINT

- 17. Name the four major regions of the stomach.
- 18. Discuss the significance of the low pH in the stomach.
- **19**. How does a large meal affect the pH of blood leaving the stomach?
- 20. When a person suffers from chronic gastric ulcers, the branches of the vagus nerves that supply the stomach are sometimes cut in an attempt to provide relief. Why might this be an effective treatment?
- See the blue Answers tab at the back of the book.

24-6 The small intestine digests and absorbs nutrients, and associated glandular organs assist with digestive processes

Learning Outcome Describe the anatomy and histology of the small intestine, explain the functions and regulation of intestinal secretions, and describe the structure, functions, and regulation of the accessory digestive organs.

The stomach is a holding tank in which food is saturated with gastric juices and exposed to stomach acid and the digestive effects of pepsin. Most of the important digestive and absorptive steps of digestion take place in the small intestine, where chemical digestion is completed and the products of digestion are absorbed. The mucosa of the small intestine produces only a few of the enzymes involved. The pancreas provides digestive enzymes, as well as buffers that help neutralize chyme. The liver secretes *bile*, a solution stored in the gallbladder for discharge into the small intestine. Bile contains buffers and *bile salts*, compounds that facilitate the digestion and absorption of lipids.

The Small Intestine

The **small intestine** plays the key role in the digestion and absorption of nutrients. Ninety percent of nutrient absorption takes place in the small intestine. Most of the rest occurs in the large intestine. The small intestine averages 6 m (19.7 ft) in length (range: 4.5–7.5 m; 14.8–24.6 ft). Its diameter ranges from 4 cm (1.6 in.) at the stomach to about 2.5 cm (1 in.) at the junction with the large intestine. It occupies all abdominal regions except the right and left hypochondriac and epigastric regions (see Figure 1–6b, p. 16). The small intestine has

SPOTLIGHT Figure 24–15 Regulation of Gastric Activity

The duodenum plays a key role in controlling digestive function because it monitors the contents of the chyme and adjusts the activities of the stomach and accessory glands to protect the delicate absorptive surfaces of the jejunum. This pivotal role of the duodenum is apparent when you consider the three phases of gastric secretion. The phases are named according to the location of the control center involved.

CEPHALIC PHASE

The **cephalic phase** of gastric secretion begins when you see, smell, taste, or think of food. This phase, which is directed by the CNS, prepares the stomach to receive food. The neural output proceeds by way of the parasympathetic division of the autonomic nervous system. The vagus nerves innervate the submucosal plexus of the stomach. Next, postganglionic parasympathetic fibers innervate mucous cells, chief cells, parietal cells, and G cells of the stomach. In response to stimulation, the production of gastric juice speeds up, reaching rates of about 500 mL/h, or about 2 cups per hour. This phase generally lasts only minutes.

Emotional states can exaggerate or inhibit the cephalic phase. For example, anger or hostility leads to excessive gastric secretion. On the other hand, anxiety, stress, or fear decreases gastric secretion and gastric contractions, or *motility*.

GASTRIC PHASE

The **gastric phase** begins with the arrival of food in the stomach and builds on the stimulation provided during the cephalic phase. This phase may continue for three to four hours while the acid and enzymes process the ingested materials. The stimuli that initiate the gastric phase are (1) distension of the stomach, (2) an increase in the pH of the gastric contents, and (3) the presence of undigested materials in the stomach, especially proteins and peptides. The gastric phase consists of the following mechanisms:

Local Response

gastric wall stimulates the release of histamine in the lamina propria, which binds to receptors on the parietal cells and stimulates acid secretion.

Neural Response

The stimulation of stretch receptors and chemoreceptors triggers short reflexes coordinated in the submucosal and myenteric plexuses. This in turn activates the stomach's secretory cells. The stimulation of the myenteric plexus produces powerful contractions called **mixing waves** in the muscularis externa.

Hormonal Response

Neural stimulation and the presence of peptides and amino acids in chyme stimulate the secretion of the hormone gastrin, primarily by G cells. Gastrin travels in the bloodstream to parietal and chief cells, whose increased secretions reduce the pH of the gastric juice. In addition, gastrin also stimulates gastric motility.

INTESTINAL PHASE

The **intestinal phase** of gastric secretion begins when chyme first enters the small intestine. The function of the intestinal phase is to control the rate of gastric emptying to ensure that the secretory, digestive, and absorptive functions of the small intestine can proceed with reasonable efficiency. Although here we consider the intestinal phase as it affects stomach activity, the arrival of chyme in the small intestine also triggers other neural and hormonal events that coordinate the activities of the intestinal tract, pancreas, liver, and gallbladder.

Neural Responses

Chyme leaving the stomach decreases the distension in the stomach, thereby reducing the stimulation of stretch receptors. Distension of the duodenum by chyme stimulates stretch receptors and chemoreceptors that trigger the **enterogastric reflex**. This reflex inhibits both gastrin production and gastric contractions and stimulates the contraction of the pyloric sphincter, which prevents further discharge of chyme. At the same time, local reflexes at the duodenum stimulate mucus production, which helps protect the duodenal lining from the arriving acid and enzymes.

Hormonal Responses

The arrival of chyme in the duodenum triggers hormonal responses:

- Arrival of lipids and carbohydrates stimulates the secretion of cholecystokinin (CCK) and gastric inhibitory peptide (GIP).
- A decrease in pH below 4.5 stimulates the secretion of secretin.
- Partially digested proteins in the duodenum stimulate G cells that secrete gastrin, which circulates to the stomach and speeds gastric processing.

CENTRAL REFLEXES

Two central reflexes, the gastroenteric reflex and gastroileal reflex, are also triggered by the stimulation of stretch receptors in the stomach wall as it fills. These reflexes accelerate movement along the small intestine while the enterogastric reflex controls the rate of chyme entry into the duodenum.

Central Gastric Reflexes

The **gastroenteric reflex** stimulates motility and secretion along the entire small intestine.

The gastroileal

(gas-trō-IL-ē-al) **reflex** triggers the opening of the ileocecal valve, allowing materials to pass from the small intestine into the large intestine.

The **ileocecal valve** controls the passage of materials into the large intestine.

In general, the rate of movement of chyme into the small intestine is highest when the stomach is greatly distended and the meal contains little protein. A large meal containing small amounts of protein, large amounts of carbohydrates (such as rice or pasta), wine (alcohol), or after-dinner coffee (caffeine) will leave your stomach very quickly. One reason is that both alcohol and caffeine stimulate gastric secretion and motility.

The *vomiting* reflex occurs in response to irritation of the fauces, pharynx, esophagus, stomach, or proximal segment of the small intestine. These sensations are relayed to the vomiting center of the medulla oblongata, which coordinates motor responses. In preparation for vomiting, the pyloric sphincter relaxes and the contents of the duodenum are discharged back into the stomach by strong peristaltic waves that travel toward the stomach. Vomiting, or **emesis** (EM-e-sis), then occurs as the gastroesophageal sphincter relaxes and the stomach regurgitates its contents through the esophagus and pharynx and out through the mouth.

three segments: the duodenum, the jejunum, and the ileum (Figure 24–16a).

The **duodenum** (dū-ō-DĒ-num), 25 cm (10 in.) in length, is the segment closest to the stomach. This portion of the small intestine is a "mixing bowl." It receives chyme from the stomach and digestive secretions from the pancreas and liver. From its connection with the stomach, the duodenum curves in a C that encloses the pancreas. Except for the proximal 2.5 cm (1 in.), the duodenum is in a retroperitoneal position between vertebrae L_1 and L_4 (Figure 24–2d).

A rather abrupt bend marks the boundary between the duodenum and the **jejunum** (je-JOO-num). At this junction, the small intestine reenters the peritoneal cavity, supported by a sheet of mesentery. The jejunum is about 2.5 meters (8.2 ft) long. The bulk of chemical digestion and nutrient absorption occurs there.

The **ileum** (IL-ē-um), the final segment of the small intestine, is also the longest. It averages 3.5 meters (11.5 ft) in length. The ileum ends at the **ileocecal** (il-ē-ō-SĒ-kal) **valve**. This sphincter controls the flow of material from the ileum into the *cecum* of the large intestine.

TIPS&TRICKS

To remember the order of the small intestine segments, beginning at the stomach, use this mnemonic: **D**on't **j**ump **i**n—**d**uodenum, **j**ejunum, and **i**leum. Also, do not confuse ileum, the last segment of the small intestine, with ilium, which is a bone.

The small intestine fills much of the peritoneal cavity. Its position is stabilized by the mesentery proper, a broad mesentery attached to the posterior body wall (Figure 24–2c,d). The stomach, large intestine, abdominal wall, and pelvic girdle restrict movement of the small intestine during digestion. Blood vessels, lymphatic vessels, and nerves reach the segments of the small intestine within the connective tissue of the mesentery. The primary blood vessels involved are branches of the superior mesenteric artery and the superior mesenteric vein. \bigcirc pp. 762, 772

The segments of the small intestine—the duodenum, jejunum, and ileum—are distinguished by both histological specialization and primary function.

Histology of the Small Intestine

The intestinal lining has a series of transverse folds called **circular folds** or *plicae circulares* (Figure 24–16b). Unlike the rugae in the stomach, the circular folds are permanent features. They do not disappear when the small intestine fills. The small intestine contains about 800 circular folds—roughly 2 per centimeter. They greatly increase the surface area available for absorption.

Intestinal Villi

The mucosa of the small intestine has a series of fingerlike projections, the **intestinal villi** (Figure 24–17a,b). The villi are covered by simple columnar epithelium that is carpeted with

microvilli. The cells are said to have a *brush border* because the microvilli project from the epithelium like the bristles on a brush (Figure 24–17d).

If the small intestine were a simple tube with smooth walls, it would have a total absorptive area of about 3300 cm^2 (3.6 ft²). Instead, the mucosa contains circular folds. Each circular fold supports a forest of villi, and epithelial cells bearing

microvilli cover each villus. This arrangement increases the total area for absorption by a factor of more than 600, to approximately 2 million cm^2 (more than 2200 ft²). This area is nearly the size of 10 lanes in a bowling alley.

The lamina propria of each villus contains an extensive network of capillaries that originate in a vascular network within the submucosa (Figure 24–17c). These capillaries carry

absorbed nutrients to the hepatic portal circulation for delivery to the liver. The liver then adjusts the nutrient concentrations of blood before the blood reaches the general systemic circulation.

In addition to capillaries and nerve endings, each villus contains a lymphatic capillary called a **lacteal** (LAK-tē-ul; *lac-teus*, milky) (Figure 24–17b,c). Lacteals transport materials that cannot enter blood capillaries. For example, absorbed fatty acids are assembled into protein–lipid packages that are too large to diffuse into the bloodstream. These packets, called *chylomicrons*, reach the venous circulation through the thoracic duct, which delivers lymph into the left subclavian vein. The name *lacteal* refers to the pale, milky appearance of lymph that contains large quantities of lipids.

The intestinal villi move back and forth, exposing the epithelial surfaces to the liquefied intestinal contents. Contractions of the muscularis mucosae and smooth muscle cells within the villi bring about this movement. The movement makes absorption more efficient by quickly eliminating local differences in nutrient concentration. Movements of the villi also squeeze the lacteals, helping to move lymph out of the villi.

Intestinal Glands

Mucous cells between the columnar epithelial cells eject mucins onto the intestinal surfaces (Figure 24–17c,d). At the bases of the villi are the entrances to the **intestinal glands**, or *crypts of Lieberkühn*. These glandular pockets extend deep into the underlying lamina propria. Near the base of each intestinal gland, stem cell divisions produce new generations of epithelial cells, which are continuously displaced toward the intestinal surface. In a few days the new cells reach the tip of a villus and are shed into the intestinal lumen. This ongoing process renews the epithelial surface. The disintegration of the shed cells adds enzymes to the lumen.

The most important of the enzymes introduced into the lumen come from the apical portions of the intestinal cells. Brush border enzymes are integral membrane proteins on the surfaces of intestinal microvilli. These enzymes break down materials that come in contact with the brush border. The epithelial cells then absorb the breakdown products. Once the epithelial cells are shed, they disintegrate within the lumen, releasing both intracellular and brush border enzymes. Enteropeptidase (previously called enterokinase) is one brush border enzyme that enters the lumen in this way. It does not directly participate in digestion. Instead, it activates a key pancreatic proenzyme, trypsinogen. (We consider the functions of enteropeptidase and other brush border enzymes in a later section.) Intestinal glands also contain enteroendocrine cells that produce several intestinal hormones, including gastrin, cholecystokinin, and secretin.

The duodenum has numerous mucous glands, both in the epithelium and deep to it. In addition to intestinal glands, its

submucosa contains **duodenal glands**, also called *submucosal glands* or *Brunner's glands*. Duodenal glands produce copious quantities of mucus when chyme arrives from the stomach. The mucus protects the epithelium from the acidity of chyme and also contains bicarbonate ions that help raise the pH of the chyme. As chyme travels the length of the duodenum, its pH increases from 1–2 to 7–8. The duodenal glands also secrete the hormone *urogastrone*, which inhibits gastric acid production and stimulates the division of epithelial stem cells along the digestive tract.

Regional Specializations

The duodenum has few circular folds, and their villi are small. The primary function of the duodenum is to receive chyme from the stomach and neutralize its acids before they can damage the absorptive surfaces of the small intestine. Over the proximal half of the jejunum, however, circular folds and villi are very prominent. Thereafter, the circular folds and villi gradually decrease in size. This reduction parallels a reduction in absorptive activity: Most nutrient absorption takes place before ingested materials reach the ileum. One rather drastic surgical method of promoting weight loss is the removal of a significant portion of the jejunum. The resulting reduction in absorptive area causes a marked weight loss and may not interfere with adequate nutrition, but the side effects can be very serious.

The distal portions of the ileum lack circular folds. The lamina propria there contains 20–30 masses of lymphoid tissue called aggregated lymphoid nodules, or *Peyer's patches*. **D p. 790** These lymphoid tissues are most abundant in the terminal portion of the ileum, near the entrance to the large intestine. The lymphocytes in the aggregated lymphoid nodules protect the small intestine from bacteria that normally inhabit the large intestine.

Intestinal Secretions

Roughly 1.8 liters of watery **intestinal juice** enters the intestinal lumen each day. Intestinal juice moistens chyme, helps buffer acids, and keeps both the digestive enzymes and the products of digestion in solution. Much of this fluid arrives by osmosis, as water flows out of the mucosa and into the concentrated chyme. The rest is secreted by intestinal glands, stimulated by the activation of touch receptors and stretch receptors in the intestinal walls.

The duodenal glands help protect the duodenal epithelium from gastric acids and enzymes. These glands increase their secretion in response to (1) local reflexes, (2) the release of the hormone *enterocrinin* by enteroendocrine cells of the duodenum, and (3) parasympathetic stimulation through the vagus nerves. The first two mechanisms operate only after chyme arrives in the duodenum. However, the duodenal glands begin secreting during the cephalic phase of gastric secretion, long before chyme reaches the pyloric sphincter. They do so because vagus nerve activity triggers their secretion. Thus, the duodenal lining has protection in advance. Sympathetic stimulation inhibits the duodenal glands, leaving the duodenal lining unprepared for the arrival of chyme. This effect probably explains why chronic stress or other factors that promote sympathetic activation can cause duodenal ulcers.

Intestinal Movements

After chyme has arrived in the duodenum, weak peristaltic contractions move it slowly toward the jejunum. The contractions are myenteric reflexes that are not under CNS control. Their effects are limited to within a few centimeters of the site of the original stimulus. Motor neurons in the submucosal and myenteric plexuses control these short reflexes. In addition, some of the smooth muscle cells contract periodically, even without stimulation, establishing a basic contractile rhythm that then spreads from cell to cell.

The stimulation of the parasympathetic system increases the sensitivity of the weak myenteric reflexes and speeds up both local peristalsis and segmentation. More elaborate reflexes coordinate activities along the entire length of the small intestine. The gastroenteric and gastroileal reflexes speed up movement along the small intestine (Spotlight Figure 24–15). This effect is the opposite from that of the enterogastric reflex.

Hormones released by the digestive tract can enhance or suppress reflexes. For example, the gastroileal reflex is triggered by stretch receptor stimulation. However, the degree of ileocecal valve relaxation is enhanced by gastrin, which is secreted in large quantities when food enters the stomach.

The Pancreas

The **pancreas** lies posterior to the stomach. It extends laterally from the duodenum toward the spleen. The pancreas is

Pancreatitis Pancreatitis (pan-krē-a-TĪ-tis) is an inflammation of the pancreas. The condition is extremely painful. The factors that may produce it include a blockage of the excretory ducts, bacterial or viral infections, ischemia, and drug reactions—especially those involving alcohol. These stimuli provoke a crisis by injuring exocrine cells in at least a portion of the organ. Then lysosomes in the damaged cells activate the proenzymes, and autolysis begins. The proteolytic enzymes digest the surrounding, undamaged cells, activating their enzymes and starting a chain reaction. In most cases, only a portion of the pancreas is affected. The condition usually subsides in a few days. In 10–15 percent of cases, the process does not subside. The enzymes can then ultimately destroy the pancreas. If the islet cells are damaged, diabetes mellitus may result. ⊃ p. 637

an elongate, pinkish-gray organ about 15 cm (6 in.) long and weighing about 80 g (3 oz) (Figure 24–18a). The broad head of the pancreas lies within the loop formed by the duodenum as it leaves the pylorus. The slender **body** of the pancreas extends toward the spleen, and the **tail** is short and bluntly rounded. The pancreas is retroperitoneal and is firmly bound to the posterior wall of the abdominal cavity. The surface of the pancreas has a lumpy, lobular texture. A thin, transparent capsule of connective tissue wraps the entire organ. The pancreatic lobules, associated blood vessels, and excretory ducts are visible through the anterior capsule and the overlying layer of peritoneum. Arterial blood reaches the pancreas by way of branches of the splenic, superior mesenteric, and common hepatic arteries. The pancreatic arteries and pancreaticoduodenal arteries are the major branches from these vessels. The splenic vein and its branches drain the pancreas.

The pancreas is primarily an exocrine organ. It produces digestive enzymes and buffers. The large **pancreatic duct** (*duct of Wirsung*) delivers these secretions to the duodenum. (In 3–10 percent of the population, a small **accessory pancreatic duct** [*Santorini duct*] branches from the pancreatic duct.) The pancreatic duct extends within the attached mesentery to reach the duodenum, where it meets the *common bile duct* from the liver and gallbladder (Figure 24–21b). The two ducts then empty into the *duodenal ampulla (ampulla of Vater)*, a chamber located roughly halfway along the length of the duodenum. When present, the accessory pancreatic duct usually empties into the duodenum independently, outside the duodenal ampulla.

Histological Organization

Partitions of connective tissue divide the interior of the pancreas into distinct lobules. The blood vessels and tributaries of the pancreatic ducts are situated within these connective tissue septa (Figure 24–18b). The pancreas is an example of a *compound tubuloalveolar gland*, a structure described in Chapter 4. **D** p. 125 In each lobule, the ducts branch repeatedly before ending in blind pockets called **pancreatic acini** (AS-i-nī). Each pancreatic acinus is lined with simple cuboidal epithelium. *Pancreatic islets*, the endocrine tissues of the pancreas, are scattered among the acini (Figure 24–18b,c). The islets account for only about 1 percent of the cell population of the pancreas.

The pancreas has two distinct functions, one endocrine and the other exocrine. The endocrine cells of the pancreatic islets secrete insulin and glucagon into the bloodstream to control blood sugar. The exocrine cells include the acinar cells and the epithelial cells that line the duct system. Together, these exocrine cells secrete **pancreatic juice**—an alkaline mixture of digestive enzymes, water, and ions—into the small intestine. Acinar cells secrete pancreatic enzymes, which do most of the digestive work in the small intestine. Pancreatic enzymes break

pylorus of the stomach.

down ingested materials into small molecules suitable for absorption. The water and ions, secreted primarily by the cells lining the pancreatic ducts, help dilute and neutralize acid in the chyme.

Physiology of the Pancreas

Each day, the pancreas secretes about 1000 mL (1 qt) of pancreatic juice. Hormones from the duodenum control these secretory activities. When chyme arrives in the duodenum, secretin is released. This hormone triggers the pancreatic secretion of a watery buffer solution with a pH of 7.5–8.8. Among its other components, the secretion contains bicarbonate and phosphate buffers that help raise the pH of the chyme.

Another duodenal hormone, cholecystokinin, stimulates the production and secretion of pancreatic enzymes. Stimulation by the vagus nerves also increases the secretion of pancreatic enzymes. Recall that this stimulation takes place during the cephalic phase of gastric regulation, so the pancreas starts to synthesize enzymes before food even reaches the stomach. This head start is important, because enzyme synthesis takes much longer than the production of buffers. By starting early, the pancreatic cells are ready to meet the demand when chyme arrives in the duodenum.

The pancreatic enzymes include the following:

- Pancreatic alpha-amylase, a carbohydrase (kar-bō-HĪ-drās)—an enzyme that breaks down certain starches.
 Pancreatic alpha-amylase is almost identical to salivary amylase.
- **Pancreatic lipase**, which breaks down certain complex lipids, releasing products (such as fatty acids) that can be easily absorbed.
- Nucleases, which break down RNA or DNA.

Proteolytic enzymes, which break apart certain proteins. These enzymes include proteases, which break apart large protein complexes, and peptidases, which break small peptide chains into individual amino acids.

Proteolytic enzymes account for about 70 percent of total pancreatic enzyme production. These enzymes are secreted as inactive proenzymes. They are activated only after they reach the small intestine. Proenzymes discussed earlier include pepsinogen, angiotensinogen, plasminogen, fibrinogen, and many of the clotting factors and enzymes of the complement system. **pp. 640, 655, 679, 799** As in the stomach, the release of a proenzyme rather than an active enzyme protects the secretory cells from the destructive effects of their own products. Among the proenzymes secreted by the pancreas are **trypsinogen** (trip-SIN-ō-jen), **chymotrypsinogen** (kā-mo-trip-SIN-ō-jen) **procarboxypeptidase** (prō-kar-bok-sē-PEP-ti-dās), and **proelastase** (pro-ē-LAS-tās).

Inside the duodenum, enteropeptidase in the brush border and the lumen triggers the conversion of trypsinogen to **trypsin**, an active protease. Trypsin then activates the other proenzymes, producing **chymotrypsin**, **carboxypeptidase**, and **elastase**. Each enzyme attacks peptide bonds linking specific amino acids and ignores others. Together, these enzymes break down proteins into a mixture of dipeptides, tripeptides, and amino acids.

The Liver

The **liver** is the largest visceral organ. It is one of our most versatile organs and the center for metabolic regulation in the body. Most of its mass lies in the right hypochondriac and epigastric regions, but it may extend into the left hypochondriac and umbilical regions as well. The liver weighs about 1.5 kg (3.3 lb). This large, firm, reddish-brown organ performs essential metabolic and synthetic functions.

Cirrhosis Any condition that severely damages the liver is a serious threat to life. The liver has a limited ability to regenerate itself after injury. Even so, liver function does not fully recover unless the normal vascular pattern is restored. Examples of important types of liver disease include **cirrhosis**, which is characterized by the replacement of lobules by fibrous tissue, and various forms of *hepatitis* caused by viral infections. In some cases, liver transplants are used to treat liver failure. Unfortunately, the supply of suitable donor tissue is limited. The success rate is highest in young, otherwise healthy individuals. Clinical trials are now under way to test an artificial liver known as *ELAD* (*ex*tracorporeal *liver assist device*). It may prove beneficial for the longterm support of individuals with chronic liver disease.

Anatomy of the Liver

The liver is wrapped in a tough fibrous capsule and is covered by a layer of visceral peritoneum. On the anterior surface, the **falciform ligament** marks the division between the organ's left and right lobes (Figure 24–19a,b). A thickening in the posterior margin of the falciform ligament is the **round ligament**, or *ligamentum teres*. This fibrous band marks the path of the fetal umbilical vein.

On the posterior surface of the liver, the impression left by the inferior vena cava marks the division between the right lobe and the small **caudate** (KAW-dāt) **lobe** (Figure 24–19a,c). Inferior to the caudate lobe lies the **quadrate lobe**, sandwiched between the left lobe and the gallbladder. Afferent blood vessels and other structures reach the liver by traveling within the connective tissue of the lesser omentum. They converge at a region called the **porta hepatis** ("doorway to the liver").

We discussed the circulation to the liver in Chapter 21 and summarized it in Figures 21–24 and 21–31, pp. 762, 771. Nearly one-third of the blood supply to the liver is arterial blood from the hepatic artery proper. The rest is venous blood from the hepatic portal vein, which begins in the capillaries of the esophagus, stomach, small intestine, and most of the large intestine. Liver cells, called **hepatocytes** (HEP-a-tō-sīts), adjust circulating levels of nutrients through selective absorption and secretion. The blood leaving the liver returns to the systemic circuit through the hepatic veins. These veins open into the inferior vena cava.

Histological Organization of the Liver

Connective tissue divides each lobe of the liver into approximately 100,000 **liver lobules**, the basic functional units of the liver. The histological organization and structure of a typical liver lobule are shown in Figure 24–20.

Each lobule is roughly 1 mm in diameter. Adjacent lobules are separated by an *interlobular septum*. The hepatocytes in a liver lobule form a series of irregular plates arranged like the spokes of a wheel (Figure 24–20a,b). The plates are only one cell thick. Exposed hepatocyte surfaces are covered with short microvilli. Within a lobule, sinusoids between adjacent plates empty into the **central vein**. (We introduced sinusoids in Chapter 21. \bigcirc p. 731) The liver sinusoids lack a basement membrane, so large openings between the endothelial cells allow solutes—even those as large as plasma proteins—to pass out of the bloodstream and into the spaces surrounding the hepatocytes.

The lining of the sinusoids contains typical endothelial cells and a large number of **Kupffer** (KOOP-fer) **cells**, also known as *stellate reticuloendothelial cells*. \bigcirc **p**. 796 These phagocytic cells are part of the monocyte–macrophage system. They engulf pathogens, cell debris, and damaged blood cells. Kupffer cells also store iron, some lipids, and heavy metals (such as tin or mercury) that are absorbed by the digestive tract.

Blood enters the liver sinusoids from small branches of the hepatic portal vein and hepatic artery proper. A typical liver lobule has a hexagonal shape in cross section (Figure 24–20a). There are six **portal areas**, or *portal triads*, one at each corner of the lobule. A portal area contains three structures: (1) a branch of the hepatic portal vein, (2) a branch of the hepatic artery proper, and (3) a small branch of the bile duct (Figure 24–20a–c).

Branches from the arteries and veins deliver blood to the sinusoids of adjacent liver lobules (Figure 24–20a,b). As blood flows through the sinusoids, hepatocytes absorb solutes from the plasma and secrete materials such as plasma proteins. Blood then leaves the sinusoids and enters the central vein of the lobule. The central veins ultimately merge to form the hepatic veins, which then empty into the inferior vena cava. Liver diseases, such as the various forms of *hepatitis*, and conditions such as alcoholism, can lead to degenerative changes in the liver tissue and constriction of the circulatory supply.

Pressures in the hepatic portal system are usually low, averaging 10 mm Hg or less. This pressure can increase markedly, however, if blood flow through the liver is restricted by a blood clot or damage to the organ. Such a rise in portal pressure is called *portal hypertension*. As pressures rise, small peripheral veins and capillaries in the portal system become distended. If they rupture, extensive bleeding can take place. Portal hypertension can also force fluid into the peritoneal cavity across the serosal surfaces of the liver and viscera, producing ascites.

The Bile Duct System

The liver secretes a fluid called **bile** into a network of narrow channels between the opposing membranes of adjacent liver cells. These passageways, called **bile canaliculi**, extend outward, away from the central vein (Figure 24–20b). Eventually, they connect with fine **bile ductules** (DUK-tūlz), which carry

Figure 24–20 Liver Histology.

bile to the bile ducts in the nearest portal area (Figure 24–20a). The **right** and **left hepatic ducts** (Figure 24–21a,c) collect bile from all the bile ducts of the liver lobes. These ducts unite to form the **common hepatic duct**, which leaves the liver. The bile in the common hepatic duct either flows into the *common bile duct*, which empties into the duodenal ampulla, or enters the *cystic duct*, which leads to the gallbladder (Figure 24–21a,b,c).

The **common bile duct** is formed by the union of the **cystic duct** and the common hepatic duct. The common bile duct passes within the lesser omentum toward the stomach, turns, and penetrates the wall of the duodenum to meet the pancreatic duct at the duodenal ampulla (Figure 24–21b).

The Physiology of the Liver

The liver carries out more than 200 functions. They fall into three general categories: (1) *metabolic regulation*, (2) *hematological regulation*, and (3) *bile production*. In this discussion we provide a general overview.

Metabolic Regulation. The liver is the primary organ involved in regulating the composition of circulating blood. All blood

Figure 24–21 The Anatomy and Physiology of the Gallbladder and Bile Ducts. ATLAS: Plates 49c,e; 51a; 54b–d

leaving the absorptive surfaces of the digestive tract enters the hepatic portal system and flows into the liver. Liver cells extract nutrients or toxins from the blood before it reaches the systemic circulation through the hepatic veins. The liver removes and stores excess nutrients. It corrects nutrient deficiencies by mobilizing stored reserves or performing synthetic activities. The liver's regulatory activities affect the following:

• *Carbohydrate Metabolism*. The liver stabilizes blood glucose levels at about 90 mg/dL. If blood glucose levels decrease,

hepatocytes break down glycogen reserves and release glucose into the bloodstream. They also synthesize glucose from other carbohydrates or from available amino acids. The synthesis of glucose from other compounds is called *gluconeogenesis*. If blood glucose levels climb, hepatocytes remove glucose from the bloodstream. They either store it as glycogen or use it to synthesize lipids that can be stored in the liver or other tissues. Circulating hormones, such as insulin and glucagon, regulate these metabolic activities. \bigcirc pp. 636–637

- *Lipid Metabolism.* The liver regulates circulating levels of triglycerides, fatty acids, and cholesterol. When those levels decline, the liver breaks down its lipid reserves and releases the breakdown products into the bloodstream. When the levels are high, the lipids are removed for storage. However, this regulation takes place only after lipid levels have risen within the general circulation, because most lipids absorbed by the digestive tract bypass the hepatic portal circulation.
- *Amino Acid Metabolism*. The liver removes excess amino acids from the bloodstream. These amino acids can be used to synthesize proteins or can be converted to lipids or glucose for energy storage.
- *Waste Product Removal.* When converting amino acids to lipids or carbohydrates, or when breaking down amino acids to get energy, the liver strips off the amino groups. This process is called *deamination*. Ammonia, a toxic waste product, is formed. The liver neutralizes ammonia by converting it to *urea*, a fairly harmless compound excreted by the kidneys. The liver also removes other waste products, circulating toxins, and drugs from the blood for inactivation, storage, or excretion.
- Vitamin Storage. Fat-soluble vitamins (A, D, E, and K) and vitamin B₁₂ are absorbed from the blood and stored in the liver. These reserves are used when your diet contains inadequate amounts of those vitamins.
- *Mineral Storage.* The liver converts iron reserves to ferritin and stores this protein–iron complex. ⊃ p. 661
- *Drug Inactivation*. The liver removes and breaks down circulating drugs, limiting the duration of their effects. When physicians prescribe a particular drug, they must take into account the rate at which the liver removes that drug from the bloodstream. For example, a drug that is absorbed relatively quickly must be administered every few hours to keep blood concentrations at therapeutic levels.

Hematological Regulation. The liver receives about 25 percent of cardiac output. It is also the largest blood reservoir in your body. As blood passes through it, the liver performs the following functions:

• *Phagocytosis and Antigen Presentation*. Kupffer cells in the liver sinusoids engulf old or damaged red blood cells,

cellular debris, and pathogens, removing them from the bloodstream. Kupffer cells are antigen-presenting cells (APCs) that can stimulate an immune response. **D p. 806**

- *Synthesis of Plasma Proteins*. Hepatocytes synthesize and release most of the plasma proteins. These proteins include the albumins (which contribute to the osmotic concentration of the blood), the various types of transport proteins, clotting proteins, and complement proteins.
- *Removal of Circulating Hormones.* The liver is the primary site for the absorption and recycling of epinephrine, norepinephrine, insulin, thyroid hormones, and steroid hormones, such as the sex hormones (estrogens and androgens) and corticosteroids. The liver also absorbs cholecalciferol (vitamin D₃) from the blood. Liver cells then convert the cholecalciferol, which may be synthesized in the skin or absorbed in the diet, into an intermediary product, 25-hydroxy-D₃, that is released back into the bloodstream. The kidneys absorb this intermediary and use it to generate calcitriol, a hormone important to Ca²⁺ metabolism. ⊃ p. 639
- *Removal of Antibodies.* The liver absorbs and breaks down antibodies, releasing amino acids for recycling.
- *Removal or Storage of Toxins.* The liver absorbs lipid-soluble toxins in the diet, such as the insecticide DDT (banned in the United States since 1972, but still found in the environment), and stores them in lipid deposits, where they do not disrupt cellular functions. The liver removes other toxins from the bloodstream and either breaks them down or excretes them in the bile.
- The Synthesis and Secretion of Bile. The liver synthesizes bile and excretes it into the lumen of the duodenum. Hormonal and neural mechanisms regulate bile secretion. Bile consists mostly of water, with minor amounts of ions, *bilirubin* (a pigment derived from hemoglobin), cholesterol, and an assortment of lipids collectively known as **bile salts**. (Bile salts play a role in the digestion of lipids, as we discuss in the next section.) The water and ions help dilute and buffer acids in chyme as it enters the small intestine. Bile salts are synthesized from cholesterol in the liver. Several related compounds are involved. The most abundant are derivatives of the steroids *cholate* and *chenodeoxycholate*.

The Functions of Bile. Most dietary lipids are not water soluble. Mechanical processing in the stomach creates large drops containing a variety of lipids. Pancreatic lipase is not lipid soluble, so the enzymes can interact with lipids only at the surface of a lipid droplet. The larger the droplet, the more lipids are inside, isolated and protected from these enzymes. Bile salts break the droplets apart in a process called **emulsification** (ē-mul-si-fi-KĀ-shun), which dramatically increases the surface area accessible to enzymes.

Emulsification creates tiny *emulsion droplets* with a superficial coating of bile salts. The formation of tiny droplets increases the surface area available for enzymatic attack. In addition, the layer of bile salts facilitates interaction between the lipids and lipid-digesting enzymes from the pancreas.

After lipid digestion has been completed, bile salts promote the absorption of lipids by the intestinal epithelium. More than 90 percent of the bile salts are themselves reabsorbed, primarily in the ileum, as lipid digestion is completed. The reabsorbed bile salts enter the hepatic portal circulation. The liver then collects and recycles them. The cycling of bile salts from the liver to the small intestine and back is called the **enterohepatic circulation of bile**.

TIPS&TRICKS

Oil and water ordinarily don't mix. The emulsification process helps mix oils and water-soluble enzymes so that fats can be broken down.

The Gallbladder

The **gallbladder** is a hollow, pear-shaped organ that stores and concentrates bile prior to its excretion into the small intestine. This muscular sac is located in a fossa, or recess, in the posterior surface of the liver's right lobe (Figure 24–21a). The gallbladder is divided into three regions: (1) the **fundus**, (2) the **body**, and (3) the **neck**. The cystic duct extends from the gallbladder to the point where it unites with the common hepatic duct to form the common bile duct. At the duodenum, the common bile duct meets the pancreatic duct before emptying into a chamber called the **duodenal ampulla** (am-PUL-luh) (Figure 24–21b), which receives buffers and enzymes from the pancreas and bile from the liver and gallbladder. The duodenal ampulla opens into the duodenum at the **duodenal papilla**, a small mound.

The muscular **hepatopancreatic sphincter** (*sphincter of Oddi*) encircles the lumen of the common bile duct and, generally, the pancreatic duct and duodenal ampulla as well.

Physiology of the Gallbladder

A major function of the gallbladder is *bile storage*, but it is released into the duodenum only under the stimulation of the intestinal hormone CCK (Figure 24–21d). Without CCK, the hepatopancreatic sphincter remains closed, so bile exiting the liver in the common hepatic duct cannot flow through the common bile duct and into the duodenum. Instead, it enters the cystic duct and is stored within the expandable gallbladder. Whenever chyme enters the duodenum, CCK is released, relaxing the hepatopancreatic sphincter and stimulating contractions of the gallbladder that push bile into the small intestine. The amount of CCK secreted increases markedly when the chyme contains large amounts of lipids. The gallbladder also functions in *bile modification*. When full, the gallbladder contains 40–70 mL of bile. The composition of bile gradually changes as it remains in the gallbladder: Much of the water is absorbed, and the bile salts and other components of bile become increasingly concentrated.

If bile becomes too concentrated, crystals of insoluble minerals and salts begin to form. These deposits are called *gall-stones*. Small gallstones are not a problem so long as they can be flushed down the bile duct and excreted. In *cholecystitis* ($k\bar{o}$ -l \bar{e} -sis-T \bar{l} -tis; *chole*, bile + *kystis*, bladder + *-itis*, inflammation), the gallstones are so large that they can damage the wall of the gall-bladder or block the cystic duct or common bile duct. In that case, the gallbladder may need to be surgically removed. This does not seriously impair digestion, because bile production continues at normal levels. However, the bile is more dilute, and its entry into the small intestine is not as closely tied to the arrival of food in the duodenum.

The Coordination of Secretion and Absorption

A combination of neural and hormonal mechanisms coordinates the activities of the digestive glands. These regulatory mechanisms are centered on the duodenum, where acids must be neutralized and appropriate enzymes added.

Neural mechanisms involving the CNS prepare the digestive tract for activity (through parasympathetic innervation) or inhibit its activity (through sympathetic innervation). Neural mechanisms also coordinate the movement of materials along the length of the digestive tract (through the enterogastric, gastroenteric, and gastroileal reflexes).

In addition, motor neurons synapsing in the digestive tract release a variety of neurotransmitters. Many of these chemicals are also released in the CNS. In general, their functions are poorly understood. Examples of neurotransmitters that may be important include substance P, enkephalins, and endorphins.

We will now summarize the information presented thus far on the regulation of intestinal and glandular function. We will also consider some additional details about the regulatory mechanisms involved.

Intestinal Hormones

The intestinal tract secretes a variety of peptide hormones with similar chemical structures. Many of these hormones have multiple effects in several regions of the digestive tract, and in the accessory glandular organs as well. The origins and primary effects of these important digestive hormones are shown in Figure 24–22.

Other intestinal hormones are produced in relatively small quantities. Examples include *motilin*, which stimulates intestinal contractions; *villikinin*, which promotes the movement of villi and the associated lymph flow; and *somatostatin*, which inhibits gastric secretion. Functional interactions among gastrin, GIP, secretin, CCK, and VIP are diagrammed in Figure 24–23.

Figure 24–22 Major Hormones of the Duodenum.

Major Hormones of the Duodenum

Gastrin

Gastrin is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins. The functions of gastrin include promoting increased stomach motility and stimulating the production of gastric acids and enzymes. (Gastrin is also produced by the stomach.)

Secretin

Secretin is released when chyme arrives in the duodenum. Secretin's primary effect is an increase in the secretion of bile (by the liver) and buffers (by the pancreas), which in turn act to increase the pH of the chyme. Among its secondary effects, secretin reduces gastric motility and secretory rates.

Gastric Inhibitory Peptide (GIP)

Gastric inhibitory peptide is secreted when fats and carbohydrates especially glucose—enter the small intestine. The inhibition of gastric activity is accompanied by the stimulation of insulin release at the pancreatic islets. GIP has several secondary effects, including stimulating duodenal gland activity, stimulating lipid synthesis in adipose tissue, and increasing glucose use by skeletal muscles.

Cholecystokinin (CCK)

Cholecystokinin is secreted when chyme arrives in the duodenum, especially when the chyme contains lipids and partially digested proteins. In the pancreas, CCK accelerates the production and secretion of all types of digestive enzymes. It also causes a relaxation of the hepatopancreatic sphincter and contraction of the gallbladder, resulting in the ejection of bile and pancreatic juice into the duodenum. Thus, the net effects of CCK are to increase the secretion of pancreatic enzymes and to push pancreatic secretions and bile into the duodenum. The presence of CCK in high concentrations has two additional effects: It inhibits gastric activity, and it appears to have CNS effects that reduce the sensation of hunger.

Vasoactive Intestinal Peptide (VIP)

Vasoactive intestinal peptide stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach. By dilating capillaries in active areas of the intestinal tract, VIP provides an efficient mechanism for removing absorbed nutrients.

Enterocrinin

Enterocrinin is released when chyme enters the duodenum. It stimulates mucin production by the submucosal glands.

Intestinal Absorption

On average, it takes about five hours for materials to pass from the duodenum to the end of the ileum. The first of the materials to enter the duodenum after you eat breakfast may leave the small intestine at lunchtime. Along the way, the organ's absorptive effectiveness is enhanced by the fact that so much of the mucosa is movable. The microvilli can be moved by their supporting microfilaments, the individual villi by smooth muscle cells, groups of villi by the muscularis mucosae, and the circular folds by the muscularis mucosae and the muscularis externa. These movements stir and mix the intestinal contents, changing the environment around each epithelial cell from moment to moment.

CHECKPOINT

- **21**. Name the three regions of the small intestine from proximal to distal.
- **22**. How is the small intestine adapted for nutrient absorption?
- 23. Does a high-fat meal raise or lower the level of cholecystokinin in the blood?
- 24. How would the pH of the intestinal contents be affected if the small intestine did not produce secretin?
- **25**. The digestion of which nutrient would be most impaired by damage to the exocrine pancreas?

See the blue Answers tab at the back of the book.

Figure 24–23 The Functions of Major Digestive Tract Hormones. The primary actions

of gastrin, GIP, secretin, CCK, and VIP are shown.

24-7 The large intestine is divided into three parts with regional specialization

Learning Outcome Describe the gross and histological structures of the large intestine, including its regional specializations and role in nutrient absorption.

The horseshoe-shaped **large intestine** begins at the end of the ileum and ends at the anus. The large intestine lies inferior

to the stomach and liver and almost completely frames the small intestine (Figure 24–1). The large intestine stores digestive wastes and reabsorbs water. Resident bacteria in the large intestine are an important source of vitamins, especially vitamin K, biotin, and vitamin B_5 .

The large intestine, also known as the *large bowel*, has an average length of about 1.5 meters (4.9 ft) and a width of 7.5 cm (3 in.). We can divide it into three parts: (1) the pouchlike *cecum*, the first portion of the large intestine;

(2) the *colon*, the largest portion; and (3) the *rectum*, the last 15 cm (6 in.) of the large intestine and the end of the digestive tract (Figure 24–24a).

The Cecum

Material arriving from the ileum first enters an expanded pouch called the **cecum** (SĒ-kum). The ileum attaches to the medial surface of the cecum and opens into the cecum at the *ileocecal valve* (Figure 24–24a,b). The cecum collects and stores materials from the ileum and begins the process of compaction.

The slender, hollow **appendix**, or *vermiform appendix* (*vermis*, worm), is attached to the posteromedial surface of the cecum (Figure 24–24a,b). The appendix is normally about 9 cm (3.6 in.) long, but its size and shape are quite variable. A small mesentery called the **mesoappendix** connects the appendix to the ileum and cecum. Lymphoid nodules dominate the mucosa and submucosa of the appendix. The primary function of the appendix is as an organ of the lymphatic system. Inflammation of the appendix is known as *appendicitis*.

The Colon

The **colon** has a larger diameter and a thinner wall than the small intestine. Distinctive features of the colon include the following (Figure 24–24a):

- The wall of the colon forms a series of pouches, or **haustra** (HAWS-truh; singular, *haustrum*). The creases between the haustra affect the mucosal lining as well, producing a series of internal folds. Haustra permit the colon to expand and elongate.
- Three separate longitudinal bands of smooth muscle called the **teniae coli** (TĒ-nē-ē KŌ-lē)—run along the outer surfaces of the colon just deep to the serosa. These bands correspond to the outer layer of the muscularis externa in other portions of the digestive tract. Muscle tone within the teniae coli is what creates the haustra.
- The serosa of the colon contains numerous teardropshaped sacs of fat called **omental appendices**, also called *fatty* or *epiploic* (ep-i-PLŌ-ik; *epiploon*, omentum) *appendages*.

We can subdivide the colon into four regions: the ascending colon, transverse colon, descending colon, and sigmoid colon (Figure 24–24a).

1. The **ascending colon** begins at the superior border of the cecum and ascends along the right lateral and posterior wall of the peritoneal cavity to the inferior surface of the

liver. There, the colon bends sharply to the left at the **right colic flexure**, or *hepatic flexure*. This bend marks the end of the ascending colon and the beginning of the transverse colon.

- 2. The **transverse colon** curves anteriorly from the right colic flexure and crosses the abdomen from right to left. The transverse colon is supported by the transverse mesocolon. It is separated from the anterior abdominal wall by the layers of the greater omentum. At the left side of the body, the transverse colon passes inferior to the greater curvature of the stomach. Near the spleen, the colon makes a 90° turn at the **left colic flexure**, or *splenic flexure*, and becomes the descending colon.
- 3. The **descending colon** proceeds inferiorly along the left side until reaching the iliac fossa formed by the inner surface of the left ilium. The descending colon is retroperitoneal and firmly attached to the abdominal wall. At the iliac fossa, the descending colon curves at the **sigmoid flexure** and becomes the sigmoid colon.
- 4. The sigmoid flexure is the start of the **sigmoid** (SIG-moyd) **colon** (*sigmeidos*, the Greek letter *S*), an S-shaped segment that is only about 15 cm (6 in.) long. The sigmoid colon lies posterior to the urinary bladder, suspended from the sigmoid mesocolon. The sigmoid colon empties into the *rectum*.

Clinical Note

Colorectal Cancer Colorectal cancer is relatively common in the United States. Aside from skin cancers, colorectal cancer is the third most common cancer in the United States, affecting both men and women. At the writing of this edition, the American Cancer Society's statistics showed that there were 102,480 new cases of colon cancer and 40.340 new cases of rectal cancer. The death rate has declined over the past 20 years for both men and women. The best defense appears to be early detection and prompt treatment. Standard screening involves checking the feces for blood. This simple procedure can be performed easily on a stool (fecal) sample as part of a routine physical. For individuals at increased risk because of family history, associated disease, or older age, visual inspection of the lumen by fiber-optic colonoscopy is prudent. Such examination can find polyps before they develop into cancers. The 5-year survival rate for people whose cancer is found at an early stage and treated immediately is greater than 90 percent.

The large intestine receives blood from branches of the superior mesenteric and inferior mesenteric arteries. The superior mesenteric and inferior mesenteric veins collect venous blood from the large intestine. \bigcirc p. 762, 771

The Rectum

The **rectum** (REK-tum) forms the last 15 cm (6 in.) of the digestive tract (Figure 24–24a,c). It is an expandable organ for the temporary storage of feces. The movement of fecal material into the rectum triggers the urge to defecate (expel feces).

The last portion of the rectum, the **anal canal**, contains small longitudinal folds called **anal columns**. The distal margins of these columns are joined by transverse folds that mark the boundary between the columnar epithelium of the proximal rectum and a stratified squamous epithelium like that in the oral cavity. The **anus**, or *anal orifice*, is the exit of the anal canal. There, the epidermis becomes keratinized and identical to the surface of the skin.

The circular muscle layer of the muscularis externa in this region forms the **internal anal sphincter** (Figure 24–24c). The smooth muscle cells of this sphincter are not under voluntary control. The **external anal sphincter**, which guards the anus,

consists of a ring of skeletal muscle fibers that encircles the distal portion of the anal canal. This sphincter consists of skeletal muscle and is under voluntary control.

The lamina propria and submucosa of the anal canal contain a network of veins. If venous pressures there rise too high due to straining during defecation or pregnancy, the veins can become distended, producing *hemorrhoids*.

Histology of the Large Intestine

The diameter of the colon is about three times that of the small intestine, but its wall is much thinner. The major characteristics of the colon are the lack of villi, the abundance of mucous cells, and the presence of distinctive intestinal glands (Figure 24–25). The glands in the large intestine are deeper than those of the small intestine and are dominated by mucous cells. The mucosa of the large intestine does not produce enzymes. Any digestion that occurs results from enzymes introduced in the small intestine or from bacterial action. The mucus provides lubrication as the fecal material becomes drier and more compact. Mucus is secreted as local stimuli, such as friction or exposure to harsh chemicals, trigger short reflexes involving local nerve plexuses. Large lymphoid nodules are scattered throughout the lamina propria and submucosa.

Figure 24–25 The Mucosa and Glands of the Colon.

The muscularis externa of the large intestine is unusual, because the longitudinal layer has been reduced to the muscular bands of the teniae coli. However, the mixing and propulsive contractions of the colon resemble those of the small intestine.

Physiology of the Large Intestine

Less than 10 percent of the nutrient absorption under way in the digestive tract occurs in the large intestine. Nevertheless, the absorptive operations in this segment of the digestive tract are important. The large intestine also prepares fecal material for defecation.

Absorption in the Large Intestine

The reabsorption of water is an important function of the large intestine. Roughly 1500 mL of material enters the colon each day, but only about 200 mL of feces is ejected. To appreciate how efficient our digestion is, consider the average composition of feces: 75 percent water, 5 percent bacteria, and the rest a mixture of indigestible materials, small quantities of inorganic matter, and the remains of epithelial cells.

In addition to reabsorbing water, the large intestine absorbs a number of other substances that remain in the feces or were secreted into the digestive tract along its length. Examples include useful compounds such as bile salts and vitamins; organic waste products such as urobilinogen; and various toxins generated by bacterial action. Most of the bile salts entering the large intestine are promptly reabsorbed in the cecum and transported in blood to the liver for secretion into bile.

Vitamins. Vitamins are organic molecules that are important as cofactors or coenzymes in many metabolic pathways. The normal bacterial residents of the colon generate three vitamins that supplement our diets:

- 1. *Vitamin K*, a fat-soluble vitamin the liver requires for synthesizing four clotting factors, including prothrombin. Intestinal bacteria produce about half of your daily vitamin K requirements.
- 2. *Biotin*, a water-soluble vitamin important in various reactions, notably those of glucose metabolism.
- 3. *Vitamin* B₅ (pantothenic acid), a water-soluble vitamin required in the manufacture of steroid hormones and some neurotransmitters.

Vitamin K deficiencies lead to impaired blood clotting. They result from either (1) not enough lipids in the diet, which impairs the absorption of all fat-soluble vitamins; or (2) problems affecting lipid processing and absorption, such as inadequate bile production or chronic diarrhea (frequent, watery bowel movements). Disorders due to deficiencies of biotin or vitamin B_5 are extremely rare after infancy. The intestinal bacteria generally produce sufficient amounts to supplement any dietary shortage.

Organic Wastes. We discussed the fate of bilirubin, a breakdown product of heme, in Chapter 19. **D p**. 661 In the large intestine, bacteria convert bilirubin to *urobilinogens* and *stercobilinogens*. Some urobilinogens are absorbed into the bloodstream and then excreted in urine. The urobilinogens and stercobilinogens remaining within the colon are converted to **urobilins** and **stercobilins** by exposure to oxygen. These pigments in various proportions give feces a yellow-brown or brown color.

Bacterial action breaks down peptides that remain in the feces. This action generates (1) ammonia, in the form of soluble *ammonium ions* (NH_4^+); (2) *indole* and *skatole*, two nitrogencontaining compounds that are primarily responsible for the odor of feces; and (3) hydrogen sulfide (H_2S), a gas with a "rotten egg" odor. Significant amounts of ammonia and smaller amounts of other toxins cross the colonic epithelium and enter the hepatic portal circulation. The liver removes these toxins and converts them to relatively nontoxic compounds that can be released into the blood and excreted at the kidneys.

Intestinal enzymes do not alter indigestible carbohydrates. These materials arrive in the colon virtually intact. These

🕞 Clinical Note

Inflammatory and Infectious Disorders of the Digestive System Digestive system disorders are both very diverse and relatively common because the system has so many parts, and each part has so many functions.

The largest category of digestive disorders includes those resulting from inflammation or infection of the digestive tract. In part, this is because the epithelium that lines most of the digestive tract has two properties that are difficult to reconcile. On one hand, it must be thin enough to absorb nutrients rapidly and efficiently. On the other hand, it must resist damage from ingested materials and enzymes.

The delicacy of the epithelium makes it susceptible to damage from chemicals or abrasion. For example, *peptic ulcers* develop if acids and enzymes contact and erode the gastric or duodenal lining. Pathogens in food, including bacteria, viruses, and multicellular parasites, may also get through the epithelial barriers and cause infections. Small battles are continually being fought. In fact, 80 percent of the body's plasma cells are normally located within the lamina propria of the digestive tract. This fact indicates how often antigens of one kind or another somehow cross the epithelial barriers.

High rates of cell division and exposure to strong chemicals are both correlated with an increased risk of cancer. As a result, cancers of the digestive tract are relatively common. Predictably, most are epithelial cancers that develop in the stem cell populations responsible for epithelial cell renewal. complex polysaccharides provide a reliable nutrient source for bacteria in the colon. The metabolic activities of these bacteria create small amounts of **flatus**, or intestinal gas. Foods with large amounts of indigestible carbohydrates (such as beans) stimulate bacterial gas production. Distension of the colon, cramps, and the frequent discharge of intestinal gases can result.

Movements of the Large Intestine

The gastroileal and gastroenteric reflexes move materials into the cecum while you eat. Movement from the cecum to the transverse colon is very slow, allowing hours for water absorption to convert the already thick material into a sludgy paste. Peristaltic waves move material along the length of the colon. Segmentation movements, called *haustral churning*, mix the contents of adjacent haustra. Powerful peristaltic contractions called **mass movements** occur a few times each day. They move material from the transverse colon through the rest of the large intestine. The stimulus is distension of the stomach and duodenum. The commands are relayed over the intestinal nerve plexuses. The contractions force feces into the rectum and produce the conscious urge to defecate.

The rectal chamber is usually empty, except when a powerful peristaltic contraction forces feces out of the sigmoid colon. Distension of the rectal wall then triggers the **defecation reflex**. This reflex involves two positive feedback loops (Figure 24–26). Both loops are triggered by the stimulation of stretch receptors in the rectum.

Rectal stretch receptors also trigger two reflexes important to the *voluntary* control of defecation. One is a long reflex mediated by parasympathetic innervation within the pelvic nerves. This reflex causes the internal anal sphincter to relax. This smooth muscle sphincter controls the movement of feces into the anal canal. The second is a somatic reflex that stimulates the immediate contraction of the external anal sphincter, a skeletal muscle. \bigcirc pp. 355–357 The pudendal nerves carry the motor commands.

Both the internal and external anal sphincters must relax for feces to be eliminated. However, the two reflexes just mentioned open the internal sphincter but close the external sphincter. The actual release of feces requires a conscious effort to open the external sphincter. In addition, other consciously directed activities can raise intra-abdominal pressures and help force fecal material out of the rectum. These activities include tensing the abdominal muscles or elevating intra-abdominal pressures by attempting to exhale forcibly with a closed glottis.

If the external anal sphincter remains constricted, the peristaltic contractions cease. However, additional rectal expansion triggers further defecation reflexes. The urge to defecate usually develops when rectal pressure reaches about 15 mm Hg. If this pressure is more than 55 mm Hg, the external anal sphincter involuntarily relaxes and defecation takes place. This mechanism brings about defecation in infants, and in adults with severe spinal cord injuries.

CHECKPOINT

- 26. Identify the four regions of the colon.
- 27. Name some major histological differences between the large intestine and the small intestine.
- **28**. Differentiate between haustral churning and mass movements.

See the blue Answers tab at the back of the book.

24-8 Digestion is the chemical alteration of food that allows the absorption and use of nutrients

Learning Outcome List the nutrients required by the body, describe the chemical events responsible for the digestion of organic nutrients, and describe the mechanisms involved in the absorption of organic and inorganic nutrients.

A balanced diet contains all the ingredients needed to maintain homeostasis. These ingredients include six nutrients: carbohydrates, lipids, proteins, vitamins, minerals, and water. This section describes the chemical events involved in the processing and absorbing of these nutrients.

The Processing and Absorbing of Nutrients

Food contains large organic molecules, many of them insoluble. The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments. This disassembly eliminates any antigenic properties, so that the fragments do not trigger an immune response after absorption. Cells absorb the molecules released into the bloodstream and either (1) break them down to provide energy for the synthesis of ATP or (2) use these molecules to synthesize carbohydrates, proteins, and lipids. In this section we focus on the mechanics of digestion and absorption. The fates of the compounds inside cells are the focus in Chapter 25.

Most ingested organic materials are complex chains of simpler molecules. In a typical dietary carbohydrate, the basic molecules are simple sugars. In a protein, the building blocks are amino acids. In lipids, they are generally fatty acids. And in nucleic acids, they are nucleotides. Digestive enzymes break the bonds between the component molecules of carbohydrates, proteins, lipids, and nucleic acids in a process called *hydrolysis*. **D p**. **37**

The classes of digestive enzymes differ with respect to their targets. *Carbohydrases* break the bonds between simple sugars, *proteases* split the linkages between amino acids, and *lipases* separate fatty acids from glycerides. Some enzymes in each class are even more selective, breaking bonds between specific molecules. For example, a particular carbohydrase might break the bond between two glucose molecules, but not those between glucose and another simple sugar.

Digestive enzymes secreted by the salivary glands, tongue, stomach, and pancreas are mixed into the ingested material as it passes along the digestive tract. These enzymes break down large carbohydrates, proteins, lipids, and nucleic acids into smaller fragments. Typically these fragments in turn must be broken down even further before absorption can occur. The final enzymatic steps involve brush border enzymes, which are attached to the exposed surfaces of intestinal microvilli.

Nucleic acids are broken down into their component nucleotides. Brush border enzymes digest these nucleotides into sugars, phosphates, and nitrogenous bases that are absorbed by active transport. However, nucleic acids represent only a small fraction of all the nutrients absorbed each day. The digestive fates of carbohydrates, lipids, and proteins, the major dietary components, are shown in **Spotlight Figure 24–27**. The major digestive enzymes and their functions are summarized in **Table 24–1**. Next we take a closer look at the digestion and absorption of carbohydrates, lipids, and proteins.

Carbohydrate Digestion and Absorption

The digestion of complex carbohydrates (simple polysaccharides and starches) proceeds in two steps. One step involves carbohydrases produced by the salivary glands and pancreas. The other step uses brush border enzymes.

SPOTLIGHT Figure 24–27 Chemical Events of Digestion

A typical meal contains carbohydrates, proteins, lipids, water, minerals (electrolytes), and vitamins. The digestive system handles each component differently. Large organic molecules must be chemically broken down before they can be absorbed. Water, minerals, and vitamins can be absorbed without processing, but they may require special transport mechanisms.

924 UNIT 5 Environmental Exchange

Table 24–1	Digestiv	estive Enzymes and Their Functions				
Enzyme (proenzy	me)	Source	Optimal pH	Target	Products	Remarks
CARBOHYDRASES	5					
Maltase, sucrase, lactase		Brush border of small intestine	7–8	Maltose, sucrose, lactose	Monosaccharides	Found in membrane surface of microvilli
Pancreatic alpha-amylase		Pancreas	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between simple sugars
Salivary amylase		Salivary glands	6.7–7.5	Complex carbohydrates	Disaccharides and trisaccharides	Breaks bonds between simple sugars
PROTEASES						
Carboxypeptidase (procarboxypeptidase)		Pancreas	7–8	Proteins, polypeptides, amino acids	Short-chain peptides	Activated by trypsin
Chymotrypsin (chymotrypsinog	en)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Activated by trypsin
Dipeptidases, pe	ptidases	Brush border of small intestine	7–8	Dipeptides, tripeptides	Amino acids	Found in membrane surface of brush border
Elastase (proelas	tase)	Pancreas	7–8	Elastin	Short-chain peptides	Activated by trypsin
Enteropeptidase		Brush border and lumen of small intestine	7–8	Trypsinogen	Trypsin	Reaches lumen through disintegration of shed epithelial cells
Pepsin (pepsinog	en)	Chief cells of stomach	1.5–2.0	Proteins, polypeptides	Short-chain polypeptides	Secreted as proenzyme pepsinogen; activated by H ⁺ in stomach acid
Rennin		Stomach	3.5–4.0	Milk proteins		Secreted only in infants; causes protein coagulation
Trypsin (trypsino	gen)	Pancreas	7–8	Proteins, polypeptides	Short-chain peptides	Proenzyme activated by enteropeptidase; activates other pancreatic proteases
LIPASES						
Lingual lipase		Glands of tongue	3.0-6.0	Triglycerides	Fatty acids and monoglycerides	Begins lipid digestion
Pancreatic lipase		Pancreas	7–8	Triglycerides	Fatty acids and monoglycerides	Bile salts must be present for efficient action
NUCLEASES						
		Pancreas	7–8	Nucleic acids	Nitrogenous bases and simple sugars	Includes ribonuclease for RNA and deoxy-ribonuclease for DNA

The Actions of Salivary and Pancreatic Enzymes

The digestion of complex carbohydrates involves two enzymes—salivary amylase and pancreatic alpha-amylase (**Spotlight Figure 24–27**). Both function effectively at a pH of 6.7–7.5. Carbohydrate digestion begins in the mouth during mastication, through the action of salivary amylase from the parotid and submandibular salivary glands. Salivary amylase breaks down starches (complex carbohydrates) into a mixture composed mostly of *disaccharides* (two simple sugars) and *trisaccharides* (three simple sugars). Salivary amylase continues to digest the starches and glycogen in the food for one to two hours before stomach acids render the enzyme inactive. Only a small amount of digestion takes place over this period because the enzymatic content of saliva is not high.

In the duodenum, pancreatic alpha-amylase breaks down the remaining complex carbohydrates. Any disaccharides or trisaccharides produced, and any present in the food, are not broken down further until they contact the intestinal mucosa.

Actions of Brush Border Enzymes

Brush border enzymes of the intestinal microvilli break disaccharides and trisaccharides into *monosaccharides* (simple sugars) prior to absorption. The enzyme **maltase** splits bonds between the two glucose molecules of the disaccharide **maltose**. **Sucrase** breaks the disaccharide **sucrose** into glucose and *fructose*, another six-carbon sugar. **Lactase** hydrolyzes the disaccharide **lactose** into a molecule of glucose and one of *galactose*. Lactose is the main carbohydrate in milk, so lactase provides an essential function in infancy and early childhood by breaking down lactose. If the intestinal mucosa stops producing lactase, the person becomes **lactose intolerant**. After ingesting milk and other dairy products, lactose-intolerant people can experience a variety of unpleasant digestive problems, including lower abdominal pain, gas, diarrhea, and vomiting.

Absorption of Monosaccharides

The intestinal epithelium then absorbs the monosaccharides by facilitated diffusion and cotransport mechanisms (see **Figure 3–18**, p. 95). Both methods involve a carrier protein. Facilitated diffusion and cotransport differ in three major ways:

- 1. Facilitated diffusion moves only one molecule or ion through the plasma membrane, whereas cotransport moves more than one molecule or ion through the membrane at the same time. In cotransport, the transported substances move in the same direction: down the concentration gradient for at least one of them.
- 2. *Facilitated diffusion does not require ATP*. Cotransport by itself does not consume ATP, but the cell must often expend ATP to preserve homeostasis. For example, the process may bring in sodium ions that must later be pumped out of the cell.
- **3.** Facilitated diffusion does not take place if there is an opposing concentration gradient for the particular molecule or ion. By contrast, cotransport can take place despite an opposing concentration gradient for one of the transported substances. For example, cells lining the small intestine continue to absorb glucose when glucose concentrations inside the cells are much higher than they are in the intestinal contents.

The cotransport system that takes up glucose also brings sodium ions into the cell. This passive process resembles facilitated diffusion, except that both a sodium ion and a glucose molecule must bind to the carrier protein before they can move into the cell. Glucose cotransport is an example of sodiumlinked cotransport. \bigcirc p. 97 Comparable cotransport mechanisms exist for other simple sugars and for some amino acids. These mechanisms deliver valuable nutrients to the cytoplasm, but they also bring in sodium ions that must be ejected by the sodium-potassium exchange pump.

The simple sugars that are transported into the cell at its apical surface diffuse through the cytoplasm. They then reach the interstitial fluid by facilitated diffusion across the basolateral surfaces. These monosaccharides diffuse into the capillaries of the villus for eventual transport to the liver in the hepatic portal vein.

Lipid Digestion and Absorption

Lipid digestion involves lingual lipase from glands of the tongue, and pancreatic lipase from the pancreas (Spotlight Figure 24–27).

The most important and abundant dietary lipids are triglycerides. They consist of three fatty acids attached to a single molecule of glycerol (see Figure 2–16, p. 49). The lingual and pancreatic lipases break off two of the fatty acids, leaving monoglycerides.

Lipases are water-soluble enzymes, and lipids tend to form large drops that exclude water molecules. As a result, lipases can attack only the exposed surfaces of the lipid drops. Lingual lipase begins breaking down triglycerides in the mouth and continues for a variable time within the stomach. The lipid drops are so large, however, and the available time so short, that only about 20 percent of the lipids have been digested by the time the chyme enters the duodenum.

Bile salts improve chemical digestion by emulsifying the lipid drops into tiny emulsion droplets, thereby providing better access for pancreatic lipase. The emulsification takes place only after the chyme has been mixed with bile in the duodenum. Pancreatic lipase then breaks apart the triglycerides to form a mixture of fatty acids and monoglycerides. As these molecules are released, they interact with bile salts in the surrounding chyme to form small lipid–bile salt complexes called **micelles** (mī-SELZ). A micelle is only about 2.5 nm (0.0025 µm) in diameter.

When a micelle contacts the intestinal epithelium, the lipids diffuse across the plasma membrane and enter the cytoplasm. The intestinal cells synthesize new triglycerides from the monoglycerides and fatty acids. These triglycerides, in company with absorbed steroids, phospholipids, and fat-soluble vitamins, are then coated with proteins. The resulting complexes are known as **chylomicrons** (kī-lō-MĪ-kronz; *chylos*, juice + *mikros*, small).

The intestinal cells then secrete the chylomicrons into interstitial fluid by exocytosis. The protein coating keeps the chylomicrons suspended in the interstitial fluid, but they are generally too large to diffuse into capillaries. Most of the chylomicrons diffuse into the intestinal lacteals, which lack basement membranes and have large gaps between adjacent endothelial cells. From the lacteals, the chylomicrons proceed along the lymphatic vessels and through the thoracic duct. They finally enter the bloodstream at the left subclavian vein.

Most of the bile salts within micelles are reabsorbed by sodium-linked cotransport. Only about 5 percent of the bile salts secreted by the liver enters the colon. Only about 1 percent is lost in feces.

Protein Digestion and Absorption

Proteins have very complex structures, so protein digestion is both complex and time-consuming. Proteolytic enzymes must access individual proteins, so the three-dimensional organization of food must first be disrupted. This step involves mechanical processing in the oral cavity, through mastication, and chemical processing in the stomach, through the action of hydrochloric acid. The strong acid in the stomach kills pathogens and breaks down plant cell walls and animal connective tissues. Acid also disrupts tertiary and secondary protein structure, exposing peptide bonds to enzymatic attack.

The acidic content of the stomach also provides the proper environment for the activity of pepsin, the proteolytic enzyme secreted in an inactive form by chief cells of the stomach (**Spotlight Figure 24–27**). Pepsin works effectively at a pH of 1.5–2.0. It breaks the peptide bonds within a polypeptide chain.

When chyme enters the duodenum, enteropeptidase from the small intestine triggers the conversion of trypsinogen to trypsin. Buffers increase the pH to 7–8. Pancreatic proteases can now begin working. Trypsin, chymotrypsin, and elastase are like pepsin in that they break specific peptide bonds within a polypeptide. For example, trypsin breaks peptide bonds involving the amino acids *arginine* or *lysine*. Chymotrypsin targets peptide bonds involving *tyrosine* or *phenylalanine*.

Carboxypeptidase also acts in the small intestine. This enzyme chops off the last amino acid of a polypeptide chain, no matter which amino acids are involved. Thus, while the other peptidases generate a variety of short peptides, carboxypeptidase produces free amino acids.

The epithelial surfaces of the small intestine contain several peptidases, notably **dipeptidases**. These enzymes break short peptide chains into individual amino acids. (Dipeptidases break apart *dipeptides*.) These amino acids, as well as those produced by the pancreatic enzymes, are absorbed through both facilitated diffusion and cotransport mechanisms.

The amino acids diffuse through the cell to its basolateral surface. There they are released into interstitial fluid by facilitated diffusion and cotransport. Once in the interstitial fluid, the amino acids diffuse into intestinal capillaries for transport to the liver by means of the hepatic portal vein.

4 Water Absorption

Cells cannot actively absorb or secrete water. All movement of water across the lining of the digestive tract involves passive water flow down osmotic gradients. The production of glandular secretions also involves passive water flow down osmotic gradients. Recall that when a selectively permeable membrane separates two solutions, water tends to flow into the solution that has the higher concentration of solutes. \bigcirc p. 93 Osmotic movements are rapid, so interstitial fluid and the fluids in the intestinal lumen always have the same osmotic concentration of solutes, or osmolarity.

Intestinal epithelial cells continuously absorb nutrients and ions. These activities gradually lower the solute concentration in the lumen. As the solute concentration drops, water

Figure 24–28Digestive Secretion and Water Reabsorption.The purple arrows indicate secretion, and the blue arrows show water

moves into the surrounding tissues, maintaining osmotic equilibrium.

Each day, about 2000 mL of water enters the digestive tract in the form of food or drink. The salivary, gastric, intestinal, colonic, pancreatic, and bile secretions provide an additional 7200 mL. Of that total, only about 150 mL is lost in feces. The sites of secretion and absorption of water are shown in Figure 24–28.

Ion Absorption

Osmosis does not distinguish among solutes. All that matters is the total concentration of solutes. To maintain homeostasis,

Table 24–2	The Absorption	of lons and Vitamins	
lon or Vitamin		Transport Mechanism	Regulatory Factors
Na ⁺		Channel-mediated diffusion, cotransport, or active transport	Increased when sodium-linked cotransport is under way; stimulated by aldosterone
Ca ²⁺		Active transport	Stimulated by calcitriol and PTH
K^+		Channel-mediated diffusion	Follows concentration gradient
Mg ²⁺		Active transport	
Fe ²⁺		Active transport	
CI ⁻		Channel-mediated diffusion or carrier-mediated transport	
I-		Channel-mediated diffusion or carrier-mediated transport	
HCO ₃ ⁻		Channel-mediated diffusion or carrier-mediated transport	
NO_3^-		Channel-mediated diffusion or carrier-mediated transport	
PO4 ³⁻		Active transport	
SO4 ²⁻		Active transport	
Water-soluble vita	amins (except B ₁₂)	Channel-mediated diffusion	Follows concentration gradient
Vitamin B ₁₂		Active transport	Must be bound to intrinsic factor prior to absorption
Fat-soluble vitami	ins	Diffusion	Absorbed from micelles along with dietary lipids

however, the concentrations of specific ions must be closely regulated. Thus, each ion must be handled individually, and the rate of intestinal absorption of each must be tightly controlled (Table 24–2). Many of the regulatory mechanisms controlling the rates of absorption are poorly understood.

Sodium ions (Na⁺) are usually the most abundant cations in food. They may enter intestinal cells by diffusion, by cotransport with another nutrient, or by active transport. These ions are then pumped into interstitial fluid across the base of the cell.

The rate of Na⁺ uptake from the lumen is generally proportional to the concentration of Na⁺ in the intestinal contents. As a result, eating heavily salted foods leads to increased sodium ion absorption and an associated gain of water through osmosis. The rate of sodium ion absorption by the digestive tract is increased by aldosterone, a steroid hormone from the adrenal cortex. \bigcirc p. 632

Calcium ion (Ca²⁺) absorption involves active transport at the epithelial surface. Calcitriol speeds up the rate of transport. \bigcirc p. 631

As other solutes move out of the lumen, the concentration of potassium ions (K^+) increases. These ions can diffuse into the epithelial cells, driven by the concentration gradient. The absorption of magnesium (Mg^{2+}), iron (Fe²⁺), and other cations involves specific carrier proteins. The cell must use ATP to obtain and transport these ions to interstitial fluid. Regulatory factors controlling their absorption are poorly understood.

The anions chloride (Cl⁻), iodide (l⁻), bicarbonate (HCO₃⁻), and nitrate (NO₃⁻) are absorbed by diffusion or

carrier-mediated transport. Phosphate (PO_4^{3-}) and sulfate (SO_4^{2-}) ions enter epithelial cells only by active transport.

Vitamin Absorption

Vitamins are organic compounds required in very small quantities. There are two major groups of vitamins: fat-soluble vitamins and water-soluble vitamins. Vitamins A, D, E, and K are **fat-soluble vitamins**. Their structure allows them to dissolve in lipids. The nine **water-soluble vitamins** include the B vitamins, common in milk and meats, and vitamin C, found in citrus fruits. We consider the functions of vitamins and associated nutritional problems in Chapter 25.

All but one of the water-soluble vitamins are easily absorbed by diffusion across the digestive epithelium. By itself vitamin B_{12} cannot be absorbed by the intestinal mucosa in normal amounts. This vitamin must be bound to *intrinsic factor*, a glycoprotein secreted by the parietal cells of the stomach. The combination is then absorbed through active transport.

Fat-soluble vitamins in the diet enter the duodenum in fat droplets, mixed with triglycerides. The vitamins remain in association with these lipids as they form emulsion droplets and, after further digestion, micelles. The fat-soluble vitamins are then absorbed from the micelles along with the fatty acids and monoglycerides. Vitamin K produced in the colon is absorbed with other lipids released through bacterial action. Taking supplements of fat-soluble vitamins while you have an empty stomach, are fasting, or are on a low-fat diet is relatively ineffective. The reason is that proper absorption of these vitamins requires the presence of other lipids.

CHECKPOINT

- 29. Name the nutrients the body requires.
- **30**. What component of food would increase the number of chylomicrons in the lacteals?
- **31**. The absorption of which vitamin would be impaired by the removal of the stomach?
- **32**. Why is it that diarrhea is potentially life threatening, but constipation (infrequent defecation) is not?

See the blue Answers tab at the back of the book.

24-9 Many age-related changes affect digestion and absorption

Learning Outcome Summarize the effects of aging on the digestive system.

Normal digestion and absorption take place in elderly people. However, many changes in the digestive system parallel agerelated changes we have already discussed in connection with other systems:

- *The division rate of epithelial stem cells declines.* The digestive epithelium becomes more susceptible to damage by abrasion, acids, or enzymes. Peptic ulcers therefore become more likely. Stem cells in the epithelium divide less frequently with age, so tissue repair is less efficient. In the mouth, esophagus, and anus, the stratified epithelium becomes thinner and more fragile.
- Smooth muscle tone decreases. General motility decreases, and peristaltic contractions are weaker as a result of a decrease in smooth muscle tone. These changes slow the rate of fecal movement and promote constipation. Sagging and inflammation of the haustra in the colon can occur. Straining to eliminate compacted feces can stress the less resilient walls of blood vessels, producing hemorrhoids. Problems are not restricted to the lower digestive tract. For example, weakening of muscular sphincters can lead to esophageal reflux and frequent bouts of "heartburn."

The effects of cumulative damage become apparent. A familiar example is the gradual loss of teeth due to *dental caries* (cavities) or gingivitis. Cumulative damage can involve internal organs as well. Toxins such as alcohol and other injurious chemicals that are absorbed by the digestive tract are transported to the liver for processing. The cells of the liver are not immune to these toxic compounds, and chronic exposure can lead to cirrhosis or other types of liver disease.

- Cancer rates increase. Cancers are most common in organs in which stem cells divide to maintain epithelial cell populations. Rates of colon cancer and stomach cancer rise with age. Oral, esophageal, and pharyngeal cancers are particularly common among elderly smokers.
- Dehydration is common among the elderly. One reason is that osmoreceptor sensitivity declines with age.
- Changes in other systems have direct or indirect effects on the digestive system. For example, reduction in bone mass and calcium content in the skeleton is associated with erosion of the tooth sockets and eventual tooth loss. The decline in olfactory and gustatory sensitivities with age can lead to dietary changes that affect the entire body.

- CHECKPOINT

- **33**. Identify general digestive system changes that occur with aging.
- See the blue Answers tab at the back of the book.

24–10 The digestive system is extensively integrated with other body systems

Learning Outcome Give examples of interactions between the digestive system and other organ systems studied so far.

Figure 24–29 summarizes the physiological relationships between the digestive system and other organ systems we have studied so far. The digestive system has particularly extensive anatomical and physiological connections to the nervous, cardiovascular, endocrine, and lymphatic systems. As we have seen, the digestive tract is also an endocrine organ that produces a variety of hormones. Many of these hormones, and some of the neurotransmitters produced by the digestive system, can enter the circulation, cross the blood–brain barrier, and alter CNS activity. In this way, a continual exchange of chemical information takes place among these systems.

CHECKPOINT

- **34**. Identify the functional relationships between the digestive system and other body systems.
- **35**. What body systems may be affected by inadequate calcium absorption?
- See the blue Answers tab at the back of the book.

SYSTEM INTEGRATOR

→ Body System

Figure 24–29 diagrams the functional relationships between the digestive system and the other body systems we have studied so far.

age 1010

Related Clinical Terms

borborygmus: A rumbling or gurgling sound made by the movement of fluids and gases in the intestines.

cathartics: Drugs that promote defecation.

- cholelithiasis: The presence of gallstones in the gallbladder.
- **cholera:** A bacterial infection of the digestive tract that causes massive fluid losses through diarrhea.
- **colitis:** A general term for a condition characterized by inflammation of the colon.
- **Crohn's disease:** An incurable chronic inflammatory bowel disease that can affect any part of the digestive tract, from the mouth to the anus. The presence of strictures, fistulas, and fissures is common.
- **diverticulitis:** An infection and inflammation of mucosal pockets of the large intestine (diverticula).
- **diverticulosis:** The formation of diverticula, generally along the sigmoid colon.
- dysphagia: Difficulty or discomfort in swallowing due to disease.
- **esophageal varices:** Swollen and fragile esophageal veins that result from portal hypertension.
- **fecal occult blood test:** Test to check for hidden blood in feces. **gastrectomy:** The surgical removal of the stomach, generally to treat advanced stomach cancer.
- **gastroesophageal reflux disease (GERD):** Chronic condition in which the lower esophageal sphincter allows gastric acids to backflow into the esophagus, causing heartburn, acid indigestion, and possible injury to the esophageal lining.
- **gastroscope:** A fiber-optic instrument inserted into the mouth and directed along the esophagus and into the stomach; used to examine the interior of the stomach and to perform minor surgical procedures.
- **halitosis:** Bad breath that may be due to poor oral hygiene, an infection, diabetes, or other disease.

- **insoluble fiber:** Indigestible plant carbohydrates that do not dissolve in water and pass through the GI tract unchanged. Found in many vegetables and the skins of fruits, insoluble fiber speeds up the passage of material in the GI tract. Individuals consuming diets rich in insoluble fiber decrease their risk for developing diabetes, atherosclerosis, and colorectal cancers, among other diseases.
- **irritable bowel syndrome (IBS):** A common disorder affecting the large intestine, accompanied by cramping, abdominal pain, bloating, gas, diarrhea, and constipation.
- **pancreatic cancer:** Malignancy of the pancreas that does not cause symptoms in its early stages, leading to late detection and a survival rate of only 4 percent.
- **periodontal disease:** A loosening of the teeth within the alveolar sockets caused by erosion of the periodontal ligaments by acids produced through bacterial action.
- **polyps:** Small growths with a stalk protruding from a mucous membrane that is usually benign.
- **pulpitis:** An infection of the pulp of a tooth; treatment may involve a root canal procedure.
- **pyloric stenosis:** Uncommon condition in which the muscle of the lower end of the stomach enlarges and prevents food from entering the small intestine.
- **pylorospasm:** Spasm of the pyloric sphincter, accompanied by pain and vomiting.
- **root canal:** Removal of the alveolar nerve in a severely damaged tooth.
- **soluble fiber:** Indigestible plant carbohydrates found in beans, oats, and citrus fruits that dissolve in water when eaten, forming a gel within the digestive tract to slow the passage of material. Diets rich in soluble fiber lower blood cholesterol levels.

- 24-1 The digestive system, consisting of the digestive tract and accessory organs, has overlapping food utilization functions p. 881
 - 1. The **digestive system** consists of the muscular **digestive tract** and various **accessory organs**. (*Figure 24–1*)

- 2. Double sheets of peritoneal membrane called **mesenteries** suspend the digestive tract. The **greater omentum** lies anterior to the abdominal viscera. Its adipose tissue provides padding, protection, insulation, and an energy reserve. (*Figure 24–2*)
- 3. The *lamina propria* and epithelium form the **mucosa** (mucous membrane) of the digestive tract. Proceeding outward is the **submucosa**, the **muscularis externa**, and a layer of areolar tissue called the *adventitia*. For viscera projecting into the peritoneal cavity, the muscularis externa is covered by a serous membrane called the **serosa**. (*Figure 24–3*)
- 4. The muscularis externa propels materials through the digestive tract by the contractions of **peristalsis**. **Segmentation** movements in the small intestine churn digestive materials. (*Figure 24–4*)
- 5. Neural reflexes, hormones, and local mechanisms control digestive tract activities. (*Figure 24–5*)

24-2 The oral cavity contains the tongue, salivary glands, and teeth, each with specific functions p. 889

6. The functions of the **oral cavity**, or **buccal cavity**, are (1) *sensory analysis* of foods; (2) *mechanical processing* by the

teeth, tongue, and palatal surfaces; (3) *lubrication*, by mixing with mucus and salivary gland secretions; and (4) limited *digestion* of carbohydrates and lipids.

- 7. The oral cavity is lined by the **oral mucosa**. The *hard* and *soft palates* form the roof of the oral cavity, and the *tongue* forms its floor. (*Figure 24–6*)
- 8. **Intrinsic** and **extrinsic tongue muscles** are controlled by the hypoglossal nerves. (*Figure 24–6*)
- 9. The **parotid**, **sublingual**, and **submandibular salivary glands** discharge their secretions into the oral cavity. (*Figure 24–7*)
- 10. Mastication (chewing) of the bolus occurs through the contact of the occlusal (opposing) surfaces of the teeth. The periodontal ligament anchors each tooth in an *alveolus*, or bony socket. Dentin forms the basic structure of a tooth. The crown is coated with enamel, the root with cementum. (*Figure 24–8*)
- 11. During childhood and early adulthood, the 20 primary teeth, or **deciduous teeth**, are replaced by the 32 teeth of the **secondary dentition**. (*Figure 24–9*)

24-3 The pharynx is a passageway between the oral cavity and esophagus p. 894

12. Propulsion of the bolus through the **pharynx** results from contractions of the *pharyngeal constrictor muscles* and the *palatal muscles*, and from elevation of the larynx.

24-4 The esophagus is a muscular tube that transports solids and liquids from the pharynx to the stomach p. 895

- **13.** The **esophagus** carries solids and liquids from the pharynx to the stomach through the **esophageal hiatus**, an opening in the diaphragm. (*Figure 24–10*)
- 14. The esophageal mucosa consists of a stratified epithelium. Mucous secretion by esophageal glands of the submucosa reduces friction during the passage of foods. The proportions of skeletal and smooth muscle of the muscularis externa change from the pharynx to the stomach. (*Figure 24–10*)
- **15.** Swallowing, or **deglutition**, can be divided into **buccal**, **pharyngeal**, and **esophageal phases**. Swallowing begins with the compaction of a bolus and its movement into the pharynx, followed by the elevation of the larynx, reflection of the *epiglottis*, and closure of the *glottis*. After the *upper esophageal sphincter* is opened, peristalsis moves the bolus down the esophagus to the *lower esophageal sphincter*. (*Figure 24–11*)

24-5 The stomach is a J-shaped organ that receives the bolus from the esophagus and aids in chemical and mechanical digestion p. 897

- **16.** The **stomach** has four major functions: (1) storage of ingested food, (2) mechanical breakdown of food, (3) disruption of chemical bonds by acid and enzymes, and (4) production of *intrinsic factor*.
- 17. The four regions of the stomach are the **cardia**, **fundus**, **body**, and **pylorus**. The **pyloric sphincter** guards the exit from the stomach. In a relaxed state, the stomach lining contains numerous **rugae** (ridges and folds). (*Figure 24–12*)
- Within the gastric glands, parietal cells secrete intrinsic factor and hydrochloric acid. Chief cells secrete pepsinogen, which is converted by acids in the gastric lumen to the enzyme pepsin. Enteroendocrine cells of the stomach secrete several compounds, notably the hormone gastrin. (*Figures 24–13, 24–14*)
- Gastric control involves (1) the **cephalic phase**, which prepares the stomach to receive ingested materials; (2) the **gastric phase**, which begins with the arrival of food in the stomach;

and (3) the **intestinal phase**, which controls the rate of gastric emptying. Vomiting, or **emesis**, is reverse peristalsis. (*Spotlight Figure 24–15*)

- 24-6 The small intestine digests and absorbs nutrients, and associated glandular organs assist with digestive processes p. 901
- **20.** Most of the important digestive and absorptive functions occur in the **small intestine**. The pancreas, liver, and gallbladder provide digestive secretions and buffers.
- **21.** The small intestine consists of the **duodenum**, the **jejunum**, and the **ileum**. A sphincter, the **ileocecal valve**, marks the transition between the small and large intestines. (*Figure 24–16*)
- 22. The intestinal mucosa has transverse folds called **circular folds** (*plicae circulares*) and small projections called **intestinal villi**. These folds and projections increase the surface area for absorption. Each villus contains a terminal lymphatic called a **lacteal**. Pockets called **intestinal glands** are lined by enteroendocrine, mucous, and stem cells. (*Figures 24–16, 24–17*)
- **23. Intestinal juice** moistens chyme, helps buffer acids, and holds digestive enzymes and digestive products in solution.
- 24. The **duodenal** (*submucosal* or *Brunner's*) **glands** of the duodenum produce mucus, bicarbonate ions, and the hormone *urogastrone*. The ileum contains masses of lymphoid tissue called *aggregated lymphoid nodules*, or *Peyer's patches*, near the entrance to the large intestine.
- **25.** The **gastroenteric reflex**, initiated by stretch receptors in the stomach, stimulates motility and secretion along the entire small intestine. The **gastroileal reflex** triggers the relaxation of the ileocecal valve.
- **26.** The **pancreatic duct** penetrates the wall of the duodenum. Within each lobule of the **pancreas**, ducts branch repeatedly before ending in the **pancreatic acini** (blind pockets). (*Figure 24–18*)
- 27. The pancreas has two functions: endocrine (secreting insulin and glucagon into the blood) and exocrine (secreting **pancreatic juice** into the small intestine). Pancreatic enzymes include **carbohydrases**, **lipases**, **nucleases**, and **proteolytic enzymes**.
- **28.** The **liver** performs metabolic and hematological regulation and produces **bile**. The bile ducts from all the **liver lobules** unite to form the **common hepatic duct**. That duct meets the **cystic duct** to form the **common bile duct**, which empties into the duodenum. (*Figures 24–19 to 24–21*)
- **29.** The liver lobule is the organ's basic functional unit. **Hepato-cytes** form irregular plates arranged in the form of spokes of a wheel. **Bile canaliculi** carry bile to the **bile ductules**, which lead to **portal areas**. (*Figure 24–20*)
- **30.** In **emulsification**, **bile salts** break apart large drops of lipids, making the lipids accessible to lipases secreted by the pancreas.
- **31.** The liver is the primary organ involved in regulating the composition of circulating blood. All the blood leaving the absorptive surfaces of the digestive tract flows into the liver before entering the systemic circulation. The liver regulates metabolism as it removes and stores excess nutrients, vitamins, and minerals from the blood; mobilizes stored reserves; synthesizes needed nutrients; and removes waste products.
- **32.** The liver's hematological activities include the monitoring of circulating blood by phagocytes and antigen-presenting cells; the synthesis of plasma proteins; the removal of circulating hormones and antibodies; and the removal or storage of toxins.

- **33.** The liver synthesizes bile, which is composed of water, ions, bilirubin, cholesterol, and bile salts (an assortment of lipids).
- 34. The **gallbladder** stores, modifies, and concentrates bile. *(Figure 24–21)*
- 35. Neural and hormonal mechanisms coordinate the activities of the digestive glands. Gastrointestinal activity is stimulated by parasympathetic innervation and inhibited by sympathetic innervation. The **enterogastric**, **gastroenteric**, and **gastroileal reflexes** coordinate movement from the stomach to the large intestine.
- 36. Intestinal hormones include **secretin**, **cholecystokinin** (CCK), gastric inhibitory peptide (GIP), vasoactive intestinal peptide (VIP), gastrin, and enterocrinin. (*Figures 24–22, 24–23*)

24-7 The large intestine is divided into three parts with regional specialization p. 916

- 37. The main functions of the **large intestine** are to (1) reabsorb water and compact materials into feces, (2) absorb vitamins produced by bacteria, and (3) store fecal material prior to defecation. The large intestine consists of the *cecum*, *colon*, and *rectum*. (*Figure 24–24*)
- **38.** The **cecum** collects and stores material from the ileum and begins the process of compaction. The **appendix** is attached to the cecum. (*Figure 24–24*)
- 39. The **colon** has a larger diameter and a thinner wall than the small intestine. The colon bears **haustra** (pouches), **teniae coli** (longitudinal bands of muscle), and sacs of fat **(omental appendices)**. (*Figure 24–24*)
- 40. The four regions of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. (*Figure 24–24*)
- 41. The **rectum** terminates in the **anal canal**, leading to the **anus**. (*Figure 24–24*)
- **42.** Histological characteristics of the colon include the absence of villi and the presence of mucous cells and deep intestinal glands. (*Figure 24–25*)
- **43.** The large intestine reabsorbs water and other substances such as vitamins, urobilinogen, bile salts, and toxins. Bacteria are responsible for intestinal gas, or **flatus**.
- 44. The gastroileal reflex moves materials from the ileum into the cecum while you eat. Distension of the stomach and duodenum stimulates **mass movements** of materials from the transverse colon through the rest of the large intestine and into the rectum. Muscular sphincters control the passage of fecal material to the anus. Distension of the rectal wall triggers the **defecation reflex**. (*Figure 24–26*)

24-8 Digestion is the chemical alteration of food that allows the absorption and use of nutrients **p.** 922

- **45.** The digestive system first breaks down the physical structure of the ingested material and then disassembles the component molecules into smaller fragments by *hydrolysis*. (*Spotlight Figure* 24–27; *Table* 24–1)
- **46.** Salivary and pancreatic amylases break down complex carbohydrates into *disaccharides* and *trisaccharides*. These in turn are broken down into *monosaccharides* by enzymes at the epithelial surface. The monosaccharides are then absorbed by the intestinal epithelium by facilitated diffusion or cotransport. (*Spotlight Figure 24–27*)
- 47. *Triglycerides* are emulsified into lipid droplets that interact with bile salts to form **micelles**. The fatty acids and monoglycerides resulting from the action of pancreatic lipase diffuse from the micelles across the intestinal epithelium. Triglycerides are then synthesized and released into the interstitial fluid, for transport to the general circulation by way of the lymphatic system. (*Spotlight Figure 24–27*)
- **48.** Protein digestion involves a low pH (which destroys tertiary and quaternary structure), the gastric enzyme pepsin, and various pancreatic proteases. Peptidases liberate amino acids that are absorbed and exported to interstitial fluid. (*Spotlight Figure* 24–27)
- **49.** About 2000 mL of water is ingested each day, and digestive secretions provide another 7200 mL. Nearly all is reabsorbed by osmosis. (*Figure 24–28*)
- **50.** Various processes, including diffusion, cotransport, and carrier-mediated and active transport, are responsible for the movements of cations (sodium, calcium, potassium, and so on) and anions (chloride, iodide, bicarbonate, and so on) into epithelial cells. (*Table 24–2*)
- **51.** The **water-soluble vitamins** (except B₁₂) diffuse easily across the digestive epithelium. **Fat-soluble vitamins** are enclosed within fat droplets and absorbed with the products of lipid digestion. (*Table 24–2*)

24-9 Many age-related changes affect digestion and absorption p. 928

52. Age-related changes include a thinner and more fragile epithelium due to a reduction in epithelial stem cell divisions, weaker peristaltic contractions as smooth muscle tone decreases, the effects of cumulative damage, increased cancer rates, and increased dehydration.

24-10 The digestive system is extensively integrated with other body systems p. 928

53. The digestive system has extensive anatomical and physiological connections to the nervous, endocrine, cardiovascular, and lymphatic systems. (*Figure 24–29*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- The enzymatic breakdown of large molecules into their basic building blocks is called (a) absorption, (b) secretion, (c) mechanical processing, (d) chemical digestion.
- The outer layer of the digestive tract is known as the (a) serosa,
 (b) mucosa, (c) submucosa, (d) muscularis.
- **3.** Double sheets of peritoneum that provide support and stability for the organs of the peritoneal cavity are the **(a)** mediastina, **(b)** mucous membranes, **(c)** omenta, **(d)** mesenteries.

See the blue Answers tab at the back of the book.

4. A branch of the hepatic portal vein, hepatic artery proper, and branch of the bile duct form (a) a liver lobule, (b) the sinusoids, (c) a portal area, (d) the hepatic duct, (e) the pancreatic duct.

5. Label the digestive system structures in the following figure.

6. Label the four layers of the digestive tract in the following figure.

Most of the digestive tract is lined by ______ epithelium. (a) pseudostratified ciliated columnar, (b) cuboidal, (c) stratified squamous, (d) simple, (e) simple columnar.

- 8. Regional movements that occur in the small intestine and function to churn and fragment the digestive material are called (a) segmentation,
 (b) pendular movements, (c) peristalsis, (d) mass movements,
 (e) mastication.
- 9. Bile release from the gallbladder into the duodenum occurs only under the stimulation of (a) cholecystokinin, (b) secretin, (c) gastrin, (d) enteropeptidase.
- **10.** Label the three segments of the small intestine in the following figure.

- 11. The major function(s) of the large intestine is (are) (a) reabsorption of water and compaction of feces, (b) absorption of vitamins liberated by bacterial action, (c) storage of fecal material prior to defecation, (d) a, b, and c.
- **12.** Vitamins generated by bacteria in the colon are **(a)** vitamins A, D, and E, **(b)** B complex vitamins and vitamin C, **(c)** vitamin K, biotin, and pantothenic acid, **(d)** niacin, thiamine, and riboflavin.
- 13. The final enzymatic steps in the digestive process are accomplished by (a) brush border enzymes of the intestinal microvilli, (b) enzymes secreted by the stomach, (c) enzymes secreted by the pancreas, (d) the action of bile from the gallbladder.
- 14. What are the six main functions of the digestive system?
- **15.** Name and describe the layers of the digestive tract, proceeding from the innermost layer nearest the lumen to the outermost layer.

24

- **16.** What three basic mechanisms regulate the activities of the digestive tract?
- 17. What are the three phases of swallowing, and how are they controlled?
- **18.** What are the primary digestive functions of the pancreas, liver, and gallbladder?
- **19.** Which hormones produced by duodenal enteroendocrine cells effectively coordinate digestive functions?
- 20. What are the three primary functions of the large intestine?
- 21. What two positive feedback loops are involved in the defecation reflex?

LEVEL 2 Reviewing Concepts

22. During defecation, **(a)** stretch receptors in the rectal wall initiate a series of peristaltic contractions in the colon and rectum, **(b)** stretch receptors in the rectal wall activate parasympathetic centers in the sacral region of the spinal cord, **(c)** the internal anal sphincter relaxes while the external anal sphincter contracts, **(d)** all of these occur, **(e)** only a and b occur.

- 23. *Increased* parasympathetic stimulation of the intestine would result in(a) decreased motility, (b) decreased secretion, (c) decreased sensitivity of local reflexes, (d) decreased segmentation, (e) none of these.
- 24. A drop in pH below 4.5 in the duodenum stimulates the secretion of (a) secretin, (b) cholecystokinin, (c) gastrin, (d) a, b, and c.
- **25.** Through which layers of a molar would an oral surgeon drill to perform a root canal (removal of the alveolar nerve in a severely damaged tooth)?
- 26. How is the epithelium of the stomach protected from digestion?
- **27.** How does each of the three phases of gastric secretion promote and facilitate gastric control?
- **28.** Nutritionists have found that after a heavy meal, the pH of blood increases slightly, especially in the veins that carry blood away from the stomach. What causes this increase in blood pH?

LEVEL 3 Critical Thinking and Clinical Applications

- 29. Some people with gallstones develop pancreatitis. How could this occur?
- **30.** Harry is suffering from an obstruction in his colon. He notices that when he urinates, the color of his urine is much darker than normal, and he wonders if there is any relationship between the color of his urine and his intestinal obstruction. What would you tell him?
- **31.** A condition known as lactose intolerance is characterized by painful abdominal cramping, gas, and diarrhea. The cause of the problem is an inability to digest the milk sugar lactose. How would this cause the observed signs and symptoms?
- **32.** Recently, more people have turned to surgery to help them lose weight. One form of weight control surgery involves stapling a portion of the stomach shut, creating a smaller volume. How would such a surgery result in weight loss?

CLINICAL CASE

An Unusual Transplant

Normally the lining of the colon is slimy with mucus and covered with millions of beneficial bacteria. These friendly, "good" bacteria generate vitamins K, B₅, and biotin. They also convert bilirubin to urobilinogens and stercobilinogens. The bacteria also break down the remaining peptides in feces.

When these normal, beneficial intestinal bacteria have been killed by antibiotics, they are always replaced by other bacteria. Often the replacing bacteria are harmful, producing toxins, irritating the intestinal lining, and causing colitis. This is the case with *Clostridium difficile* infections.

One way of treating *C. difficile* infections is with a fecal transplant, as Mirasol's doctor suggests. Normal feces from a healthy donor contain populations of good bacteria that usually colonize large intestines. With a minimal amount of processing, the donated feces can be infused through a nose tube (nasogastric or NG tube). Then the normal intestinal bacteria can

Wrap-Up

take up residence in the recipient's large intestine, crowd out the harmful *C. difficile* bacteria, and resume their usual work of protecting the lining

of the large intestine, producing vitamins, and recycling.

After overcoming her initial disgust, Mirasol agrees to the transplant. She recovers completely and leaves the hospital two days after her treatment.

- 1. If Mirasol's *Clostridium difficile* colitis is not treated with a fecal transplant, what kind of health problems might she continue to experience?
- **2.** If you could look inside Mirasol's large intestine with a colonoscope, what do you think you would see?

See the blue Answers tab at the back of the book.

Metabolism and Energetics

Learning Outcomes

25

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **25-1** Define energetics and metabolism, and explain why cells must synthesize new organic components.
- **25-2** Describe the basic steps in glycolysis, the citric acid cycle, and the electron transport system, and summarize the energy yields of glycolysis and cellular respiration.
- **25-3** Describe the pathways involved in lipid metabolism, and summarize the mechanisms of lipid transport and distribution.
- **25-4** Summarize the main processes of protein metabolism, and discuss the use of protein as an energy source.
- **25-5** Differentiate between the absorptive and postabsorptive metabolic states, and summarize the characteristics of each.
- **25-6** Explain what makes up a balanced diet and why such a diet is important.
- **25-7** Define metabolic rate, discuss the factors involved in determining an individual's BMR, and discuss the homeostatic mechanisms that maintain a constant body temperature.

CLINICAL CASE

The Miracle Supplement

Justine, a pregnant 30-year-old Kenyan woman, is walking home from the clinic after her final pre-

natal visit. As the sun sets, she realizes she is suddenly no longer able to see. Terrified, she manages to walk home blind, in rural Kenya, after dark. The next morning, her vision returns.

Justine knows children who have experienced night blindness. Many of them died young; in fact, every family in Justine's village has experienced childhood death. Several of the village's children also have stunted growth and slow skeletal development. They seem to have diminished ability to fight infections, and commonly develop malarial, respiratory, and diarrheal infections.

Fortunately, Justine goes on to deliver a healthy baby at the clinic. Shortly after giving birth, doctors treat Justine with a

single high-dose vitamin supplement. She is told this will help her night blindness and ensure that there is enough of this vitamin in her breast milk to keep her baby healthy too.

When Justine's baby is six months old, Justine takes her for her first dose of vitamin supple-

ment. This will be repeated every six months until the child is five. Costing only two cents per dose and reducing overall childhood mortality (death rate) by 23 percent, this vitamin supplement has been called the best public health investment ever. What could this critical vitamin be? To find out, turn to Clinical Case Wrap-Up on p. 971.

An Introduction to Metabolism and Energetics

The amount and type of nutrients you get from meals can vary widely. Your body builds energy reserves when nutrients are abundant. It mobilizes these reserves when nutrients are in short supply. The nervous and endocrine systems adjust and coordinate the metabolic activities of the body's tissues. These systems control the storage and mobilization of these energy reserves. In this chapter we examine (1) how the body obtains energy from the breakdown of organic molecules, stores it in the form of the energy transfer molecule ATP, and uses it to support intracellular operations such as the construction of new organic molecules, and (2) how the body balances heat gains and losses to maintain homeostasis.

25–1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy

Learning Outcome Define energetics and metabolism, and explain why cells must synthesize new organic components.

Cells are chemical factories that break down organic molecules to obtain energy. Our cells can then use this energy to generate ATP. Reactions within mitochondria provide most of the energy a typical cell needs. \bigcirc **p**. 80 To carry out these reactions, cells must have a reliable supply of oxygen and nutrients, including water, vitamins, mineral ions, and organic substrates (the reactants in enzymatic reactions). The lungs absorb oxygen. The other substances are absorbed by the digestive tract. The cardiovascular system then carries these substances throughout the body. They diffuse from the bloodstream into the tissues, where our cells can absorb and use them.

Mitochondria break down the organic nutrients to provide energy for cell growth, cell division, contraction, secretion, and other functions. Each tissue contains a unique mixture of various kinds of cells. As a result, the energy and nutrient requirements of any two tissues, such as loose connective tissue and cardiac muscle, can be quite different. Also, activity levels can change rapidly within a tissue, and such changes affect the requirements of the body. For example, when skeletal muscles start contracting, the tissue demand for oxygen increases dramatically. Thus, the energy and nutrient requirements of the body vary from moment to moment (resting versus exercising), hour to hour (asleep versus awake), and year to year (growing child versus adult). Understanding energy requirements is one aspect of **energetics**, the study of the flow of energy and its change(s) from one form to another.

The term **metabolism** (me-TAB-ō-lizm) refers to all the chemical reactions that take place in an organism. Chemical reactions within cells, collectively known as *cellular metabolism*, provide the energy needed to maintain homeostasis and to perform essential functions. Such functions include (1) *metabolic turnover*, the periodic breakdown and replacement of the organic components of a cell; (2) growth and cell division; and (3) special processes, such as secretion, contraction, and the propagation of action potentials.

Figure 25–1 provides a broad overview of the processes involved in cellular metabolism. The cell absorbs organic molecules from the surrounding interstitial fluids. Amino acids,

25

Figure 25–1 An Introduction to Cellular Metabolism. Cells obtain organic molecules from the interstitial fluid and break them down to produce ATP. Only about 40 percent of the energy released by catabolism is captured in the form of ATP; the rest is lost as heat. The ATP generated by catabolism provides energy for all vital cellular activities, including anabolism.

lipids, and simple sugars cross the plasma membrane and join nutrients already in the cytosol. All the cell's organic building blocks collectively form a *nutrient pool* that the cell draws on to provide energy and to create new intracellular components.

The breakdown of organic molecules is called **catabolism**. This process releases energy that can be used to synthesize ATP or other high-energy compounds. Catabolism proceeds in a series of steps. In general, the first steps take place in the cytosol. Enzymes there break down large organic molecules previously assembled by the cell (such as glycogen, triglycerides, or proteins) into smaller fragments that join the nutrient pool. For example, carbohydrates are broken down into simple sugars, triglycerides are split into fatty acids and glycerol, and proteins are broken down to individual amino acids.

These preparatory steps produce relatively little ATP. However, further catabolic activity yields smaller organic molecules that mitochondria can absorb and process. Mitochondrial activity releases significant amounts of energy. As mitochondrial enzymes break the covalent bonds that hold these molecules together, they capture about 40 percent of the energy released and use it to convert ADP to ATP. The other 60 percent escapes as heat that warms the cell and the surrounding tissues.

The ATP produced by mitochondria provides energy to support both **anabolism**, which is the synthesis of new organic molecules, and other cell functions. Those functions vary among cell types, and they include ciliary or cell movement, contraction, active transport, and cell division. For example, muscle fibers need ATP to provide energy for contraction, but gland cells need ATP to synthesize and transport secretions. We have considered such specialized functions in other chapters, so here we focus on anabolic processes.

In terms of energy, anabolism is an "uphill" process that involves the formation of new chemical bonds. Cells synthesize new organic components for four basic reasons:

1. *To Carry Out Structural Maintenance or Repairs.* All cells must expend energy for ongoing maintenance and repairs, because most structures in the cell are temporary rather

than permanent. Their removal and replacement are part of the process of *metabolic turnover*. $\supset p$. 59

- **2.** *To Support Growth.* Cells preparing to divide increase in size and synthesize extra proteins and organelles.
- **3.** *To Produce Secretions.* Secretory cells must synthesize their products and deliver them to the interstitial fluid.
- 4. To Store Nutrient Reserves. Most cells "prepare for a rainy day"—a period of emergency, an interval of extreme activity, or a time when the supply of nutrients in the bloodstream is inadequate. Cells prepare for such times by building up reserves—nutrients stored in a form that can be mobilized as needed. The most abundant storage form of carbohydrate is glycogen, a branched chain of glucose molecules. The most abundant storage lipids are triglycerides, consisting primarily of fatty acids. Muscle cells and liver cells, for example, store glucose in the form of glycogen, but adipocytes and liver cells store triglycerides. Proteins are the most abundant organic components

Figure 25–2 Nutrient Use in Cellular Metabolism. Cells use the contents of the nutrient pool to build up reserves and to synthesize cellular structures. Catabolism within mitochondria provides the ATP needed to sustain cell functions. Mitochondria are "fed" small carbon chains produced by the breakdown of carbohydrates (primarily glucose, stored as glycogen), lipids (especially fatty acids from triglycerides), and proteins (amino acids). The mitochondria absorb these breakdown products for further catabolism by means of the citric acid cycle and the electron transport system.

in the body. They perform a variety of vital functions for the cell, and when energy is available, cells synthesize additional proteins. However, when glucose or fatty acids are unavailable, cells can break down proteins into their component amino acids, and use the amino acids as an energy source. The primary function of proteins is not to serve as an energy source, but proteins are so abundant and accessible that they represent an important "last-ditch" nutrient reserve.

The nutrient pool is the source of the substrates for both catabolism and anabolism. As you might expect, cells tend to conserve the materials needed to build new compounds and break down the rest. Cells continuously replace membranes, organelles, enzymes, and structural proteins. These anabolic activities require more amino acids than lipids, and few carbohydrates. In general, when a cell with excess carbohydrates, lipids, and amino acids needs energy, it first breaks down carbohydrates. Lipids are the second choice. Amino

acids are seldom broken down if other energy sources are available.

Mitochondria provide the energy that supports cellular operations. The cell feeds its mitochondria from its nutrient pool. In return, the cell gets the ATP it needs. However, mitochondria are picky eaters: They accept only specific organic molecules for processing and energy production. For this reason, chemical reactions in the cytosol take whichever organic nutrients are available and break them down into smaller fragments that the mitochondria can process. The mitochondria then break the fragments down further, generating carbon dioxide, water, and ATP (Figure 25-2). This mitochondrial activity involves two pathways: the citric acid cycle and the electron transport system. We describe these important catabolic and anabolic cellular reactions in the next section.

CHECKPOINT

- 1. Define metabolism.
- 2. Define catabolism.
- **3**. Define anabolism.

See the blue Answers tab at the back of the book.

25–2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis

Learning Outcome Describe the basic steps in glycolysis, the citric acid cycle, and the electron transport system, and summarize the energy yields of glycolysis and cellular respiration.

Most cells generate ATP and other high-energy compounds by breaking down carbohydrates, especially glucose. We can summarize the complete reaction as follows:

 $\begin{array}{ccc} C_6H_{12}O_6+6O_2 & \longrightarrow & 6CO_2+6H_2O \\ \text{glucose oxygen} & \text{carbon water} \\ & \text{dioxide} \end{array}$

The breakdown takes place in a series of small steps. Several of these steps release sufficient energy to convert ADP to ATP. The complete catabolism of one molecule of glucose provides a typical body cell a net gain of 36 molecules of ATP.

Most ATP production takes place inside mitochondria, but the first steps take place in the cytosol. In Chapter 10 we introduced the process of *glycolysis*, which breaks down glucose in the cytosol into smaller molecules that mitochondria can absorb and utilize. \bigcirc **p**. 317 These reactions are said to be *anaerobic* because glycolysis does not require oxygen. The subsequent reactions take place in mitochondria. These reactions use oxygen and are considered *aerobic*. The mitochondrial activity responsible for ATP production is called **aerobic metabolism**, also known as **cellular respiration**.

Glycolysis

Glycolysis (glī-KOL-i-sis; *glykus*, sweet + *lysis*, a loosening) is the breakdown of glucose to **pyruvic acid**. In this process, a series of enzymatic steps breaks the six-carbon glucose molecule ($C_6H_{12}O_6$) into two 3-carbon molecules of pyruvic acid (CH_3 —CO—COOH). At the normal pH inside cells, each pyruvic acid molecule loses a hydrogen ion and exists as the negatively charged ion CH_3 —CO—COO⁻. This ionized form is called **pyruvate**.

Glycolysis requires (1) glucose molecules; (2) appropriate cytosolic enzymes; (3) ATP and ADP; (4) inorganic phosphates; and (5) **NAD** (*nicotinamide adenine dinucleotide*), a coenzyme that removes hydrogen atoms during one of the enzymatic reactions. Recall from Chapter 2 that coenzymes are organic molecules that are essential to enzyme function. \bigcirc p. 55 If any of these participants is missing, glycolysis cannot take place.

Figure 25–3 provides an overview of the steps in glycolysis. Glycolysis begins when an enzyme *phosphorylates*—that is, attaches a phosphate group—to the last (sixth) carbon atom of a glucose molecule, creating **glucose-6-phosphate**. This step "costs" the cell 1 ATP molecule. It has two important results: (1) It traps the glucose molecule within the cell, because phosphorylated glucose cannot cross the plasma membrane; and (2) it prepares the glucose molecule for further biochemical reactions.

A second phosphorylation takes place in the cytosol before the 6-carbon chain is broken into two 3-carbon fragments. Then energy benefits begin to appear as these fragments are converted to pyruvate. Two of the steps release enough energy to generate ATP from ADP and inorganic phosphate (PO_4^{3-} or P_i). In addition, 2 molecules of NAD are converted to NADH. The net reaction of glycolysis looks like this:

Glucose + 2NAD + 2ADP + 2 $P_i \longrightarrow$ 2 Pyruvate + 2 NADH + 6ATP

This reaction sequence is anaerobic (without oxygen) and provides the cell a net gain of 2 molecules of ATP for each glucose molecule converted to two pyruvate molecules. A few highly specialized cells, such as red blood cells, lack mitochondria and derive all their ATP through glycolysis. Skeletal muscle fibers rely on glycolysis for ATP production during periods of active contraction. Most cells can survive for brief periods using the ATP provided by glycolysis alone. However, when oxygen is readily available, mitochondrial activity provides most of the ATP that cells need.

Mitochondrial ATP Production

For the cell, glycolysis yields an immediate net gain of 2 ATP molecules for each glucose molecule it breaks down. However, a great deal of additional energy is still stored in the chemical bonds of pyruvate. The cell's ability to capture that energy depends on the availability of oxygen. If oxygen supplies are adequate, mitochondria absorb the pyruvate molecules and break them down. As you will see in the next section, the hydrogen atoms of each pyruvate molecule (CH_3 —CO— COO^-) are removed by coenzymes and are ultimately the source of most of the cell's energy gain. The carbon and oxygen atoms are removed and released as carbon dioxide in a process called **decarboxylation** (dē-kar-boks-i-LĀ-shun).

Recall that a double membrane surrounds each mitochondrion. The *outer membrane* contains large pores that are permeable to ions and small organic molecules such as pyruvate. Ions and molecules easily enter the *intermembrane space* separating the outer membrane from the *inner membrane*. The inner membrane contains a carrier protein that moves pyruvate into the mitochondrial matrix, where it is broken down through the citric acid cycle.

The Citric Acid Cycle

In the mitochondrion, a pyruvate molecule participates in a complex reaction involving NAD and another coenzyme called **coenzyme A**, or **CoA**. This reaction yields 1 molecule of carbon dioxide, 1 of NADH, and 1 of **acetyl-CoA** (a-SĒ-til KÕ-ā)— a 2-carbon **acetyl group** (CH₃CO) bound to coenzyme A. This sets the stage for a sequence of enzymatic reactions

Figure 25–3 Glycolysis. Glycolysis breaks down a 6-carbon glucose molecule into two 3-carbon molecules of pyruvate through a series of enzymatic steps. Further catabolism of pyruvate begins with its entry into a mitochondrion.

called the **citric acid cycle**. It is also known as the *tricarboxylic* (trī-kar-bok-SIL-ik) *acid cycle* (TCA cycle) and the *Krebs cycle*. Because citric acid is the first substrate of the cycle, we'll use citric acid cycle as the preferred term.

The function of the citric acid cycle is to remove hydrogen atoms from organic molecules and transfer them to coenzymes. The overall pattern of the citric acid cycle is shown in Figure 25–4.

At the start of the citric acid cycle, the 2-carbon acetyl group carried by CoA is transferred to a 4-carbon oxaloacetic acid molecule to make the 6-carbon compound citric acid. Coenzyme A is released intact and can thus bind another acetyl group. A complete revolution or "turn" of the citric acid cycle removes 2 carbon atoms, regenerating the 4-carbon chain. (This is why the reaction sequence is called a *cycle*.) We can summarize the fate of the atoms in the acetyl group as follows:

- The 2 carbon atoms are removed in enzymatic reactions that incorporate 4 oxygen atoms and form 2 molecules of carbon dioxide, a waste product.
- The hydrogen atoms are removed by the coenzyme NAD or a related coenzyme called FAD (*flavin adenine dinucleotide*) (Figure 25–4).

Figure 25–4 The Citric Acid Cycle.

Several of the steps in a turn of the citric acid cycle involve more than one reaction and require more than one enzyme. Water molecules are tied up in two of those steps. We can summarize the entire sequence as follows:

$$CH_3CO - CoA + 3NAD + FAD + GDP + P_i + 2H_2O \longrightarrow$$

 $CoA + 2CO_2 + 3NADH + FADH_2 + 2H^+ + GTP$

The only immediate energy benefit of one turn of the citric acid cycle is the formation of a single molecule of GTP (*guanosine triphosphate*) from GDP (*guanosine diphosphate*) and P_i. In practical terms, GTP is the equivalent of ATP, because GTP readily transfers a phosphate group to ADP, producing ATP:

$$GTP + ADP \longrightarrow GDP + ATP$$

The formation of GTP from GDP in the citric acid cycle is an example of **substrate-level phosphorylation**. In this process, an enzyme uses the energy released by a chemical reaction to transfer a phosphate group to a suitable acceptor molecule. GTP is formed in the citric acid cycle, but many reaction pathways in the cytosol phosphorylate ADP and form ATP directly. For example, the ATP produced during glycolysis is generated through substrate-level phosphorylation. Normally, however, substrate-level phosphorylation provides a relatively small amount of energy compared with *oxidative phosphorylation*, which we discuss next.

Oxidative Phosphorylation and the ETS

Oxidative phosphorylation is the generation of ATP within mitochondria in a reaction sequence that requires coenzymes and consumes oxygen. The process produces more than 90 percent of the ATP used by body cells. The key reactions take place in the *electron transport system (ETS)*, a series of integral and peripheral proteins in the inner mitochondrial membrane. The basis of oxidative phosphorylation is the formation of water, a very simple reaction:

$$2H_2 + O_2 \longrightarrow 2H_2O$$

Cells can easily obtain the ingredients for this reaction. Hydrogen is a component of all organic molecules, and oxygen is an atmospheric gas. The only problem is that the reaction releases a tremendous amount of energy all at once. In fact, this reaction releases so much energy that it is used to launch space shuttles into orbit. Cells cannot handle energy explosions. Instead, energy release must be gradual, as it is in oxidative phosphorylation. This powerful reaction proceeds in a series of small, enzymatically controlled steps. Under these controlled conditions, energy can be captured safely, and ATP generated.

Oxidation, Reduction, and Energy Transfer. The enzymatic steps of oxidative phosphorylation involve oxidation and reduction. (There are different types of oxidation and reduction

reactions, but for our purposes the most important are those involving the transfer of electrons.) The loss of electrons is a form of **oxidation**. The gain of electrons is a form of **reduction**. The two reactions are always paired. When electrons pass from one molecule to another, the electron donor is oxidized and the electron recipient is reduced. Oxidation and reduction are important because electrons carry chemical energy. In a typical oxidation–reduction reaction, *the reduced molecule gains energy at the expense of the oxidized molecule*.

TIPS&TRICKS

To remember what occurs with electrons in oxidation and reduction reactions, think **OIL RIG** for **o**xidation **i**s **I**oss and **r**eduction **i**s **g**ain.

In such an exchange, the reduced molecule does not gain all the energy released by the oxidized molecule. Some energy is always released as heat. The remaining energy may be used to do physical or chemical work, such as forming ATP. By passing electrons through a series of oxidation–reduction reactions, cells can capture and use much of the energy that is released as water is formed. Water is formed as these electrons ultimately combine with hydrogen ions and oxygen atoms.

Coenzymes play a key role in this process. A coenzyme acts as an intermediary that accepts electrons from one molecule and transfers them to another molecule. In the citric acid cycle, the coenzymes NAD and FAD remove hydrogen atoms from organic molecules. Each hydrogen atom consists of an electron (e^-) and a proton (a hydrogen ion, H⁺). Thus, when a coenzyme accepts hydrogen atoms, the coenzyme is reduced and gains energy. The donor molecule loses electrons and energy as it gives up its hydrogen atoms.

Note that NADH and $FADH_2$ are the reduced forms of NAD and FAD. As indicated in **Figure 25–4a**, they then transfer their newly acquired hydrogen atoms to other coenzymes. The protons are subsequently released. The electrons, which carry the chemical energy, enter a sequence of oxidation–reduction reactions known as the *electron transport system*. This sequence ends with the transfer of electrons to oxygen and the formation of a water molecule. At several steps along the oxidation–reduction sequence, enough energy is released to support the synthesis of ATP from ADP. Now let's consider that reaction sequence in greater detail.

The coenzyme FAD accepts two hydrogen atoms from the citric acid cycle. In doing so, FAD gains 2 electrons, forming FADH₂. The oxidized form of the coenzyme NAD has a positive charge (NAD⁺). This coenzyme also gains 2 electrons as 2 hydrogen atoms are removed from the donor molecule, resulting in the formation of NADH and the release of a proton (H⁺). For this reason, the reduced form of NAD is often described as "NADH + H⁺."

The Electron Transport System. The **electron transport system (ETS)**, or *respiratory chain*, is a sequence of proteins called **cytochromes** (SĪ-tō-krōmz; *cyto-*, cell + *chroma*, color). Each cytochrome has two parts: a protein and a pigment. The protein is embedded in the inner membrane of a mitochondrion. The protein surrounds the pigment complex, which contains a metal ion, either iron (Fe³⁺) or copper (Cu²⁺). We will consider four cytochromes: *b*, *c*, *a*, and *a*₃.

Figure 25–5 summarizes the basic steps in oxidative phosphorylation. Let's first look at the general path taken by the electrons that are captured and delivered by coenzymes (**Figure 25–5a**):

• A coenzyme strips a pair of hydrogen atoms from a substrate molecule. As we have seen, different coenzymes are used for different substrate molecules. Recall that during glycolysis, which takes place in the cytosol, NAD is reduced to NADH. Within mitochondria, both NAD and FAD are reduced through reactions of the citric acid cycle, producing NADH and FADH₂, respectively.

2 NADH and FADH₂ deliver hydrogen atoms to coenzymes embedded in the inner mitochondrial membrane. The electrons carry the energy, and the protons that accompany them are released before the electrons are transferred to the ETS. As indicated in Figure 25–5a, the electrons travel to the ETS by one of two paths. Which one depends on whether the donor is NADH or FADH₂. The path from NADH involves the coenzyme FMN (*flavin mononucleotide*). The path from FADH₂ proceeds directly to **coenzyme Q** (*ubiquinone*). Both FMN and coenzyme Q are bound to the inner mitochondrial membrane.

3 Coenzyme Q releases hydrogen ions and passes electrons to cytochrome b.

4 Electrons are passed along the electron transport system, losing energy in a series of small steps. The sequence is cytochrome b to c to a to a_3 .

5 At the end of the ETS, an oxygen atom accepts the electrons and combines with hydrogen ions to form water.

Notice that this reaction sequence starts with the removal of 2 hydrogen atoms from a substrate molecule and ends with the formation of water from 2 hydrogen ions and 1 oxygen ion. This is the reaction we described earlier as releasing too much energy if performed in a single step. However, because the reaction takes place in a series of small steps, the hydrogen and oxygen combine safely rather than explosively.

ATP Generation and the ETS. As we noted in Chapter 3, concentration gradients across membranes represent a form of potential energy that can be harnessed by the cell. The electron transport system does not produce ATP directly. Instead, it creates the conditions necessary for ATP production. It creates a steep concentration gradient across the inner mitochondrial

membrane. The electrons that travel along the ETS release energy as they pass from coenzyme to cytochrome and from cytochrome to cytochrome. The energy released at each of several steps drives hydrogen ion pumps. These pumps move hydrogen ions from the mitochondrial matrix into the space between the inner and outer mitochondrial membranes. The pumps create a large concentration gradient for hydrogen ions across the inner membrane. This concentration gradient provides the energy to convert ADP to ATP.

Despite the concentration gradient, hydrogen ions cannot diffuse into the matrix because they are not lipid soluble. However, hydrogen ion channels in the inner membrane permit H^+ to diffuse into the matrix. These ion channels and their attached *coupling factors* make up a protein complex called *ATP synthase*. The kinetic energy of passing hydrogen ions generates ATP in a process known as *chemiosmosis* (kem-ē-oz-MŌ-sis), or *chemiosmotic phosphorylation*.

Figure 25–5b diagrams the mechanism of ATP generation. Hydrogen ions are pumped at three places, as (1) FMN reduces coenzyme Q; (2) cytochrome *b* reduces cytochrome *c*; and (3) electrons are passed from cytochrome *a* to cytochrome a_3 .

For each pair of electrons removed from a substrate in the citric acid cycle by NAD, 6 hydrogen ions are pumped across the inner membrane of the mitochondrion and into the intermembrane space (Figure 25–5b). Their reentry into the matrix provides the energy to generate three molecules of ATP.

Alternatively, for each pair of electrons removed from a substrate in the citric acid cycle by FAD, 4 hydrogen ions are pumped across the inner membrane and into the intermembrane space. Their reentry into the matrix provides the energy to generate 2 molecules of ATP.

The Importance of Oxidative Phosphorylation. Oxidative phosphorylation is the most important cellular mechanism for generating ATP. In most cases, if oxidative phosphorylation slows or stops, the cell dies. If many cells are affected, the individual may die. Oxidative phosphorylation requires both oxygen and electrons. For this reason, the rate of ATP generation is limited by the availability of either oxygen or electrons.

Cells obtain oxygen by diffusion from the extracellular fluid. If the supply of oxygen is cut off, mitochondrial ATP production stops, because reduced cytochrome a_3 will have no acceptor for its electrons. With the last reaction stopped, the entire ETS comes to a halt, like cars at a washed-out bridge. Oxidative phosphorylation can no longer take place, and cells quickly succumb to energy starvation. Because neurons have a high demand for energy, the brain is one of the first organs to be affected.

Hydrogen cyanide gas is sometimes used as a pesticide to kill rats or mice. In some states where capital punishment is legal, it is used to execute criminals. The cyanide ion (CN^-) binds to cytochrome a_3 and prevents the transfer of electrons to oxygen. As a result, cells die from energy starvation.
Figure 25–5 Oxidative Phosphorylation.

b The locations of the coenzymes and the electron transport system. Notice the sites where hydrogen ions are pumped into the intermembrane space, providing the concentration gradient essential to the generation of ATP. The red line indicates the path taken by the electrons.

Energy Yield of Glycolysis and Cellular Respiration

For most cells, the main method of generating ATP is the complete reaction pathway that begins with glucose and ends with carbon dioxide and water. **Figure 25–6** summarizes the process in terms of energy production:

• *Glycolysis.* During glycolysis, the cell gains a net 2 molecules of ATP for each glucose molecule broken down anaerobically to 2 molecules of pyruvate. Two molecules of NADH are also produced. In most cells, electrons are passed from NADH to FAD by an intermediate in the intermembrane space, and

then to CoQ and the electron transport system. This sequence of events ultimately provides an additional 4 ATP molecules.

- *The Electron Transport System.* The citric acid cycle breaks down the 2 pyruvate molecules, transferring hydrogen atoms to NADH and FADH₂. These coenzymes provide electrons to the ETS. Each of the 8 molecules of NADH yields 3 molecules of ATP and 1 water molecule. Each of the 2 FADH₂ molecules yields 2 ATP molecules and 1 water molecule. Thus, the shuffling from the citric acid cycle to the ETS yields 28 molecules of ATP.
- *The Citric Acid Cycle*. Each of the two revolutions of the citric acid cycle required to break down both pyruvate

Figure 25–6 A Summary of the Energy Yield of Aerobic Metabolism. For each glucose molecule broken down by glycolysis, only 2 molecules of ATP (net) are produced. However, glycolysis, the formation of acetyl-CoA, and the citric acid cycle all yield molecules of reduced coenzymes (NADH or FADH₂). Many additional ATP molecules are produced when electrons from these coenzymes pass through the electron transport system. In most cells, each of the 2 NADH molecules produced in glycolysis provides another 2 ATP molecules. Each of the 8 NADH molecules produced in the mitochondria yields 3 ATP molecules, for a total of 24. Another 2 ATP molecules are gained from each of the 2 FADH₂ molecules generated in the mitochondria. The citric acid cycle generates an additional 2 ATP molecules in the form of GTP.

Figure 25–7 Carbohydrate Breakdown and Synthesis. The pathways for glycolysis and gluconeogenesis. Many of the reactions are freely reversible, but separate regulatory enzymes control the key steps, which are indicated by colored arrows. Some amino acids, carbohydrates, lactate, and glycerol can be converted to glucose. The enzymatic reaction that converts pyruvate to acetyl-CoA cannot be reversed.

molecules completely yields 1 molecule of ATP by way of GTP. This cycling provides an additional gain of 2 molecules of ATP.

Summing up, for each glucose molecule processed, the cell gains 36 molecules of ATP: 2 from glycolysis, 4 from the NADH generated in glycolysis, 2 from the citric acid cycle (by means of GTP), and 28 from the ETS.

Cardiac muscle cells and liver cells are able to gain an additional 2 ATP molecules for each glucose molecule broken down. They do so by increasing the energy yield from the 2 NADH generated during glycolysis from 4 to 6 ATP molecules. Although the NADH produced during glycolysis does not enter mitochondria in these cells, each NADH molecule passes its electrons to an intermediate molecule that can cross the mitochondrial membrane. Inside the matrix, NAD strips electrons from the intermediate molecule, forming NADH. The subsequent transfer of electrons to FMN, CoQ, and the ETS results in the production of 6 ATP molecules, just as if the 2 NADH molecules formed during glycolysis had been generated in the citric acid cycle.

Gluconeogenesis

Some of the steps in the breakdown of glucose, or glycolysis, are essentially irreversible. For this reason, cells cannot generate glucose simply by using the same enzymes and reversing the steps of glycolysis (Figure 25–7). Glycolysis and the production of glucose involve different sets of regulatory enzymes. As a result, the two processes are regulated independently.

Some 3-carbon molecules other than pyruvate can be used to synthesize glucose. For this reason, a cell can create glucose molecules from other carbohydrates, lactate, glycerol, or some amino acids. However, cells cannot use acetyl-CoA to make glucose. The reason is that the decarboxylation step (removal of CO_2) between pyruvate and acetyl-CoA cannot be reversed. **Gluconeogenesis** (glū-kō-nē-ō-JEN-e-sis) is the synthesis of glucose from noncarbohydrate precursors, such as lactate, glycerol, or amino acids. Fatty acids and many amino acids cannot be used for gluconeogenesis, because their catabolic pathways produce acetyl-CoA.

Glucose molecules formed by gluconeogenesis can be used to manufacture other simple sugars, complex carbohydrates, proteoglycans, or nucleic acids. In the liver and in skeletal muscle, glucose molecules are stored as glycogen. Glycogen is an important energy reserve that can be broken down when the cell cannot obtain enough glucose from interstitial fluid. Glycogen molecules are large, but glycogen reserves take up very little space because they form compact, insoluble granules.

The formation of glycogen from glucose, known as **glycogenesis**, is a complex process. It involves several steps and

Clinical Note

Carbohydrate Loading Eating carbohydrates just before exercise does not improve your performance. In fact, it can decrease your endurance by slowing the mobilization of existing energy reserves. Runners or swimmers preparing for lengthy endurance events, such as a marathon or 5-km swim, do not eat immediately before participating. For two hours before the event, they also limit their intake to just drinking water.

Performance in endurance sports improves if muscles have large stores of glycogen. Endurance athletes try to build these stores by eating carbohydrate-rich diets for three days before competing. This practice is called *carbohydrate loading*. Studies in Sweden, Australia, and South Africa have recently shown that attempts to deplete stores by exercising to exhaustion before carbohydrate loading, a practice called *carbohydrate depletion/loading*, are less effective than three days of rest or minimal exercise during carbohydrate loading. The less intense approach improves mood and reduces the risks of muscle and kidney damage.

requires the high-energy compound *uridine triphosphate (UTP)*. The breakdown of glycogen, called **glycogenolysis**, takes place quickly and involves a single enzymatic step.

TIPS&TRICKS

To make several similar-sounding terms easier to tell apart, learn these word parts: *genesis* means "the formation of," *lysis* means "a loosening," *glyco* and *gluco* refer to glucose, and *neo* means "new." So, **gluconeogenesis** is the formation of new glucose, **glycogenesis** is the formation of glycogen (the storage form of glucose), **glycogenolysis** is the breakdown of glycogen to glucose, and **glycolysis** is the breakdown of glucose to pyruvate.

CHECKPOINT

- 4. What is the primary role of the citric acid cycle in the production of ATP?
- 5. Each NADH produced by glycolysis in skeletal muscle fibers leads to the production of 2 ATP molecules in the mitochondria, but each NADH produced by glycolysis in cardiac muscle cells leads to the production of 3 ATP molecules. Why?
- 6. How would a decrease in the level of NAD in the cytosol affect ATP production in mitochondria?

25-3 Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as free fatty acids and lipoproteins

Learning Outcome Describe the pathways involved in lipid metabolism, and summarize the mechanisms of lipid transport and distribution.

Like carbohydrates, lipid molecules contain carbon, hydrogen, and oxygen, but the atoms are present in different proportions. Triglycerides are the most abundant lipid in the body, so our discussion focuses on pathways for triglyceride breakdown and synthesis.

Lipid Catabolism

During lipid catabolism, or **lipolysis**, lipids are broken down into pieces that can be either converted to pyruvate or channeled directly into the citric acid cycle (Figure 25–8). A triglyceride is first split into its component parts by hydrolysis, yielding 1 molecule of glycerol and 3 fatty acid molecules. Enzymes in the cytosol convert glycerol to pyruvate, which then enters the citric acid cycle. The catabolism of fatty acids involves a completely different set of enzymes that generate acetyl-CoA directly.

Beta-Oxidation

Beta-oxidation is a sequence of reactions in which fatty acid molecules are broken down into 2-carbon acetic acid fragments, and FAD and NAD⁺ are reduced. Each acetic acid ultimately forms acetyl-CoA. This process takes place inside mitochondria, so the carbon chains can enter the citric acid cycle immediately as acetyl-CoA. **Figure 25–8** diagrams one step in the process of beta-oxidation. Each step generates molecules of acetyl-CoA, NADH, and FADH₂ and leaves a shorter carbon chain bound to coenzyme A.

Beta-oxidation has substantial energy benefits. For each 2-carbon fragment removed from the fatty acid, the cell gains 12 ATP molecules from the processing of acetyl-CoA in the citric acid cycle, plus 5 ATP molecules from the NADH and FADH₂. The cell can therefore gain 144 ATP molecules from the breakdown of one 18-carbon fatty acid molecule. By comparison, this number of ATP molecules yields almost 1.5 times the energy obtained by the complete breakdown of three 6-carbon glucose molecules. The catabolism of other lipids follows similar patterns, generally ending with the formation of acetyl-CoA.

Lipids and Energy Production

Lipids are important energy reserves because they can provide large amounts of ATP. Lipids can be stored in compact droplets in the cytosol because they are insoluble in water. This

Figure 25–8 Beta-Oxidation. During beta-oxidation, the carbon chains of fatty acids are broken down to yield molecules of acetyl-CoA, which can be used in the citric acid cycle. The reaction also donates hydrogen atoms to coenzymes, which then deliver them to the electron transport system. H₂O CO_2

storage method saves space, but when the lipid droplets are large, it is difficult for water-soluble enzymes to get at them. For this reason, lipid reserves are more difficult to access than carbohydrate reserves. Also, most lipids are processed inside mitochondria, and mitochondrial activity is limited by the availability of oxygen.

The net result is that lipids cannot provide large amounts of ATP quickly. However, cells with modest energy demands can shift to lipid-based energy production when glucose supplies are limited. Skeletal muscle fibers normally cycle between lipid metabolism and carbohydrate metabolism. At rest (when energy demands are low), these cells break down fatty acids. During activity (when energy demands are high and immediate), skeletal muscle fibers shift to glucose metabolism.

Lipid Synthesis

Lipogenesis (lip-ō-JEN-e-sis) is the synthesis of lipids. Glycerol is synthesized from *dihydroxyacetone phosphate*, one of the 3-carbon intermediate products shared by the pathways of glycolysis and gluconeogenesis. The synthesis of most types of lipids, including nonessential fatty acids and steroids, begins with acetyl-CoA. Lipogenesis can use almost any organic substrate, because lipids, amino acids, and carbohydrates can be converted to acetyl-CoA. In other words, the body can turn just about anything we eat into fat.

Fatty acid synthesis involves a reaction sequence quite distinct from that of beta-oxidation. Body cells cannot *build* every fatty acid they can break down. For example, **linoleic acid** and **linolenic acid** are both 18-carbon unsaturated fatty acids synthesized by plants. They cannot be synthesized in the human body. They are considered **essential fatty acids**, because they must be included in your diet. These fatty acids are also needed to synthesize prostaglandins and some of the phospholipids in plasma membranes throughout the body.

Lipid Transport and Distribution

Like glucose, lipids are needed throughout the body. All cells need lipids to maintain their plasma membranes. Important steroid hormones must reach target cells in many different tissues. Free fatty acids make up a small percentage of the total circulating lipids. Because most lipids are not soluble in water, special transport mechanisms carry them from one region of the body to another. Most lipids circulate through the blood-stream as lipoproteins (Figure 25–9).

Free Fatty Acids

Free fatty acids (FFAs) are lipids that can diffuse easily across plasma membranes. In the blood, free fatty acids are generally bound to albumin, the most abundant plasma protein. Sources of free fatty acids in the blood include the following:

- Fatty acids that are not used in the synthesis of triglycerides, but diffuse out of the intestinal epithelium and into the blood.
- Fatty acids that diffuse out of lipid reserves (such as those in the liver and adipose tissue) when triglycerides are broken down.

Liver cells, cardiac muscle cells, skeletal muscle fibers, and many other body cells can metabolize free fatty acids. These lipids are an important energy source during periods of starvation, when glucose supplies are limited.

Lipoproteins

Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and cholesterol. A superficial coating of phospholipids and proteins makes the entire complex soluble. Exposed proteins of the complexes bind to specific membrane receptors. For this reason, these membrane proteins determine which cells absorb the associated lipids.

Lipoproteins are usually classified into five major groups according to size and the relative proportions of lipid and protein:

- Chylomicrons. Chylomicrons are the largest lipoproteins, ranging in diameter from 0.03 to 0.5 μm. About 95 percent of the weight of a chylomicron consists of triglycerides. They are produced by intestinal epithelial cells from the fats in food. D p. 906 Chylomicrons carry absorbed lipids from the intestinal tract into the lymph and then to the blood-stream. The liver is the primary source of all the other groups of lipoproteins, which shuttle lipids among various tissues.
- 2. Very Low Density Lipoproteins (VLDLs). Very low density lipoproteins contain triglycerides manufactured by the liver, plus small amounts of phospholipids and cholesterol. The primary function of VLDLs is to transport these triglycerides to skeletal muscles and adipose tissues. The VLDLs range in diameter from 25 to 75 nm ($0.025-0.075 \ \mu$ m).
- 3. Intermediate-Density Lipoproteins (IDLs). Intermediatedensity lipoproteins are intermediate in size and lipid composition between VLDLs and low-density lipoproteins (LDLs). IDLs contain smaller amounts of triglycerides than do VLDLs. IDLs also have more phospholipids and cholesterol than LDLs.
- 4. *Low-Density Lipoproteins (LDLs)*. Low-density lipoproteins contain cholesterol, lesser amounts of phospholipids, and very few triglycerides. These lipoproteins are about 25 nm in diameter. They deliver cholesterol to peripheral tissues. LDL cholesterol is often called "bad cholesterol" because the cholesterol may wind up in arterial plaques.
- 5. *High-Density Lipoproteins (HDLs)*. High-density lipoproteins have roughly equal amounts of lipid and protein. The lipids are largely cholesterol and phospholipids. HDLs are about 10 nm in diameter. Their primary function is to transport excess cholesterol from peripheral tissues back to the liver for storage or excretion in the bile. HDL cholesterol is called "good cholesterol" because it is returning from peripheral tissues and does not cause circulatory problems. Actually, applying the terms *good* and *bad* to cholesterol can be misleading, for cholesterol metabolism is complex and variable. (For more details, see the Clinical Note "Dietary

Figure 25–9 Lipid Transport and Utilization.

Clinical Note

Dietary Fats and Cholesterol Elevated cholesterol levels are associated with the development of coronary artery disease (CAD) **p.** 698 and atherosclerosis **p**. 728. Nutritionists now recommend that you keep your cholesterol intake under 300 mg per day. This amount represents a 40 percent reduction for the average American adult. Due to rising concerns about cholesterol, such phrases as "low cholesterol," "contains no cholesterol," and "cholesterol free" are now widely used in the advertising and packaging of foods. Cholesterol content alone, however, does not tell the entire story. Consider the following basic information about cholesterol and about lipid metabolism in general:

- Cholesterol Has Many Vital Functions in the Human Body. Cholesterol serves as a waterproofing for the epidermis, a lipid component of all plasma membranes, a key constituent of bile, and the precursor of several steroid hormones and one vitamin (vitamin D₃). Because cholesterol is so important, the goal of dietary restrictions is not to eliminate it from the diet or from the circulating blood. The goal is to keep cholesterol levels within acceptable limits.
- The Cholesterol Content of the Diet Is Not the Only Source of Circulating Cholesterol. The human body can manufacture cholesterol from acetyl-CoA obtained through glycolysis or the beta-oxidation of other lipids. Such cholesterol probably accounts for only about 20 percent of the cholesterol in the bloodstream. The rest comes from metabolism of saturated fats in the diet. If the diet contains an abundance of saturated fats, cholesterol levels in the blood rise because excess lipids are broken down to acetyl-CoA and used to synthesize cholesterol. Consequently, individuals trying to lower serum cholesterol levels by dietary control must also restrict other lipids, especially saturated fats.
- Genetic Factors Affect Each Individual's Cholesterol Level. If you reduce the cholesterol in your diet, your body synthesizes more to maintain "acceptable" concentrations in the blood. But what is an "acceptable" level? It depends on your genetic makeup. Because individuals have different genes, their cholesterol levels can vary, even on similar diets. In virtually all instances, however, dietary restrictions can lower blood cholesterol significantly.
- Cholesterol Levels Vary with Age and Physical Condition. In general, as we age, our cholesterol levels gradually climb. At age 19, three out of four males have fasting cholesterol levels (levels measured 8–12 hours after a meal) below 170 mg/dL. Cholesterol levels in females of this age are slightly higher, typically at or below 175 mg/dL. As age

increases, the cholesterol levels gradually climb. Over age 70, the levels are 230 mg/dL (males) and 250 mg/dL (females). Cholesterol levels are considered unhealthy if they are higher than those of 90 percent of the population in that age group. For males, this level ranges from 185 mg/dL at age 19 to 250 mg/dL at age 70. For females, the comparable levels are 190 mg/dL and 275 mg/dL respectively.

The levels that are considered optimal to reduce risk of atherosclerosis and coronary artery disease depend on the presence or absence of associated risk factors. These factors include, but are not limited to, hypertension, diabetes mellitus, personal and family history of heart disease, and smoking. The recommendations and guidelines vary depending on the reference consulted. However, everyone should be screened for high blood cholesterol levels as they age. Men should be screened at a younger age than women.

When ordering a blood test for cholesterol, most physicians also request information about circulating triglycerides. In fasting individuals, triglycerides are usually present at levels of 40–150 mg/dL. (After a person has consumed a fatty meal, triglyceride levels may be temporarily elevated.)

When cholesterol levels are high, or when an individual has a family history of atherosclerosis or CAD, further tests and calculations may be performed. The HDL level is measured, and the LDL level is calculated as:

$$\mathsf{LDL} = \mathsf{cholesterol} - \mathsf{HDL} - \frac{\mathsf{triglycerides}}{5}$$

A high total cholesterol value linked to a high LDL level spells trouble. In effect, too much cholesterol is being exported to peripheral tissues. Problems can also exist in individuals with high total cholesterol—or even normal total cholesterol—but low HDL levels (below 35 mg/dL). In such cases, excess cholesterol delivered to the tissues cannot easily be returned to the liver for excretion. In either event, the amount of cholesterol in peripheral tissues—and especially in arterial walls—is likely to increase.

For years, LDL:HDL ratios were considered valid predictors of the risk of developing atherosclerosis. Risk-factor analysis and LDL levels are now thought to be more accurate indicators. For males with more than one risk factor, many clinicians recommend dietary changes and drug therapy if LDL levels exceed 130 mg/dL, or even 100 mg/dL, regardless of the total cholesterol or HDL levels. Fats and Cholesterol" on p. 951.) Figure 25–9 also shows the relationship between LDL and HDL lipoproteins and the transport of cholesterol.

We now know that exercise lowers cholesterol levels. It is recommended that individuals get 30 minutes per day of moderate to vigorous exercise. Recent studies have also shown that vigorous exercise—the equivalent of 20 miles of jogging per week—lowered LDL levels even more than moderate exercise.

CHECKPOINT

- 7. Define beta-oxidation.
- 8. Identify the five major groups of lipoproteins.
- 9. Why are high-density lipoproteins (HDLs) considered beneficial to health?

See the blue Answers tab at the back of the book.

25-4 Protein catabolism involves transamination and deamination, whereas protein synthesis involves amination and transamination

Learning Outcome Summarize the main processes of protein metabolism, and discuss the use of protein as an energy source.

The body can synthesize 100,000 to 140,000 different proteins. They have various functions and structures. Yet, each protein contains some combination of the same 20 amino acids. Under normal conditions, cellular proteins are continuously recycled in the cytosol. Peptide bonds are broken, and the free amino acids are used in new proteins.

If other energy sources are inadequate, mitochondria can generate ATP by breaking down amino acids in the citric acid cycle. Not all amino acids enter the cycle at the same point, however, so the ATP benefits vary. Nonetheless, the average ATP yield per gram is comparable to that of carbohydrate catabolism.

Amino Acid Catabolism

The first step in amino acid catabolism is the removal of the amino group $(-NH_2)$. This process requires a coenzyme derivative of **vitamin B**₆ (*pyridoxine*). The amino group is removed by *transamination* (tranz-am-i-NĀ-shun) or *deamination* (dē-am-i-NĀ-shun). We consider other aspects of amino acid catabolism in a later section.

Transamination

Transamination attaches the amino group of an amino acid to a **keto acid**, which resembles an amino acid except that the second carbon binds an oxygen atom rather than an amino group (**Figure 25–10a**). This transfer converts the keto acid into an amino acid that can leave the mitochondrion and enter the cytosol. There it can be used for protein synthesis. In the process, the original amino acid becomes a keto acid that can be broken down in the citric acid cycle.

Cells in many different tissues perform transaminations, enabling cells to synthesize many of the amino acids needed for protein synthesis. Cells of the liver, skeletal muscles, heart, lung, kidney, and brain are particularly active in protein synthesis. They carry out many transaminations.

Deamination

Deamination prepares an amino acid for breakdown in the citric acid cycle (Figure 25–10b). Deamination is the removal of an amino group and a hydrogen atom in a reaction that generates an ammonium ion (NH_4^+) . Ammonium ions are highly toxic, even in low concentrations.

Liver cells are the primary sites of deamination. They also have enzymes that remove ammonium ions by synthesizing **urea**, a fairly harmless water-soluble compound excreted in urine. The **urea cycle** is the reaction sequence that produces urea (Figure 25–10c).

When glucose supplies are low and lipid reserves are inadequate, liver cells break down internal proteins and absorb additional amino acids from the blood. The amino acids are deaminated, and their carbon chains are broken down to provide ATP.

Proteins and ATP Production

Three factors make protein catabolism an impractical source of quick energy:

- Proteins are more difficult to break apart than are complex carbohydrates or lipids.
- 2. One of the by-products, ammonium ions, is toxic to cells.
- **3.** Proteins form the most important structural and functional components of any cell. Extensive protein catabolism threatens homeostasis at the cellular and system levels.

Several inherited metabolic disorders result from an inability to produce specific enzymes involved in amino acid metabolism. For example, individuals with *phenylketonuria* (fen-il-kē-tō-NOO-rē-uh), or PKU, have a defect in the enzyme *phenylalanine hydroxylase*. They cannot convert phenylalanine to tyrosine. This reaction is an essential step in the synthesis of norepinephrine, epinephrine, dopamine, and melanin. If PKU is not detected in infancy, phenylalanine builds up and central nervous system development is inhibited. Severe brain damage results. The condition is common enough that a warning is printed on the packaging of products that contain phenylalanine, such as diet drinks.

Protein Synthesis

We discussed the basic mechanism for protein synthesis in Chapter 3 (Figures 3–12 and 3–13, pp. 85, 88–89). Your body

Figure 25–10 Amino Acid Catabolism and Synthesis.

can synthesize about half of the various amino acids needed to build proteins. There are 10 **essential amino acids**, which must come from the diet. Your body cannot synthesize eight of them (*isoleucine*, *leucine*, *lysine*, *threonine*, *tryptophan*, *phenylalanine*, *valine*, and *methionine*). The other two (*arginine* and *histidine*) can be synthesized, but not in the amounts that growing children need.

Other amino acids are called **nonessential amino acids** because the body can make them on demand. Your body cells can readily synthesize their carbon frameworks. Then an amino group can be added by transamination or by **amination**—using an ammonium ion as a reactant (Figure 25–10d).

Protein deficiency diseases develop in people who do not eat adequate amounts of all essential amino acids. All amino acids must be available if protein synthesis is to take place. Every transfer RNA molecule must appear at the active ribosome in the proper sequence, bearing its individual amino acid. If that does not happen, the entire process comes to a halt. A person will be malnourished to some degree if the diet is deficient in essential amino acids, regardless of its energy content. Examples of protein deficiency diseases include *marasmus* and *kwashiorkor*. More than 100 million children worldwide have symptoms of these disorders, although none of these conditions is common in the United States today.

Spotlight Figure 25–11 summarizes the metabolic pathways for lipids, carbohydrates, and proteins. The diagrams present the reactions in a "typical" cell. Note, however, that no one

SPOTLIGHT Figure 25–11 Absorptive and Postabsorptive States

The **absorptive state** is the time following a meal, when nutrient absorption is under way. Nutrient absorption was outlined in Spotlight Figure 24–27. After a typical meal, the absorptive state lasts for about 4 hours. If you are fortunate enough to eat three meals a day, you spend 12

out of every 24 hours in the absorptive state. Insulin is the primary hormone of the absorptive state. Various other hormones stimulate amino acid uptake (growth hormone) and protein synthesis (growth hormone, androgens, and estrogens).

Glucose released

The **postabsorptive state** is the time when nutrients are not being absorbed and your body must rely on internal energy reserves to meet its energy demands. You spend about 12 hours each day in the postabsorptive state. If you skip meals, however, you can extend that time considerably. Metabolic activity in the postabsorptive state is focused on mobilizing energy reserves and

POSTABSORPTIVE STATE

cell can carry out all the anabolic and catabolic operations and interconversions required by the body as a whole. As cells differentiate, each type develops its own set of enzymes. These enzymes determine the cell's metabolic capabilities. In the face of such cellular diversity, homeostasis can be preserved only when the metabolic activities of tissues, organs, and organ systems are coordinated.

CHECKPOINT

- **10**. Define transamination.
- **11**. Define deamination.
- 12. How would a diet that is deficient in pyridoxine (vitamin B₆) affect protein metabolism?

See the blue Answers tab at the back of the book.

25-5 The body experiences two patterns of metabolic activity: the absorptive and postabsorptive states

Learning Outcome Differentiate between the absorptive and postabsorptive metabolic states, and summarize the characteristics of each.

The nutrient requirements of each tissue vary with the types and quantities of enzymes present in the cytosol of cells. From a metabolic standpoint, we consider the body to have five distinctive components: the liver, adipose tissue, skeletal muscle, neural tissue, and other peripheral tissues:

- 1. *The Liver*. The liver is the focal point of metabolic regulation and control. Liver cells contain a great diversity of enzymes, so they can break down or synthesize most of the carbohydrates, lipids, and amino acids needed by other body cells. Liver cells have an extensive blood supply, so they are in an excellent position to monitor and adjust the nutrient composition of circulating blood. The liver also contains significant energy reserves in the form of glycogen.
- 2. *Adipose Tissue*. Adipose tissue stores lipids, primarily as triglycerides. Adipocytes are located in many areas: in areolar tissue, in mesenteries, within red and yellow bone marrows, in the epicardium, and around the eves and the kidneys.
 - 3. *Skeletal Muscle.* Skeletal muscle accounts for almost half of a healthy person's body weight. Skeletal muscle fibers maintain substantial glycogen reserves. In addition, if other nutrients are unavailable, their contractile proteins can be broken down and the amino acids used as an energy source.
 - 4. *Neural Tissue*. Neural tissue has a high demand for energy, but the cells do not maintain reserves of carbohydrates, lipids, or proteins. Neurons must have a reliable supply of glucose, because they are generally unable to metabolize

other molecules. If blood glucose levels become too low, neural tissue in the central nervous system cannot continue to function, and the person falls unconscious.

5. *Other Peripheral Tissues.* Other peripheral tissues do not maintain large metabolic reserves, but they are able to metabolize glucose, fatty acids, or other substrates. Their preferred source of energy varies according to instructions from the endocrine system.

To understand the interrelationships among these five components, let's consider events over a typical 24-hour period. During this time, the body experiences two broad patterns of metabolic activity: the *absorptive state* and the *postabsorptive state* (Spotlight Figure 25–11).

In the absorptive state that follows a meal, cells absorb nutrients to be used for growth, maintenance, and energy reserves. Hours later, in the postabsorptive state, metabolic reactions are focused on maintaining blood glucose levels that meet the needs of neural tissue.

During the postabsorptive state, liver cells conserve glucose and break down lipids and amino acids. Both lipid catabolism and amino acid catabolism generate acetyl-CoA. As the concentration of acetyl-CoA rises, compounds called *ketone bodies* begin to form. A **ketone body** is an organic compound produced by fatty acid metabolism that dissociates in solution, releasing a hydrogen ion. There are three such compounds: (1) **acetoacetate** (as-e-tō-AS-e-tāt), (2) **acetone** (AS-e-tōn), and (3) **betahydroxybutyrate** (bā-ta-hī-droks-ē-BŪ-te-rāt). Liver cells do not catabolize any of the ketone bodies. Instead, these compounds diffuse through the cytosol and into the general circulation. Cells in peripheral tissues then absorb the ketone bodies and reconvert them to acetyl-CoA for breakdown in the citric acid cycle.

The normal concentration of ketone bodies in the blood is about 30 mg/dL. Very few of these compounds normally appear in urine. During even a brief period of fasting, the increased production of ketone bodies results in *ketosis* (kē-TŌsis), a high concentration of ketone bodies in body fluids. The appearance of ketone bodies in the bloodstream—*ketonemia* lowers blood pH, which must be controlled by buffers. During prolonged starvation, ketone levels continue to rise. Eventually, buffering capacities are exceeded and a dangerous drop in pH takes place. This acidification of the blood by ketone bodies is called *ketoacidosis* (kē-tō-as-i-DŌ-sis). In severe ketoacidosis, the circulating concentration of ketone bodies can reach 200 mg/dL, and the pH may drop below 7.05. A pH that low can disrupt tissue activities and cause coma, cardiac arrhythmias, and death.

In summary, during the postabsorptive state, the liver acts to stabilize blood glucose concentrations. It does so first by the breakdown of glycogen reserves and later by gluconeogenesis. Over the remainder of the postabsorptive state, the combination of lipid and amino acid catabolism provides the necessary ATP. These processes generate large quantities of ketone bodies that diffuse into the bloodstream. Amino acid catabolism results in the release of toxic ammonium ions, which become tied up in the formation of urea.

Changes in the activity of the liver, adipose tissue, skeletal muscle, and other peripheral tissues ensure a steady supply of glucose to the nervous system. The supply remains steady despite daily or even weekly changes in nutrient availability. Only after a prolonged period of starvation does neural tissue begin to metabolize ketone bodies and lactate molecules, as well as glucose.

TIPS&TRICKS

The absorptive state is like harvest time: Food is being gathered and stored. The postabsorptive state corresponds to the time between harvests, when stored food is used for nourishment.

CHECKPOINT

- **13**. What process in the liver increases after you have eaten a high-carbohydrate meal?
- 14. Why do blood levels of urea increase during the postabsorptive state?
- **15**. If a cell accumulates more acetyl-CoA than it can metabolize in the citric acid cycle, what products are likely to form?

See the blue Answers tab at the back of the book.

25-6 Adequate nutrition is necessary to prevent deficiency disorders and ensure physiological functioning

Learning Outcome Explain what makes up a balanced diet and why such a diet is important.

The postabsorptive state can be maintained for a considerable period. For homeostasis to be maintained indefinitely, however, the digestive tract must regularly absorb enough fluids, organic substrates, minerals, and vitamins to keep pace with cellular demands. The absorption of nutrients from food is called **nutrition**.

The body's requirement for each nutrient varies from day to day and from person to person. *Nutritionists* attempt to analyze a diet in terms of its ability to meet the needs of a specific individual. A **balanced diet** contains all the ingredients needed to maintain homeostasis. Such a diet must include adequate essential amino acids and fatty acids, minerals, and vitamins, and substrates for energy generation. In addition, the diet must include enough water to replace losses in urine, feces, and evaporation. A balanced diet prevents **malnutrition**, an unhealthy state resulting from inadequate or excessive absorption of one or more nutrients.

Food Groups and a Balanced Diet

One way of avoiding malnutrition is to consume a diet based on the ChooseMyPlate plan (Figure 25–12 and Table 25–1). The United States Department of Agriculture created this diagram to offer personalized eating plans and food assessments based on the current Dietary Guidelines for Americans. The colorcoded food group slices indicate the proportions of food we should consume from each of the **five basic food groups**: grains (orange), vegetables (green), fruits (red), dairy products (blue), and protein (purple). Oils should be used sparingly in addition to the five basic food groups. For more information, visit www.choosemyplate.gov.

What is important concerning the food you eat is that you take in nutrients in sufficient *quantity* (adequate to meet your energy needs) and *quality* (including essential amino acids, fatty acids, vitamins, and minerals). There is nothing magical about five groups. At various times since 1940, the U.S. government has advocated 11, 7, 4, or 6 food groups. The key is making intelligent choices about what you eat. Poor choices can lead to malnutrition even if all five groups are represented.

For example, consider the essential amino acids. The liver cannot synthesize any of these amino acids, so you must obtain them from your diet. Some foods in the dairy and protein groups-specifically, beef, fish, poultry, eggs, and milkprovide all the essential amino acids in sufficient quantities. They are said to contain **complete proteins**. Many plants also supply adequate *amounts* of protein but contain **incomplete** proteins, which are deficient in one or more of the essential amino acids. People who follow a vegetarian diet, which is largely restricted to the grains, vegetables, and fruits groups (with or without the dairy products group), must become adept at varying their food choices to include combinations of ingredients that meet all their amino acid requirements. Even with a proper balance of amino acids, people who eat a vegan diet, which avoids all animal products, face a significant problem, because vitamin B₁₂ is obtained only from animal products or from fortified cereals or tofu. (Some health-food products, such as Spirulina, are marketed as sources of this vitamin. Unfortunately, humans cannot utilize the form of B_{12} that they contain.)

Nitrogen Balance

A variety of important compounds in the body contain nitrogen atoms. These **N compounds** include:

- Amino acids, which are part of the framework of all proteins and protein derivatives, such as glycoproteins and lipoproteins.
- Purines and pyrimidines, the nitrogenous bases of RNA and DNA.

Figure 25–12 MyPlate Plan. The proportion of each food group is indicated by the size of its color-coded area. Foods should be consumed in proportions based on both the food group and the person's level of activity.

Find your balance between food and physical activity

- Be sure to stay within your daily calorie needs.
- Be physically active for at least 30 minutes most days of the week.
- About 60 minutes a day of physical activity may be needed to prevent weight gain.
- For sustaining weight loss, at least 60 to 90 minutes a day of physical activity may be required.
- Children and teenagers should be physically active for 60 minutes most days.

Know the limits on fats, sugars, and salt (sodium)

- Make most of your fat sources from fish, nuts, and vegetable oils.
- Limit solid fats like butter, margarine, shortening, and lard.
- Check the nutrition facts label to keep saturated fats, trans fats, and sodium low.
- Choose food and beverages low in added sugars. Added sugars contribute calories with few, if any, nutrients.

Table 25–1	Basic Food Groups	Food Groups and Their General Effects on Health				
Nutrient Group		Provides	Health Effects			
Grains (recomme the total eaten as	ended: at least half of s whole grains)	Carbohydrates; vitamins E, thiamine, niacin, folate; calcium; phosphorus; iron; sodium; dietary fiber	Whole grains prevent rapid rise in blood glucose levels, and consequent rapid rise in insulin levels			
Vegetables (reco dark-green and c	mmended: especially prange vegetables)	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate) and prostate cancer (lycopene in tomatoes)			
Fruits (recommer each day)	nded: a variety of fruit	Carbohydrates; vitamins A, C, E, folate; dietary fiber; potassium	Reduce risk of cardiovascular disease; protect against colon cancer (folate)			
Dairy (recommer free milk, yogurt	nded: low-fat or fat- , and cheese)	Complete proteins; fats; carbohydrates; calcium; potassium; magnesium; sodium; phosphorus; vitamins A, B ₁₂ , pantothenic acid, thiamine, riboflavin	Whole milk: High in calories, may cause weight gain; saturated fats correlated with heart disease			
Protein (recomm fish, poultry, egg legumes)	ended: lean meats, s, dry beans, nuts,	Complete proteins; fats; calcium; potassium; phosphorus; iron; zinc; vitamins E, thiamine, B ₆	Fish and poultry lower risk of heart disease and colon cancer (compared to red meat). Consumption of up to one egg per day does not appear to increase incidence of heart disease; nuts and legumes improve blood cholesterol ratios, lower risk of heart disease and diabetes			

- *Creatine*, important in energy storage in muscle tissue (as creatine phosphate).
- Porphyrins, complex ring-shaped molecules that bind metal ions and are essential to the function of hemoglobin, myoglobin, and the cytochromes.

Despite the importance of nitrogen to these compounds, your body neither stores nitrogen nor maintains reserves of N compounds, as it does carbohydrates (glycogen) and lipids (triglycerides). Your body can synthesize the carbon chains of the N compounds, but you must obtain nitrogen atoms either by recycling N compounds already in the body or by absorbing nitrogen from your diet. You are in **nitrogen balance** when

the amount of nitrogen you absorb from your diet balances the amount you lose in urine and feces. This is the normal condition, and it means that the rates of synthesis and breakdown of N compounds are equivalent.

Growing children, athletes, people recovering from an illness or injury, and pregnant or lactating women actively synthesize N compounds. These individuals must absorb more nitrogen than they excrete. Such individuals are in a state of **positive nitrogen balance**.

When excretion exceeds ingestion, a **negative nitrogen balance** exists. This is an extremely unsatisfactory situation. The body contains only about a kilogram of nitrogen tied up in N compounds, and a decrease of one-third can be fatal. Even

when energy reserves are mobilized (as during starvation), carbohydrates and lipid reserves are broken down first and N compounds are conserved.

Like N compounds, minerals and vitamins are essential parts of the diet. Your body cannot synthesize minerals, and your cells can generate only a small quantity of a very few vitamins. We consider minerals and vitamins next.

Minerals

Minerals are inorganic ions released through the dissociation of electrolytes. Minerals are important for three reasons:

- 1. *Ions such as sodium and chloride determine the osmotic concentrations of body fluids.* Potassium is important in maintaining the osmotic concentration of the cytosol inside body cells.
- 2. *Ions in various combinations play major roles in important physiological processes.* As we have seen, these processes include the maintenance of membrane potentials; the construction and maintenance of the skeleton; muscle contraction; the generation of action potentials; the release of

neurotransmitters; hormone production; blood clotting; the transport of respiratory gases; buffer systems; fluid absorption; and waste removal.

3. Ions are essential cofactors in a variety of enzymatic reactions. For example, calcium-dependent ATPase in skeletal muscle also requires the presence of magnesium ions. Another ATPase required for the conversion of glucose to pyruvate needs both potassium and magnesium ions. Carbonic anhydrase is important in CO_2 transport, buffering systems, and gastric acid secretion. This enzyme requires the presence of zinc ions. Finally, each component of the electron transport system requires an iron atom. The final cytochrome (a_3) of the ETS must bind a copper ion as well.

The major minerals and a summary of their functional roles are listed in Table 25–2. Your body contains significant reserves of several important minerals. These reserves help reduce the effects of variations in the dietary supply. However, the reserves are often small. Chronic dietary reductions can lead to a variety of clinical problems. Alternatively, a dietary excess of mineral ions can be equally dangerous, because storage capabilities are limited.

Table 25–2	Minerals and Mineral Reserves			
Mineral	Significance	Total Body Content	Primary Route of Excretion	Recommended Daily Allowance (RDA) in mg
BULK MINERALS				
Sodium	Major cation in body fluids; essential for normal membrane function	110 g, primarily in body fluids	Urine, sweat, feces	1500
Potassium	Major cation in cytoplasm; essential for normal membrane function	140 g, primarily in cytoplasm	Urine	4700
Chloride	Major anion in body fluids; functions in forming HCl	89 g, primarily in body fluids	Urine, sweat	2300
Calcium	Essential for normal muscle and neuron function and normal bone structure	1.36 kg, primarily in skeleton	Urine, feces	1000–1200
Phosphorus	In high-energy compounds, nucleic acids, and bone matrix (as phosphate)	744 g, primarily in skeleton	Urine, feces	700
Magnesium	Cofactor of enzymes, required for normal membrane functions	29 g (skeleton, 17 g; cytoplasm and body fluids, 12 g)	Urine	310-400
TRACE MINERALS				
Iron	Component of hemoglobin, myoglobin, and cytochromes	3.9 g (1.6 g stored as ferritin or hemosiderin)	Urine (traces)	8–18
Zinc	Cofactor of enzyme systems, notably carbonic anhydrase	2 g	Urine, hair (traces)	8–11
Copper	Required as cofactor for hemoglobin synthesis	127 mg	Urine, feces (traces)	0.9
Manganese	Cofactor for some enzymes	11 mg	Feces, urine (traces)	1.8–2.3
Cobalt	Cofactor for transaminations; mineral in vitamin B_{12} (cobalamin)	1.1 g	Feces, urine	0.0001
Selenium	Antioxidant	Variable	Feces, urine	0.055
Chromium	Cofactor for glucose metabolism	0.0006 mg	Feces, urine	0.02-0.035

Problems involving iron are particularly common. The body of a healthy man contains about 3.5 g of iron in the ionic form Fe^{2+} . Of that amount, 2.5 g is bound to the hemoglobin in circulating red blood cells. The rest is stored in the liver and red bone marrow. In women, the total body iron content averages 2.4 g, with roughly 1.9 g incorporated into red blood cells. Thus, a woman's iron reserves consist of only 0.5 g, half that of a typical man. For this reason, if the diet contains inadequate amounts of iron, premenopausal women are more likely to develop signs of iron deficiency than are men.

Vitamins

A vitamin is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. Vitamins are assigned to either of two groups based on their chemical structure and characteristics: *fat-soluble vitamins* or *water-soluble vitamins*.

Fat-Soluble Vitamins

Vitamins A, D, E, and K are the **fat-soluble vitamins**. Fatsoluble vitamins dissolve in lipids. You absorb these vitamins primarily from the digestive tract, along with the lipid contents of micelles. However, when exposed to sunlight, your skin can synthesize small amounts of vitamin D, and intestinal bacteria produce some vitamin K.

The modes of action of these vitamins require further study. Vitamin A has long been recognized as a structural component of the visual pigment retinal. Its more general metabolic effects are not well understood. Vitamin D is ultimately converted to calcitriol. This hormone binds to cytoplasmic receptors within the intestinal epithelium and helps to increase the rate of intestinal absorption of calcium and phosphorus. Vitamin E is thought to stabilize intracellular membranes. Vitamin K is necessary in a reaction that is essential to the synthesis of several

Clinical Note

Vitamins "If a little is good, a lot must be better" is a common—but dangerously incorrect—attitude about vitamins. When you take too much of a fat-soluble vitamin, tissue lipids absorb the excess. Because these vitamins later diffuse back into the bloodstream, the signs and symptoms of hypervitaminosis, once apparent, are likely to persist. When taken in massive amounts (from ten to thousands of times the recommended daily allowance), fat-soluble vitamins can produce acute symptoms of vitamin toxicity. Vitamin A toxicity is the most common condition. It afflicts some children whose parents are overanxious about proper nutrition and vitamins. A single enormous overdose can produce nausea, vomiting, headache, dizziness, lethargy, and even death. Chronic overdose can lead to hair loss, joint pain, hypertension, weight loss, and liver enlargement.

proteins, including at least three of the clotting factors. Current information about the fat-soluble vitamins is summarized in Table 25–3.

Fat-soluble vitamins normally diffuse into plasma membranes and other lipids in the body, including the lipid inclusions in the liver and adipose tissue. As a result, your body contains a significant reserve of these vitamins. Normal metabolic operations can continue for several months after dietary sources have been cut off. For this reason, a dietary insufficiency of fat-soluble vitamins rarely causes signs and symptoms of **hypovitaminosis** (hī-pō-vi-ta-min-Ō-sis) or *vitamin deficiency disease*. However, other factors can cause hypovitaminosis involving either fat-soluble or water-soluble vitamins. Problems

Table 25	-3 The Fat-Soluble Vitamins				
Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess
A	Maintains epithelia; required for synthesis of visual pigments; supports immune system; promotes growth and bone remodeling	Leafy green and yellow vegetables	0.7–0.9	Retarded growth, night blindness, deterioration of epithelial membranes	Liver damage, skin paling, CNS effects (nausea, anorexia)
D (also known as D ₃)	Required for normal bone growth, intestinal calcium and phosphorus absorption, and retention of these ions at the kidneys	Synthesized in skin exposed to sunlight	0.005–0.015*	Rickets, skeletal deterioration	Calcium deposits in many tissues, disrupting functions
E	Prevents breakdown of vitamin A and fatty acids	Meat, milk, vegetables	15	Anemia, other problems suspected	Nausea, stomach cramps, blurred vision, fatigue
К	Essential for liver synthesis of prothrombin and other clotting factors	Vegetables; production by intestinal bacteria	0.09–0.12	Bleeding disorders	Liver dysfunction, jaundice

* Unless exposure to sunlight is inadequate for extended periods and alternative sources are unavailable

Table 25–4	The Water-Soluble Vitamins						
Vitamin	Significance	Sources	Recommended Daily Allowance (RDA) in mg	Effects of Deficiency	Effects of Excess		
B ₁ (thiamine)	Coenzyme in many pathways	Milk, meat, bread	1.1–1.2	Muscle weakness, CNS and cardiovascular problems, including heart disease; called <i>beriberi</i>	Hypotension		
B ₂ (riboflavin)	Part of FAD, involved in multiple pathways, including glycolysis and citric acid cycle	Milk, meat, eggs and cheese	1.1–1.3	Epithelial and mucosal deterioration	Itching, tingling		
B ₃ (niacin)	Part of NAD, involved in multiple pathways	Meat, bread, potatoes	14–16	CNS, GI, epithelial, and mucosal deterioration; called <i>pellagra</i>	ltching, burning; vasodilation; death after large dose		
B₅ (pantothenic acid)	Coenzyme A, in multiple pathways	Milk, meat	10	Retarded growth, CNS disturbances	None reported		
B ₆ (pyridoxine)	Coenzyme in amino acid and lipid metabolism	Meat, whole grains, vegetables, orange juice, cheese and milk	1.3–1.7	Retarded growth, anemia, convulsions, epithelial changes	CNS alterations, perhaps fatal		
B ₉ (folic acid)	Coenzyme in amino acid and nucleic acid metabolism	Leafy vegetables, some fruits, liver, cereal and bread	0.2–0.4	Retarded growth, anemia, gastrointestinal disorders, developmental abnormalities	Few noted, except at massive doses		
B ₁₂ (cobalamin)	Coenzyme in nucleic acid metabolism	Milk, meat	0.0024	Impaired RBC production, causing pernicious anemia	Polycythemia		
B ₇ (biotin)	Coenzyme in many pathways	Eggs, meat, vegetables	0.03	Fatigue, muscular pain, nausea, dermatitis	None reported		
C (ascorbic acid)	Coenzyme in many pathways	Citrus fruits	75–90; Smokers add 35 mg	Epithelial and mucosal deterioration: called scurvy	Kidney stones		

may be due to an inability to absorb a vitamin from the digestive tract, inadequate storage, or excessive demand.

Too much of a vitamin can also have harmful effects. **Hyper-vitaminosis** (hī-per-vī-tuh-min-Ō-sis) occurs when dietary intake exceeds the body's ability to use, store, or excrete a particular vitamin. This condition usually involves one of the fat-soluble vitamins, because the excess is retained and stored in body lipids.

Water-Soluble Vitamins

Most of the **water-soluble vitamins** (Table 25–4) are components of coenzymes. For example, NAD is derived from niacin, FAD from vitamin B_2 (riboflavin), and coenzyme A from vitamin B_5 (pantothenic acid).

Water-soluble vitamins are rapidly exchanged between the fluid compartments of the digestive tract and the circulating blood. Excessive amounts are readily excreted in urine. For this reason, hypervitaminosis involving water-soluble vitamins is relatively uncommon, except among people who take large doses of vitamin supplements. Only vitamins B₁₂ and C are stored in significant quantities. Insufficient intake of other water-soluble vitamins can lead to initial signs and symptoms of vitamin deficiency within a period of days to weeks.

The bacteria that live in the intestines help prevent deficiency diseases. They produce small amounts of five of the nine water-soluble vitamins, in addition to fat-soluble vitamin K. The intestinal epithelium can easily absorb all the water-soluble vitamins except B_{12} . The B_{12} molecule is large. It must be bound to *intrinsic factor* from the gastric mucosa before absorption can take place, as we discussed in Chapter 24. $D_{p.899}$

Diet and Disease

Diet has a profound influence on a person's general health. We have already considered the effects of too many or too few nutrients, above-normal or below-normal concentrations of minerals, and hypervitaminosis or avitaminosis. More subtle long-term problems can occur when the diet includes the wrong proportions or combinations of nutrients. The average diet in the United States contains too much sodium and too many calories. Lipids—particularly saturated fats—provide too great a proportion of those calories. This diet increases the incidence of obesity, heart disease, atherosclerosis, hypertension, and diabetes in the U.S. population.

- CHECKPOINT

- 16. Identify the two classes of vitamins.
- 17. Would an athlete in intensive training try to maintain a positive or a negative nitrogen balance?
- 18. How would a decrease in the amount of bile salts in the bile affect the amount of vitamin A in the body?
- See the blue Answers tab at the back of the book.

Clinical Note

Alcohol Alcohol production and sales are big business throughout the world. We see beer commercials on television, billboards advertising various brands of liquor, and TV or movie characters enjoying a drink. All demonstrate the prominence of alcohol in many societies. Many people are unaware of the medical consequences of this cultural fondness for alcohol. Problems with alcohol are usually divided into those stemming from alcohol abuse and those involving alcoholism. The boundary between these conditions is hazy. *Alcohol abuse* is the general term for overuse and its behavioral and physical effects. *Alcoholism* is chronic alcohol abuse accompanied by the physiological changes associated with addiction to other CNS-active drugs. Alcoholism has received the most attention in recent years, but alcohol abuse—especially when combined with driving a car—is also in the spotlight.

Consider these statistics provided by the CDC and the National Council on Alcoholism and Drug Dependence for people living in the United States:

- One in four children—over 7 million—grows up in a home where somebody abuses alcohol.
- 17.6 million people—1 in every 12 adults—abuse alcohol.
- 79,000 deaths are attributed to alcohol use annually.
- Alcoholism remains the third leading cause of lifestylerelated deaths.
- Some major clinical conditions are caused almost entirely by alcohol consumption. For example, alcohol is responsible for 60–90 percent of all liver disease in the United States.
- Alcohol affects all physiological systems. Major clinical symptoms of alcoholism include (1) disorientation and confusion (nervous system); (2) ulcers, diarrhea, and cirrhosis (digestive system); (3) cardiac arrhythmias, cardiomyopathy, and anemia (cardiovascular system); (4) depressed sexual drive and testosterone levels (reproductive system); and (5) itching and angiomas (benign blood vessel or lymphatic vessel tumors) (integumentary system).
- The toll on newborn infants has risen steadily since the 1960s as the number of female drinkers has increased.

Women who consume 1 ounce of alcohol per day during pregnancy have a higher rate of spontaneous abortion and bear children with lower birth weights than do women who consume no alcohol. Women who drink heavily may have children with *fetal alcohol syndrome (FAS)*. Facial abnormalities, a small head, slow growth, and mental retardation characterize this condition.

Alcohol abuse is considerably more widespread than alcoholism. The medical effects are less well documented, but they are clearly significant.

Several factors interact to produce alcoholism. The primary risk factors are sex (males are more likely to become alcoholics than are females) and a family history of alcoholism. There does appear to be a genetic component: A gene on chromosome 11 has been implicated in some inherited forms of alcoholism. The relative importance of genes versus social environment has been difficult to assess. It is likely that alcohol abuse and alcoholism result from a variety of factors.

Treatment may consist of counseling and behavior modification. To be successful, treatment must include total avoidance of alcohol. Support groups, such as Alcoholics Anonymous (AA), can be very helpful in providing a social framework for abstinence. The drug *disulfiram* (*Antabuse*) sensitizes an individual to alcohol such that a drink produces intense nausea. Unfortunately, it has not proved to be as effective a deterrent as originally anticipated. Clinical tests indicated that it could increase the time between drinks but could not prevent drinking altogether.

Another drug, naltrexone (ReVia, Depade, and injectable Vivitrol), has shown promise in reducing the frequency and severity of drinking relapses in alcoholics. Naltrexone is an opioid receptor antagonist. It blocks the part of the brain that elicits pleasurable feelings after the consumption of alcohol. The result is a decreased craving for alcohol, enabling individuals to stop drinking more readily. Unlike Antabuse, it does not cause nausea.

25-7 Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms

Learning Outcome Define metabolic rate, discuss the factors involved in determining an individual's BMR, and discuss the homeostatic mechanisms that maintain a constant body temperature.

A person's daily energy expenditures vary widely with activity. For example, a person leading a sedentary life may have minimal energy demands, but a single hour of swimming can significantly increase daily energy use. If your daily energy intake exceeds your total energy demands, you store the excess energy, primarily as triglycerides in adipose tissue. If your daily energy expenditures exceed your intake, the result is a net reduction in your body's energy reserves and a corresponding loss in weight. In this section, first we consider aspects of energy intake and expenditure. Then we turn to the topic of thermoregulation.

Energy Gains and Losses

When chemical bonds are broken, energy is released. Inside cells, a significant amount of energy may be used to synthesize

ATP, but much of it is lost to the environment as heat. The process of *calorimetry* (kal- \bar{o} -RIM-e-tr \bar{e}) measures the total amount of energy released when the bonds of organic molecules are broken. The unit of measurement is the **calorie** (KAL- \bar{o} -r \bar{e}) (cal), defined as the amount of energy required to raise the temperature of 1 g of water 1 degree Celsius. One gram of water is not a very practical measure when you are interested in the metabolic processes that keep a 70-kg human alive, so we use the **kilocalorie** (KIL- \bar{o} -kal- \bar{o} -r \bar{e}) (kcal), or **Calorie** (with a capital C), also known as the "large calorie," instead. One Calorie is the amount of energy needed to raise the temperature of 1 *kilogram* of water 1 degree Celsius. Calorie-counting guides list the caloric value of foods in Calories, not calories.

The Energy Content of Food

In cells, organic molecules are oxidized to carbon dioxide and water. Oxidation also takes place when something burns, and this process can be experimentally controlled. A known amount of food is placed in a chamber called a **calorimeter** (kal-ō-RIM-e-ter), which is filled with oxygen and surrounded by a known volume of water. Once the food is inside, the chamber is sealed and the contents are electrically ignited. When the material has completely oxidized and only ash remains in the chamber, the number of Calories released can be determined by comparing the water temperatures before and after the test.

The energy potential of food is usually expressed in Calories per gram (Cal/g). The catabolism of lipids releases a considerable amount of energy, roughly 9.46 Cal/g. The catabolism of carbohydrates or proteins is not as productive, because many of the carbon and hydrogen atoms are already bound to oxygen. Their average yields are comparable: 4.18 Cal/g for carbohydrates and 4.32 Cal/g for proteins. Most foods are mixtures of fats, proteins, and carbohydrates, so the calculated values listed in a "calorie counter" vary.

Energy Expenditure: Metabolic Rate

Clinicians can examine your metabolic state and determine how many Calories you are utilizing. The result can be expressed as Calories per hour, Calories per day, or Calories per unit of body weight per day. What is actually measured is the sum of all the varied anabolic and catabolic processes taking place in your body-your metabolic rate at that time. The metabolic rate changes according to the activity under way. For instance, measurements taken while a person is sprinting are quite different from those taken while a person is sleeping. Figure 25-13 shows the caloric expenditures for various common activities. In an attempt to reduce the variations in studies of energetics and metabolism, physiologists and clinicians standardize the testing conditions so as to determine the **basal metabolic rate (BMR)**. Ideally, the BMR is the minimum resting energy expenditure of an awake, alert person.

A direct method of determining the BMR involves monitoring respiratory activity. In resting individuals, energy use is proportional to oxygen consumption. If we assume that average amounts of carbohydrates, lipids, and proteins are being catabolized, 4.825 Calories are expended per liter of oxygen consumed.

An average individual has a BMR of 70 Cal per hour, or about 1680 Cal per day. Although the test conditions are standardized, many uncontrollable factors can influence the BMR. These factors include age, gender, physical condition, body weight, and genetic differences.

Rather than measuring the actual metabolic rate, clinicians usually monitor the concentration of thyroid hormones. Clinicians take this approach because the BMR is technically difficult to measure, and because circulating thyroid hormone levels have a profound effect on the BMR. The results are then compared with normal values to obtain an index of metabolic activity. One such test, the T_4 **assay**, measures the amount of thyroxine in the blood.

Obesity is defined as body weight more than 20 percent above the ideal weight for a given individual. Currently, obesity is considered an epidemic and is taking its toll on the health of adults and children. Diseases associated with obesity include heart disease, cancer, and diabetes. For this reason, Calorie counting and exercise are important in a weight-control program.

The control of appetite is poorly understood. Stretch receptors along the digestive tract, especially in the stomach, play a role, but other factors are probably more significant. Social factors, psychological pressures, and dietary habits are important. Evidence also indicates that complex hormonal stimuli interact to affect appetite. For example, the hormones *cholecystokinin (CCK)* and *adrenocorticotropic hormone (ACTH)* suppress the appetite. The hormone *leptin*, released by adipose tissues, also plays a role. During the absorptive state, adipose tissues release leptin into the bloodstream as they synthesize triglycerides. When leptin binds to CNS neurons that function in emotion

Figure 25–13 Caloric Expenditures for Various Activities.

25

and the control of appetite, the result is a sense of satiation and the suppression of appetite. *Ghrelin* (GREL-in), a hormone secreted from the gastric mucosa, stimulates appetite. Ghrelin levels decline when the stomach is full, and increase during the fasting state. Blood ghrelin levels tend to be low in obese individuals, suggesting that it plays a role in obesity. Other effects of ghrelin are currently being studied. $\supset p. 900$

Thermoregulation

The BMR estimates the rate of energy use by the body. The energy that cells do not capture and harness is released as heat. This heat serves an important homeostatic purpose. Humans are subject to vast changes in environmental temperatures, but our complex biochemical systems have a major limitation. Our enzymes operate over only a relatively narrow temperature range. Accordingly, our bodies have anatomical and physiological mechanisms that keep body temperatures within acceptable limits, regardless of environmental conditions. This homeostatic process is called **thermoregulation**. Failure to control body temperature can result in a series of physiological changes. For example, a body temperature below 36°C (97°F) or above 40°C (104°F) can cause disorientation. A temperature above 42°C (108°F) can cause convulsions and permanent cell damage.

We continuously produce heat as a by-product of metabolism. When energy use increases due to physical activity, or when our cells are more active metabolically (as they are during the absorptive state), additional heat is generated. The heat produced by biochemical reactions is retained by water,

Figure 25–14 Mechanisms of Heat Transfer.

Rediation

which makes up nearly two-thirds of body weight. Water is an excellent conductor of heat, so the heat produced in one region of the body is rapidly distributed by diffusion, as well as through the bloodstream. If body temperature is to remain constant, that heat must be lost to the environment at the same rate it is generated. When environmental conditions rise above or fall below "ideal," the body must control the gains or losses to maintain homeostasis.

Mechanisms of Heat Transfer

Heat exchange with the environment involves four basic processes: (1) *radiation*, (2) *convection*, (3) *evaporation*, and (4) *conduction* (Figure 25–14).

Objects warmer than the environment lose heat as **radia-tion**. When you feel the heat from the sun, you are experiencing radiant heat. Your body loses heat the same way, but in proportionately smaller amounts. More than 50 percent of the heat you lose indoors is lost through radiation. The exact amount varies with both body temperature and skin temperature.

Convection is heat loss to the cooler air that moves across the surface of your body. As your body loses heat to the air next to your skin, that air warms and rises, moving away from the surface of the skin. Cooler air replaces it, and this air in turn becomes warmed. This pattern then repeats. Convection accounts for roughly 15 percent of the body's heat loss indoors but is insignificant as a mechanism of heat gain.

When water evaporates, it changes from a liquid to a vapor. **Evaporation** absorbs energy—about 0.58 Cal per gram of water evaporated—and cools the surface where evaporation occurs. The rate of evaporation at your skin is highly variable.

Each hour, 20–25 mL of water crosses epithelia and evaporates from the alveolar surfaces and the surface of the skin. This *insensible water loss* remains relatively constant. At rest, it accounts for roughly 20 percent of your body's average indoor heat loss. The sweat glands responsible for *sensible perspiration* have a tremendous scope of activity, ranging from virtual inactivity to secretory rates of 2–4 liters (2.1–4.2 quarts) per hour. ⊃ p. 155

Conduction is the direct transfer of energy through physical contact. When you come into an air-conditioned classroom and sit on a cold plastic chair, you are immediately aware of this process. Conduction is generally not an effective way of gaining or losing heat. Its impact depends on the temperature of the object and the amount of skin surface area involved. When you are lying on cool sand in the shade, conductive losses can be considerable. When you are standing on the same sand, conductive losses are negligible.

The Regulation of Heat Gain and Heat Loss

Heat loss and heat gain involve the activities of many systems. Those activities are coordinated by the **heat-loss center** and **heat-gain center**, respectively, in the preoptic area of the anterior hypothalamus. **Dp**. 480 These centers modify the activities of other hypothalamic nuclei. The overall effect is to control temperature by influencing two processes: the rate of heat production and the rate of heat loss to the environment. Changes in behavior may also support these processes.

Mechanisms for Increasing Heat Loss. When the temperature at the preoptic nucleus rises above its set point, the heat-loss center is stimulated, producing three major effects:

- 1. The inhibition of the vasomotor center causes peripheral vasodilation, and warm blood flows to the surface of the body. The skin takes on a reddish color, skin temperatures rise, and radiative and convective losses increase.
- 2. As blood flow to the skin increases, sweat glands are stimulated to increase their secretory output. The perspiration flows across the body surface, and evaporative heat losses accelerate. Maximal secretion, if completely evaporated, would remove 2320 Cal per hour.
- **3.** *The respiratory centers are stimulated, and the depth of respiration increases.* Often, the individual begins breathing through an open mouth rather than through the nasal passageways. This increases evaporative heat losses through the lungs.

Mechanisms for Promoting Heat Gain. The function of the heat-gain center of the brain is to prevent **hypothermia** (hī-pō-THER-mē-uh), or below-normal body temperature. When the temperature at the preoptic nucleus drops below acceptable levels, the heat-loss center is inhibited and the heat-gain center is activated.

Heat Conservation. The sympathetic vasomotor center decreases blood flow to the dermis, thereby reducing losses by radiation, convection, and conduction. The skin cools. With blood flow restricted, the skin may take on a bluish or pale color. The epithelial cells are not damaged, because they can tolerate extended periods at temperatures as low as 25° C (77° F) or as high as 49° C (120° F).

In addition, blood returning from the limbs is shunted into a network of deep veins. ⊃p. 763 Under warm conditions, blood flows in a superficial venous network (Figure 25–15a). In cold conditions, blood is diverted to a network of veins that lie deep to an insulating layer of subcutaneous fat (Figure 25–15b). This venous network wraps around the deep arteries, and

Induced Hypothermia Hypothermia may be intentionally produced during surgery. The goal is to reduce the metabolic rate of a particular organ or of the patient's entire body. In controlled hypothermia, the patient is first anesthetized to prevent shivering, which would act to fight off hypothermia.

During open-heart surgery, the body is typically cooled to $25^{\circ}C-32^{\circ}C$ (79°F–89°F). This cooling reduces the metabolic demands of the body, which will be receiving blood from an external pump or oxygenator. The heart must be stopped completely during the operation, and it cannot be well supplied with blood over this period. For this reason, the heart is perfused with an *arresting solution* at 0°–4°C ($32^{\circ}F-39^{\circ}F$) and maintained at a temperature below 15°C ($60^{\circ}F$) during the operation. At these temperatures, the cardiac muscle can tolerate several hours of ischemia (inadequate blood supply) without damage.

When cardiac surgery is performed on infants, a deep hypothermia may be produced by cooling the entire body to temperatures as low as 11°C (52°F) for an hour or more. In effect, these conditions are similar to those experienced by victims of accidental drowning.

heat is conducted from the warm blood flowing outward to the limbs to the cooler blood returning from the periphery (Figure 25–15c). This arrangement traps the heat close to the body core and restricts heat loss. Such exchange between fluids that are moving in opposite directions is called *countercurrent exchange*. (We return to this topic in Chapter 26.)

Heat Generation. We can divide the mechanisms for generating heat into two broad categories: shivering thermogenesis and nonshivering thermogenesis. In **shivering thermogenesis** (ther-mō-JEN-e-sis), a gradual increase in muscle tone increases the energy consumption of skeletal muscle tissue throughout your body. The more energy used, the more heat is produced. Both agonist and antagonist muscles are involved. The degree of stimulation varies with the demand.

If the heat-gain center is extremely active, muscle tone increases to the point at which stretch receptor stimulation will produce brief, oscillatory contractions of antagonistic muscles. In other words, you begin to **shiver**. Shivering increases the workload of the muscles and further elevates oxygen and energy consumption. The heat that is produced warms the deep vessels, to which blood has been shunted by the sympathetic vasomotor center. Shivering can elevate body temperature quite effectively, increasing the rate of heat generation by as much as 400 percent.

The intermittent cycle of capillary vasoconstriction and vasodilation in our hands when they are exposed to cold

temperature is called the *Lewis Wave* or the *hunter's response*. This is an autonomic response to reduce heat loss at the extremities.

Nonshivering thermogenesis involves the release of hormones that increase the metabolic activity of all tissues:

- The heat-gain center stimulates the adrenal medullae through the sympathetic division of the autonomic nervous system. As a result, epinephrine is released. It increases the rates of glycogenolysis in liver and skeletal muscle, and the metabolic rate of most tissues. The effects are immediate.
- The preoptic nucleus regulates the production of thyrotropinreleasing hormone (TRH) by the hypothalamus. In children, when body temperatures are below normal, additional TRH is released. This hormone stimulates the release of thyroidstimulating hormone (TSH) by the anterior lobe of the pituitary gland. In response to this release of TSH, the thyroid

gland increases the rate of thyroxine release into the blood. Thyroxine increases not only the rate of carbohydrate catabolism, but also the rate of catabolism of all other nutrients. These effects develop gradually, over a period of days to weeks.

Sources of Individual Variation in Thermoregulation

The timing of thermoregulatory responses differs from person to person. A person may undergo **acclimatization** (a-klī-ma-ti- $Z\bar{A}$ -shun)—a physiological adjustment to a particular environment over time. For example, natives of Tierra del Fuego (off the southernmost tip of South America) once lived naked in the snow, but Hawaii residents often unpack their sweaters when the temperature drops below 22°C (72°F).

Another source of variation is body size. Although heat *production* takes place within the mass of the body, heat *loss*

than it was when it left the trunk.

This mechanism decreases the

rate of heat loss by conserving body heat within the trunk.

Figure 25–15 Vascular Adaptations for Heat Loss and Conservation.

a Circulation through the blood vessels of the forearm in a warm environment. Blood enters the limb in a deep artery and returns to the trunk in a network of superficial veins that radiate heat to the environment through the overlying skin. b Circulation through the blood vessels of the forearm in a cold environment. Blood now returns to the trunk by a network of deep veins that flow around the artery. The amount of heat loss is decreased, as shown in part (c). takes place across a body surface. As an object (or person) gets larger, its surface area increases at a much slower rate than does its total volume. This relationship affects thermoregulation, because heat generated by the "volume" (that is, by internal tissues) is lost at the body surface. For this reason, small individuals lose heat more readily than do large individuals.

Thermoregulatory Problems in Infants. During embryonic development, the mother's body is at normal body temperature. At birth, the infant's temperature-regulating mechanisms are not fully functional. Infants also lose heat quickly as a result of their small size. Consequently, newborns must be dried promptly and kept bundled up. Those born prematurely need a thermally regulated incubator. Infants' body temperatures are also less stable than those of adults.

Infants cannot shiver, but they have a different mechanism for raising body temperature rapidly. In infants, the adipose tissue between the shoulder blades, around the neck, and possibly elsewhere in the upper body, is histologically and functionally different from most of the adipose tissue in adults. The tissue is highly vascularized, and individual adipocytes contain numerous mitochondria. Together, these characteristics give the tissue a deep, rich color that is the source of the name **brown fat**. \supset p. 129

Individual adipocytes in brown fat are innervated by sympathetic fibers. When these nerves are stimulated, lipolysis speeds up in the adipocytes. The cells do not capture the energy released through fatty acid catabolism. Instead, the energy radiates into the surrounding tissues as heat. This heat quickly warms the blood passing through the surrounding network of vessels, and it is then distributed throughout the body. In this way, an infant can very quickly speed up metabolic heat generation by 100 percent. In contrast, nonshivering thermogenesis in an adult raises heat production by only 10–15 percent after a period of weeks.

Thermoregulatory Disorders Heat exhaustion and heat stroke are malfunctions of thermoregulatory mechanisms. With **heat exhaustion**, also known as *heat prostration*, excessive fluids are lost in perspiration, and the individual has difficulty maintaining blood volume. The heat-loss center stimulates sweat glands, whose secretions moisten the surface of the skin to provide evaporative cooling. As fluid losses mount, blood volume decreases. The resulting decline in blood pressure is not countered by peripheral vasoconstriction, because the heat-loss center is actively stimulating peripheral vasodilation. As blood flow to the brain declines, headache, nausea, and eventual collapse follow. Treatment is straightforward: Provide fluids, salts, and a cooler environment.

In **heat stroke**, body temperature rises uncontrollably because the thermoregulatory center stops functioning. The sweat glands are inactive, and the skin becomes hot and dry. Heat stroke is more serious and can follow an untreated case of heat exhaustion. Predisposing factors include any preexisting condition that affects peripheral circulation, such as heart disease or diabetes. Unless the problem is recognized in time, body temperature may climb to 41°C–45°C (106°F–113°F). Temperatures in this range quickly disrupt a variety of vital physiological systems and destroy brain, liver, skeletal muscle, and kidney cells. Effective treatment involves lowering the body temperature as rapidly as possible.

Hypothermia is below-normal body temperature. If body temperature drops significantly below normal levels, thermoregulatory mechanisms become less sensitive and less effective. Cardiac output and respiratory rate decrease. If the core temperature falls below 28°C (82°F), cardiac arrest is likely. The individual then has no heartbeat, no respiratory rate, and no response to external stimuli—even painful ones. The body temperature continues to decline, and the skin turns blue or pale and cold.

At this point, people commonly assume that the person has died. But because metabolic activities have decreased system-wide, the victim may still be saved, even after several hours. Treatment consists of cardiopulmonary support and gradual rewarming, both external and internal. The skin can be warmed up to 45°C (113°F) without damage. Warm baths or blankets can be used. One effective method of raising internal temperatures involves the introduction of warm saline solution into the peritoneal cavity.

Hypothermia is a significant risk for people engaged in water sports. It may complicate the treatment of a drowning victim. Water absorbs heat about 27 times as fast as air does, and the body's heat-gain mechanisms are unable to keep pace over long periods or when faced with a large temperature gradient. But hypothermia in cold water does have a positive side. On several occasions, small children who have "drowned" in cold water have been successfully revived after periods of up to four hours. Children lose body heat quickly, and their systems soon stop functioning as their body temperature declines. This rapid drop in temperature prevents the oxygen starvation and tissue damage that would otherwise take place when breathing stops.

Resuscitation is not attempted if the person has actually frozen. Water expands roughly 7 percent during ordinary freezing. The process destroys plasma membranes throughout the body. Very small organisms can be frozen and subsequently thawed without ill effects, because their surface-tovolume ratio is enormous, and the freezing process occurs so rapidly that ice crystals never form. With increasing age and size, an infant's body temperature becomes more stable. As a result, brown fat becomes less important. With increased body size, skeletal muscle mass, and insulation, shivering thermogenesis becomes more effective in raising body temperature. Adults have little, if any, brown fat.

Thermoregulatory Variations among Adults. Adults of a given body weight may differ in their thermal responses due to variations in body mass and tissue distribution. Adipose tissue is an excellent insulator. It conducts heat at only about one-third the rate of other tissues. As a result, people with a more substantial layer of subcutaneous fat may not begin to shiver until long after their thinner companions.

Two otherwise similar individuals may also differ in their response to temperature changes because their hypothalamic "thermostats" are at different settings. We all experience daily oscillations in body temperature. Temperatures peak during the day or early evening. They fall 1°C–2°C (1.8°F–3.6°F) at night. The ovulatory cycle also causes temperature fluctuations in women, as you will see in Chapter 28.

Individuals vary in the timing of their maximum temperature setting. Some have a series of peaks, with an afternoon low. The origin of these patterns is unclear. The patterns do not result from daily activity regimens. For example, the temperatures of people who work at night still peak during the same range of times as the rest of the population.

Fevers

Any elevated body temperature is called **pyrexia** (pī-REK-sē-uh). Pyrexia is usually temporary. A **fever** is a body temperature

greater than 37.2°C (99°F). We discussed fevers when we examined innate (nonspecific) immunity. \bigcirc **p**. 802 Fevers occur for a variety of reasons, not all of them pathological. In young children, transient fevers with no ill effects can result from exercise in warm weather. Similar exercise-related elevations were rarely seen in adults until running marathons became popular. Temperatures from 39°C to 41°C (103°F to 109°F) may result. For this reason, competitions are usually held when the air temperature is below 28°C (82°F).

Fevers can also result from the following factors:

- Abnormalities that affect the entire thermoregulatory mechanism, such as heat exhaustion or heat stroke.
- Clinical problems that restrict blood flow, such as congestive heart failure.
- Conditions that impair sweat gland activity, such as drug reactions and some skin conditions.
- The resetting of the hypothalamic "thermostat" by circulating *pyrogens*—most notably, interleukin-1.

CHECKPOINT

- **19**. How would the BMR of a pregnant woman compare with her own BMR before she became pregnant?
- 20. What effect does peripheral vasoconstriction on a hot day have on an individual's body temperature?
- **21**. Why do infants have greater problems with thermoregulation than adults?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

anorexia: Persistent loss of appetite.

- **anorexia nervosa:** Eating disorder occurring primarily among girls and women characterized by a desire to lose, or not gain, weight through starvation, due to a distorted view of the person's own body. There are typically two types: strict diet and exercise, and binging and purging.
- **binge-purge syndrome:** Eating disorder characterized by excessive eating followed by periods of fasting or self-induced vomiting.
- **bulimia:** An eating disorder usually characterized by episodic binge eating that is followed by feelings of guilt, depression, and self-condemnation. It is often associated with steps taken to lose weight, such as self-induced vomiting, the use of laxatives, dieting, or fasting.
- **eating disorders:** Psychological problems that result in inadequate or excessive food consumption. Examples include anorexia nervosa and bulimia.
- **familial hypercholesterolemia:** The most common inherited type of hyperlipidemia characterized by high levels of lipids in one's blood. It affects one in every 500 children born, who then present with LDL levels in excess of 190.

- **heat cramps:** A condition that usually follows heavy sweating due to strenuous activity that causes a loss of salt in the body and results in painful muscle spasms in the abdomen, arms, or legs.
- **hyperuricemia:** A condition in which the plasma uric acid level exceeds 7.4 mg/dL. It can result in the condition called *gout*.

ketonuria: The presence of ketone bodies in the urine.

- **kwashiorkor:** A form of malnutrition due to a protein deficiency in the diet that typically affects young children in tropical regions.
- **marasmus:** Severe malnourishment that causes a child's weight to fall significantly below the standards set for children of similar age.

orexigenic: Having a stimulating effect on the appetite.

- **pica:** Tendency or craving for substances other than normal food. Possible organic causes are iron deficiency, lead encephalopathy, pregnancy, and zinc deficiency.
- **protein-calorie malnutrition (PCM):** A severe deficiency of protein in the diet in addition to inadequate caloric intake. It results in the condition termed *kwashiorkor*.
- skin-fold test: Test to estimate the amount of body fat on a person.

25-1 Metabolism refers to all the chemical reactions in the body, and energetics refers to the flow and transformation of energy p. 936

- 1. **Energetics** is the study of the flow of energy and its change(s) from one form to another. Its focus includes understanding a range of energy requirements from cells to the whole body.
- In general, during *cellular metabolism*, cells break down excess carbohydrates first and then lipids, while conserving amino acids. Only about 40 percent of the energy released through **catabolism** is captured in ATP; the rest is released as heat. (*Figure 25–1*)
- 3. Cells synthesize new compounds **(anabolism)** to (1) perform structural maintenance or repairs, (2) support growth, (3) produce secretions, and (4) build and store nutrient reserves.
- 4. Cells "feed" small organic molecules to their mitochondria; in return, the cells get the ATP they need to perform cellular functions. (*Figure 25–2*)

25-2 Carbohydrate metabolism involves glycolysis, ATP production, and gluconeogenesis p. 939

- 5. Most cells generate ATP and other high-energy compounds through the breakdown of carbohydrates.
- Glycolysis and aerobic metabolism, or *cellular respiration*, provide most of the ATP used by typical cells. Glycogen can be broken down to glucose molecules. In glycolysis, each molecule of glucose yields 2 molecules of pyruvic acid (as pyruvate ions), a net 2 molecules of ATP, and 2 NADH molecules. (*Figure 25–3*)
- 7. In the presence of oxygen, pyruvate molecules enter mitochondria, where they are broken down completely in the citric acid cycle. Carbon and oxygen atoms are lost as carbon dioxide (decarboxylation); hydrogen atoms are passed to coenzymes, which initiate the oxygen-consuming and ATPgenerating reaction oxidative phosphorylation. (*Figure 25–4*)
- 8. Cytochromes of the electron transport system (ETS) pass electrons to oxygen, resulting in the formation of water. As this transfer occurs, the ETS generates ATP. (*Figure 25–5*)
- 9. For each glucose molecule processed through glycolysis, the citric acid cycle, and the ETS, most cells gain 36 molecules of ATP. (*Figure 25–6*)
- **10.** Cells can break down other nutrients to provide substrates for the citric acid cycle if supplies of glucose are limited.
- 11. Gluconeogenesis, the synthesis of glucose from noncarbohydrate precursors such as lactate, glycerol, or amino acids, enables a liver cell to synthesize glucose molecules when carbohydrate reserves are depleted. Glycogenesis is the process of glycogen formation. Glycogen is an important energy reserve

when cells cannot obtain enough glucose from interstitial fluid. (*Figure 25–7*)

- **25-3** Lipid metabolism involves lipolysis, beta-oxidation, and the transport and distribution of lipids as free fatty acids and lipoproteins p. 947
- **12.** During **lipolysis** (lipid catabolism), lipids are broken down into pieces that can be converted into pyruvate or channeled into the citric acid cycle.
- 13. Triglycerides, the most abundant lipids in the body, are split into glycerol and fatty acids. The glycerol enters the glycolytic pathways (glycolysis and gluconeogenesis), and the fatty acids enter the mitochondria.
- 14. **Beta-oxidation** is the breakdown of a fatty acid molecule into 2-carbon fragments that can be used in the citric acid cycle. The steps of beta-oxidation cannot be reversed, and the body cannot manufacture all the fatty acids needed for normal metabolic operations. (*Figure 25–8*)
- **15.** Lipids cannot provide large amounts of ATP quickly. However, cells can shift to lipid-based energy production when glucose reserves are limited.
- **16.** In **lipogenesis** (the synthesis of lipids), almost any organic substrate can be used to form glycerol. **Essential fatty acids** are those that cannot be synthesized and must be included in the diet.
- 17. Most lipids circulate as **lipoproteins** (lipid–protein complexes that contain large glycerides and cholesterol). The largest lipoproteins, chylomicrons, carry absorbed lipids from the intestinal tract to the bloodstream. All other lipoproteins are derived from the liver and carry lipids to and from various tissues of the body. (*Figure 25–9*)
- **18.** Capillary walls of adipose tissue, skeletal muscle, cardiac muscle, and the liver contain **lipoprotein lipase**, an enzyme that breaks down lipids, releasing a mixture of fatty acids and monoglycerides into the interstitial fluid. (*Figure 25–9*)

25-4 Protein catabolism involves transamination and deamination, whereas protein synthesis involves amination and transamination **p**. 952

- If other energy sources are inadequate, mitochondria can break down amino acids in the citric acid cycle to generate ATP. In the mitochondria, the amino group can be removed by either transamination (an exchange reaction) or deamination. (*Figure 25–10*)
- 20. Protein catabolism is impractical as a source of quick energy.
- **21.** Roughly half the amino acids needed to build proteins can be synthesized. There are 10 **essential amino acids**, which must be acquired through the diet. **Amination**, the attachment of an amino group to a carbon framework, is an important step in the synthesis of **nonessential amino acids**. (*Figure 25–10*, *Spotlight Figure 25–11*)

25-5 The body experiences two patterns of metabolic activity: the absorptive and postabsorptive states p. 956

- 22. No one cell of a human can perform all the anabolic and catabolic operations necessary to support life. Homeostasis can be preserved only when metabolic activities of different tissues are coordinated.
- **23.** The body has five metabolic components: the liver, adipose tissue, skeletal muscle, neural tissue, and other peripheral

tissues. The liver is the focal point for metabolic regulation and control. Adipose tissue stores lipids, primarily in the form of triglycerides. Skeletal muscle contains substantial glycogen reserves, and the contractile proteins can be degraded and the amino acids used as an energy source. Neural tissue does not contain energy reserves; glucose must be supplied to it for energy. Other peripheral tissues are able to metabolize glucose, fatty acids, or other substrates under the direction of the endocrine system.

- 24. For about four hours after a meal, nutrients enter the blood as intestinal absorption proceeds. (*Spotlight Figure 25–11*)
- **25.** The liver closely regulates the circulating levels of glucose and amino acids.
- **26.** The **absorptive state** exists when nutrients are being absorbed by the digestive tract. Adipocytes remove fatty acids and glycerol from the bloodstream and synthesize new triglycerides to be stored for later use. (*Spotlight Figure 25–11*)
- 27. During the absorptive state, glucose molecules are catabolized and amino acids are used to build proteins. Skeletal muscles may also catabolize circulating fatty acids, and the energy obtained is used to increase glycogen reserves.
- **28.** The **postabsorptive state** extends from the end of the absorptive state to the next meal. (*Spotlight Figure 25–11*)
- **29.** When blood glucose levels fall, the liver begins breaking down glycogen reserves and releasing glucose into the bloodstream. As the time between meals increases, liver cells synthesize glucose molecules from smaller carbon fragments and from glycerol molecules. Fatty acids undergo beta-oxidation; the fragments enter the citric acid cycle or combine to form **ketone bodies**. (*Spotlight Figure 25–11*)
- **30.** Some amino acids can be converted to pyruvate and used for gluconeogenesis; others, including most of the essential amino acids, are converted to acetyl-CoA and are either catabolized or converted to ketone bodies.
- **31.** Neural tissue continues to be supplied with glucose as an energy source until blood glucose levels become very low.
- 25-6 Adequate nutrition is necessary to prevent deficiency disorders and ensure physiological functioning p. 957
- **32. Nutrition** is the absorption of nutrients from food. A **bal-anced diet** contains all the ingredients needed to maintain homeostasis; a balanced diet prevents **malnutrition**.
- **33.** The five **basic food groups** are grains, vegetables, fruits, dairy, and protein. These are arranged on a *plate* to reflect the recommended daily food consumption balanced with daily physical activity. (*Figure 25–12; Table 25–1*)
- 34. Amino acids, purines, pyrimidines, creatine, and porphyrins are **N compounds**, which contain nitrogen atoms. An adequate dietary supply of nitrogen is essential, because the body does not maintain large nitrogen reserves. **Nitrogen balance**

Review Questions

is a state in which the amount of nitrogen absorbed equals that lost in urine and feces.

- **35. Minerals** act as cofactors in a variety of enzymatic reactions. They also contribute to the osmotic concentration of body fluids and play a role in membrane potentials, action potentials, the release of neurotransmitters, muscle contraction, skeletal construction and maintenance, gas transport, buffer systems, fluid absorption, and waste removal. (*Table 25–2*)
- **36.** Vitamins are needed in very small amounts. Vitamins A, D, E, and K are **fat-soluble vitamins**; taken in excess, they can lead to **hypervitaminosis**. **Water-soluble vitamins** are not stored in the body; a lack of adequate dietary supplies may lead to **hypovitaminosis** (*vitamin deficiency disease*). (*Tables 25–3, 25–4*)
- 37. A balanced diet can improve one's general health.
- **25-7** Metabolic rate is the average caloric expenditure, and thermoregulation involves balancing heat-producing and heat-losing mechanisms **p**. 962
- **38**. The energy content of food is usually expressed in **kilocalories (kcal)** or as **Calories** per gram (Cal/g).
- **39.** The catabolism of lipids releases 9.46 Cal/g, about twice the amount released by equivalent weights of carbohydrates or proteins.
- 40. The sum of all the anabolic and catabolic processes under way is an individual's metabolic rate. The basal metabolic rate (BMR) is the rate of energy utilization by a person at rest. (*Figure 25–13*)
- **41.** The homeostatic regulation of body temperature is **thermo-***regulation*. Heat exchange with the environment involves four processes: *radiation*, *convection*, *evaporation*, and *conduction*. (*Figure 25–14*)
- **42.** The *preoptic area* of the hypothalamus acts as the body's thermostat, affecting the **heat-loss center** and the **heat-gain center**.
- **43.** Mechanisms for increasing heat loss include both physiological mechanisms (peripheral vasodilation, increased perspiration, and increased respiration) and behavioral modifications.
- 44. Responses that conserve heat include a decreased blood flow to the dermis and *countercurrent exchange*. (*Figure 25–15*)
- **45.** Heat is generated by **shivering thermogenesis** and **nonshivering thermogenesis**.
- **46.** Thermoregulatory responses differ among individuals. One important source of variation is **acclimatization** (a physiological adjustment to an environment over time).
- **47. Pyrexia** is an elevated body temperature. **Fever**, a body temperature above 37.2 °C (99 °F), can result from problems with the thermoregulatory mechanism, circulation, or sweat gland activity, or from the resetting of the hypothalamic "thermostat" by circulating pyrogens.

See the blue Answers tab at the back of the book.

- LEVEL 1 Reviewing Facts and Terms
 - Catabolism refers to (a) the creation of a nutrient pool, (b) the sum total of all chemical reactions in the body, (c) the production of organic compounds, (d) the breakdown of organic substrates.
- The breakdown of glucose to pyruvate is an _____ process.
 (a) anaerobic, (b) aerobic, (c) anabolic, (d) oxidative, (e) both a and d.
- **3.** The process that produces more than 90 percent of the ATP used by our cells is **(a)** glycolysis, **(b)** the citric acid cycle, **(c)** substrate-level phosphorylation, **(d)** oxidative phosphorylation.
- The sequence of reactions responsible for the breakdown of fatty acid molecules is (a) beta-oxidation, (b) the citric acid cycle, (c) lipogenesis, (d) all of these.
- 5. The citric acid cycle must turn ______ time(s) to completely metabolize the pyruvate produced from one glucose molecule.
 (a) 1, (b) 2, (c) 3, (d) 4, (e) 5.
- 6. The largest metabolic reserves for the average adult are stored as
 (a) carbohydrates, (b) proteins, (c) amino acids, (d) triglycerides,
 (e) fatty acids.

7. Use the following word bank to fill in the missing terms in the Nutrient Use in Cellular Metabolism diagram below.

Word Bank: citric acid cycle, amino acids, glucose, electron transport system, fatty acids, ATP, CO₂, two-carbon chains, H₂O.

(a)	 (b)	
(c)	 (d)	
(e)	(f)	
(g)	 (h)	
(i)		

- The vitamins generally associated with vitamin toxicity are

 (a) fat-soluble vitamins,
 (b) water-soluble vitamins,
 (c) the B complex vitamins,
 (d) vitamins C and B₁₂.
- **9.** What is a lipoprotein? What are the major groups of lipoproteins, and how do they differ?

LEVEL 2 Reviewing Concepts

- **10.** What is oxidative phosphorylation? Explain how the electron transport system is involved in this process.
- **11.** How are lipids catabolized in the body? How is beta-oxidation involved in lipid catabolism?
- **12.** How do the absorptive and postabsorptive states maintain normal blood glucose levels?
- 13. Why is the liver the focal point for metabolic regulation and control?
- 14. Why are vitamins and minerals essential components of the diet?
- **15.** Some articles in the popular media refer to "good cholesterol" and "bad cholesterol." To which types and functions of cholesterol do these terms refer? Explain your answer.

LEVEL 3 Critical Thinking and Clinical Applications

- 16. When blood levels of glucose, amino acids, and insulin are high, and glycogenesis is occurring in the liver, the body is in the _____ state.(a) fasting, (b) postabsorptive, (c) absorptive, (d) stress, (e) bulimic.
- 17. Charlie has a blood test that shows a normal level of LDLs but an elevated level of HDLs in his blood. Given that his family has a history of cardiovascular disease, he wonders if he should modify his lifestyle. What would you tell him?
- **18.** Jill suffers from anorexia nervosa. One afternoon she is rushed to the emergency room because of cardiac arrhythmias. Her breath smells fruity, and her blood and urine samples contain high levels of ketone bodies. Why do you think she is having the arrhythmias?

CLINICAL CASE

The Miracle Supplement

Vitamin A is the miracle vitamin supplement that can reduce overall childhood mortality by 23 percent in high-risk areas like rural Kenya. Preschool-age children and pregnant women in their last trimester are the most vulnerable to vitamin A deficiency.

Like other fat-soluble vitamins, vitamin A is an essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. In the retina of the eye, retinal (made from vitamin A) combines with opsin to form rhodopsin, which is necessary for low-light and color vision. Vitamin A deficiency is the leading cause of preventable childhood blindness, affecting as many as half a million children worldwide. As a coenzyme, vitamin A is critical in many steps in the immune system. Vitamin A deficiency leads to a decreased immune response and increased vulnerability to malaria, respiratory infections, and diarrhea. Vitamin A is also critical for normal bone growth and development, and its deficiency can lead to stunting and skeletal deformities.

Wrap-Up

Vitamin A is found naturally in leafy green, yellow, and orange vegetables and fruits. Vitamin A is also available in milk, liver, eggs, and some fatty fish. None of these food items are available to Justine, who is among the very poor living in sub-Saharan Africa. But thanks to inexpensive

vitamin A supplements, Justine's daughter will be protected from the health problems caused by vitamin A deficiency.

- 1. Other than diet and vitamin supplementation, is there any other available source of vitamin A?
- 2. If Justine's diet—which includes very little milk, liver, eggs, fish, leafy green, yellow, and orange vegetables, and fruits—is deficient in vitamin A, what other vitamin deficiencies might be expected?

See the blue Answers tab at the back of the book.

The Urinary System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **26-1** Identify the organs of the urinary system, and describe the functions of the system.
- **26-2** Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, describe the structure of a nephron, and identify the functions of each region of the nephron and collecting system.
- **26-3** Describe the basic processes that form urine.
- **26-4** Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation.
- **26-5** Identify the types and functions of transport mechanisms found along each segment of the nephron, explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample.
- **26-6** Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the micturition reflex.
- **26-7** Describe the effects of aging on the urinary system.
- **26-8** Give examples of interactions between the urinary system and other organ systems studied so far.

A Case of "Hidden" Bleeding

The motorcycle accident scene is horrific. The driver is dead, and his passenger—a 14-year-old

high school freshman named Mike—is unconscious more than 50 feet from the wreckage. When emergency responders deliver Mike to the trauma center, he has no measurable blood pressure, in spite of the 4 liters of fluids they have infused. The trauma team begins administering whole blood transfusions, but Mike is bleeding faster than replacement blood can be supplied.

Noting Mike's bloated abdominal appearance and the abrasions on his left posterior chest and flank, the trauma team suspects that the massive blood loss is due to intra-abdominal injuries. An x-ray of Mike's chest and abdomen shows fractured left 8th through 12th ribs and fractures of the left transverse processes of L₁, L₂, and L₃ vertebrae. A nurse inserts a urinary catheter into Mike's bladder, which drains clear urine.

Upon opening Mike's abdomen through a midline incision, the surgeon encounters a copious amount of free blood. Clearing this blood quickly, and moving the abdominal contents out of the way, he finds a shattered spleen that is

bleeding profusely. The surgeon performs an emergency splenectomy. Rinsing the abdominal contents reveals no further visible bleeding, but the surgical team cannot stabilize Mike's blood pressure, no matter how quickly they transfuse blood. **Something is still bleeding, but from where? To find out, turn to the Clinical Case Wrap-Up on p. 1014.**

An Introduction to the Urinary System

The urinary system removes most physiological wastes. In this chapter, we consider the functional organization of the urinary system and describe how the kidneys remove metabolic wastes from the circulation to produce urine. We also explain the major regulatory mechanisms controlling urine production and concentration, and identify how urine is transported to the urinary bladder and released from the body through the urinary tract passageways.

26–1 The kidneys, ureters, urinary bladder, and urethra make up the urinary system, which has three primary functions

Learning Outcome Identify the organs of the urinary system, and describe the functions of the system.

The **urinary system** has three major functions: (1) *excretion*, the removal of organic waste products from body fluids; (2) *elimination*, the discharge of these waste products into the environment; and (3) *homeostatic regulation* of the volume and solute concentration of blood.

The organs of the urinary system include the paired kidneys, paired ureters, urinary bladder, and urethra (Figure 26–1). The two **kidneys** perform the excretory functions of the urinary system. These organs produce **urine**, which is a fluid that contains water, ions, and small soluble compounds. Urine leaving the kidneys flows along the **urinary tract**, which consists of paired tubes called **ureters** (\bar{u} -RĒ-terz), to the **urinary** **Figure 26–1** An Introduction to the Urinary System. An anterior view of the urinary system, showing the positions of its organs.

bladder, a muscular sac for temporary storage of urine. After leaving the urinary bladder, urine passes through the **urethra** (\bar{u} -R \bar{E} -thra), which conducts the urine to the exterior.

26

The urinary bladder and the urethra eliminate urine. This process is called **urination** or **micturition** (mik-chū-RISH-un). In this process, the muscular urinary bladder contracts and forces urine through the urethra and out of the body. ATLAS: Embryology Summary 20: The Development of the Urinary System

The urinary system removes wastes generated by cells throughout the body, but it has several other essential homeostatic functions. They include the following:

- *Regulating blood volume and blood pressure,* by adjusting the volume of water lost in urine, releasing erythropoietin, and releasing renin.
- *Regulating plasma concentrations of sodium, potassium, chloride, and other ions,* by influencing the quantities lost in urine. The kidneys also control calcium ion levels through the synthesis of calcitriol.
- *Helping to stabilize blood pH*, by controlling the loss of hydrogen ions and bicarbonate ions in urine.
- *Conserving valuable nutrients,* by preventing their loss in urine while removing organic wastes—especially nitrogenous wastes such as *urea* and *uric acid*.
- Assisting the liver in detoxifying poisons and, during starvation, deaminating amino acids for their metabolic use by other tissues.

Figure 26–2 The Position of the Kidneys. ATLAS: Plates 57a,b

Adrenal gland

These activities are carefully regulated to keep the composition of blood within acceptable limits. A disruption of any one of them has immediate consequences and can be fatal.

- CHECKPOINT

- 1. Name the three major functions of the urinary system.
- 2. Identify the organs of the urinary system.
- **3**. Define micturition.
- See the blue Answers tab at the back of the book.

26–2 Kidneys are highly vascular organs containing functional units called nephrons, which filter, reabsorb, and secrete

Learning Outcome Describe the location and structures of the kidneys, identify major blood vessels associated with each kidney, trace the path of blood flow through a kidney, describe the structure of a nephron, and identify the functions of each region of the nephron and collecting system.

The kidneys are located on either side of the vertebral column, between vertebrae T_{12} and L_3 (Figure 26–2a). The left kidney lies slightly superior to the right kidney. The right kidney is slightly inferior due to the position of the right lobe of the liver.

The superior surface of each kidney is capped by an adrenal gland. The kidneys and adrenal glands lie between the muscles of the posterior body wall and the parietal peritoneum, in a retroperitoneal position (Figure 26–2b).

TIPS&TRICKS

To visualize the kidneys' retroperitoneal positions, think of each kidney as a picture on the body wall that got covered over by wallpaper (the parietal peritoneum). To remember the organs positioned entirely or partially retroperitoneally, use the mnemonic **SAD PUCKER** for **S**uprarenal (adrenal) glands, **A**orta and inferior vena cava, **D**uodenum, **P**ancreas, **U**reters, **C**olon, **K**idneys, **E**sophagus, **R**ectum.

The kidneys are held in position within the abdominal cavity by (1) the overlying peritoneum, (2) contact with adjacent visceral organs, and (3) supporting connective tissues. Three concentric layers of connective tissue protect and stabilize each kidney (Figure 26–2b):

- 1. The **fibrous capsule**, a layer of collagen fibers that covers the outer surface of the entire organ.
- **2.** The **perinephric fat**, a thick layer of adipose tissue that surrounds the fibrous capsule.
- **3.** The **renal fascia**, a dense, fibrous outer layer that anchors the kidney to surrounding structures. Collagen fibers extend outward from the fibrous capsule through the perinephric fat to this layer. Posteriorly, the renal fascia fuses

with the deep fascia surrounding the muscles of the body wall. Anteriorly, the renal fascia forms a thick layer that fuses with the peritoneum.

In effect, each kidney hangs suspended by collagen fibers from the renal fascia and is packed in a soft cushion of adipose tissue. This arrangement prevents the jolts and shocks of dayto-day living from disturbing normal kidney function. If the suspensory fibers break or become detached, a slight bump or hit can displace the kidney and stress the attached vessels and ureter. This condition is called a *floating kidney*. It may cause pain or other problems from the distortion of the ureter or blood vessels during movement.

A typical adult kidney is reddish-brown and about 10 cm (4 in.) long, 5.5 cm (2.2 in.) wide, and 3 cm (1.2 in.) thick (Figures 26–3 and 26–4). Each kidney weighs about 150 g (5.25 oz). The **hilum**, a prominent medial indentation, is the point of entry for the *renal artery* and *renal nerves*. The hilum is also the point of exit for the *renal vein* and the ureter.

Sectional Anatomy of the Kidneys

The fibrous capsule covering the outer surface of the kidney also lines the **renal sinus**, an internal cavity within the kidney

Figure 26–3 The Gross Anatomy of the Urinary System. The abdominopelvic cavity (with the digestive organs removed), showing the kidneys, ureters, urinary bladder, and blood supply to the urinary structures. ATLAS: Plates 61a; 62a,b

Anterior view

(Figure 26–4a,b). The fibrous capsule is bound to the outer surfaces of the structures within the renal sinus. In this way, it stabilizes the positions of the ureter, renal blood vessels, and nerves.

The kidney itself has an outer cortex and an inner medulla. The **renal cortex** is the superficial portion of the kidney, in contact with the fibrous capsule. The cortex is reddish brown and granular.

The **renal medulla** consists of 6 to 18 distinct triangular structures called **renal pyramids**. The base of each pyramid touches the cortex. The tip of each pyramid—a region known as the **renal papilla**—projects into the renal sinus. Each pyramid has a series of fine grooves that converge at the papilla. Bands of cortical tissue called **renal columns** extend into the medulla and separate adjacent renal pyramids. The columns have a distinctly granular texture, similar to that of the cortex. A **kidney lobe** consists of a renal pyramid, the overlying area of renal cortex, and adjacent tissues of the renal columns.

Urine is produced in the kidney lobes. Ducts within each renal papilla discharge urine into a cup-shaped drain called a **minor calyx** (KĀ-liks). Four or five minor calyces (KAL-i-sēz) merge to form a **major calyx**, and two or three major calyces combine to form the **renal pelvis**, a large, funnel-shaped chamber. The renal pelvis fills most of the renal sinus and is connected to the ureter, which drains the kidney.

Urine production begins in microscopic, tubular structures called *nephrons* (NEF-ronz) in the cortex of each kidney lobe.

Each kidney has about 1.25 million nephrons, with a combined length of about 145 km (85 miles).

Blood Supply and Innervation of the Kidneys

The kidneys receive 20–25 percent of the total cardiac output. In normal, healthy people, about 1200 mL of blood flow through the kidneys each minute—a phenomenal amount of blood for organs with a combined weight of less than 300 g (10.5 oz)!

Each kidney receives blood through a renal artery. This vessel originates along the lateral surface of the abdominal aorta near the level of the superior mesenteric artery (Figure 21-23, pp. 760–761). As it enters the renal sinus, the renal artery provides blood to the segmental arteries (Figure 26-5a). Segmental arteries further divide into a series of interlobar arteries. These arteries radiate outward through the renal columns between the renal pyramids. The interlobar arteries supply blood to the arcuate (AR-kū-āt) arteries, which arch along the boundary between the cortex and medulla of the kidney. Each arcuate artery gives rise to a number of cortical radiate arteries, also called interlobular arteries. They supply the cortical portions of the adjacent kidney lobes. Branching from each cortical radiate artery are numerous afferent arterioles. These vessels deliver blood to the capillaries supplying individual nephrons (Figure 26–5b,c).

Figure 26–5 The Blood Supply to the Kidneys. ATLAS: Plates 53c,d; 61a-c

淎 Clinical Note

Analysis of Renal Blood Flow The rate of blood flow through the kidneys can be estimated by administering the compound para-aminohippuric acid (PAH). This compound is removed by the nephrons and eliminated in urine. Virtually all the PAH contained in the blood that arrives at the kidneys is removed before the blood leaves in the renal veins. For this reason, renal blood flow can be approximated by comparing plasma concentrations of PAH with the amount secreted in urine. In practice, however, it is usually easier to measure the glomerular filtration rate (p. 989).

c A flowchart of renal circulation

arteriole

After passing through the capillaries of the nephrons, blood enters a network of venules and small veins that converge on the **cortical radiate veins**, also called *interlobular veins* (Figure 26–5a,c). The cortical radiate veins deliver blood to arcuate veins. These veins in turn empty into interlobar veins, which drain directly into the renal vein. There are no segmental veins.

978 UNIT 5 Environmental Exchange

Renal nerves innervate the kidneys and ureters. Most of the nerve fibers involved are sympathetic postganglionic fibers from the celiac plexus and the inferior splanchnic nerves. **> pp. 538, 548** A renal nerve enters each kidney at the hilum and follows the branches of the renal arteries to reach individual nephrons. The sympathetic innervation (1) adjusts rates of urine formation by changing blood flow and blood pressure at the nephron; and (2) stimulates the release of renin, which ultimately restricts water and salt loss in the urine by stimulating reabsorption by the nephron. When a substance is reabsorbed, it is "reclaimed," eventually reentering the blood.

The Nephron

Recall that the kidneys remove wastes from the blood and help to regulate blood volume and blood pressure, blood ion levels, and blood pH. In the kidneys, the functional units—the smallest structures that can carry out all the functions of a system—are the **nephrons** (NEF-ronz). Each nephron consists of a renal corpuscle and a renal tubule (Figure 26–6). The **renal corpuscle** (KOR-pus-ul) is a spherical structure consisting of the *glomerular* (Bowman's) *capsule*, a cup-shaped chamber approximately 200 μ m in diameter, and a capillary network known as

Figure 26–6 The Functional Anatomy of a Representative Nephron and the Collecting System.

The major functions and characteristic cells of each segment of the nephron (purple) and the collecting system (tan) are noted. In this representative figure, the nephron has been significantly shortened and some components rearranged.

the *glomerulus*. The **renal tubule** begins at the renal corpuscle. It is a long tubular passageway that may be 50 mm (1.97 in.) in length.

Blood arrives at the renal corpuscle by way of an afferent arteriole. This arteriole delivers blood to the **glomerulus** (glo-MER-ū-lus; plural, *glomeruli*), which consists of about 50 intertwined capillaries. The glomerulus projects into the glomerular capsule much as the heart projects into the pericardial cavity. Blood leaves the glomerulus in an **efferent arteriole**. It flows into a network of capillaries called the *peritubular capillaries*, which surround the renal tubule. These capillaries in turn drain into small venules that return the blood to the venous system (**Figure 26–7b,c**).

The process of *filtration* takes place in the renal corpuscle. In this process, blood pressure forces water and dissolved solutes out of the glomerular capillaries and into a chamber—the *capsular space*—that is continuous with the lumen of the renal tubule (Figure 26–6). Filtration produces an essentially proteinfree solution, known as a **filtrate**, that is otherwise similar to blood plasma. From the renal corpuscle, filtrate enters the renal tubule. The renal tubule has three crucial functions: (1) reabsorbing all the useful organic nutrients in the filtrate; (2) reabsorbing more than 90 percent of the water in the filtrate; and (3) secreting into the tubule lumen any wastes that did not pass into the filtrate at the glomerulus.

The renal tubule has two convoluted (coiled or twisted) segments—the *proximal convoluted tubule* (PCT) and the *distal convoluted tubule* (DCT). They are separated by a simple U-shaped tube, the *nephron loop*, also called the *loop of Henle* (HEN-lē). The convoluted segments lie in the cortex of the kidney, and the nephron loop dips at least partially into the medulla. For clarity, the nephron shown in **Figure 26–6** has been shortened and straightened.

The regions of the nephron vary by structure and function. As the filtrate travels along the renal tubule, it is now called **tubular fluid**, and it gradually changes in composition. The changes that take place and the characteristics of the urine that result are due to the activities under way in each segment of the nephron. Figure 26–6 and Table 26–1 survey the regional specializations.

Figure 26–7 The Locations and Structures of Cortical and Juxtamedullary Nephrons.

Table 26–1	The Organization of the Nephron and Collecting System				
Region		Histological Characteristics	Length	Diameter	Primary Function
NEPHRON					
Renal corpuscle Capsular Space Capsular epithelium Capillaries of glomerulus Visceral epithelium		Glomerulus (capillary knot), mesangial cells, and dense layer, enclosed by the glomerular capsule; visceral epithelium (podocytes) and capsular epithelium separated by capsular space	150–250 μm (spherical)	150–250 μm	Filtration of blood plasma
Renal tubule					
Proximal convoluted tubule (PCT) Microvilli		Cuboidal cells with microvilli	14 mm	60 µm	Reabsorption of ions, organic molecules, vitamins, water; secretion of drugs, toxins, acids
Nephron loop	0	Squamous or low cuboidal cells	30 mm		
C				15 μm	Descending limb: reabsorption of water from tubular fluid
				30 µm	Ascending limb: reabsorption of ions; assists in creation of a concentration gradient in the medulla
Distal convoluted tu	ibule (DCT)	Cuboidal cells with few if any microvilli	5 mm	30–50 μm	Reabsorption of sodium ions and calcium ions; secretion of acids, ammonia, drugs, toxins
COLLECTING SYSTE	EM				
Collecting duct Intercalated cell Principal cell		Cuboidal cells	15 mm	50–100 μm	Reabsorption of water, sodium ions; secretion or reabsorption of bicarbonate ions or hydrogen ions
Papillary duct		Columnar cells	5 mm	100–200 μm	Conduction of tubular fluid to minor calyx; contributes to concentration gradient of the medulla

TIPS&TRICKS

In the nephron, the terms *proximal tubule* and *distal tubule* refer to how far along the renal tubule these structures are situated from the renal corpuscle. Think of *proximal* (nearer the renal corpuscle) as being first, and *distal* (farther from the renal corpuscle) as being last.

Each nephron empties into the **collecting system**, a series of tubes that carry tubular fluid away from the nephron. *Collecting ducts* receive this fluid from many nephrons. Each collecting duct begins in the cortex and descends into the medulla, carrying fluid to a *papillary duct* that drains into a minor calyx.

Nephrons from different locations within a kidney differ slightly in structure. Approximately 85 percent of all nephrons

are **cortical nephrons**, located almost entirely within the superficial cortex of the kidney (Figure 26–7a,b). In a cortical nephron, the nephron loop is relatively short, and the efferent arteriole delivers blood to a network of **peritubular capillaries**, which surround the entire renal tubule. These capillaries drain into small venules that carry blood to the cortical radiate veins (Figure 26–5c).

The remaining 15 percent of nephrons, termed **juxta-medullary** (juks-tuh-MED-u-lār-ē; *juxta*, near) **nephrons**, have long nephron loops that extend deep into the medulla (Figure 26–7a,c). In juxtamedullary nephrons, the peritubular capillaries are connected to the **vasa recta** (*vasa*, vessel + *recta*, straight)—long, straight capillaries that parallel the nephron loop.

Cortical nephrons do most of the reabsorption and secretion in the kidneys because they are more numerous than juxtamedullary nephrons. However, as you will see later in the chapter, it is the juxtamedullary nephrons that enable the kidneys to produce concentrated urine. Next let's examine the structure of each segment of a representative nephron.

The Renal Corpuscle

Each renal corpuscle is $150-250 \ \mu$ m in diameter (Figure 26–8). It includes both the **glomerular capsule** and the capillary network known as the *glomerulus* (Figure 26–8a). The glomerular capsule is connected to the initial segment of the renal tubule and forms the outer wall of the renal corpuscle. It encapsulates the glomerular capillaries.

The outer wall of the capsule is lined by a simple squamous **capsular epithelium (Figure 26–8a**). This layer is continuous with the **visceral epithelium**, which covers the glomerular capillaries. The **capsular space** separates the capsular and visceral epithelia. The two epithelial layers are continuous where the glomerular capillaries are connected to the afferent arteriole and efferent arteriole.

The visceral epithelium consists of large cells with complex processes, or "feet," that wrap around the specialized *dense layer*

Figure 26–8 The Renal Corpuscle.

Clinical Note

Glomerulonephritis Glomerulonephritis (glo-mer-ū-lōnef-RĪ-tis) is an inflammation of the glomeruli that affects filtration in the kidneys. The condition is often an *immune complex disorder*. It may develop after an infection involving *Streptococcus* bacteria. \bigcirc p. 822 The kidneys are not the sites of infection, but as the immune system responds, the number of circulating antigen–antibody complexes skyrockets. These complexes are small enough to pass through the dense layer, but too large to fit through the filtration slits of the filtration membrane. The complexes clog up the filtration mechanism. As a result, filtrate production decreases. Any condition that leads to a massive immune response, including viral infections and autoimmune disorders, can cause glomerulonephritis.

of the glomerular capillaries. These unusual cells are called **podocytes** ($P\bar{O}$ -d \bar{o} -s \bar{i} ts; *podos*, foot + *-cyte*, cell). Their feet are known as **pedicels** (Figure 26–8b). Materials passing out of the blood at the glomerulus must be small enough to pass through the narrow gaps, called **filtration slits**, between adjacent pedicels.

Mesangial cells are special supporting cells that lie between adjacent capillaries. Actin-like filaments in these cells enable them to contract. In this way these cells control capillary diameter and the rate of capillary blood flow. Several substances, including angiotensin II, ADH (vasopressin), and histamine, affect mesangial cell contraction. \bigcirc p. 640 Some evidence suggests that these cells also make renin.

The glomerular capillaries are fenestrated capillaries. That is, their endothelium contains large-diameter pores (Figure 26–8b). The dense layer differs from that found in the basement membrane of other capillary networks in that it may encircle more than one capillary.

Together, the fenestrated endothelium, the dense layer, and the filtration slits form the *filtration membrane*. During filtration, blood pressure forces water and small solutes across this membrane and into the capsular space. The larger solutes, especially plasma proteins, do not pass through.

Filtration by the renal corpuscle is both effective and passive, but it has one major drawback: In addition to metabolic wastes and excess ions, useful substances such as glucose, free fatty acids, amino acids, vitamins, and other solutes also enter the capsular space. These substances are reabsorbed before the filtrate leaves the kidneys. Much of this reabsorption takes place in the proximal convoluted tubules.

The Proximal Convoluted Tubule

Recall that the renal tubule consists of three segments: the proximal convoluted tubule, the nephron loop, and the distal convoluted tubule. The **proximal convoluted tubule (PCT)** is the first segment (Figure 26–6). Its entrance lies almost directly opposite the point where the afferent and efferent arterioles connect to the glomerulus. The lining of the PCT is a simple cuboidal epithelium whose apical surfaces have microvilli (Table 26–1). The tubular cells reabsorb organic nutrients, ions, water, and plasma proteins (if present) from the tubular fluid and release them into the **peritubular fluid**, the interstitial fluid surrounding the renal tubule. The reabsorbed substances in the peritubular fluid eventually reenter the blood. *Reabsorption* is the primary function of the PCT, but the epithelial cells can also secrete substances into the lumen of the renal tubule.

The Nephron Loop (Loop of Henle)

The PCT makes an acute bend that turns the renal tubule toward the renal medulla. This turn leads to the **nephron loop**, or *loop of Henle* (Figures 26–6, 26–7). We divide the nephron loop into a **descending limb** and an **ascending limb**. Fluid in the descending limb flows toward the renal pelvis. Fluid in the ascending limb flows toward the renal cortex. Each limb contains a **thick segment** and a **thin segment**. The terms *thick* and *thin* refer to the height of the epithelium, not to the diameter of the lumen: Thick segments have a cuboidal epithelium. Thin segments are lined with a squamous epithelium (Table 26–1).

The entire descending limb is permeable to water. Its thick descending segment has functions similar to those of the PCT: It reabsorbs sodium and chloride ions out of the tubular fluid. The ascending limb is impermeable to water, but passively and actively removes sodium and chloride ions from the tubular fluid. Its thin ascending segment is permeable to sodium ions, which diffuse into the surrounding peritubular fluid. The thick ascending segment actively transports sodium and chloride ions out of the tubular fluid. The effect of this movement is most noticeable in the renal medulla, where the long ascending limbs of juxtamedullary nephrons create unusually high solute concentrations in the peritubular fluid. The descending limb is freely permeable to water, but not to solutes, such as sodium and chloride ions. Water moves out of the descending limb, helping to increase the solute concentration of the tubular fluid.

The Distal Convoluted Tubule

The thick ascending limb of the nephron loop ends where it forms a sharp angle near the renal corpuscle. The **distal con-voluted tubule (DCT)**, the third segment of the renal tubule, begins there. The initial segment of the DCT passes between the afferent and efferent arterioles (Figure 26–8a).

In sectional view, the DCT differs from the PCT in that the DCT has a smaller diameter and its epithelial cells lack microvilli (Table 26–1). The DCT is an important site for three vital processes: (1) the active secretion of ions, acids, drugs, and toxins into the tubule; (2) the selective reabsorption of sodium ions and calcium ions from tubular fluid; and (3) the selective reabsorption of water, which assists in concentrating the tubular fluid.

The Juxtaglomerular Complex. The epithelial cells of the DCT near the renal corpuscle are taller than those elsewhere along the DCT, and their nuclei are clustered together. This region is called the **macula densa** (MAK-ū-la DEN-sa) (**Figure 26–8a**). The cells of the macula densa are closely associated with unusual smooth muscle fibers in the wall of the afferent arteriole. These fibers are known as **juxtaglomerular cells**. Together, the macula densa and juxtaglomerular cells form the **juxtaglomerular complex (JGC)**, an endocrine structure that secretes the hormone *erythropoietin* and the enzyme *renin*. \supset **p**. 640

The Collecting System

The distal convoluted tubule, the last segment of the nephron, opens into the collecting system (Figure 26–6). Individual nephrons drain into a nearby **collecting duct**. Several collecting ducts then converge into a larger **papillary duct**, which in turn empties into a minor calyx. The epithelium lining the papillary duct is typically columnar (Table 26–1).

Two main types of cells are found in the collecting duct: intercalated cells and principal cells. Intercalated cells are cuboidal cells with microvilli. Alpha-intercalated cells and beta-intercalated cells make up the population of intercalated cells. Alpha-intercalated cells secrete hydrogen ions and reabsorb bicarbonate ions, while beta-intercalated cells secrete bicarbonate ions and reabsorb hydrogen ions. Principal cells are cuboidal cells that reabsorb water and secrete potassium. Together, these cells regulate the acid-base balance in the blood.

The collecting system does more than simply transport tubular fluid from the nephrons to the renal pelvis. It also adjusts the fluid's composition and determines the final osmotic concentration and volume of urine, the final product. We consider these activities of the collecting system later in the chapter.

CHECKPOINT

- 4. Which portions of a nephron are in the renal cortex?
- 5. Why don't plasma proteins pass into the capsular space under normal circumstances?
- 6. Damage to which part of a nephron would interfere with the hormonal control of blood pressure?

See the blue Answers tab at the back of the book.

26–3 Different segments of the nephron form urine by filtration, reabsorption, and secretion

Learning Outcome Describe the basic processes that form urine.

Most people don't commonly think of it this way, but the goal of urine production is to maintain homeostasis by regulating the volume and composition of blood. This process involves the excretion of solutes—specifically, metabolic wastes. Our bodies form three important organic wastes:

- 1. *Urea*. Urea is the most abundant organic waste. You generate approximately 21 g of urea each day, most of it through the breakdown of amino acids.
- Creatinine. Skeletal muscle tissue generates creatinine through the breakdown of *creatine phosphate*, a high-energy compound that plays an important role in muscle contraction. ⊃ p. 316 Your body generates roughly 1.8 g of creatinine each day. Virtually all of it is excreted in urine.
- **3.** *Uric Acid.* **Uric acid** is a waste formed during the recycling of the nitrogenous bases from RNA molecules. You produce approximately 480 mg of uric acid each day.

These wastes are dissolved in the bloodstream. They can be eliminated only when dissolved in urine. For this reason, their removal involves an unavoidable water loss. The kidneys are usually capable of producing concentrated urine with an osmotic concentration of 1200–1400 mOsm/L, more than four times that of plasma. (We discuss methods of reporting solute concentrations in a later section.) If the kidneys were unable to concentrate the filtrate produced by glomerular filtration, fluid losses would lead to fatal dehydration in a matter of hours. The kidneys also ensure that the fluid that *is* lost does not contain potentially useful organic substrates that are present in blood plasma, such as sugars or amino acids. These valuable materials must be reabsorbed and retained for use by other tissues.

Basic Processes of Urine Formation

In forming urine, the kidneys use three distinct processes that we have already mentioned:

- 1. *Filtration*. In **filtration**, blood pressure forces water and solutes across the wall of the glomerular capillaries and into the capsular space. Solute molecules small enough to pass through the filtration membrane are carried by the surrounding water molecules.
- 2. *Reabsorption*. **Reabsorption** is the removal of water and solutes from the filtrate, and their movement across the tubular epithelium and into the peritubular fluid. Reabsorption

takes place after filtrate has left the renal corpuscle. Most of the reabsorbed materials are nutrients the body can use. Filtration is based solely on size, but reabsorption is a selective process. Reabsorption involves either simple diffusion or the activity of carrier proteins in the tubular epithelium. The reabsorbed substances in the peritubular fluid eventually reenter the blood. Water reabsorption takes place passively, through osmosis.

3. Secretion. Secretion is the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid. Secretion is necessary because filtration does not force all the dissolved materials out of the plasma. Tubular secretion, which removes substances from the blood, can further lower the plasma concentration of undesirable materials. It provides a backup process for filtration. Secretion is often the primary method of preparing substances, including many drugs, for excretion.

Together, these processes produce a fluid that is very different from other body fluids. Table 26–2 shows the efficiency of the renal system by comparing the concentrations of some substances in urine and plasma.

TIPS&TRICKS

Secretion by the urinary system takes place when cells produce and then discharge substances into the urine, whereas *excretion* is the elimination of wastes from the body in the form of urine, sweat, and feces.

Table 26–2	Normal Laboratory Values for Solutes in Plasma and Urine			
Solute		Plasma	Urine	
IONS (mEq/L)				
Sodium (Na ⁺)		135–145	40-220	
Potassium (K ⁺)		3.5–5.0	25-100	
Chloride (Cl ⁻)		100–108	110–250	
Bicarbonate (I	20–28	1–9		
METABOLITES AND NUTRIENTS (mg/dL)				
Glucose		70–110	0.009	
Lipids		450-1000	0.002	
Amino acids		40	0.188	
Proteins		6–8 g/dL	0.000	
NITROGENOUS WASTES (mg/dL)				
Urea		8–25	1800	
Creatinine		0.6–1.5	150	
Uric acid		2–6	40	
Ammonia		<0.1	60	

An Overview of Renal Function

Figure 26–9 summarizes the general functions of the various segments of the nephron and collecting system in the formation of urine. Most regions carry out a combination of reabsorption and secretion. Note that the balance between the two processes shifts from one region to another.

Normal kidney function can continue only as long as filtration, reabsorption, and secretion function within relatively narrow limits. A disruption in kidney function has immediate effects on the composition of the circulating blood. If both kidneys are affected, death follows within a few days unless medical assistance is provided.

Before we take a closer look at the functions of the individual portions of the nephron, let's briefly examine each of the three major processes involved in urine formation.

Filtration

In filtration, hydrostatic pressure forces water through membrane pores, and solute molecules small enough to pass through those pores are carried along. Filtration takes place as larger solutes and suspended materials are left behind. We can see filtration in action in a drip coffee machine. Gravity forces hot water through the filter, and the water carries a variety of dissolved compounds into the pot. The large coffee grounds never reach the pot, because they cannot fit through the pores of the filter. In other words, they are "filtered out" of the solution; the coffee we drink is the filtrate.

In the body, the heart pushes blood around the cardiovascular system and generates hydrostatic pressure. As you have seen, filtration takes place across the walls of capillaries as water and dissolved materials are pushed into the interstitial fluids of the body (see Figure 21–10, p. 739). In some sites (for example, the liver), the pores are so large that even plasma proteins can enter the interstitial fluids. At the renal corpuscle, however, the specialized filtration membrane restricts the passage of even the smallest circulating proteins.

Reabsorption and Secretion

The processes of reabsorption and secretion by the kidneys involve a combination of diffusion, osmosis, channel-mediated diffusion, and carrier-mediated transport. We considered diffusion and osmosis in several other chapters. Here we briefly review carrier-mediated transport mechanisms.

Types of Carrier-Mediated Transport. In previous chapters, we looked at four major types of *carrier-mediated transport*:

In *facilitated diffusion*, a carrier protein transports a molecule across the plasma membrane without expending energy (see Figure 3–18, p. 95). Such transport always follows the concentration gradient for the ion or molecule transported.

Figure 26–9 An Overview of Urine Formation.

and elimination

KEY

- Filtration occurs exclusively in the renal corpuscle, across the filtration membrane.
- Water reabsorption occurs primarily along the PCT and the descending limb of the nephron loop, but also to a variable degree in the DCT and collecting system.
- Variable water reabsorption occurs in the DCT and collecting system.
- Solute reabsorption occurs along the PCT, the ascending limb of the nephron loop, the DCT, and the collecting system.

- Active transport is driven by the hydrolysis of ATP to ADP on the inner plasma membrane surface (see Figure 3–19, p. 96). Exchange pumps and other carrier proteins are active along the kidney tubules. Active transport can operate despite an opposing concentration gradient.
- In *cotransport*, carrier protein activity is not directly linked to the hydrolysis of ATP (see Figure 3–20, p. 97). Instead, two substrates (ions, molecules, or both) cross the membrane while bound to the carrier protein. The movement

of the substrates always follows the concentration gradient of at least one of the transported substances. Cotransport is used for the reabsorption of organic and inorganic compounds from the tubular fluid.

Countertransport resembles cotransport, except that the two transported ions move in *opposite* directions (see Figures 23–23, p. 865, and 24–14, p. 900). Countertransport operates in the PCT, DCT, and collecting system.

Characteristics of Carrier-Mediated Transport. All carriermediated processes share five features that are important for an understanding of kidney function:

- **1.** A specific substrate binds to a carrier protein that facilitates movement across the membrane. The movement may be active or passive.
- 2. A given carrier protein typically works in one direction only. In facilitated diffusion, the concentration gradient of the substance being transported determines that direction. In active transport, cotransport, and countertransport, the location and orientation of the carrier proteins determine whether a particular substance is reabsorbed or secreted. The carrier protein that transports amino acids from the tubular fluid to the cytosol, for example, will not carry amino acids back into the tubular fluid.
- **3.** The distribution of carrier proteins can vary among portions of the cell surface. Transport between tubular fluid and interstitial (peritubular) fluid involves two steps. First, the material enters the cell at its apical surface. Then the material leaves the cell at its basolateral surface and enters the peritubular fluid. Each step involves a different carrier protein. For example, the apical surfaces of cells along the proximal convoluted tubule contain carrier proteins that bring amino acids, glucose, and many other nutrients into these cells by sodium-linked cotransport. In contrast, the basolateral surfaces out of the cell by facilitated diffusion.
- 4. *The membrane of a single tubular cell contains many types of carrier proteins.* Each cell can have multiple functions. A cell that reabsorbs one compound can secrete another.
- 5. Carrier proteins, like enzymes, can be saturated. Recall that when an enzyme is saturated, further increases in substrate concentration have no effect on the rate of reaction. \bigcirc p. 55 Likewise, when a carrier protein is saturated, further increases in substrate concentration have no effect on the rate of transport across the plasma membrane. For any substance, the concentration at saturation is called the **transport maximum** (T_m) or tubular maximum. In healthy people, carrier proteins involved in tubular secretion seldom become saturated. However, carriers involved in tubular reabsorption are often at risk of saturation, especially during the absorptive state following a meal.

Variable solute reabsorption or secretion occurs at the PCT, the DCT, and the collecting system.

 T_m and the Renal Threshold. Normally, any plasma proteins and nutrients, such as amino acids and glucose, are removed from the tubular fluid by cotransport or facilitated diffusion. If the concentrations of these nutrients rise in the tubular fluid, the rate of reabsorption increases until the carrier proteins are saturated. A concentration higher than the transport maximum exceeds the reabsorptive abilities of the nephron. In this case, some of the material will remain in the tubular fluid and appear in the urine. The transport maximum thus determines the **renal threshold**—the plasma concentration at which a specific substance or ion begins to appear in the urine.

The renal threshold varies with the substance involved. The renal threshold for glucose is approximately 180 mg/dL. When plasma glucose concentrations exceed 180 mg/dL, glucose appears in urine; this condition is called *glycosuria* or *glucosuria*. After you have eaten a meal rich in carbohydrates, your plasma glucose levels may exceed the T_m for a brief period. The liver quickly lowers circulating glucose levels, and very little glucose is lost in your urine. However, chronically increased plasma and urinary glucose concentrations are abnormal. (Glycosuria is one of the key signs of diabetes mellitus. $\supset p. 638$)

The renal threshold for amino acids is lower than that for glucose. Amino acids appear in urine when plasma concentrations exceed 65 mg/dL. Plasma amino acid levels commonly exceed the renal threshold after you have eaten a protein-rich meal, causing some amino acids to appear in your urine. This condition is termed **aminoaciduria** (am-i-nōas-i-DYŪ-rē-uh).

 T_m values for water-soluble vitamins are relatively low. As a result, you excrete excess quantities of these vitamins in urine. (This is typically the fate of water-soluble vitamins in daily supplements.) Cells of the renal tubule ignore a number of other substances in the tubular fluid. As water and other substances are removed, the concentrations of the ignored materials in the tubular fluid gradually rise. Table 26–3 lists some substances that are actively reabsorbed or secreted by the renal tubules, as well as several that are not transported at all.

Ways of Expressing Osmotic Concentration. The osmotic concentration, or *osmolarity*, of a solution is the total number of solute particles in each liter. \bigcirc p. 92 We usually express osmolarity in **osmoles** per liter (Osm/L) or **milliosmoles** per liter (mOsm/L). If each liter of a fluid contains 1 mole of dissolved particles, the solute concentration is 1 Osm/L, or 1000 mOsm/L. Body fluids have an osmotic concentration of about 300 mOsm/L. For comparison, seawater is about 1000 mOsm/L and fresh water is about 5 mOsm/L. In a clinical setting, the osmolarity of urine is often reported as osmolality, expressed as milliosmoles per kilogram of water

Table 26–3	Tubular Reabsorption and Secretion		
Reabsorbed	Secreted	No Transport Mechanism	
lons Na ⁺ , Cl ⁻ , K ⁺ Ca ₂ ⁺ , Mg ²⁺ , SO ₄ ²⁻ , HCO ₃ ⁻	lons K ⁺ , H ⁺ , Ca ²⁺ , PO ₄ ³⁻	Urea Water Urobilinogen Bilirubin	
Metabolites Glucose Amino acids Proteins	Wastes Creatinine Ammonia Organic acids and bases		
Vitamins	Miscellaneous Neurotransmitters (ACh, NE, E, dopamine) Histamine Drugs (penicillin, atropine, morphine, many others)		

(mOsm/kg H_2O). When discussing osmotic concentrations in body fluids, these terms are often used interchangeably.

Ion concentrations are often reported in *milliequivalents* per liter (mEq/L). Milliequivalents indicate the number of positive or negative charges in solution, rather than the number of solute particles; multiply mmol/L by the charges on each ion to convert to mEq/L. For example, each sodium ion has one charge only, so for Na⁺, 1 mmol/L = 1 mEq/L; for Ca²⁺, each ion has two charges, so 1 mmol/L = 2 mEq/L. The concentrations of large organic molecules are usually reported in grams, milligrams, or micrograms per unit volume of solution (typically, per dL).

Cortical and Juxtamedullary Nephrons. In the next sections, we proceed along the nephron to consider the formation of filtrate and its subsequent changes in composition and concentration as it passes along the renal tubule. Most of what follows applies equally to cortical and juxtamedullary nephrons. The functions of the renal corpuscle and of the proximal and distal convoluted tubules are the same in all nephrons. The major difference between the two types of nephron is that the nephron loop of a cortical nephron is shorter. Note that it does not extend as far into the medulla as does the nephron loop of a juxtamedullary nephron (Figure 26–7a).

The long nephron loop in a juxtamedullary nephron extends deep into the renal pyramids. There it plays a key role in water conservation and the formation of concentrated urine. This process is vitally important, affecting the tubular fluid produced by every nephron in the kidney. For this reason, we use a juxtamedullary nephron as our example. **Table 26–4** summarizes the functions of the various parts of the nephron.

Table 26–4	Renal Structures and Their Function			
Segment	General Functions	Specific Functions	Mechanisms	
Renal corpuscle	<i>Filtration</i> of plasma; generates approximately 180 L/day of filtrate similar in composition to blood plasma without plasma proteins	<i>Filtration</i> of water, inorganic and organic solutes from plasma; retention of plasma proteins and blood cells	Glomerular hydrostatic (blood) pressure working across capillary endothelium, dense layer, and filtration slits	
Proximal convolu tubule (PCT)	ed Reabsorption of 60%–70% of the water (108–116 L/day), 99%–100% of the organic substrates, and 60%– 70% of the sodium and chloride ions in the original filtrate	Active reabsorption: Glucose, other simple sugars, amino acids, vitamins, ions (including sodium, potassium, calcium, magnesium, phosphate, and bicarbonate) Passive reabsorption: Urea, chloride ions.	Carrier-mediated transport, including facilitated transport (glucose, amino acids), cotransport (glucose, ions), and countertransport (with secretion of H ⁺) Diffusion (solutes) or osmosis (water)	
		lipid-soluble materials, water	(, , , , , , , , , , , , , , , , , , ,	
		<i>Secretion</i> : Hydrogen ions, ammonium ions, creatinine, drugs, and toxins (as at DCT)	Countertransport with sodium ions	
Nephron loop	<i>Reabsorption</i> of 25% of the water (45 L/day) and 20%–25% of the sodium and chloride ions present in the original filtrate; creation of the concentration gradient in the medulla	<i>Reabsorption</i> : Sodium and chloride ions Water	Active transport by Na ⁺ −K ⁺ /2 Cl [−] transporter Osmosis	
Distal convoluted	Reabsorption of a variable amount of	Reabsorption: Sodium and chloride ions	Cotransport	
tubule (DCT)	water (usually 5%, or 9 L/day), under ADH stimulation, and a variable	Sodium ions (variable)	Countertransport with potassium ions; aldosterone-regulated	
	amount of sodium ions, under aldosterone stimulation	Calcium ions (variable)	Carrier-mediated transport stimulated by parathyroid hormone and calcitriol	
		Water (variable)	Osmosis; ADH regulated	
		Secretion: Hydrogen ions, ammonium ions	Countertransport with sodium ions	
		Creatinine, drugs, toxins	Carrier-mediated transport	
Collecting system	<i>Reabsorption</i> of a variable amount of water (usually 9.3%, or 16.8 L/ day) under ADH stimulation, and a variable amount of sodium ions, under aldosterone stimulation	<i>Reabsorption</i> : Sodium ions (variable) Bicarbonate ions (variable) Water (variable) Urea (distal portions only)	Countertransport with potassium or hydrogen ions; aldosterone-regulated Diffusion, generated within tubular cells Osmosis; ADH-regulated Diffusion	
		<i>Secretion</i> : Potassium and hydrogen ions (variable)	Carrier-mediated transport	
Peritubular capil	ries Redistribution of water and solutes reabsorbed in the cortex	Return of water and solutes to the general circulation	Osmosis and diffusion	
Vasa recta	<i>Redistribution</i> of water and solutes reabsorbed in the medulla and stabilization of the concentration gradient of the medulla	Return of water and solutes to the general circulation	Osmosis and diffusion	

CHECKPOINT

- 7. Identify the three distinct processes that form urine in the kidney.
- 8. What occurs when the plasma concentration of a substance exceeds its tubular maximum?

See the blue Answers tab at the back of the book.

26-4 Hydrostatic and colloid osmotic pressures influence glomerular filtration pressure, which in turn affects the glomerular filtration rate

Learning Outcome Describe the factors that influence glomerular filtration pressure and the rate of filtrate formation.

Filtration takes place in the renal corpuscle as fluids move across the wall of the glomerulus and into the capsular space. The process of **glomerular filtration** involves passage across a filtration membrane. Recall that this membrane has three components: (1) the capillary endothelium, (2) the dense layer, and (3) the filtration slits (Figures 26–8b and 26–10).

Glomerular capillaries are fenestrated capillaries with pores ranging from 60 to 100 nm (0.06 to 0.1 μ m) in diameter. These openings are small enough to prevent the passage of blood cells, but they are too large to restrict the diffusion of solutes, even those the size of plasma proteins. The dense layer is more selective: Only small plasma proteins, nutrients, and ions can cross it. The filtration slits are the finest filters of all. Their gaps are only 6–9 nm wide. These gaps are small enough to prevent the passage of most small plasma proteins. As a result, under

Factors Controlling Glomerular Filtration

The **glomerular hydrostatic pressure (GHP)** is the blood pressure in the glomerular capillaries. This pressure tends to push water and solute molecules out of the plasma and into the filtrate. The GHP, which averages 50 mm Hg, is significantly higher than capillary pressures elsewhere in the systemic circuit, because the efferent arteriole is smaller in diameter than the afferent arteriole.

The **blood colloid osmotic pressure** (**BCOP**) tends to draw water out of the filtrate and into the plasma; it thus opposes filtration. Over the entire length of the glomerular capillary bed, the BCOP averages about 25 mm Hg.

The **net filtration pressure (NFP)** is the net pressure acting across the glomerular capillaries. It represents the sum of the hydrostatic pressures and the colloid osmotic pressures. Under normal circumstances, the net filtration pressure is approximately 10 mm Hg. This is the average pressure forcing water and dissolved substances out of the glomerular capillaries and into the capsular space.

Capsular hydrostatic pressure (CsHP) opposes GHP. CsHP, which tends to push water and solutes out of the filtrate and into the plasma, results from the resistance of filtrate already present in the nephron that must be pushed toward the renal pelvis. The difference between GHP and CsHP is the *net hydrostatic pressure (NHP)*.

26

b Net filtration pressure

Filtration Pressures

normal circumstances only a few plasma proteins—such as albumin molecules, with an average diameter of 7 nm—can cross the filtration membrane and enter the capsular space. However, plasma proteins are all that stay behind, so the filtrate contains dissolved ions and small organic molecules in roughly the same concentrations as in plasma.

Figures 21–10 and **21–11**, pp. 739, 740, before you proceed.) The primary factor involved in glomerular filtration is basically the same one that regulates fluid and solute movement across capillaries throughout the body. This factor is the balance between *hydrostatic pressure*, or fluid pressure, and *colloid osmotic pressure*, or pressure due to materials in solution, on either side of the capillary walls.

Hydrostatic Pressure

We discussed the major forces that act across capillary walls in Chapters 21 and 22. (You may find it helpful to review Blood pressure is low in typical systemic capillaries. The reason is that capillary blood flows into the venous system, where resistance is fairly low. However, at the glomerulus, blood leaving the glomerular capillaries flows into an efferent arteriole, whose diameter is *smaller* than that of the afferent arteriole. For this reason, the efferent arteriole offers considerable resistance. Relatively high pressures are needed to force blood into it. As a result, glomerular pressures are similar to those of small arteries. These pressures average about 50 mm Hg, instead of the 35 mm Hg typical of peripheral capillaries. Glomerular hydrostatic pressure (GHP), capsular hydrostatic pressure (CsHP), blood colloid osmotic pressure (BCOP), and net filtration pressure (NFP) are shown in Figure 26–10.

Capsular hydrostatic pressure (CsHP) opposes glomerular hydrostatic pressure. This pressure results from the resistance to flow along the nephron and the conducting system. (Before additional filtrate can enter the capsule, some of the filtrate already present must be forced into the PCT.) The CsHP averages about 15 mm Hg.

The *net hydrostatic pressure (NHP)* is the difference between the glomerular hydrostatic pressure, which tends to push water and solutes out of the bloodstream, and the capsular hydrostatic pressure, which tends to push water and solutes into the bloodstream. We can calculate net hydrostatic pressure as follows:

NHP = (GHP - CsHP) = (50 mm Hg - 15 mm Hg)= 35 mm Hg

Colloid Osmotic Pressure

The *colloid osmotic pressure* of a solution is the osmotic pressure resulting from suspended proteins. Under normal conditions, very few plasma proteins enter the capsular space, so no opposing colloid osmotic pressure exists within the capsule. However, if the glomeruli are damaged by disease or injury, and plasma proteins begin passing into the capsular space, a *capsular colloid osmotic pressure* is created that promotes filtration and increases fluid losses in urine.

Net Filtration Pressure

The net filtration pressure (NFP) at the glomerulus is the difference between the net hydrostatic pressure and the blood colloid osmotic pressure acting across the glomerular capillaries. Under normal circumstances, we can summarize this relationship as

or

NFP = 35 mm Hg - 25 mm Hg = 10 mm Hg

NFP = NHP - BCOP

This is the average pressure forcing water and dissolved materials out of the glomerular capillaries and into the capsular spaces (Figure 26–10b). Problems that affect the net filtration pressure can seriously disrupt kidney function and cause a variety of clinical signs and symptoms.

The Glomerular Filtration Rate

The **glomerular filtration rate (GFR)** is the amount of filtrate the kidneys produce each minute. Each kidney contains about 6 m²—some 64 square feet—of filtration surface, and the GFR averages an astounding 125 mL per minute. This means that nearly 10 percent of the fluid delivered to the kidneys by the renal arteries leaves the bloodstream and enters the capsular spaces.

A *creatinine clearance test* is often used to estimate the GFR. Creatinine results from the breakdown of creatine phosphate in muscle tissue and is normally eliminated in urine. Creatinine enters the filtrate at the glomerulus and is not reabsorbed in significant amounts. By monitoring the creatinine concentrations in blood and the amount excreted in urine in a 24-hour period, a clinician can easily estimate the GFR.

Consider, for example, a person who eliminates 84 mg of creatinine each hour and has a plasma creatinine concentration of 1.4 mg/dL. The GFR is equal to the amount secreted divided by the plasma concentration, so this person's GFR is

$$\frac{84 \text{ mg/h}}{1.4 \text{ mg/dL}} = 60 \text{ dL/h} = 100 \text{ mL/min}$$

The GFR is usually reported in milliliters per minute.

The value 100 mL/min is only an approximation of the GFR. The reason is that up to 15 percent of creatinine in the urine enters by means of active tubular secretion. When necessary, a more accurate GFR can be obtained by using the complex carbohydrate *inulin*. This compound is not metabolized in the body and is neither reabsorbed nor secreted by the kidney tubules.

In the course of a single day, the glomeruli generate about 180 liters (48 gal) of filtrate, approximately 70 times the total plasma volume. But as filtrate passes through the renal tubules, about 99 percent of it is reabsorbed. You should now appreciate the significance of tubular reabsorption!

The glomerular filtration rate depends on the net filtration pressure across glomerular capillaries. Any factor that alters the net filtration pressure also alters the GFR and affects kidney function. One of the most significant factors is a decrease in renal blood pressure. If blood pressure at the glomeruli decreases by 20 percent (from 50 mm Hg to 40 mm Hg), kidney filtration ceases, because the net filtration pressure is 0 mm Hg. For this reason, the kidneys are sensitive to changes in blood pressure that have little or no effect on other organs. Hemorrhaging, shock, and dehydration are relatively common clinical conditions that can cause a dangerous decrease in the GFR and lead to acute renal failure (p. 1008).

Control of the GFR

Glomerular filtration is the vital first step for all other kidney functions. If filtration does not take place, waste products are not excreted, pH control is jeopardized, and an important mechanism for regulating blood volume is lost. It should be no surprise that a variety of regulatory mechanisms ensure that GFR remains within normal limits.

Filtration depends on adequate blood flow to the glomerulus and on the maintenance of normal filtration pressures. Three interacting levels of control stabilize GFR: (1) *autoregulation*, at the local level; (2) *hormonal regulation*, initiated by the kidneys; and (3) *autonomic regulation*, primarily by the sympathetic division of the autonomic nervous system.

Autoregulation of the GFR

Autoregulation (local blood flow regulation) maintains an adequate GFR despite changes in local blood pressure and blood flow. *Myogenic mechanisms*—how arteries and arterioles react to an increase or decrease in blood pressure—play a role in the autoregulation of blood flow. Changes to the diameters of afferent arterioles, efferent arterioles, and glomerular capillaries maintain GFR. The most important regulatory mechanisms stabilize the GFR when systemic blood pressure drops (Figure 26–11).

The GFR also remains relatively constant when systemic blood pressure increases. An increase in renal blood pressure stretches the walls of afferent arterioles, and the smooth muscle cells respond by contracting. The reduction in the diameter of afferent arterioles decreases glomerular blood flow and keeps the GFR within normal limits.

Hormonal Regulation of the GFR

The GFR is regulated by the hormones of the renin–angiotensinaldosterone system and the natriuretic peptides (ANP and BNP). We introduced these hormones and their actions in Chapters 18 and 21. → pp. 639–641, 746–749 There are three triggers for the release of renin by the juxtaglomerular complex (JGC). They are (1) a decrease in blood pressure at the glomerulus as the result of a decrease in blood volume, a decrease in systemic pressures, or a blockage in the renal artery or its branches; (2) stimulation of juxtaglomerular cells by sympathetic innervation; or (3) a decrease in the osmotic concentration of the tubular fluid at the macula densa.

These triggers are often interrelated. For example, a decrease in systemic blood pressure reduces the glomerular filtration rate, while baroreceptor reflexes cause sympathetic activation. Meanwhile, a decrease in the GFR slows the movement of tubular fluid along the nephron. As a result, the tubular fluid is in the ascending limb of the nephron loop longer, and the concentration of sodium and chloride ions in the tubular fluid reaching the macula densa and DCT becomes abnormally low.

Figure 26–11 provides a general overview of the response of the renin–angiotensin-aldosterone system to a decrease in GFR. A decrease in GFR leads to the release of renin by the juxtaglomerular complex. Renin converts the inactive protein angiotensinogen to angiotensin I. Angiotensin I is also inactive but is then converted to angiotensin II by **angiotensin-converting enzyme (ACE)**. This conversion takes place primarily in the capillaries of the lungs. Angiotensin II acts at the nephron, adrenal glands, and in the CNS. In peripheral capillary beds, angiotensin II causes a brief but powerful vasoconstriction of arterioles and precapillary sphincters, increasing arterial pressures throughout the body. The combined effect is an increase in systemic blood volume and blood pressure and the restoration of normal GFR.

If blood volume increases, the GFR increases automatically. This increase promotes fluid losses that help return blood volume to normal levels. If the increase in blood volume is severe, hormonal factors further increase the GFR and speed up fluid losses in the urine. As noted in Chapter 18, the heart releases *natriuretic peptides* when increased blood volume or blood pressure stretches the walls of the heart. The atria release atrial natriuretic peptide (ANP), and the ventricles release brain natriuretic peptide (BNP). ⊃ pp. 640, 749 Among their other effects, these hormones trigger the dilation of afferent arterioles and the constriction of efferent arterioles. This mechanism increases glomerular pressures and increases the GFR. The natriuretic peptides also decrease sodium reabsorption at the renal tubules. The net result is increased urine production and decreased blood volume and pressure.

Autonomic Regulation of the GFR

Most of the autonomic innervation of the kidneys consists of sympathetic postganglionic fibers. (The role of the few parasympathetic fibers in regulating kidney function is not known.) Sympathetic activation has a direct effect on the GFR. It produces a powerful vasoconstriction of afferent arterioles, which decreases the GFR and slows the production of filtrate. In this way, the sympathetic activation triggered by an acute decrease in blood pressure or a heart attack overrides the local regulatory mechanisms that act to stabilize the GFR. As the crisis passes and sympathetic tone decreases, the filtration rate gradually returns to normal.

When the sympathetic division alters regional patterns of blood circulation, blood flow to the kidneys is often affected. For example, the dilation of superficial vessels in warm weather shunts blood away from the kidneys. As a result, glomerular filtration decreases temporarily. The effect becomes especially pronounced during strenuous exercise. As the blood flow to your skin and skeletal muscles increases, kidney perfusion gradually decreases. These changes may be opposed, with variable success, by autoregulation at the local level.

At maximal levels of exertion, renal blood flow may be less than 25 percent of normal resting levels. This reduction can create problems for endurance athletes. Metabolic wastes build up

over the course of a long event. *Proteinuria* (protein in the urine) commonly occurs after such events because the glomerular cells have been injured by prolonged hypoxia (low oxygen levels). If the damage is substantial, *hematuria* (blood in the urine) occurs. Hematuria develops in about 18 percent of marathon runners. The cause is trauma to the bladder epithelium from the shocks of running. Proteinuria and hematuria generally disappear within 48 hours as the glomerular tissues are repaired. However, a small number of marathon and ultramarathon runners experience *acute renal failure*, with permanent impairment of kidney function.

CHECKPOINT

- 9. What nephron structures are involved in filtration?
- 10. List the factors that influence net filtration pressure.
- **11**. List the factors that influence the rate of filtrate formation.
- 12. How would a decrease in blood pressure affect the GFR?

See the blue Answers tab at the back of the book.

26-5 Countercurrent multiplication, antidiuretic hormone, and aldosterone affect reabsorption and secretion

Learning Outcome Identify the types and functions of transport mechanisms found along each segment of the nephron, explain the role of countercurrent multiplication, describe hormonal influence on the volume and concentration of urine, and describe the characteristics of a normal urine sample.

Reabsorption recovers useful materials that have entered the filtrate. Secretion ejects wastes, toxins, or other undesirable solutes that did not leave the bloodstream at the glomerulus. Both processes take place in every segment of the nephron except the renal corpuscle. Their relative importance changes from segment to segment.

Reabsorption and Secretion at the PCT

The cells of the proximal convoluted tubule normally reabsorb 60–70 percent of the volume of the filtrate produced in the renal corpuscle. The reabsorbed materials enter the peritubular fluid, diffuse into peritubular capillaries, and are quickly returned to the circulation.

The PCT has five major functions:

1. *Reabsorption of Organic Nutrients.* Under normal circumstances, before the tubular fluid enters the nephron loop, the PCT reabsorbs more than 99 percent of the glucose, amino acids, and other organic nutrients in the fluid. This reabsorption involves a combination of facilitated transport and cotransport.

- 2. Active Reabsorption of Ions. The PCT actively transports several ions, including sodium, potassium, and bicarbonate ions, plus magnesium, phosphate, and sulfate ions (Figure 26–12). Although the ion pumps involved are individually regulated, they may be influenced by circulating ion or hormone levels. For example, angiotensin II stimulates Na⁺ reabsorption along the PCT. By absorbing carbon dioxide, the PCT indirectly recaptures about 90 percent of the bicarbonate ions from tubular fluid. Bicarbonate is important in stabilizing blood pH. We examine this process further in Chapter 27.
- **3.** *Reabsorption of Water.* The reabsorptive processes have a direct effect on the solute concentrations inside and outside the tubules. The filtrate entering the PCT has the same osmotic concentration as that of the surrounding peritubular fluid. As reabsorption proceeds, the solute concentration of tubular fluid decreases, and that of peritubular fluid and adjacent capillaries increases. Osmosis then pulls water out of the tubular fluid and into the peritubular fluid. Along the PCT, this mechanism results in the reabsorption of about 108 liters of water each day.
- 4. *Passive Reabsorption of Ions.* As active reabsorption of ions takes place and water leaves the tubular fluid by osmosis, the concentration of other solutes in the tubular fluid increases above that in the peritubular fluid. If the tubular cells are permeable to them, those solutes move across the tubular cells and into the peritubular fluid by passive diffusion. Urea, chloride ions, and lipid-soluble materials may diffuse out of the PCT in this way. Such diffusion further decreases the solute concentration of the tubular fluid and promotes additional water reabsorption by osmosis.
- 5. *Secretion.* Active secretion of hydrogen ions also takes place along the PCT (Table 26-4). Because the PCT and DCT secrete similar substances, and the DCT carries out comparatively little reabsorption, we will consider secretory mechanisms when we discuss the DCT.

Sodium ion reabsorption plays an important role in all of these processes. Sodium ions may enter tubular cells by diffusion through Na⁺ leak channels; by the sodium-linked cotransport of glucose, amino acids, or other organic solutes; or by countertransport for hydrogen ions (Figure 26–12). Once inside the tubular cells, sodium ions diffuse toward the basement membrane. The plasma membrane in this area contains sodium–potassium exchange pumps that eject sodium ions in exchange for extracellular potassium ions. Reabsorbed sodium ions then diffuse through the peritubular fluid and into adjacent peritubular capillaries.

The reabsorption of ions and compounds along the PCT involves many different carrier proteins. Some people have an inherited inability to manufacture one or more of these carrier

The Nephron Loop and Countercurrent Multiplication

Approximately 60–70 percent of the volume of filtrate produced by the glomerulus has been reabsorbed before the tubular fluid reaches the nephron loop. In the process, useful organic substrates and many mineral ions have been reclaimed. The nephron loop reabsorbs about half of the remaining water and two-thirds of the remaining sodium and chloride ions. This reabsorption takes place efficiently according to the principle of countercurrent exchange. We introduced this principle in Chapter 25 in our discussion of heat conservation mechanisms. \bigcirc **p**. 965

The thin descending limb and the thick ascending limb of the nephron loop lie very close together. They are separated only by peritubular fluid. The exchange between these segments is

Figure 26–12 Transport Activities at the PCT. Sodium ions may enter a tubular cell from the filtrate by diffusion, cotransport, or countertransport. The sodium ions are then pumped into the peritubular fluid by the sodium–potassium exchange pump. Other reabsorbed solutes may be ejected into the peritubular fluid by separate active transport mechanisms. The absorption of bicarbonate is indirectly associated with the reabsorption of sodium ions and the secretion of hydrogen ions.

called **countercurrent multiplication**. *Countercurrent* refers to the fact that the exchange takes place between fluids moving in opposite directions: Tubular fluid in the descending limb flows toward the renal pelvis, while tubular fluid in the ascending limb flows toward the cortex. *Multiplication* refers to the fact that the effect of the exchange increases as movement of the fluid continues.

The two parallel limbs of the nephron loop have very different permeability characteristics. The thin descending limb is permeable to water but relatively impermeable to solutes. The thick ascending limb is relatively impermeable to both water and solutes, but it contains active transport mechanisms that pump sodium and chloride ions from the tubular fluid into the peritubular fluid of the medulla.

A quick overview of countercurrent multiplication will help you make sense of the details:

- Sodium and chloride ions are pumped out of the thick ascending limb and into the peritubular fluid. This dilutes the tubular fluid.
- The pumping action increases the osmotic concentration in the peritubular fluid around the thin descending limb.
- This creates a small concentration difference between the tubular fluid and peritubular fluid in the renal medulla.
- The concentration difference results in an osmotic flow of water out of the thin descending limb and into the peritubular fluid. As a result, the solute concentration increases in the thin descending limb.
- The arrival of the highly concentrated solution in the thick ascending limb speeds up the transport of sodium and chloride ions into the peritubular fluid.

Solute pumping at the ascending limb leads to higher solute concentrations in the descending limb, which then brings about increased solute pumping in the ascending limb. Notice that this process is a simple positive feedback loop that multiplies the concentration difference between the hypotonic tubular fluid in the ascending limb and the hypertonic peritubular fluid in the renal medulla.

We can now take a closer look at the mechanics of the process. Figure 26–13a diagrams ion transport across the epithelium of the thick ascending limb. Active transport at the apical surface moves sodium, potassium, and chloride ions out of the tubular fluid. The carrier is called a $Na^+-K^+/2$ Cl⁻ transporter, because each cycle of the pump carries a sodium ion, a potassium ion, and two chloride ions into the tubular cell. Then cotransport carriers pump potassium and chloride ions into the peritubular fluid. However, potassium ions are removed from the peritubular fluid as the sodium–potassium exchange pump pumps sodium ions out of the tubular cell. The potassium ions then diffuse back into the lumen of the tubule through potassium leak channels. The net result is that Na^+ and Cl⁻ enter the peritubular fluid of the renal medulla. The removal of sodium and chloride ions from the tubular fluid in the ascending limb raises the osmotic concentration of the peritubular fluid around the thin descending limb (Figure 26–13b). Recall that the thin descending limb is permeable to water but not to solutes. As tubular fluid travels deeper into the medulla within the thin descending limb, osmosis moves water into the peritubular fluid. Solutes remain behind. As a result, the tubular fluid at the turn of the nephron loop has a higher osmotic concentration than it did at the start.

The pumping mechanism of the thick ascending limb is highly effective. Almost two-thirds of the sodium and chloride ions that enter it are pumped out of the tubular fluid before that fluid reaches the DCT. In other tissues, differences in solute concentration are quickly resolved by osmosis. However, osmosis cannot take place across the wall of the thick ascending limb, because the epithelium there is impermeable to water. So, as Na⁺ and CI⁻ are removed, the solute concentration in the tubular fluid decreases. Tubular fluid arrives at the DCT with an osmotic concentration of only about 100 mOsm/L. This value is one-third the concentration of the peritubular fluid of the renal cortex.

The rate of ion transport across the thick ascending limb is proportional to an ion's concentration in tubular fluid. As a result, more sodium and chloride ions are pumped into the medulla at the start of the thick ascending limb, where NaCl concentrations are highest, than near the cortex. This regional difference in the rate of ion transport is the basis of the concentration gradient within the medulla.

The Concentration Gradient of the Medulla

Normally, the maximum solute concentration of the peritubular fluid near the turn of the nephron loop is about 1200 mOsm/L (Figure 26–13b). Sodium and chloride ions pumped out of the loop's ascending limb make up about twothirds of that gradient (750 mOsm/L). The rest of the concentration gradient results from the presence of urea.

To understand how urea arrives in the medulla, let's look ahead to events in the last segments of the collecting system (Figure 26–13c). The thick ascending limb of the nephron loop, the DCT, and the collecting ducts are all impermeable to urea. As water is reabsorbed, the concentration of urea gradually increases in the tubular fluid. When the tubular fluid reaches the papillary duct, it typically contains urea at a concentration of about 450 mOsm/L. Because the papillary ducts are permeable to urea, the urea concentration in the deepest parts of the medulla also averages 450 mOsm/L.

Benefits of Countercurrent Multiplication

The countercurrent mechanism performs two functions:

1. It efficiently reabsorbs solutes and water before the tubular fluid reaches the DCT and collecting system.

ing duct tend to concentrate urea in the tubular fluid and in the medulla. The nephron loop, DCT, and collecting duct are impermeable to urea. As water reabsorption occurs, the urea concentration increases. Papillary duct permeability to urea makes up nearly one-third of the solutes in the deepest portions of the medulla.

2. It establishes a concentration gradient that permits the passive reabsorption of water from the tubular fluid in the collecting system. Circulating levels of antidiuretic hormone (ADH) regulate this reabsorption.

In summary, countercurrent multiplication is a way to either concentrate or dilute urine. The tubular fluid entering the descending limb of the nephron loop has an osmotic concentration of roughly 300 mOsm/L, due primarily to the presence of ions such as Na⁺ and CI⁻. The concentration of organic wastes, such as urea, is low. About half of the tubular fluid entering the nephron loop is then reabsorbed along the thin descending limb. Two-thirds of the Na⁺ and CI⁻ is reabsorbed along the thick ascending limb. As a result, the DCT receives a reduced volume of tubular fluid with an osmotic concentration of about 100 mOsm/L. Urea and other organic wastes, which were not pumped out of the thick ascending limb, now represent a significant proportion of the dissolved solutes.

Reabsorption and Secretion at the DCT

As we have just seen, the composition and volume of tubular fluid change dramatically as it flows from the capsular space to the distal convoluted tubule. Only 15–20 percent of the initial filtrate volume reaches the DCT. The concentrations of electrolytes and organic wastes in the arriving tubular fluid no longer resemble the concentrations in blood plasma. Selective reabsorption or secretion, primarily along the DCT, makes the final adjustments in the solute composition and volume of the tubular fluid.

Reabsorption at the DCT

Throughout most of the DCT, the tubular cells actively transport Na⁺ and Cl⁻ out of the tubular fluid (Figure 26–14a). Tubular cells along the distal portions of the DCT also contain ion pumps that reabsorb tubular Na⁺ in exchange for another cation (usually K⁺) (Figure 26–14b). The hormone *aldosterone*, produced by the adrenal cortex, controls the Na⁺ channels and the ion pump. This hormone stimulates the synthesis and incorporation of sodium channels and sodium ion pumps in plasma membranes along the DCT and collecting duct. The net result is a reduction in the number of sodium ions lost in urine.

However, sodium ion conservation is associated with potassium ion loss. Prolonged aldosterone stimulation can therefore produce *hypokalemia*, a dangerous reduction in the plasma K^+ concentration. The secretion of aldosterone and its actions on the DCT and collecting system are opposed by the natriuretic peptides (ANP and BNP).

The DCT is also the primary site of Ca^{2+} reabsorption. Circulating levels of parathyroid hormone and calcitriol regulate this process. \bigcirc pp. 630–631

Secretion at the DCT

The blood entering the peritubular capillaries still contains a number of potentially undesirable substances that did not cross the filtration membrane at the glomerulus. In most cases, the concentrations of these substances are too low to cause physiological problems. However, any ions or compounds in peritubular capillaries will diffuse into the peritubular fluid. If those concentrations become too high, the tubular cells may absorb these substances from the peritubular fluid and secrete them into the tubular fluid. Table 26–3 (p. 986) lists some of the substances secreted into tubular fluid by the proximal and distal convoluted tubules.

The rate of K^+ and H^+ secretion increases or decreases in response to changes in their concentrations in peritubular fluid. The higher their concentration in the peritubular fluid, the higher the rate of secretion. Potassium and hydrogen ions merit special attention, because their concentrations in body fluids must be maintained within narrow limits.

Potassium lon Secretion. Figure 26–14a,b diagrams the mechanism of K^+ secretion. In effect, tubular cells trade sodium ions in the tubular fluid for excess potassium ions in body fluids. Potassium ions are removed from the peritubular fluid in exchange for sodium ions from the tubular fluid. These potassium ions diffuse into the lumen of the DCT through potassium leak channels at the apical surfaces of the tubular cells.

Hydrogen lon Secretion. Hydrogen ion secretion is also associated with the reabsorption of sodium. Figure 26–14c depicts two routes of secretion. Both involve the generation of carbonic acid by the enzyme *carbonic anhydrase*. \bigcirc pp. 862, 900 Hydrogen ions generated by the dissociation of the carbonic acid are secreted by sodium-linked countertransport in exchange for Na⁺ in the tubular fluid. The bicarbonate ions diffuse into the peritubular fluid and then into the bloodstream. There they help prevent changes in plasma pH.

Hydrogen ion secretion acidifies the tubular fluid while increasing the pH of the blood. Hydrogen ion secretion speeds up when the pH of the blood decreases. This can happen in *lactic acidosis*, which can develop after exhaustive muscle activity, or *ketoacidosis*, which can develop in starvation or diabetes mellitus. \bigcirc p. 956 The combination of H⁺ removal and HCO₃⁻ production by the kidneys plays an important role in the control of blood pH. Because one of the secretory pathways is aldosterone sensitive, aldosterone stimulates H⁺ secretion. Prolonged aldosterone stimulation can cause *alkalosis*, or abnormally high blood pH.

In Chapter 25, we noted that the production of lactic acid and ketone bodies during the postabsorptive state could cause acidosis. Under these conditions, the PCT and DCT

Clinical Note

Diuretics *Diuresis* (dī-ū-RĒ-sis; *dia*, through + *ouresis*, urination) is the elimination of urine. *Urination* is an equivalent term in a general sense, but *diuresis* typically indicates the production of a large volume of urine. **Diuretics** (dī-ū-RET-iks) are drugs that promote water loss in urine. The usual goal in diuretic therapy is to decrease blood volume, blood pressure, extracellular fluid volume, or all three. The ability to control renal water losses with relatively safe and effective diuretics has saved the lives of many people, especially those with high blood pressure or congestive heart failure.

Diuretics have many mechanisms of action. However, all such drugs affect transport activities or water reabsorption along the nephron and collecting system. For example, consider the class of diuretics called *thiazides* (THĪ-uh-zīdz). These drugs increase water loss by decreasing so-dium and chloride ion transport in the proximal and distal convoluted tubules.

Diuretic use for nonclinical reasons is on the rise. For example, some bodybuilders take large doses of diuretics to improve muscle definition temporarily. Some fashion models or horse jockeys do the same. Their goal is to reduce body weight for brief periods. This practice of "cosmetic dehydration" is extremely dangerous. It has caused several deaths due to electrolyte imbalance and consequent cardiac arrest.

deaminate amino acids in reactions that strip off the amino groups ($-NH_2$). The reaction sequence ties up H⁺ and yields both **ammonium ions** (NH_4^+) and HCO_3^- . As indicated in **Figure 26–14c**, the ammonium ions are then pumped into the tubular fluid by sodium-linked countertransport, and the bicarbonate ions enter the bloodstream by way of the peritubular fluid.

Tubular deamination thus has two major benefits. It provides carbon chains suitable for catabolism. It also generates bicarbonate ions that add to the buffering capacity of plasma.

Reabsorption and Secretion along the Collecting System

The collecting ducts receive tubular fluid from many nephrons and carry it toward the renal sinus, through the concentration gradient in the medulla. The normal amount of water and solute loss in the collecting system is regulated in two ways:

 By aldosterone, which controls sodium ion pumps along most of the DCT and the proximal portion of the collecting system. As we have noted, these actions are opposed by the natriuretic peptides.

 By ADH, which controls the permeability of the DCT and collecting system to water. The secretion of ADH is suppressed by the natriuretic peptides, and this—combined with the effects of natriuretic peptide on aldosterone secretion and action—can dramatically increase urinary water losses.

The collecting system also has other reabsorptive and secretory functions. Many of them are important to the control of body fluid pH.

Reabsorption in the Collecting System

The collecting system reabsorbs sodium ions, bicarbonate ions, and urea as follows:

- Sodium Ion Reabsorption. The collecting system contains aldosterone-sensitive ion pumps that exchange Na⁺ in tubular fluid for K⁺ in peritubular fluid (Figure 26–14b).
- Bicarbonate Reabsorption. Bicarbonate ions are reabsorbed in exchange for chloride ions in the peritubular fluid (Figure 26–14c).
- *Urea Reabsorption.* The concentration of urea in the tubular fluid entering the collecting duct is relatively high. The fluid entering the papillary duct generally has the same osmotic concentration as that of interstitial fluid of the medulla— about 1200 mOsm/L—but contains a much higher concentration of urea. As a result, urea tends to diffuse out of the tubular fluid and into the peritubular fluid in the deepest portion of the medulla.

Secretion in the Collecting System

The collecting system is important in controlling the pH of body fluids through the secretion of hydrogen or bicarbonate ions. If the pH of the peritubular fluid decreases, carrier proteins pump hydrogen ions into the tubular fluid and reabsorb bicarbonate ions that help restore normal pH. If the pH of the peritubular fluid rises (a much less common event), the collecting system secretes bicarbonate ions and pumps hydrogen ions into the peritubular fluid. The net result is that the body eliminates a buffer and gains hydrogen ions that lower the pH. We examine these responses in more detail in Chapter 27, when we consider acid–base balance.

The Control of Urine Volume and Osmotic Concentration

Urine volume and osmotic concentration are regulated through the control of water reabsorption. Water is reabsorbed by osmosis along the proximal convoluted tubule and the descending limb of the nephron loop. The water permeabilities

of these regions cannot be adjusted. As a result, water reabsorption takes place wherever the osmotic concentration of the peritubular fluid is greater than that of the tubular fluid. The ascending limb of the nephron loop is impermeable to water. In the distal convoluted tubule and collecting system, 1–2 percent of the volume of water in the original filtrate is recovered during sodium ion reabsorption. All these water movements represent *obligatory water reabsorption* because they cannot be prevented. This reabsorption usually recovers 85 percent of the volume of filtrate.

The volume of water lost in urine depends on how much of the remaining water in the tubular fluid is reabsorbed along the DCT and collecting system. (This remaining water represents 15 percent of the filtrate volume, or approximately 27 liters per day.) The amount reabsorbed can be precisely controlled by a process called *facultative*

c Hydrogen ion secretion and the acidification of urine occur by two routes. The central theme is the exchange of hydrogen ions in the cytosol for sodium ions in the tubular fluid, and the reabsorption of the bicarbonate ions generated in the process.

water reabsorption. Precise control is possible because these segments are relatively impermeable to water except in the presence of ADH. This hormone causes special *water channels*, or *aquaporins*, to be inserted into the apical plasma membranes. These water channels dramatically enhance the rate of osmotic water movement. The higher the circulating levels of ADH, the greater the number of water channels, and the greater the water permeability of these segments.

As noted earlier in this chapter, the tubular fluid arriving at the DCT has an osmotic concentration of only about 100 mOsm/L. In the presence of ADH, osmosis takes place. Water moves out of the DCT until the osmotic concentration of the tubular fluid equals that of the surrounding cortex (roughly 300 mOsm/L).

The tubular fluid then flows along the collecting duct, which passes through the concentration gradient of the medulla. Additional water is then reabsorbed. The urine reaching the minor calyx has an osmotic concentration closer to 1200 mOsm/L. Just how closely the osmotic concentration approaches 1200 mOsm/L depends on how much ADH is present.

Figure 26–15 diagrams the effects of ADH on the DCT and collecting system. Without ADH (Figure 26–15a), water is not reabsorbed in these segments, so all the fluid reaching the DCT is lost in the urine. The person then produces large amounts of very dilute urine. That is just what happens in cases of *diabetes insipidus*. ⊃ p. 623 With this condition, urinary water losses may reach 24 liters (6.3 gal) per day and the urine osmotic concentration is 30–400 mOsm/L.

As ADH levels rise (Figure 26–15b), the DCT and collecting system become more permeable to water. As a result, the amount of water reabsorbed increases. At the same time, the osmotic concentration of the urine climbs. Under maximum ADH stimulation, the DCT and collecting system become so permeable to water that the osmotic concentration of the urine equals that of the deepest portion of the medulla. Note that the concentration of urine can never *exceed* that of the medulla, because the concentrating mechanism relies on osmosis.

The hypothalamus continuously secretes ADH at low levels. For this reason, the DCT and collecting system always have a significant degree of water permeability. At these low ADH levels, the DCT reabsorbs approximately 9 liters of water per day, or about 5 percent of the original volume of filtrate produced by the

glomeruli. At normal ADH levels, the collecting system reabsorbs about 16.8 liters per day, or about 9.3 percent of the original volume of filtrate. A healthy adult typically produces 1200 mL of urine per day (about 0.6 percent of the filtrate volume). Its osmotic concentration range is 855–1335 mOsm/L.

The effects of ADH are opposed by those of the natriuretic peptides, ANP and BNP. These hormones stimulate the production of a large volume of relatively dilute urine. This water loss reduces plasma volume to normal.

The Function of the Vasa Recta

The solutes and water reabsorbed in the renal medulla must be returned to the bloodstream without disrupting the concentration gradient. This return is the function of the vasa recta. Recall that the vasa recta are long, straight capillaries that parallel the long nephron loop of juxtamedullary nephrons.

Blood entering the vasa recta from the peritubular capillaries has an osmotic concentration of approximately 300 mOsm/L. As the blood descends into the medulla, it gradually increases in osmotic concentration as the solute concentration in the peritubular fluid increases. This increase in blood osmotic concentration involves both solute absorption and water loss. Solute absorption predominates, however, because the plasma proteins limit the osmotic flow of water out of the blood. \supset p. 739

Blood ascending toward the cortex gradually decreases in osmotic concentration as the solute concentration of the peritubular fluid decreases. Again, this decrease involves both solute diffusion and osmosis. In this case osmosis predominates, because the presence of plasma proteins does not oppose the osmotic flow of water into the blood.

The net results are that (1) some of the solutes absorbed in the descending portion of the vasa recta do not diffuse out in the ascending portion and (2) more water moves into the ascending portion of the vasa recta than moves out in the descending portion. Thus, the vasa recta carries both water and solutes out of the medulla. Under normal conditions, the removal of solutes and water by the vasa recta precisely balances the rates of solute reabsorption and osmosis in the medulla.

The Composition of Normal Urine

As we have seen, more than 99 percent of the 180 liters of filtrate produced each day by the glomeruli is reabsorbed. It never reaches the renal pelvis for elimination. General characteristics of the remaining filtrate—normal urine—are listed in Table 26–5. However, the composition of the urine produced each day varies with the metabolic and hormonal events under way.

The composition and concentration of urine are two related but distinct properties. The *composition* of urine reflects the filtration, reabsorption, and secretion activities of the nephrons. Some substances (such as urea) are neither actively excreted nor reabsorbed along the nephron. In contrast, organic nutrients are completely reabsorbed. Other substances, such as

Table 26–5	General Characteristics of Normal Urine			
Characteristic		Normal Range		
рН		4.5–8 (average: 6.0)		
Specific gravity		1.003–1.030		
Osmotic concentration (osmolarity) 855–1335 mOsm/L		855–1335 mOsm/L		
Water content		93%–97%		
Volume		700–2000 mL/day		
Color		Clear yellow		
Odor		Varies with composition		
Bacterial content		None (sterile)		

creatinine, are missed by filtration but are actively secreted into the tubular fluid.

Filtration, reabsorption, and secretion determine the kinds and amounts of substances excreted in urine. The *concentration* of these substances in a given urine sample depends on the osmotic movement of water across the walls of the tubules and collecting ducts. Because the composition and concentration of urine vary independently, you can produce a small volume of concentrated urine or a large volume of dilute urine and still excrete the same amount of dissolved substances. For this reason, physicians who are interested in a detailed assessment of renal function commonly analyze the urine produced over a 24-hour period rather than a single urine sample.

Urinalysis is the analysis of a urine sample. It is an important diagnostic tool, even in high-technology medicine. A standard urinalysis includes an assessment of the color and appearance of urine. These two characteristics can be determined without specialized equipment. In the 17th century, physicians classified the taste of the urine as sweet, salty, and so on, but quantitative analytical tests have long since replaced the taste-bud assay.

Normal urine is a clear, sterile solution. Its yellow color comes from the pigment urobilin. The kidneys generate this pigment from the urobilinogens produced by intestinal bacteria and absorbed in the colon (see Figure 19–4, p. 662). The characteristic odor of urine is due to the evaporation of small molecules, such as ammonia. Other substances not normally present, such as acetone or other ketone bodies, can also impart a distinctive smell.

Table 26–6 gives some typical values obtained from urinalysis. Spotlight Figure 26–16 provides a summary of kidney function showing the major steps in the reabsorption of water and the production of concentrated urine.

SPOTLIGHT Figure 26–16 Summary of Renal Function

The filtrate produced by the renal corpuscle has the same osmotic concentration as plasma—about 300 mOsm/L. It has the same composition as blood plasma but does not contain plasma proteins.

2

In the proximal convoluted tubule (PCT), the active removal of ions and organic nutrients produces a continuous osmotic flow of water out of the tubular fluid. This decreases the volume of filtrate but keeps the solutions inside and outside the tubule isotonic. Between 60 and 70 percent of the filtrate volume is absorbed here.

3

In the PCT and descending limb of the nephron loop, water moves into the surrounding peritubular fluids, leaving a small volume of highly concentrated tubular fluid. This reduction occurs by obligatory water reabsorption.

1004 UNIT 5 Environmental Exchange

Table 26–6	Typical Values Obtained from Standard Urinalysis	5		
Compound	Primary Source	Daily Elimination*	Concentration	Remarks
NITROGENOUS W	ASTES			
Urea	Deamination of amino acids by liver and kidneys	21 g	1800 mg/dL	Increases if negative nitrogen balance exists
Creatinine	Breakdown of creatine phosphate in skeletal muscle	1.8 g	150 mg/dL	Proportional to muscle mass; decreases during atrophy or muscle disease
Ammonia	Deamination by liver and kidney, absorption from intestinal tract	0.68 g	60 mg/dL	
Uric acid	Breakdown of purines	0.53 g	40 mg/dL	Increases in gout, liver diseases
Hippuric acid	Breakdown of dietary toxins	4.2 mg	350 µg/dL	
Urobilin	Urobilinogens absorbed at colon	1.5 mg	125 μ g/dL	Gives urine its yellow color
Bilirubin	Hemoglobin breakdown product	0.3 mg	20 µg/dL	Increase may indicate problem with liver elimination or excess production; causes yellowing of skin and mucous membranes in jaundice
NUTRIENTS AND I	NETABOLITES			
Carbohydrates		0.11 g	9 μg/dL	Primarily glucose; <i>glycosuria</i> develops if T_m is exceeded
Ketone bodies		0.21 g	17 μg/dL	Ketonuria may occur during postabsorptive state
Lipids		0.02 g	0.002 mg/dL	May increase in some kidney diseases
Amino acids		2.25 g	188 µg/dL	Note relatively high loss compared with other metabolites due to low T_m ; excess (<i>aminoaciduria</i>) indicates T_m problem
IONS				
Sodium		4.0 g	40–220 mEq/L	Varies with diet, urine pH, hormones, etc.
Potassium		2.0 g	25–100 mEq/L	Varies with diet, urine pH, hormones, etc.
Chloride		6.4 g	110–250 mEq/L	
Calcium		0.2 g	17 mg/dL	Hormonally regulated (PTH/CT)
Magnesium		0.15 g	13 mg/dL	
BLOOD CELLS[‡]				
RBCs		130,000/day	100/mL	Excess (<i>hematuria</i>) indicates vascular damage in urinary system
WBCs		650,000/day	500/mL	Excess (pyuria) indicates renal infection or inflammation

*Representative values for a 70-kg (154-lb) male.

[‡]Usually estimated by counting the cells in a sample of sediment after urine centrifugation.

CHECKPOINT

- **13**. What effect would increased amounts of aldosterone have on the K⁺ concentration in urine?
- 14. What effect would a decrease in the Na⁺ concentration of filtrate have on the pH of tubular fluid?
- **15**. How would the lack of juxtamedullary nephrons affect the volume and osmotic concentration of urine?
- 16. Why does a decrease in the amount of Na⁺ in the distal convoluted tubule lead to an increase in blood pressure?

See the blue Answers tab at the back of the book.

26-6 Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra, aided by the micturition reflex

Learning Outcome Describe the structures and functions of the ureters, urinary bladder, and urethra, discuss the voluntary and involuntary regulation of urination, and describe the micturition reflex.

Filtrate modification and urine production end when the fluid enters the renal pelvis. The urinary tract (the ureters, urinary bladder, and urethra) transports, stores, and eliminates urine. A **pyelogram** (PĪ-el-ō-gram) is an image of the urinary system (**Figure 26–17**). It is obtained by taking an x-ray of the kidneys after a radiopaque dye has been administered intravenously. Such an image provides an orientation to the relative sizes and positions of the main structures. Note that the sizes of the minor and major calyces, the renal pelvis, the ureters, the urinary bladder, and the proximal portion of the urethra are somewhat variable. These regions are lined by a *transitional epithelium* that can tolerate cycles of distension and contraction without damage. \supset p. 120

The Ureters

The ureters are a pair of muscular tubes that extend from the kidneys to the urinary bladder—a distance of about 30 cm (12 in.). Each ureter begins at the funnel-shaped renal pelvis (Figure 26–4). The ureters extend inferiorly and medially, passing over the anterior surfaces of the *psoas major muscles* (Figure 26–3).

Ureter Urinary bladder Renal pelvis Kidney

The ureters are retroperitoneal and are firmly attached to the posterior abdominal wall. The paths taken by the ureters in men and women are different, due to variations in the nature, size, and position of the reproductive organs. In males, the base of the urinary bladder lies between the rectum and the pubic symphysis (Figure 26–18a). In females, the base of the urinary bladder sits inferior to the uterus and anterior to the vagina (Figure 26–18b).

The ureters penetrate the posterior wall of the urinary bladder without entering the peritoneal cavity. They pass through the bladder wall at an oblique angle. The **ureteral openings** are slit-like rather than rounded (Figure 26–18c). This shape helps prevent the backflow of urine toward the ureter and kidneys when the urinary bladder contracts.

Histology of the Ureters

The wall of each ureter consists of three layers (Figure 26–19a): (1) an inner mucosa, made up of a transitional epithelium and the surrounding lamina propria; (2) a middle muscular layer made up of longitudinal and circular bands of smooth muscle; and (3) an outer connective tissue layer that is continuous with the fibrous capsule and peritoneum. About every 30 seconds, a peristaltic contraction begins at the renal pelvis. As it sweeps along the ureter, it forces urine toward the urinary bladder.

The Urinary Bladder

The urinary bladder is a hollow, muscular organ that serves as a temporary reservoir for urine (Figure 26–18c). The dimensions of the urinary bladder vary with its state of distension. A full urinary bladder can contain as much as a liter of urine.

A layer of peritoneum covers the superior surfaces of the urinary bladder. Several peritoneal folds assist in stabilizing its position. The **median umbilical ligament** extends from the anterior, superior border toward the umbilicus (navel). The **lateral umbilical ligaments** pass along the sides of the bladder to the umbilicus. These fibrous cords are the vestiges of the two *umbilical arteries*, which supplied blood to the placenta during embryonic and fetal development. \bigcirc p. 772 The urinary bladder's posterior, inferior, and anterior surfaces lie outside the peritoneal cavity. In these areas, tough ligamentous bands anchor the urinary bladder to the pelvic and pubic bones.

In sectional view, the mucosa lining the urinary bladder is usually thrown into folds, or **rugae**, that disappear as the bladder fills. The triangular area bounded by the openings of the ureters and the entrance to the urethra makes up a region called the **trigone** (TRĪ-gōn) of the urinary bladder. There, the mucosa is smooth and very thick. The trigone acts as a funnel that channels urine into the urethra when the urinary bladder contracts.

The urethral entrance lies at the apex of the trigone, at the most inferior point in the urinary bladder. The region surrounding the urethral opening is known as the **neck** of the urinary bladder. It contains a muscular **internal urethral sphincter**.

Figure 26–18 Organs for Conducting and Storing Urine. ATLAS: Plates 62b; 64; 65

The smooth muscle fibers of this sphincter provide involuntary control over the discharge of urine from the bladder. The urinary bladder is innervated by postganglionic fibers from ganglia in the hypogastric plexus and by parasympathetic fibers from intramural ganglia that are controlled by branches of the pelvic nerves.

Histology of the Urinary Bladder

The wall of the urinary bladder contains mucosa, submucosa, and muscularis layers (Figure 26–19b). The muscularis layer consists of inner and outer layers of longitudinal smooth muscle, with a circular layer between the two. Together, these layers form the powerful **detrusor** (de-TRŪ-sor) **muscle** of the urinary bladder. When this muscle contracts, it compresses the urinary bladder and expels urine into the urethra.

The Urethra

The urethra extends from the neck of the urinary bladder and transports urine to the exterior of the body. The urethrae of males and females differ in length and in function. In males, the urethra extends from the neck of the urinary bladder to the tip of the penis (Figure 26–18a,c). This distance may be 18–20 cm (7-8 in.). We subdivide the male urethra into three segments: the prostatic urethra, the membranous urethra, and the spongy ure thra. The prostaticure thra passes through the center of the prostate gland. The membranous urethra includes the short segment that penetrates the urogenital diaphragm, the muscular floor of the pelvic cavity. The spongy urethra, or penile (PE-nīl) urethra, extends from the distal border of the urogenital diaphragm to the external opening, or external urethral orifice, at the tip of the penis. In females, the urethra is very short. It extends 3-5 cm (1-2 in.) from the bladder to the vestibule (Figure 26–18b). The external urethral orifice is near the anterior wall of the vagina.

In both sexes, where the urethra passes through the urogenital diaphragm, a circular band of skeletal muscle forms the **external urethral sphincter**. This muscular band acts as a valve. The external urethral sphincter is under voluntary control through the perineal branch of the pudendal nerve. This sphincter has a resting muscle tone and must be voluntarily relaxed to permit micturition.

Figure 26–19 The Histology of the Ureter, Urinary Bladder, and Urethra.

 A transverse section through the female urethra. A thick layer of smooth muscle surrounds the lumen.

TIPS&TRICKS

To remember that the urethra is the urinary tract's pipeline to the exterior, proclaim, "Eureka! Your urine! It's coming out the urethra!"

Histology of the Urethra

The urethral lining consists of a stratified epithelium that varies from transitional epithelium at the neck of the urinary bladder, to stratified columnar epithelium at the midpoint, to stratified squamous epithelium near the external urethral orifice. The lamina propria is thick and elastic. The mucosa is folded into longitudinal creases (Figure 26–19c). Mucinsecreting cells are located in the epithelial pockets. In males, the epithelial mucous glands may form tubules that extend

into the lamina propria. Connective tissues of the lamina propria anchor the urethra to surrounding structures. In females, the lamina propria contains an extensive network of veins. Concentric layers of smooth muscle surround the entire complex.

The Micturition Reflex and Urination

As we have seen, urine reaches the urinary bladder by peristaltic contractions of the ureters. The **micturition reflex** coordinates the process of urination (Figure 26–20).

As the bladder fills with urine, stretch receptors in the bladder wall are stimulated. Afferent fibers in the pelvic nerves carry impulses to the sacral spinal cord. The increased level of activity in the fibers (1) facilitates parasympathetic motor neurons in

the sacral spinal cord and (2) stimulates interneurons that relay sensations to the thalamus and then, through projection fibers, to the cerebral cortex. As a result, you become aware of the fluid pressure in your urinary bladder.

The urge to urinate generally appears when your bladder contains about 200 mL of urine. As **Figure 26–20** shows, the micturition reflex begins when the stretch receptors provide adequate stimulation to parasympathetic preganglionic motor neurons. A further increase in bladder volume begins the cycle again, usually within an hour. Each increase in urinary volume leads to an increase in stretch receptor stimulation that makes the sensation more acute. Once the volume exceeds 500 mL, the bladder contractions triggered by the micturition reflex may generate enough pressure to force open the internal urethral sphincter. This opening leads to a reflexive relaxation of the external urethral sphincter. Urination takes place despite voluntary opposition or

Clinical Note

Urinary Obstruction Local blockages of the collecting ducts or ureters can result from *casts*—small blood clots, epithelial cells, lipids, or other materials that form in the collecting ducts. Casts are commonly eliminated in urine. They are visible in microscopic analyses of urine samples. **Renal calculi** (KAL-kū-lī), or *kidney stones*, form within the urinary tract from calcium deposits, magnesium salts, or crystals of uric acid. The condition is called *nephrolithiasis* (nef-rō-li-THĪ-uh-sis; *nephros*, kidney; *lithos*, stone). The blockage of the ureter by a stone or by other means (such as external compression) creates **urinary obstruction**. This problem is serious. In addition to causing pain, it decreases or prevents filtration in the affected kidney by increasing the capsular hydrostatic pressure.

Calculi are generally visible on an x-ray. If peristalsis and fluid pressures cannot dislodge them, they must be either surgically removed or destroyed. One nonsurgical procedure involves disintegrating the stones with a *lithotripter*, a device originally developed from machines used to de-ice airplane wings. Lithotripters focus sound waves on the stones, breaking them into smaller fragments that can be passed in the urine. Another nonsurgical approach is the insertion of a catheter armed with a laser that can shatter calculi with intense light beams.

potential inconvenience. At the end of a typical micturition, less than 10 mL of urine remains in the bladder.

Infants lack voluntary control over urination, because the necessary corticospinal connections have yet to be established. Accordingly, "toilet training" before age 2 often involves training the parent to anticipate the timing of the reflex rather than training the child to exert conscious control.

Incontinence (in-KON-ti-nens) is the inability to control urination voluntarily. Trauma to the internal or external urethral sphincter can contribute to incontinence in otherwise healthy adults. For example, some mothers develop *stress urinary incontinence* (SUI) if childbirth overstretches and damages the sphincter muscles. In this condition, increased intra-abdominal pressures—caused, for example, by a cough or sneeze—can overwhelm the sphincter muscles, causing urine to leak out. Incontinence can also develop in older people due to a general loss of muscle tone.

Damage to the central nervous system, the spinal cord, or the nerve supply to the urinary bladder or external urethral sphincter can also produce incontinence. For example, incontinence commonly accompanies Alzheimer's disease or spinal cord damage. In most cases, the affected individual develops an *automatic bladder*. The micturition reflex remains intact, but voluntary

Clinical Note

Renal Failure and Kidney Transplant Renal failure

occurs when the kidneys cannot filter wastes from the blood and maintain homeostasis. When kidney filtration slows for any reason, urine production decreases. As the decrease continues, signs and symptoms of renal failure appear because water, ions, and metabolic wastes are retained. Virtually all systems in the body are affected. The person generally becomes hypertensive; anemia develops due to a decrease in erythropoietin production; and CNS problems can lead to sleeplessness, seizures, delirium, and even coma.

Acute renal failure occurs when filtration slows suddenly or stops due to renal ischemia, urinary obstruction, trauma, or nephrotoxic drugs. The reduction in kidney function takes place over a few days and may persist for weeks. Sensitized individuals can also develop acute renal failure after an allergic response to antibiotics or anesthetics.

In *chronic renal failure*, kidney function deteriorates gradually. The associated problems accumulate over years. This condition generally cannot be reversed. Its progression

can only be slowed. Eventually, symptoms of *end-stage renal failure* develop. *Hemodialysis* is a treatment that "cleanses" the blood by serving as a substitute for normal kidney functioning. It can relieve the symptoms of end-stage and acute renal failure. However, this treatment is not a cure.

In terms of overall quality of life, probably the most satisfactory solution to the problem of end-stage renal failure is **kidney transplant**. This procedure involves implanting a new kidney from a living donor or a deceased donor. Of the 16,812 kidneys transplanted as of June 2013, 11,043 transplants came from deceased donors and 5,769 came from living donors. At the writing of this text, 96,645 people were awaiting a kidney transplant. The recipient's nonfunctioning kidney(s) may be removed, especially if an infection is present. The transplanted kidney and ureter are usually placed extraperitoneally in the pelvic cavity (within the iliac fossa). The ureter is connected to the recipient's urinary bladder. Patient survival is more than 90 percent at two years after the transplant.

control of the external urethral sphincter is lost, so the person cannot prevent the reflexive emptying of the urinary bladder. Damage to the pelvic nerves can abolish the micturition reflex entirely, because those nerves carry both afferent and efferent fibers of this reflex arc. The urinary bladder then becomes greatly distended with urine. It remains filled to capacity while the excess urine flows into the urethra in an uncontrolled stream. The insertion of a catheter is often needed to facilitate the discharge of urine.

CHECKPOINT

- **17**. What effect would a high-protein diet have on the composition of urine?
- **18**. Obstruction of a ureter by a kidney stone would interfere with the flow of urine between which two points?
- **19**. The ability to control the micturition reflex depends on your ability to control which muscle?

See the blue Answers tab at the back of the book.

26-7 Age-related changes affect kidney function and the micturition reflex

Learning Outcome Describe the effects of aging on the urinary system.

In general, aging is associated with an increased incidence of kidney problems. One example—*nephrolithiasis*, the formation of calculi, or kidney stones—is described in the Urinary Obstruction Clinical Note (p. 1008). Other age-related changes in the urinary system include the following:

- A Decrease in the Number of Functional Nephrons. The total number of kidney nephrons decreases by 30–40 percent between ages 25 and 85.
- A *Reduction in the GFR*. This reduction results from fewer glomeruli, cumulative damage to the filtration apparatus in the remaining glomeruli, and reduced renal blood flow.
- A *Reduced Sensitivity to ADH*. With age, the distal portions of the nephron and collecting system become less responsive to ADH. Water and sodium ions are reabsorbed at a reduced rate, and more sodium ions are lost in urine.
- Problems with the Micturition Reflex. Three factors are involved in such problems: (1) The sphincter muscles lose muscle tone and become less effective at voluntarily retaining urine. This leads to incontinence, often involving a slow leakage of urine. (2) The ability to control micturition can be lost due to a stroke, Alzheimer's disease, or other CNS problems affecting the cerebral cortex or hypothalamus. (3) In males, *urinary retention* may develop if the prostate gland enlarges and compresses the urethra, restricting the flow of urine.

- CHECKPOINT

- **20**. List four age-related changes in the urinary system.
- **21**. Define nephrolithiasis.
- 22. Describe how incontinence may develop in an elderly person.
- See the blue Answers tab at the back of the book.

SYSTEM INTEGRATOR

Body System — Vrinary System

Urinary System ----- Body System

26-8 The urinary system is one of several body systems involved in waste excretion

Learning Outcome Give examples of interactions between the urinary system and other organ systems studied so far.

The urinary system excretes wastes produced by other body systems, but it is not the only organ system involved in excretion. Indeed, the urinary, integumentary, respiratory, and digestive systems are together regarded as an anatomically diverse **excretory system** whose components perform all the excretory functions that affect the composition of body fluids:

- Integumentary System. Water losses and electrolyte losses in sensible perspiration can affect the volume and composition of the plasma. The effects are most apparent when losses are extreme, such as during peak sweat production. Small amounts of metabolic wastes, including urea, also are eliminated in perspiration.
- Respiratory System. The lungs remove the carbon dioxide generated by cells. Small amounts of other compounds, such as acetone and water, evaporate into the alveoli and are eliminated when you exhale.

• *Digestive System.* The liver excretes small amounts of metabolic waste products in bile. You lose a variable amount of water in feces.

These excretory activities have an impact on the composition of body fluids. The respiratory system, for example, removes carbon dioxide from the body. Note that the excretory functions of these systems are not regulated as closely as are those of the kidneys. Under normal circumstances, the effects of integumentary and digestive excretory activities are minor compared with those of the urinary system.

Figure 26–21 summarizes the functional relationships between the urinary system and other systems. We explore many of these relationships further in Chapter 27 when we consider major aspects of fluid, pH, and electrolyte balance.

CHECKPOINT

- **23**. Identify the role the urinary system plays for all other body systems.
- 24. Name the body systems that make up the excretory system.
- See the blue Answers tab at the back of the book.

Related Clinical Terms

- **azotemia:** The condition characterized by excessive urea or other nitrogen-containing compounds in the blood.
- **cystocele:** Condition that occurs when the supportive tissue between a woman's bladder and vaginal wall weakens, stretches, and allows the bladder to bulge into the vagina.
- **cystoscopy:** Diagnostic procedure using an optical instrument called a cystoscope that is inserted through the urethra to visually examine the bladder and lower urinary tract, to collect urine samples, or to view the prostate gland.
- **enuresis:** Involuntary urination, especially that of a child while asleep. **nephroptosis:** Condition in which the kidney is displaced downward from its usual and normal position; also called a floating kidney.

- **nephrotic syndrome:** A kidney disorder that causes one to excrete excessive protein in the urine.
- **nephrotoxin:** A toxin that has a specific harmful effect on the kidney.
- **polycystic kidney disease:** An inherited abnormality that affects the development and structure of kidney tubules.
- **shock-wave lithotripsy:** A noninvasive technique used to pulverize kidney stones by passing high-pressure shock waves through a water-filled tub in which the patient sits.
- **urologist:** Physician who specializes in functions and disorders of the urinary system.

- 26-1 The kidneys, ureters, urinary bladder, and urethra make up the urinary system, which has three primary functions p. 973
 - 1. The three major functions of the **urinary system** are *excretion*, the removal of organic waste products from body fluids; *elimination*, the discharge of these waste products into the environment; and homeostatic regulation of the volume and solute concentration of blood plasma. Other homeostatic functions include regulating blood volume and pressure by adjusting the volume of water lost and releasing hormones; regulating plasma concentrations of ions; helping to stabilize

blood pH; conserving nutrients; assisting the liver in detoxifying poisons; and, during starvation, deaminating amino acids so that they can be catabolized by other tissues.

- 2. The urinary system includes the **kidneys**, the **ureters**, the **urinary bladder**, and the **urethra**. The kidneys produce **urine**, which is a fluid that contains water, ions, and soluble compounds. During **urination (micturition)**, urine is forced out of the body. (*Figure 26–1*)
- **26-2** Kidneys are highly vascular organs containing functional units called nephrons, which filter, reabsorb, and secrete p. 974
- **3.** The left kidney extends superiorly slightly more than the right kidney. Both kidneys and the adrenal gland that overlies each are retroperitoneal. (*Figures 26–1, 26–2, 26–3*)
- 4. The **hilum**, a medial indentation, provides entry for the *renal artery* and *renal nerves* and exit for the *renal vein* and the ureter. (*Figures* 26–3, 26–4)
- 5. The superficial portion of the kidney, the cortex, surrounds the **medulla**. The ureter communicates with the **renal pelvis**, a chamber that branches into two **major calyces**. Each major calyx is connected to four or five **minor calyces**, which enclose the **renal papillae**. (*Figure 26–4*)
- 6. The blood supply to the kidneys includes the **renal**, **segmental**, **interlobar**, **arcuate**, and **cortical radiate arteries**. (*Figure 26–5*)
- 7. The **renal nerves**, which innervate the kidneys and ureters, are dominated by sympathetic postganglionic fibers.
- The nephron is the basic functional unit in the kidney. It consists of the renal corpuscle and renal tubule. The renal tubule is long and narrow and divided into the *proximal convoluted tubule*, the *nephron loop*, and the *distal convoluted tubule*. Filtrate is produced at the renal corpuscle. The nephron empties tubular fluid into the collecting system, consisting of collecting ducts and papillary ducts. (*Figures 26–6, 26–7*)
- 9. Nephrons produce filtrate; reabsorb organic nutrients, water, and ions; and secrete into the tubular fluid various waste products. (*Table 26–1*)
- **10.** Roughly 85 percent of the nephrons are **cortical nephrons**, located in the renal cortex. **Juxtamedullary nephrons** are closer to the renal medulla, with their *nephron loops* extending deep into the **renal pyramids**. (*Figure 26–7*)
- 11. Blood travels from the efferent arteriole to the **peritubular capillaries** and the **vasa recta**. (*Figure 26–7*)
- 12. The renal tubule begins at the renal corpuscle, which includes a knot of intertwined capillaries called the **glomerulus**, surrounded by the **glomerular capsule**. Blood arrives at the glomerulus by the **afferent arteriole** and departs in the **efferent arteriole**. (*Figure 26–8*)
- At the glomerulus, podocytes cover the dense layer of the capillaries that project into the capsular space. The pedicels of the podocytes are separated by narrow filtration slits. Mesangial cells lie between adjacent capillaries and control capillary diameter. (*Figure 26–8*)
- 14. The **proximal convoluted tubule (PCT)** actively reabsorbs nutrients, plasma proteins, and ions from the filtrate. These substances are released into the **peritubular fluid**, which surrounds the nephron. (*Figure 26–6*)
- **15.** The **nephron loop**, also called the **loop of Henle**, includes a **descending limb** and an **ascending limb**. Each limb contains a **thick segment** and a **thin segment**. The ascending limb delivers fluid to the **distal convoluted tubule (DCT)**, which actively secretes ions, toxins, and drugs, and reabsorbs sodium ions from the tubular fluid. (*Figures 26–6, 26–7*)

26-3 Different segments of the nephron form urine by filtration, reabsorption, and secretion p. 983

- **16.** Urine production maintains homeostasis by regulating blood volume and composition. In the process, organic waste products—notably urea, creatinine, and uric acid—are excreted.
- **17.** Urine formation involves **filtration**, **reabsorption**, and **secretion**.
- 18. Four types of *carrier-mediated transport (facilitated diffusion, active transport, cotransport,* and *countertransport)* are involved in modifying filtrate. The saturation limit of a carrier protein is its **transport maximum**, which determines the **renal threshold**—the plasma concentration at which various compounds will appear in urine. (*Table 26–2*)
- **19.** The transport maximum determines the renal threshold for the reabsorption of substances in tubular fluid. (*Table 26–3*)
- **20.** Most regions of the nephron perform a combination of reabsorption and secretion. (*Figure 26–9; Table 26–4*)
- **26-4** Hydrostatic and colloid osmotic pressures influence glomerular filtration pressure, which in turn affects the glomerular filtration rate p. 987
- 21. **Glomerular filtration** occurs as fluids move across the wall of the glomerulus into the capsular space in response to the **glomerular hydrostatic pressure (GHP)**—the hydrostatic (blood) pressure in the glomerular capillaries. This movement is opposed by the **capsular hydrostatic pressure (CsHP)** and by the **blood colloid osmotic pressure (BCOP)**. The **net filtration pressure (NFP)** at the glomerulus is the difference between the blood pressure and the opposing capsular and osmotic pressures. (*Figure 26–10*)
- **22.** The **glomerular filtration rate (GFR)** is the amount of filtrate produced in the kidneys each minute. Any factor that alters the filtration pressure acting across the glomerular capillaries will change the GFR and affect kidney function.
- 23. A drop in filtration pressures stimulates the juxtaglomerular complex (JGC) to release renin and erythropoietin. (*Figure 26–11*)
- 24. Sympathetic activation (1) produces a powerful vasoconstriction of the afferent arterioles, decreasing the GFR and slowing the production of filtrate; (2) alters the GFR by changing the regional pattern of blood circulation; and (3) stimulates the release of renin by the juxtaglomerular complex. (*Figure 26–11*)

26-5 Countercurrent multiplication, antidiuretic hormone, and aldosterone affect reabsorption and secretion p. 992

- **25.** Glomerular filtration produces a filtrate with a composition similar to blood plasma, but with few, if any, plasma proteins.
- **26.** The cells of the PCT normally reabsorb sodium and other ions, water, and almost all the organic nutrients that enter the filtrate. These cells also secrete various substances into the tubular fluid. (*Figure 26–12*)
- 27. Water and ions are reclaimed from tubular fluid by the nephron loop. A concentration gradient in the renal medulla encourages the osmotic flow of water out of the tubular fluid. The **countercurrent multiplication** between the ascending and descending limbs of the nephron loop helps create the osmotic gradient in the medulla. As water is lost by osmosis and the volume of tubular fluid decreases, the urea concentration increases. (*Figure 26–13*)
- **28.** The DCT performs final adjustments by actively secreting or absorbing materials. Sodium ions are actively absorbed, in exchange for potassium or hydrogen ions discharged into

tubular fluid. Aldosterone secretion increases the rate of sodium reabsorption and potassium loss. (*Figure 26–14*)

- **29.** The amount of water and solutes in the tubular fluid of the collecting ducts is further regulated by aldosterone and ADH secretions. *(Figure 26–14)*
- **30.** Urine volume and osmotic concentration are regulated by controlling water reabsorption. Precise control over this occurs by *facultative water reabsorption*. (*Figure 26–15*)
- **31.** Normally, the removal of solutes and water by the vasa recta precisely balances the rates of reabsorption and osmosis in the renal medulla.
- **32.** More than 99 percent of the filtrate produced each day is reabsorbed before reaching the renal pelvis. *(Table 26–5)*
- **33.** *Urinalysis* is the chemical and physical analysis of a urine sample. *(Table 26–6)*
- 34. Each segment of the nephron and collecting system contributes to the production of concentrated urine. (*Spotlight Figure* 26–16; *Table* 26–4)
- **26-6** Urine is transported by the ureters, stored in the bladder, and eliminated through the urethra, aided by the micturition reflex p. 1004
- **35.** Urine production ends when tubular fluid enters the renal pelvis. The rest of the urinary system transports, stores, and eliminates urine. (*Figure 26–17*)
- **36.** The ureters extend from the renal pelvis to the urinary bladder. Peristaltic contractions by smooth muscles move the urine along the tract. (*Figures 26–18, 26–19*)
- **37.** The urinary bladder is stabilized by the **middle umbilical ligament** and the **lateral umbilical ligaments**. Internal features include the **trigone**, the **neck**, and the **internal**

urethral sphincter. The mucosal lining contains prominent **rugae** (folds). Contraction of the **detrusor muscle** compresses the urinary bladder and expels urine into the urethra. (*Figures* 26–18, 26–19)

- **38.** In both sexes, where the urethra passes through the *urogenital diaphragm*, a circular band of skeletal muscles forms the **external urethral sphincter**, which is under voluntary control. (*Figure* 26–18)
- **39.** Urination is coordinated by the **micturition reflex**, which is initiated by stretch receptors in the wall of the urinary bladder. Voluntary urination involves coupling this reflex with the voluntary relaxation of the external urethral sphincter, which allows the opening of the **internal urethral sphincter**. (*Figure 26–20*)

26-7 Age-related changes affect kidney function and the micturition reflex p. 1009

40. Aging is generally associated with increased kidney problems. Age-related changes in the urinary system include (1) declining numbers of functional nephrons, (2) reduced GFR, (3) reduced sensitivity to ADH, and (4) problems with the micturition reflex. (Urinary retention may develop in men whose prostate gland is enlarged.)

26-8 The urinary system is one of several body systems involved in waste excretion p. 1011

41. The urinary system is the major component of an anatomically diverse **excretory system** that includes the integumentary system, the respiratory system, and the digestive system. (*Figure 26–21*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

1. Identify the structures of the kidney in the following diagram.

See the blue Answers tab at the back of the book.

- The basic functional unit of the kidney is the (a) nephron, (b) renal corpuscle, (c) glomerulus, (d) nephron loop, (e) filtration unit.
- The process of urine formation involves all of the following, *except*
 (a) filtration of plasma, (b) reabsorption of water, (c) reabsorption of certain solutes, (d) secretion of wastes, (e) secretion of excess lipoprotein and glucose molecules.
- The glomerular filtration rate is regulated by all of the following, *except* (a) autoregulation, (b) sympathetic neural control, (c) cardiac output, (d) angiotensin II, (e) the hormone ADH.
- 5. The distal convoluted tubule is an important site for (a) active secretion of ions, (b) active secretion of acids and other materials, (c) selective reabsorption of sodium ions from the tubular fluid, (d) all of these.
- 6. Changing the diameters of the afferent and efferent arterioles to alter the GFR can be an example of ______ regulation. (a) hormonal, (b) autonomic, (c) autoregulation, (d) a, b, and c.
- 7. What is the primary function of the urinary system?
- 8. What organs make up the urinary system?
- 9. Trace the pathway of the protein-free filtrate from where it is produced in the renal corpuscle until it drains into the renal pelvis in the form of urine. (Use arrows to indicate the direction of flow.)
- **10.** Name the segments of the nephron distal to the renal corpuscle, and state the functions of each.
- 11. What is the function of the juxtaglomerular complex?
- **12.** Using arrows, trace a drop of blood from its entry into the renal artery until its exit by a renal vein.
- **13.** Name and define the three distinct processes involved in the production of urine.

- 14. What are the primary effects of angiotensin II on kidney function and regulation?
- **15.** Which structures of the urinary system are responsible for the transport, storage, and elimination of urine?

LEVEL 2 Reviewing Concepts

- 16. When the renal threshold for a substance exceeds its tubular maximum (a) more of the substance will be filtered, (b) more of the substance will be reabsorbed, (c) more of the substance will be secreted, (d) the amount of the substance that exceeds the tubular maximum will be found in the urine, (e) both a and d occur.
- 17. Sympathetic activation of nerve fibers in the nephron causes (a) the regulation of glomerular blood flow and pressure, (b) the stimulation of renin release from the juxtaglomerular complex, (c) the direct stimulation of water and Na* reabsorption, (d) all of these.
- 18. Sodium reabsorption in the DCT and in the cortical portion of the collecting system is accelerated by the secretion of (a) ADH, (b) renin, (c) aldosterone, (d) erythropoietin.
- 19. When ADH levels rise, (a) the amount of water reabsorbed increases, (b) the DCT becomes impermeable to water, (c) the amount of water reabsorbed decreases, (d) sodium ions are exchanged for potassium ions.
- 20. The control of blood pH by the kidneys during acidosis involves(a) the secretion of hydrogen ions and reabsorption of bicarbonate ions from the tubular fluid, (b) a decrease in the amount of water reabsorbed, (c) hydrogen ion reabsorption and bicarbonate ion loss, (d) potassium ion secretion.
- 21. How are proteins excluded from filtrate? Why is this important?
- 22. What interacting controls stabilize the glomerular filtration rate (GFR)?
- **23.** What primary changes occur in the composition and concentration of filtrate as a result of activity in the proximal convoluted tubule?

- 24. Describe two functions of countercurrent multiplication in the kidney.
- **25.** Describe the micturition reflex.

LEVEL 3 Critical Thinking and Clinical Applications

- 26. In a normal kidney, which of the following conditions would cause an increase in the glomerular filtration rate (GFR)? (a) constriction of the afferent arteriole, (b) a decrease in the pressure of the glomerulus, (c) an increase in the capsular hydrostatic pressure, (d) a decrease in the concentration of plasma proteins in the blood, (e) a decrease in the net glomerular filtration process.
- 27. In response to *excess* water in the body, (a) antidiuretic hormone is secreted by the anterior lobe of the pituitary gland, (b) the active transport mechanisms in the ascending limb of the nephron loop cease functioning, (c) the permeability of the distal convoluted tubules and collecting ducts to water is decreased, (d) the permeability of the ascending limb of the nephron loop is increased, (e) the glomerular filtration rate is reduced.
- **28.** Sylvia is suffering from severe edema in her arms and legs. Her physician prescribes a diuretic (a substance that increases the volume of urine produced). Why might this help alleviate Sylvia's problem?
- **29.** David's grandfather suffers from hypertension. His doctor tells him that part of his problem stems from renal arteriosclerosis. Why would this cause hypertension?
- **30.** *Mannitol* is a sugar that is filtered, but not reabsorbed, by the kidneys. What effect would drinking a solution of mannitol have on the volume of urine produced?
- **31.** The drug *Diamox* is sometimes used to treat mountain sickness. Diamox inhibits the action of carbonic anhydrase in the proximal convoluted tubule. Polyuria (the elimination of an unusually large volume of urine) is a side effect associated with the medication. Why does polyuria occur?

CLINICAL CASE

A Case of "Hidden" Bleeding

Normally, when a kidney is injured, the urine appears very bloody (hematuria). Mike has made very little urine since his injury and massive blood loss, but the urine in his

catheter is clear. This reduces the initial suspicion of a renal injury.

However, when the surgeon opens the left retroperitoneal space, he finds another large collection of free blood. When the surgeon clears this blood away, the source of Mike's continued bleeding becomes apparent. His left renal artery, renal vein, and ureter have been completely torn away from the kidney at the hilum. The renal artery is briskly pumping what circulatory blood volume is left into the retroperitoneal space, where it is walled off from the abdominal space by the parietal peritoneum. Because the left ureter is completely torn from the damaged kidney, there is no visible blood in the urine. This kidney is too damaged to heal. The surgeon quickly performs a left nephrectomy (kidney removal). If Mike survives this trauma, he will have to live

Wrap-Up

with a solitary kidney. With the bleeding stopped, including the "hidden" bleeding, the trauma team is finally able to sustain an adequate circulating blood volume.

- 1. How could you tell from Mike's x-rays that there is a high probability of renal injury?
- 2. What do you think will happen to the glomerular filtration rate (GFR) of Mike's remaining right kidney if he survives this trauma?

See the blue Answers tab at the back of the book.

Fluid, Electrolyte, and Acid–Base Balance

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **27-1** Explain what is meant by the terms fluid balance, electrolyte balance, and acid–base balance, and discuss their importance for homeostasis.
- **27-2** Compare the composition of intracellular and extracellular fluids, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation.
- **27-3** Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.
- **27-4** Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance.
- **27-5** Explain the buffering systems that balance the pH of the intracellular and extracellular fluids, and describe the compensatory mechanisms involved in maintaining acid–base balance.
- **27-6** Identify the most frequent disturbances of acid–base balance, and explain how the body responds when the pH of body fluids varies outside normal limits.
- **27-7** Describe the effects of aging on fluid, electrolyte, and acid–base balance.

SPOTLIGHT

• The Diagnosis of Acid–Base Disorders p. 1044

CLINICAL CASE

• When Treatment Makes You Worse p. 1016

Clinical Notes

- Water and Weight Loss p. 1023
- Athletes and Salt Loss p. 1027
CLINICAL CASE

When Treatment Makes You Worse

Marquis is a 43-year-old office worker who is slightly overweight. At his annual checkup, his blood pressure measures 150/96, which is considered moderately high. Marquis feels fine, but his doctor tells him it is time to treat his hypertension. Marquis's doctor advises him to improve his diet and get more exercise. He also prescribes a new medication, hydrochlorothiazide, or HCTZ, which he instructs him to take every morning. HCTZ is a diuretic that is commonly used to lower blood pressure.

Marquis begins taking HCTZ and continues to feel well, although he notices the medication makes him need to urinate more frequently. A few weeks later he and a group of coworkers eat some bad potato salad at the office picnic and come down with food poisoning. After three days of diarrhea, Marquis feels absolutely horrible. He is so weak he is barely able to get out of bed. His muscles ache and his legs and feet cramp a lot. Worst of all, he feels as if there is a frog jumping around in his chest. He is often dizzy when this happens.

After a week in bed, Marquis feels even weaker. He goes to see his doctor, who sends him to the lab for some tests. "I know why you feel so terrible," says his doctor when he sees the lab results. **What is happening to Marquis? To find out, turn to Clinical Case Wrap-Up on p. 1049.**

An Introduction to Fluid, Electrolyte, and Acid–Base Balance

The next time you see a small pond, think about the fish in it. They live their entire lives totally dependent on the quality of that isolated environment. Severe water pollution will kill them, but even subtle changes can have equally grave effects. Changes in the volume of the pond, for example, can be quite important. If evaporation removes too much water, the fish become overcrowded. The oxygen and food supplies will run out, and the fish will suffocate or starve. The ionic concentration of the water is also crucial. Most of the fish in a freshwater pond will die if the water becomes too salty. Fish in a saltwater pond will die if their environment becomes too dilute. The pH of the pond water, too, is a vital factor. This is another reason that acid rain is such a problem.

Your cells live in a pond whose shores are the exposed surfaces of your skin. Most of your body weight is water. Water makes up about 99 percent of the volume of the fluid outside cells, and it is also an essential ingredient of cytoplasm. All of a cell's operations rely on water as a diffusion medium for the distribution of gases, nutrients, and wastes. If the water content of the body changes, cellular activities are jeopardized. For example, when the water content reaches very low levels, proteins denature, enzymes cease functioning, and cells die. In this chapter we discuss the homeostatic mechanisms that regulate ion concentrations, volume, and pH in the fluid surrounding cells.

27-1 Fluid balance, electrolyte balance, and acid–base balance are interrelated and essential to homeostasis

Learning Outcome Explain what is meant by the terms fluid balance, electrolyte balance, and acid–base balance, and discuss their importance for homeostasis.

To survive, we must maintain a normal volume and composition of both the **extracellular fluid** or **ECF** (the interstitial fluid, plasma, and other body fluids) and the **intracellular fluid** or **ICF** (the cytosol). The ionic concentrations and pH (hydrogen ion concentration) of these fluids are as important as their absolute quantities. If concentrations of calcium or potassium ions in the ECF become too high, cardiac arrhythmias develop and death can result. A pH outside the normal range can also lead to a variety of serious problems. Low pH acidity—is especially dangerous, because hydrogen ions break chemical bonds, change the shapes of complex molecules, disrupt plasma membranes, and impair tissue functions.

TIPS&TRICKS

The "p" in pH refers to power. Hence, pH refers to the **p**ower of **H**ydrogen.

In this chapter, we will explore the dynamics of exchange among the various body fluids, and between the body and the external environment. Stabilizing the volumes, solute concentrations, and pH of the ECF and the ICF involves three interrelated processes:

- 1. *Fluid Balance*. You are in **fluid balance** when the amount of water you gain each day is equal to the amount you lose to the environment. The maintenance of normal fluid balance involves regulating the content and distribution of body water in the ECF and the ICF. The digestive system is the main source of water gains. Metabolic activity generates a small amount of additional water. The urinary system is the primary route for water loss under normal conditions, but as we saw in Chapter 25, sweating can become important when body temperature is elevated. ⊃ p. 965 Although cells and tissues cannot transport water, they can transport ions and create concentration gradients that are then eliminated by osmosis.
- Electrolyte Balance. Electrolytes are ions released when inorganic compounds dissociate. They are so named because they can conduct an electrical current in a solution.
 p. 41 Each day, your body fluids gain electrolytes from the food and drink you consume. Your body fluids also lose electrolytes in urine, sweat, and feces. For each ion, daily gains must balance daily losses. For example, if you lose 500 mg of Na⁺ in urine and sweat, you need to gain 500 mg of Na⁺ from food and drink to remain in sodium balance. If the gains and losses for every electrolyte are in balance, you are said to be in electrolyte balance. Electrolyte balance primarily involves balancing the rates of absorption across the digestive tract with rates of loss by the kidneys, although losses at sweat glands and other sites can play a secondary role.
- 3. Acid–Base Balance. You are in acid–base balance when the production of hydrogen ions in your body is precisely offset by their loss. When acid–base balance exists, the pH of body fluids remains within normal limits. ⊃ p. 41 Preventing a decrease in pH is the primary problem, because your body generates a variety of acids during normal metabolic operations. The kidneys play a major role by secreting hydrogen ions into the urine and generating buffers that enter the bloodstream. Such secretion takes place primarily in the distal segments of the distal convoluted tubule (DCT) and along the collecting system. ⊃ p. 996 The lungs also play a key role by eliminating carbon dioxide.

Much of the information in this chapter should be familiar to you from discussions in earlier chapters about aspects of fluid, electrolyte, or acid–base balance that affect specific systems. In this chapter we provide an overview that integrates those discussions to highlight important functional patterns.

This chapter has wide-ranging clinical importance: Steps to restore normal fluid, electrolyte, and acid-base balances must be part of the treatment of any serious illness affecting the nervous, cardiovascular, respiratory, urinary, or digestive system. Because this chapter builds on information in earlier chapters, we have included many references to relevant discussions and figures that can provide a quick review.

CHECKPOINT

- 1. Identify the three interrelated processes essential to stabilizing body fluid volumes.
- 2. List the components of extracellular fluid (ECF) and intracellular fluid (ICF).
- See the blue Answers tab at the back of the book.

27-2 The ECF and ICF make up the fluid compartments, which also contain cations and anions

Learning Outcome Compare the composition of intracellular and extracellular fluids, explain the basic concepts involved in the regulation of fluids and electrolytes, and identify the hormones that play important roles in fluid and electrolyte regulation.

Figure 27–1a presents an overview of the body makeup of a 70-kg (154-lb) person with a minimum of body fat. The distribution is based on overall average values for males and females ages 18–40 years. Water makes up about 60 percent of the total body weight of an adult male, and 50 percent of that of an adult female (**Figure 27–1b**). This difference between the sexes reflects the proportionately larger mass of adipose tissue in adult females, and the greater average muscle mass in adult males. (Adipose tissue is only 10 percent water, whereas skeletal muscle is 75 percent water.)

In both sexes, intracellular fluid contains a greater proportion of total body water than does extracellular fluid. Exchange between the ICF and the ECF takes place across plasma membranes by osmosis, diffusion, and carrier-mediated transport. (To review the mechanisms involved, see **Spotlight Figure 3–22**, p. 98.)

The ECF and the ICF

The largest subdivisions of the ECF are the interstitial fluid of peripheral tissues and the plasma of circulating blood (Figure 27–1a). Minor components of the ECF include lymph, cerebrospinal fluid (CSF), synovial fluid, serous fluids (pleural, pericardial, and peritoneal fluids), aqueous humor, perilymph, and endolymph. More precise measurements of total body water provide additional information on differences between the sexes in the distribution of body water (Figure 27–1b). The greatest variation is in the ICF, as a result of differences in the intracellular water content of fat versus muscle. Less striking differences occur in the ECF values, due to variations in the interstitial fluid volume of various tissues and the larger blood volume in males versus females.

a The body composition (by weight, averaged for both sexes) and major body fluid compartments of a 70-kg (154-lb) person. For technical reasons, it is extremely difficult to determine the precise size of any of these compartments; estimates of their relative sizes vary widely.

b A comparison of the body compositions of adult males and females, ages 18–40 years.

In clinical situations, it is customary to estimate that twothirds of the total body water is in the ICF and one-third in the ECF. This ratio underestimates the real volume of the ECF, but that underestimation is appropriate because portions of the ECF—including the water in bone, in many dense connective tissues, and in many of the minor ECF components—are relatively isolated. Exchange between these fluid volumes and the rest of the ECF takes place more slowly than does exchange between plasma and other interstitial fluids. For this reason, they can be safely ignored in many cases. Clinical attention usually focuses on the rapid fluid and solute movements that accompany the administration of blood, plasma, or saline solutions to counteract blood loss or dehydration. Exchange among the subdivisions of the ECF occurs primarily across the endothelial lining of capillaries. Fluid may also travel from the interstitial spaces to plasma through lymphatic vessels that drain into the venous system. \bigcirc p. 784 The kinds and quantities of dissolved electrolytes, proteins, nutrients, and wastes in the ECF vary regionally. (For a chemical analysis of the composition of ECF compartments, see the Appendix.) Still, the variations among the compartments of the ECF seem minor compared with the major differences between the ECF and the ICF.

The ECF and ICF are called **fluid compartments**, because they commonly behave as separate sections. The presence of a plasma membrane and active transport at the membrane surface

Figure 27–2 Cations and Anions in Body Fluids. Notice the differences in cation and anion concentrations in the various body fluid compartments.

enable cells to maintain internal environments with a composition that differs from their surroundings. The principal ions in the ECF are sodium, chloride, and bicarbonate (HCO_3^-). The ICF contains an abundance of potassium, magnesium, and phosphate ions (HPO_4^{2-}), plus large amounts of negatively charged proteins. **Figure 27–2** compares the ICF with the two major subdivisions of the ECF (plasma and interstitial fluid).

If the plasma membrane were freely permeable, diffusion would continue until these ions were evenly distributed across the membrane. But it does not, because plasma membranes are selectively permeable: Ions can enter or leave the cell only by specific membrane channels. Also, carrier mechanisms move specific ions into or out of the cell.

Despite the differences in the concentration of specific substances, the osmotic concentrations of the ICF and ECF are identical. Osmosis eliminates minor differences in concentration almost at once, because most plasma membranes are freely permeable to water. (The only noteworthy exceptions are the apical surfaces of epithelial cells along the ascending limb of the nephron loop, the distal convoluted tubule, and the collecting system.) The regulation of fluid balance and electrolyte balance are tightly intertwined because changes in solute concentrations lead to immediate changes in water distribution. Physiologists and clinicians pay particular attention to ionic distributions across membranes and to the electrolyte composition of body fluids. The Appendix at the end of the book reports normal values in the units most often used in clinical reports.

Basic Concepts in the Regulation of Fluids and Electrolytes

Four basic principles are key to understanding fluid balance and electrolyte balance:

1. All the homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF, not in the ICF. Receptors monitoring the composition of two key components of the ECF—plasma and cerebrospinal fluid—detect significant changes in their composition or volume and trigger appropriate neural and endocrine responses. This arrangement makes functional sense, because a change in one ECF component will spread rapidly throughout the extracellular compartment and affect all the body's cells. In contrast, the ICF is contained within trillions of individual cells that are physically and chemically isolated from one another by their plasma membranes. For

this reason, changes in the ICF in one cell have no direct effect on the composition of the ICF in distant cells and tissues, unless those changes also affect the ECF.

- 2. No receptors directly monitor fluid or electrolyte balance. In other words, receptors cannot detect how many liters of water or grams of sodium, chloride, or potassium the body contains. Nor can they count how many liters or grams we gain or lose throughout the day. But receptors *can* monitor *plasma volume* and *osmotic concentration*. The plasma volume and osmotic concentration are good indicators of the state of fluid balance and electrolyte balance for the body as a whole, because fluid continuously circulates between interstitial fluid and plasma, and because exchange occurs between the ECF and the ICF.
- 3. Cells cannot move water molecules by active transport. All movement of water across plasma membranes and epithelia takes place passively, in response to osmotic gradients established by the active transport of specific ions, such as sodium and chloride. You may find it useful to remember, *"water follows salt."* As we saw in earlier chapters, when sodium and chloride ions (or other solutes) are actively transported across a membrane or epithelium, water follows by osmosis. ⊃ p. 994 This basic principle accounts for water absorption across the digestive epithelium, and for water conservation by the kidneys.
- 4. The body's content of water or electrolytes will increase if dietary gains exceed losses to the environment, and will decrease if losses exceed gains. This basic rule is important when you consider the mechanics of fluid balance and electrolyte balance. Homeostatic adjustments affect the balance between urinary excretion and dietary absorption. As we saw in Chapter 26, circulating hormones regulate renal function. These hormones can also produce complementary changes in behavior. For example, the combination of angiotensin II and aldosterone can give you a sensation of thirst—which stimulates you to drink fluids—and a taste for heavily salted foods.

An Overview of the Primary Regulatory Hormones

Three hormones mediate physiological adjustments to fluid balance and electrolyte balance. They are (1) *antidiuretic hormone (ADH)*, (2) *aldosterone*, and (3) the *natriuretic peptides (ANP and BNP)*. We introduced and discussed these hormones in earlier chapters. We summarize their effects next. For a more detailed review, refer to the appropriate sections of Chapters 18, 21, and 26. The interactions among these hormones are illustrated in **Figures 18–19b, 21–15, 21–16,** and **26–11** (pp. 641, 748, 751, 991).

Antidiuretic Hormone

The hypothalamus contains special cells known as **osmore-ceptors**, which monitor the osmotic concentration of the ECF. These cells are sensitive to subtle changes: A 2 percent change in osmotic concentration (approximately 6 mOsm/L) is enough to alter osmoreceptor activity.

The population of osmoreceptors includes neurons that secrete ADH. These neurons are located in the anterior hypothalamus. Their axons release ADH near fenestrated capillaries in the posterior lobe of the pituitary gland. The rate of ADH release varies directly with osmotic concentration: The higher the osmotic concentration, the more ADH is released.

Increased release of ADH has two important effects: (1) It stimulates water conservation by the kidneys, reducing urinary water losses and concentrating the urine; and (2) it stimulates the hypothalamic thirst center, promoting the intake of fluids. As we saw in Chapter 21, the combination of decreased water loss and increased water gain gradually restores the normal plasma osmotic concentration. \bigcirc pp. 746–748

Aldosterone

The secretion of aldosterone by the adrenal cortex plays a major role in determining the rate of Na⁺ absorption and K⁺ loss along the distal convoluted tubule (DCT) and collecting system of the kidneys. \bigcirc p. 996 The higher the plasma concentration of aldosterone, the more efficiently the kidneys conserve Na⁺. Because "water follows salt," the conservation of Na⁺ also increases water retention. As Na⁺ is reabsorbed, Cl⁻ follows (see **Figure 26–14a**, p. 998), and water follows by osmosis as sodium and chloride ions move out of the tubular fluid. Aldosterone also increases the sensitivity of salt receptors on the tongue. This effect may increase your consumption of salty foods.

Aldosterone is secreted in response to increasing K^+ or decreasing Na⁺ levels in the blood reaching the adrenal cortex, or in response to the activation of the renin–angiotensin-aldosterone system. As we saw in earlier chapters, renin release occurs in response to any of three changes. They are (1) a decrease in plasma volume or blood pressure at the juxtaglomerular complex of the nephron; (2) a decrease in the osmotic concentration of tubular fluid at the DCT; or, as we will soon see, (3) decreasing Na⁺ or increasing K⁺ concentrations in the renal circulation.

Natriuretic Peptides

The natriuretic (*natrium*, sodium; *-uretic*, urine) peptides, atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP), are released by cardiac muscle cells in response to abnormal stretching of the heart walls. Increased blood pressure or increased blood volume causes this stretching. Among their other effects, these peptides reduce thirst and block the release of ADH and aldosterone that might otherwise lead to water and

salt conservation. The resulting diuresis (fluid loss by the kidneys) decreases both blood pressure and plasma volume, eliminating the stretching.

The Interplay between Fluid Balance and Electrolyte Balance

At first glance, it can be very difficult to distinguish between water balance and electrolyte balance. For example, when you lose body water, plasma volume decreases and electrolyte concentrations increase. Conversely, when you gain or lose excess electrolytes, you also gain or lose water due to osmosis.

However, it is often useful to consider fluid balance and electrolyte balance separately because the regulatory mechanisms involved are quite different. This distinction is absolutely vital in a clinical setting, where problems with fluid balance and electrolyte balance must be identified and corrected promptly.

CHECKPOINT

- Name three hormones that play a major role in adjusting fluid and electrolyte balance in the body.
- 4. What effect would drinking a half-gallon of distilled water have on ADH levels?

See the blue Answers tab at the back of the book.

27-3 Hydrostatic and osmotic pressures regulate the movement of water and electrolytes to maintain fluid balance

Learning Outcome Describe the movement of fluid within the ECF, between the ECF and the ICF, and between the ECF and the environment.

Water circulates freely within the ECF compartment. At capillary beds throughout the body, hydrostatic pressure forces water out of plasma and into interstitial spaces. Some of that water is then reabsorbed along the distal portion of the capillary bed, and the rest enters lymphatic vessels for transport to the venous circulation. Fluid also moves continuously among the minor components of the ECF:

- Water moves back and forth across the mesothelial surfaces that line the peritoneal, pleural, and pericardial cavities, and through the synovial membranes that line joint capsules. The flow rate is significant. For example, about 7 liters (1.8 gal) of peritoneal fluid are produced and reabsorbed each day. However, the actual volume present at any time in the peritoneal cavity is very small—less than 35 mL (1.2 oz).
- 2. Water also moves between blood and cerebrospinal fluid (CSF), between the aqueous humor and vitreous humor of

the eye, and between the perilymph and endolymph of the internal ear. The volumes involved in these water movements are very small, and the volume and composition of the fluids are closely regulated. For those reasons, we will largely ignore them in the discussion that follows.

Water movement can also take place between the ECF and the ICF, but under normal circumstances the two are in osmotic equilibrium. For this reason, no large-scale circulation occurs between the two compartments. (A small amount of water moves from the ICF to the ECF each day, as the result of mitochondrial water generation. We will consider this topic in a separate section.)

We cannot easily determine the body's water content. However, the concentration of Na^+ , the most abundant ion in the ECF, provides useful clues to the state of water balance. When the body's water content increases, the Na^+ concentration of the ECF becomes abnormally low. And when the body's water content decreases, the Na^+ concentration becomes abnormally high.

Fluid Movement within the ECF

In our discussion of capillary dynamics in Chapter 21, we considered the basic principles that determine fluid movement among the divisions of the ECF. \supset p. 739 Recall that the exchange between plasma and interstitial fluid, by far the largest components of the ECF, is due to the relationship between the net hydrostatic pressure, which tends to push water out of the plasma and into the interstitial fluid, and the net colloid osmotic pressure, which tends to draw water out of the interstitial fluid and into the plasma. The interaction between these opposing forces is diagrammed in Figure 21-11 (p. 740). It results in the continuous filtration of fluid from the capillaries into the interstitial fluid. This volume of fluid is then redistributed: After passing through the channels of the lymphatic system, the fluid returns to the venous system. At any moment, interstitial fluid and minor fluid compartments contain approximately 80 percent of the ECF volume, and plasma contains the other 20 percent.

Any factor that affects the net hydrostatic pressure or the net colloid osmotic pressure will alter the distribution of fluid within the ECF. The movement of abnormal amounts of water from plasma into interstitial fluid is called *edema*. Pulmonary edema, for example, can result from an increase in the blood pressure in pulmonary capillaries. Generalized edema can result from a decrease in blood colloid osmotic pressure, as in advanced starvation, when plasma protein concentrations decrease. Localized edema can result from damage to capillary walls (as in bruising), the constriction of regional venous circulation, or a blockage of the lymphatic drainage (as in *lymphedema*, introduced in Chapter 22). \supset p. 786

TIPS&TRICKS

Water movement between compartments, driven by osmotic pressure, is like water movements between compartments in a waterbed mattress: The total amount of fluid doesn't change. Fluid merely moves from one compartment to another, driven by pressure differences.

Fluid Gains and Losses

Figure 27–3 and **Table 27–1** indicate the major factors involved in fluid balance and highlight the routes of fluid exchange with the environment:

- Water Losses. You lose about 2500 mL of water each day through urine, feces, and *insensible perspiration*—the gradual movement of water across the epithelia of the skin and lungs. The losses due to *sensible perspiration*—the secretory activities of the sweat glands—vary with physical activity. Sensible perspiration can cause significant water deficits, with maximum perspiration rates reaching 4 liters per hour. ¹⊃ p. 964 Fever can also increase water losses. For each degree that body temperature rises above normal, daily insensible water losses increase by 200 mL. The advice "Drink plenty of fluids" for anyone who is sick has a definite physiological basis.
- Water Gains. A water gain of about 2500 mL/day is required to balance your average water losses. This value amounts to about 40 mL/kg of body weight per day. You obtain water through eating (1000 mL), drinking (1200 mL), and metabolic generation (300 mL).

Metabolic generation of water is the production of water within cells, primarily as a result of oxidative phosphorylation

Table 27–1	Water Balance			
Source		Daily Input (mL)

Method of Elimin Urination Evaporation at ski Evaporation at lur	ation in ngs	Daily Output (mL) 1200 750 400		
Method of Elimin Urination Evaporation at ski Evaporation at lur Loss in feces	ation in ngs	Daily Output (mL) 1200 750 400 150		

in mitochondria. (In Chapter 25 we described the synthesis of water at the end of the electron transport system. \bigcirc p. 943) When cells break down 1 g of lipid, 1.7 mL of water is generated. Breaking down proteins or carbohydrates yields much lower amounts (0.41 mL/g and 0.55 mL/g, respectively).

A typical diet in the United States contains 46 percent carbohydrates, 40 percent lipids, and 14 percent protein. Such a diet produces approximately 300 mL of water per day, about 12 percent of your average daily requirement.

Fluid Shifts

A rapid water movement between the ECF and the ICF in response to an osmotic gradient is called a **fluid shift**. Fluid shifts occur quickly in response to changes in the osmotic concentration of the ECF and reach equilibrium within minutes to hours (Figure 27–4).

Figure 27–3 Fluid Gains and Losses. Fluid movements that maintain fluid balance in a normal person. The volumes are drawn to scale; the ICF is about twice as large as the ECF.

Figure 27–4 Fluid Shifts between the ICF and ECF.

- If the osmotic concentration of the ECF increases, that fluid will become hypertonic with respect to the ICF. Water will then move from the cells into the ECF until osmotic equilibrium is restored. The osmotic concentration of the ECF will increase if you lose water but retain electrolytes.
- If the osmotic concentration of the ECF decreases, that fluid will become hypotonic with respect to the ICF. Water will then move from the ECF into the cells, and the ICF volume will increase. The osmotic concentration of the ECF will decrease if you gain water but do not gain electrolytes.

To summarize, if the osmotic concentration of the ECF changes, a fluid shift between the ICF and ECF will tend to oppose the change. The ICF acts as a water reserve, because the volume of the ICF is much greater than that of the ECF. In effect, instead of a large change in the osmotic concentration of the ECF, smaller changes occur in both the ECF and ICF.

Dehydration and drinking a glass of tap water are two examples that demonstrate the dynamic exchange of water between the ECF and ICF, as we will now see.

Allocation of Water Losses

Dehydration, or *water depletion*, develops when water losses outpace water gains. When you lose water but retain electrolytes, the osmotic concentration of the ECF increases. Osmosis then moves water out of the ICF and into the ECF until the two solutions are again isotonic. At that point, both the ECF and ICF are somewhat more concentrated than normal, and both volumes are lower than they were before the fluid loss. Because the ICF has about twice the functional volume of the ECF, the net change in the ICF is small. However, if the fluid imbalance continues unchecked, the loss of body water will produce severe thirst, dryness, and wrinkling of the skin. Eventually a significant decrease in plasma volume and blood pressure occurs, and shock may develop.

Conditions that cause severe water losses include excessive perspiration (as when you exercise in hot weather), inadequate water consumption, repeated vomiting, and diarrhea. These conditions promote water losses far in excess of electrolyte losses, so

🌛 Clinical Note

Water and Weight Loss The safest way to lose weight is to reduce your intake of food while ensuring that all nutrient requirements are met. Water must be included on the list of nutrients, along with carbohydrates, fats, proteins, vitamins, and minerals. Nearly half of our normal water intake comes from food. For this reason, when you eat less, you become more dependent on drinking fluids and on whatever water is generated metabolically.

At the start of a diet, your body conserves water and catabolizes lipids. That is why the first week of dieting may seem rather unproductive. Over that week, the level of circulating ketone bodies gradually increases. In the weeks that follow, the rate of water loss by the kidneys increases in order to excrete wastes, such as the hydrogen ions released by ketone bodies and the urea and ammonia generated during protein catabolism. Your rate of fluid intake must also increase, or else you risk dehydration. While you are dieting, dehydration is especially serious, because as water is lost, the concentration of solute in the extracellular fluid (ECF) climbs, further increasing the concentration of wastes and acids generated during the catabolism of energy reserves. This soon becomes a positive feedback loop: These wastes enter the filtrate at the kidneys, and their excretion accelerates urinary water losses.

body fluids become increasingly concentrated, and sodium ion concentrations become abnormally high (a condition called *hypernatremia*).

Homeostatic responses include physiologic mechanisms (ADH and renin secretion) and behavioral changes (increasing fluid intake, preferably as soon as possible). Clinical therapies for acute dehydration include administering hypotonic fluids by mouth or intravenous infusion. These procedures rapidly increase ECF volume and promote the shift of water back into the ICF.

Distribution of Water Gains

When you drink a glass of tap water or when you are given hypotonic solutions intravenously, your body's water content increases without a corresponding increase in the concentration of electrolytes. As a result, the ECF increases in volume but becomes hypotonic with respect to the ICF. A fluid shift then occurs, and the volume of the ICF increases at the expense of the ECF. Once again, the larger volume of the ICF limits the amount of osmotic change. After the fluid shift, the ECF and ICF have slightly larger volumes and slightly lower osmotic concentrations than they did originally.

Normally, this situation will be promptly corrected. The decreased plasma osmotic concentration depresses the secretion of ADH, discouraging fluid intake and increasing water losses in urine. If the situation is *not* corrected, a variety of clinical problems will develop as water shifts into the intracellular fluid, distorting cells, changing the solute concentrations around enzymes, and disrupting normal cell functions. This condition is called **hyperhydration**, or *water excess*. It can be caused by (1) drinking a large volume of water or the infusion (injection into the bloodstream) of a hypotonic solution; (2) an inability to eliminate excess water in urine, due to chronic renal failure, heart failure, cirrhosis, or some other disorder; and (3) endocrine disorders, such as excessive ADH production.

The most obvious sign of overhydration is abnormally low sodium ion concentrations *(hyponatremia)*. This reduction in Na⁺ concentrations in the ECF leads to a fluid shift into the ICF. The first signs are the effects on central nervous system function. The individual initially acts drunk. This condition, called *water intoxication*, may sound odd, but is extremely dangerous. Untreated cases can rapidly progress from confusion to hallucinations, convulsions, coma, and then death. To demonstrate the seriousness of this condition, in 2007 a 28-year-old woman died of water intoxication after entering a water-drinking contest, "Hold Your Wee for a Wii," sponsored by a Sacramento, California, radio station. Treatment of severe overhydration generally involves administering diuretics and infusing a concentrated salt solution that promotes a fluid shift from the ICF to the ECF and returns Na⁺ concentrations to near-normal levels.

CHECKPOINT

- **5**. Define edema.
- 6. Describe a fluid shift.
- 7. Define dehydration.

- See the blue Answers tab at the back of the book.

27-4 Sodium, potassium, calcium, magnesium, phosphate, and chloride balance is essential for maintaining homeostasis

Learning Outcome Discuss the mechanisms by which sodium, potassium, calcium, magnesium, phosphate, and chloride ion concentrations are regulated to maintain electrolyte balance.

You are in electrolyte balance when gains and losses are equal for each electrolyte in your body. Electrolyte balance is important because:

- Total electrolyte concentrations directly affect water balance, as previously described, and
- The concentrations of individual electrolytes can affect cell functions. We saw many examples in earlier chapters, including the effect of abnormal Na⁺ concentrations on neuron activity and the effects of high or low Ca²⁺ and K⁺ concentrations on cardiac muscle tissue.

Two cations, Na^+ and K^+ , merit particular attention because (1) they are major contributors to the osmotic concentrations of the ECF and the ICF, respectively, and (2) they directly affect the normal functioning of all cells. Sodium is the main cation in the ECF. More than 90 percent of the osmotic concentration of the ECF results from sodium salts, mainly sodium chloride (NaCl) and sodium bicarbonate (NaHCO₃). Changes in the osmotic concentration of body fluids generally reflect changes in Na⁺ concentration.

Electrolytes in body fluids are measured in terms of *equivalents (Eq)*. An **equivalent (Eq)** is the amount of a positive or negative ion that supplies one mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq). For example, 1 mole of potassium ions (K⁺) and 1 mole of chloride ions (Cl⁻) are each 1 Eq (1000 mEq), but 1 mole of Ca²⁺ is 2 Eq (2000 mEq) because the calcium ion has a charge of +2. \bigcirc **p**. 986

Normal Na⁺ concentrations in the ECF average about 140 mEq/L, versus 10 mEq/L or less in the ICF. Potassium is the main cation in the ICF, where concentrations reach 160 mEq/L. Extracellular K⁺ concentrations are generally very low, from 3.5 to 5.5 mEq/L (Figure 27–2).

Two general rules concerning sodium balance and potassium balance are worth noting:

- **1.** The most common problems with electrolyte balance are caused by an imbalance between gains and losses of sodium ions.
- **2.** Problems with potassium balance are less common but significantly more dangerous than problems related to sodium balance.

Sodium Balance

The total amount of sodium in the ECF represents a balance between two factors:

- 1. *Sodium Ion Uptake across the Digestive Epithelium.* Sodium ions enter the ECF by crossing the digestive epithelium through diffusion and carrier-mediated transport. The rate of absorption varies directly with the amount of sodium in the diet.
- Sodium Ion Excretion by the Kidneys and Other Sites. Sodium losses take place primarily by excretion in urine and through perspiration. The kidneys are the most important sites of Na⁺ regulation. We discussed the mechanisms for sodium reabsorption by the kidneys in Chapter 26.
 ⊃ pp. 992, 996

A person in sodium balance typically gains and loses 48-144 mEq (1.1-3.3 g) of Na⁺ each day. When sodium gains exceed sodium losses, the total Na⁺ content of the ECF increases. When losses exceed gains, the Na⁺ content decreases. However, a change in the Na⁺ content of the ECF does not produce a change in the Na⁺ concentration. When sodium intake or output changes, a corresponding gain or loss of water tends to keep the Na^+ concentration constant. For example, if you eat a very salty meal, the osmotic concentration of the ECF will not increase. When sodium ions are pumped across the digestive epithelium, the solute concentration in that portion of the ECF increases, and that of the intestinal contents decreases. Osmosis then occurs. Additional water enters the ECF from the digestive tract, increasing the blood volume and blood pressure. For this reason, people with high blood pressure or a renal salt sensitivity are advised to restrict the amount of salt in their diets.

Sodium Balance and ECF Volume

The sodium regulatory mechanism is diagrammed in Figure 27–5. It changes the ECF volume but keeps the Na⁺ concentration fairly stable. If you consume large amounts of salt *without* adequate fluid, as when you eat salty potato chips without taking a drink, the plasma Na⁺ concentration increases temporarily. A change in ECF volume soon follows, however. Fluid will exit the ICF, increasing ECF volume and decreasing Na⁺ concentrations somewhat. The secretion of ADH restricts water loss and stimulates thirst, promoting additional water consumption. Due to the inhibition of water receptors in the pharynx, ADH secretion begins even before Na⁺ absorption

Figure 27–5 The Homeostatic Regulation of Normal Sodium Ion Concentration in Body Fluids.

occurs. The ADH secretion rate increases more after Na⁺ absorption, due to osmoreceptor stimulation. \bigcirc pp. 569, 623

When sodium losses exceed gains, the volume of the ECF decreases. This reduction occurs without a significant change in the osmotic concentration of the ECF. Thus, if you perspire heavily but consume only tap water, you will lose sodium, and the osmotic concentration of the ECF will decrease briefly. However, as soon as the osmotic concentration drops by 2 percent or more, ADH secretion decreases, so water losses by your kidneys increase. As water leaves the ECF, the osmotic concentration returns to normal.

Minor changes in ECF volume do not matter, because they do not cause adverse physiological effects. If, however, regulation of Na⁺ concentrations results in a large change in ECF volume, the situation will be corrected by the same homeostatic mechanisms responsible for regulating blood volume and blood pressure. This is the case because when ECF volume changes, so does plasma volume and, in turn, blood volume. If ECF volume increases, blood volume increases, and if ECF volume decreases, blood volume decreases. As we saw in Chapter 21, blood volume has a direct effect on blood pressure. An increase in blood volume decreases blood pressure, and a decrease in blood volume decreases blood pressure.

The net result is that homeostatic mechanisms can monitor ECF volume indirectly by monitoring blood pressure. The receptors involved are baroreceptors at the carotid sinus, the aortic sinus, and the right atrium. The regulatory steps involved are reviewed in Figure 27–6.

Sustained abnormalities in the Na⁺ concentration in the ECF occur only when there are severe problems with fluid balance, such as dehydration or overhydration. When the body's water content increases enough to decrease the Na⁺ concentration of the ECF below 135 mEq/L, a state of **hyponatremia** (*natrium*, sodium) exists. When body water content decreases, the Na⁺ concentration increases. When that concentration exceeds 145 mEq/L, **hypernatremia** exists.

If the ECF volume is inadequate, both blood volume and blood pressure decrease, and the renin–angiotensin-aldosterone system is activated. In response, losses of water and Na⁺ are decreased, and gains of water and Na⁺ are increased. The net result is that ECF volume increases. Although the total amount of Na⁺ in the ECF is increasing (gains exceed losses), the Na⁺ concentration in the ECF remains unchanged, because osmotic water movement accompanies Na⁺ absorption.

If the plasma volume becomes abnormally large, venous return increases, stretching the atrial and ventricular walls and stimulating the release of natriuretic peptides (ANP and BNP). This in turn decreases thirst and blocks the secretion of ADH and aldosterone, which together promote water or salt conservation. As a result, salt and water loss by the kidneys increases and the volume of the ECF decreases.

Potassium Balance

About 98 percent of the body's potassium is in the ICF. Cells expend energy to recover potassium ions as they diffuse across their plasma membranes and into the ECF. The K⁺ concentration outside the cell is relatively low, and the concentration in the ECF at any moment represents a balance between (1) the rate of gain across the digestive epithelium and (2) the rate of loss into urine. Potassium loss in urine is regulated by controlling the activities of ion pumps along the distal portions of the nephron and collecting system. Whenever a sodium ion is reabsorbed from the tubular fluid, it generally is exchanged for a cation (typically K⁺) from the peritubular fluid. \supset p. 998

Urinary K^+ losses are usually limited to the amount gained by absorption across the digestive epithelium, typically 50–150 mEq (1.9–5.8 g) per day. (Potassium losses in feces and perspiration are negligible.) The K^+ concentration in the ECF is controlled by adjustments in the rate of active secretion along the distal convoluted tubule and collecting system of the nephron.

The rate of tubular secretion of K⁺ into urine varies in response to three factors:

- 1. *Changes in the* K⁺ *Concentration of the ECF.* In general, the higher the extracellular concentration of potassium, the higher the rate of secretion.
- 2. Changes in pH. When the pH of the ECF decreases, so does the pH of peritubular fluid. The rate of potassium secretion then decreases, because hydrogen ions, rather than potassium ions, are secreted in exchange for sodium ions in tubular fluid. The mechanisms for H⁺ secretion were summarized in Figure 26–14c (p. 999).
- **3.** *Aldosterone Levels.* The hormone aldosterone strongly affects the rate at which K⁺ is lost in urine. The ion pumps that are sensitive to this hormone reabsorb Na⁺ from tubular fluid in exchange for K⁺ from peritubular fluid. Aldosterone secretion is stimulated by angiotensin II as part of the regulation of blood volume. High plasma K⁺ concentrations also stimulate aldosterone secretion directly. Either way, under the influence of aldosterone the amount of sodium conserved and the amount of potassium excreted in urine are directly related.

Clinical Note

Athletes and Salt Loss Unfounded notions and rumors about water and salt requirements during exercise are common. Sweat is a hypotonic solution that contains Na⁺ in lower concentration than the ECF. As a result, a person who is sweating profusely loses more water than salt. This loss leads to an increase in the Na⁺ concentration of the ECF. The water content of the ECF decreases as the water loss occurs, so blood volume decreases. Clinically, this condition is often called *volume depletion*. Because volume depletion takes place at the same time that blood is being shunted away from the kidneys, kidney function is impaired. As a result, wastes accumulate in the blood.

To prevent volume depletion, exercising athletes should drink liquids at regular intervals. The primary problem in volume depletion is water loss. Research has revealed no basis for the rumor that cramps will result if you drink while exercising. Salt pills and the various sports beverages that claim "faster absorption" and "better electrolyte balance" have no apparent benefits. Body reserves of electrolytes are sufficient to tolerate extended periods of strenuous activity. Problems with Na⁺ balance are extremely unlikely, except during marathons or other activities that involve maximal exertion for more than six hours. However, both volume depletion (causing acute renal failure) and water intoxication (causing fatal hyponatremia) have occurred in marathon runners.

Some sports beverages contain sugars and vitamins as well as electrolytes. During endurance events (marathons, ultramarathons, and distance cycling), solutions containing less than 10 g/dL of glucose may improve performance if consumed late in the event, when metabolic reserves are exhausted. However, high sugar concentrations (above 10 g/dL) can cause cramps, diarrhea, and other problems. The benefit of "glucose polymers" (often cornstarch) in sports drinks has yet to be proved. Drinking beverages "fortified" with vitamins is actively discouraged: Vitamins are not lost during exercise, and the consumption of these beverages in large volumes could, over time, cause hypervitaminosis.

Two disorders of potassium imbalance are hypokalemia and hyperkalemia. **Hypokalemia** (*hypo-*, below + *kalium*, potassium) is a deficiency of potassium in the bloodstream. **Hyperkalemia** (*hyper-*, above) is an elevated level of potassium in the bloodstream (Figure 27–7).

TIPS&TRICKS

The chemical symbols for sodium (Na) and potassium (K) are derived from their Latin names, **Na**trium and **K**alium.

Figure 27–7 Major Factors Involved in Disturbances of Potassium Balance.

When the blood concentration of potassium falls below 2 mEq/L, extensive muscular weakness develops, followed by eventual paralysis. Severe hypokalemia is potentially lethal due to its effects on the heart.

Factors Promoting Hypokalemia

Several diuretics, including *Lasix*, can produce hypokalemia by increasing the volume of urine produced. The endocrine disorder called aldosteronism, characterized by excessive aldosterone secretion, results in hypokalemia by overstimulating sodium retention and potassium loss. Normal potassium levels in blood: (3.5–5.0 mEq/L) High K⁺ concentrations in the blood produce an equally dangerous condition known as hyperkalemia. Severe hyperkalemia occurs when the K⁺ concentration exceeds 7 mEq/L, which results in cardiac arrhythmias.

Factors Promoting Hyperkalemia

Kidney failure Chronically low Several drugs promote due to damage blood pH diuresis by blocking Na⁺ promotes or disease will reabsorption by the kidneys. hyperkalemia by prevent normal When sodium reabsorption interfering with K⁺ secretion and slows down, so does K⁺ excretion by thereby produce potassium secretion, and the kidneys. hyperkalemia. hyperkalemia can result.

Balance of Other Electrolytes

The ECF concentrations of other electrolytes are regulated as well. Here we will consider the most important ions involved: calcium, magnesium, phosphate, and chloride. Additional information about sodium, potassium, and these other ions is listed in Table 27–2, along with information about disorders that occur if we have too much or too little of them in the body.

Calcium Balance

Calcium is the most abundant mineral in the body. A typical person has 1-2 kg (2.2–4.4 lb) of this element. Ninety-nine percent of it is in the skeleton. In addition to forming the crystalline component of bone, calcium ions play key roles in controlling muscular and neural activities, in blood clotting, as cofactors for enzymatic reactions, and as second messengers.

As noted in Chapters 6 and 18, calcium homeostasis primarily reflects an interplay between the reserves in bone, the rate of absorption across the digestive tract, and the rate of loss by the kidneys. The hormones parathyroid hormone (PTH), calcitriol, and (to a lesser degree) calcitonin maintain calcium homeostasis in the ECF. Parathyroid hormone and calcitriol increase Ca^{2+} concentrations. Their actions are opposed by calcitonin. \Box pp. 629–631

A small amount of Ca^{2+} is lost in the bile. Under normal circumstances, very little Ca^{2+} escapes in urine or feces. To keep pace with these losses, an adult must absorb only 0.8-1.2 g/day of Ca^{2+} . That amount represents only about 0.03 percent of the calcium reserve in the skeleton. PTH from the parathyroid glands and calcitriol from the kidneys stimulate calcium absorption by the digestive tract and calcium reabsorption along the distal convoluted tubule.

Hypercalcemia exists when the Ca^{2+} concentration of the ECF exceeds 5.3 mEq/L. The primary cause of hypercalcemia

in adults is *hyperparathyroidism*, a condition resulting from PTH oversecretion. Less common causes include malignant cancers of the breast, lung, kidney, and bone marrow, and excessive use of calcium or vitamin D supplements. Severe hypercalcemia (12–13 mEq/L) causes such signs and symptoms as fatigue, confusion, cardiac arrhythmias, and calcification of the kidneys and soft tissues throughout the body.

Hypocalcemia (a Ca²⁺ concentration under 4.3 mEq/L) is much less common than hypercalcemia. *Hypoparathyroidism* (undersecretion of PTH), vitamin D deficiency, or chronic renal failure is typically responsible for hypocalcemia. Signs and symptoms include muscle spasms, sometimes with generalized convulsions, weak heartbeats, cardiac arrhythmias, and osteoporosis.

Magnesium Balance

The adult body contains about 29 g of magnesium. Almost 60 percent of it is in the skeleton. The magnesium in body fluids is found primarily in the ICF. There the concentration of Mg^{2+} averages about 26 mEq/L. Magnesium is required as a cofactor for several important enzymatic reactions, including the phosphorylation of glucose within cells and the use of ATP by contracting muscle fibers.

The typical range of Mg^{2+} concentrations in the ECF is 1.4–2.0 mEq/L, considerably lower than levels in the ICF. The proximal convoluted tubule reabsorbs magnesium very effectively. Keeping pace with the daily urinary loss requires a minimum dietary intake of only 24–32 mEq (0.3–0.4 g) per day.

Phosphate Balance

Phosphate ions (PO_4^{3-}) are required for bone mineralization. About 740 g are bound up in the mineral salts of the skeleton. In body fluids, the most important functions of PO_4^{3-} involve

lon and Normal ECF Range (mEq/L)	Disorder (mEq/L)	Signs and Symptoms	Causes	Treatments
Sodium (135–145)	Hypernatremia (>145)	Thirst, dryness and wrinkling of skin, reduced blood volume and pressure, eventual circulatory collapse	Dehydration; loss of hypotonic fluid	Ingestion of water or intravenous infusion of hypotonic solution
	Hyponatremia (<135)	Disturbed CNS function (water intoxication): confusion, hallucinations, convulsions, coma; death in severe cases	Infusion or ingestion of large volumes of hypotonic solution	Diuretic use and infusion of hypertonic salt solution
Potassium (3.5–5.0)	Hyperkalemia (>5.0)	Severe cardiac arrhythmias; muscle spasms	Renal failure; use of diuretics; chronic acidosis	Infusion of hypotonic solution; selection of different diuretics; infusion of buffers; dietary restrictions
	Hypokalemia (<3.5)	Muscular weakness and paralysis	Low-potassium diet; diuretics; hypersecretion of aldosterone; chronic alkalosis	Increase in dietary K ⁺ content; ingestion of K ⁺ tablets or solutions; infusion of potassium solution
Calcium (4.3–5.3)	Hypercalcemia (>5.3)	Confusion, muscle pain, cardiac arrhythmias, kidney stones, calcification of soft tissues	Hyperparathyroidism; cancer; vitamin D toxicity; calcium supplement overdose	Infusion of hypotonic fluid to lower Ca ²⁺ levels; surgery to remove parathyroid gland; administration of calcitonin
	Hypocalcemia (<4.3)	Muscle spasms, convulsions, intestinal cramps, weak heartbeats, cardiac arrhythmias, osteoporosis	Poor diet; lack of vitamin D; renal failure; hypoparathyroidism; hypomagnesemia	Calcium supplements; administration of vitamin D
Magnesium (1.4–2.0)	Hypermagnesemia (>2.0)	Confusion, lethargy, respiratory depression, hypotension	Overdose of magnesium supplements or antacids (rare)	Infusion of hypotonic solution to lower plasma concentration
	Hypomagnesemia (<1.4)	Hypocalcemia, muscle weakness, cramps, cardiac arrhythmias, hypertension	Poor diet; alcoholism; severe diarrhea; kidney disease; malabsorption syndrome; ketoacidosis	Intravenous infusion of solution high in Mg ²⁺
Phosphate (1.8–3.0)	Hyperphosphatemia (>3.0)	No immediate symptoms; chronic elevation leads to calcification of soft tissues	High dietary phosphate intake; hypoparathyroidism	Dietary reduction; PTH supplementation
	Hypophosphatemia (<1.8)	Anorexia, dizziness, muscle weakness, cardiomyopathy, osteoporosis	Poor diet; kidney disease; malabsorption syndrome; hyperparathyroidism; vitamin D deficiency	Dietary improvement; vitamin D and/or calcitriol supplementation
Chloride (100–108)	Hyperchloremia (>108)	Acidosis, hyperkalemia	Dietary excess; increased chloride retention	Infusion of hypotonic solution to lower plasma concentration
	Hypochloremia (<100)	Alkalosis, anorexia, muscle cramps, apathy	Vomiting; hypokalemia	Diuretic use and infusion of hypertonic salt solution

Table 27–2 Electrolyte Balance for Average Advised to the second se

the ICF. Inside cells the ions are required for the formation of high-energy compounds, the activation of enzymes, and the synthesis of nucleic acids.

The PO_4^{3-} concentration of the plasma is usually 1.8– 3.0 mEq/L. Phosphate ions are reabsorbed from tubular fluid along the proximal convoluted tubule. Calcitriol stimulates phosphate ion reabsorption along the PCT. Urinary and fecal losses of PO_4^{3-} amount to 30–45 mEq (0.8–1.2 g) per day.

Chloride Balance

Chloride ions (Cl⁻) are the most abundant anions in the ECF. The normal plasma concentration is 100-108 mEq/L. In the ICF, Cl⁻ concentrations are usually low (3 mEq/L). Chloride ions are absorbed across the digestive tract together with sodium

ions. Several carrier proteins along the renal tubules reabsorb Cl^- with Na⁺. \bigcirc pp. 994, 996 The amount of Cl^- loss is small. A gain of 48–146 mEq (1.7–5.1 g) per day will keep pace with losses in urine and perspiration.

CHECKPOINT

- **9**. Identify four physiologically important cations and two important anions in the extracellular fluid.
- **10**. Why does prolonged sweating increase plasma sodium ion levels?
- 11. Which is more dangerous, disturbances of sodium balance or disturbances of potassium balance? Explain your answer.

See the blue Answers tab at the back of the book.

27-5 In acid–base balance, regulation of hydrogen ions in body fluids involves buffer systems and respiratory and renal compensatory mechanisms

Learning Outcome Explain the buffering systems that balance the pH of the intracellular and extracellular fluids, and describe the compensatory mechanisms involved in maintaining acid–base balance.

We introduced the topic of pH and the chemical nature of acids, bases, and buffers in Chapter 2. Table 27–3 reviews key terms important to the discussion that follows. For a more detailed review, refer to the appropriate sections of Chapter 2 before you proceed. \bigcirc pp. 39–43

The pH of body fluids can be altered by adding either acids or bases. In general, we can categorize acids and bases as either *strong* or *weak*.

• *Strong acids* and *strong bases* dissociate completely in solution. For example, hydrochloric acid (HCl), a strong acid, dissociates in solution by the reaction

$$HCl \longrightarrow H^+ + Cl^-$$

• When *weak acids* or *weak bases* enter a solution, a significant number of molecules remain intact, so dissociation is not complete. In other words, if you place molecules of a weak acid in one solution and the same number of molecules of a strong acid in another solution, the weak acid will release fewer hydrogen ions and have less effect on the pH of the solution than will the strong acid.

Table 27–3	A Review of Important Terms Relating to Acid–Base Balance
рН	The negative exponent (negative logarithm) of the hydrogen ion concentration $[\mathrm{H}^+]$
Neutral	A solution with a pH of 7; the solution contains equal numbers of hydrogen ions and hydroxide ions
Acidic	A solution with a pH below 7; in this solution, hydrogen ions (H $^+$) predominate
Basic, or alkaline	A solution with a pH above 7; in this solution, hydroxide ions (OH $^-$) predominate
Acid	A substance that dissociates to release hydrogen ions, decreasing pH
Base	A substance that dissociates to release hydroxide ions or to tie up hydrogen ions, increasing pH
Salt	An ionic compound consisting of a cation other than hydrogen and an anion other than a hydroxide ion
Buffer	A substance that tends to oppose changes in the pH of a solution by removing or replacing hydrogen ions; in body fluids, buffers maintain blood pH within normal limits (7.35–7.45)

Carbonic acid is a weak acid. At the normal pH of the ECF, an equilibrium exists, and the reaction can be diagrammed as follows:

H_2CO_3	\rightleftharpoons	H^+	+	HCO_3^-
Carbonic acid		hydrogen ion		bicarbonate ion

The Importance of pH Control

The pH of body fluids reflects interactions among all the acids, bases, and salts in solution in the body. The pH of the ECF normally remains within narrow limits, usually 7.35-7.45. Any deviation from the normal range is extremely dangerous. Changes in H⁺ concentrations disrupt the stability of plasma membranes, alter the structure of proteins, and change the activities of important enzymes. You could not survive for long with an ECF pH below 6.8 or above 7.7.

When the pH of blood falls below 7.35, *acidemia* exists. The physiological state that results is called **acidosis**. When the pH of blood rises above 7.45, *alkalemia* exists. The physiological state that results is called **alkalosis**.

Acidosis and alkalosis affect virtually all body systems, but the nervous and cardiovascular systems are particularly sensitive to pH fluctuations. For example, severe acidosis (pH below 7.0) can be deadly, because (1) central nervous system function deteriorates, and the person may become comatose; (2) cardiac contractions grow weak and irregular, and signs and symptoms of heart failure may develop; and (3) peripheral vasodilation produces a dramatic decrease in blood pressure, potentially producing circulatory collapse.

The control of pH is a homeostatic process of great physiological and clinical significance. Both acidosis and alkalosis are dangerous, but in practice, problems with acidosis are much more common. This is so because normal cellular activities generate several acids, including carbonic acid.

Types of Acids in the Body

There are three general categories of acids in the body. They are (1) **fixed acids**, which do not leave solution, (2) **organic acids**, which take part in or are produced by cellular metabolism, and (3) **volatile acids**, which can leave the body and enter the atmosphere through the lungs. Figure 27–8 includes examples of each.

Carbonic acid (H_2CO_3) is an important volatile acid in body fluids. It forms spontaneously from carbon dioxide and water in body fluids, but this reaction proceeds much more rapidly in the presence of the enzyme *carbonic anhydrase*. This enzyme is found in the cytoplasm of red blood cells, liver and kidney cells, parietal cells of the stomach, and many other types of cells.

The partial pressure of carbon dioxide (P_{CO_2}) is the most important factor affecting the pH in body tissues. Most of the

carbon dioxide in solution is converted to carbonic acid, and most of the carbonic acid dissociates into hydrogen ions and bicarbonate ions. For this reason, the partial pressure of carbon dioxide and the pH are inversely related, as the seesaw in Figure 27–9 illustrates. In other words, when carbon dioxide levels increase, additional hydrogen ions and bicarbonate ions are released, so the pH decreases. (Recall that the pH is a *negative exponent,* so when the concentration of hydrogen ions goes up, the pH value goes down.)

In contrast, as carbon dioxide leaves the bloodstream and diffuses into the alveoli, the number of hydrogen ions and bicarbonate ions in the alveolar capillaries decreases, and blood pH increases. We will consider this process, which effectively removes hydrogen ions from solution, in more detail later in the chapter.

Mechanisms of pH Control

To maintain acid–base balance over long periods of time, your body must balance gains and losses of hydrogen ions. Hydrogen ions are gained at the digestive tract and through metabolic activities within cells. Your kidneys eliminate these ions, by secreting H^+ into urine. The lungs eliminate them by forming water and carbon dioxide from H^+ and HCO_3^- . These sites of elimination are far removed from the sites of acid production. As the hydrogen ions travel through the body, they must be neutralized to avoid tissue damage.

Buffers and buffer systems in body fluids temporarily neutralize the acids produced by normal metabolic operations. *Buffers* are dissolved compounds that stabilize the pH of a solution by adding or removing H^+ . Buffers include weak acids that can donate H^+ , and weak bases that can absorb H^+ . A **buffer system** in body fluids generally consists of a combination of a weak acid and the anion released by its dissociation. The anion functions as a weak base. In solution, molecules of the weak acid exist in equilibrium with its dissociation products. In chemical notation, this relationship is represented as

$$HY \Longrightarrow H^+ + Y^-$$

Adding H^+ to the solution upsets the equilibrium. As a result, additional molecules of the weak acid form, removing some of the H^+ from the solution.

The body has three major buffer systems: phosphate buffer system, protein buffer system, and carbonic acid-bicarbonate buffer system. Each has slightly different characteristics and distributions (Figure 27–10).

As we look more closely at these buffer systems, remember that they provide only a temporary solution to an acid–base imbalance. To preserve homeostasis, the H^+ that these systems capture must ultimately be either permanently tied up in water molecules, through the removal of carbon dioxide by the lungs, or removed from body fluids, through secretion by the kidneys. For that, respiratory and renal mechanisms are needed, as we will see later in the chapter. The *combination* of buffer systems and these respiratory and renal mechanisms maintains body pH within narrow limits.

The Phosphate Buffer System

The **phosphate buffer system** consists of the anion $H_2PO_4^-$, which is a weak acid. The operation of the phosphate buffer system resembles that of the carbonic acid-bicarbonate buffer system, which is discussed below. The reversible reaction involved is

$H_2PO_4^-$	\rightleftharpoons	H^+	+	PO_4^{2-}
dihydrogen				monohydrogen
phosphate				phosphate

Figure 27–10 Buffer Systems in Body Fluids.

The weak acid is *dihydrogen phosphate* $(H_2PO_4^{-})$, and the anion released is *monohydrogen phosphate* (HPO_4^{2-}) . In the ECF, the phosphate buffer system plays only a supporting role in the regulation of pH, primarily because the concentration of HCO_3^{-} far exceeds that of HPO_4^{2-} . However, the phosphate buffer system is quite important in buffering the pH of the ICF. In addition, cells contain a *phosphate reserve* in the form of the weak base *sodium monohydrogen phosphate* (Na_2HPO_4) . The phosphate buffer system is also important in stabilizing the pH of urine. The dissociation of Na_2HPO_4 provides additional HPO_4^{2-} for use by this buffer system:

$2Na^+$	+	HPO_4^{2-}	\rightarrow	Na ₂ HPO ₄
		monohydrogen		sodium
		phosphate		monohydrogen
				phosphate

Protein Buffer Systems

Protein buffer systems depend on the ability of amino acids to respond to pH changes by accepting or releasing H⁺, that is, by acting as a base or an acid. Such molecules are said to be *amphoteric (ampho*, both). The underlying mechanism is shown in **Figure 27–11**:

If pH increases, the carboxyl group (—COOH) of the amino acid can dissociate, acting as a weak acid and releasing a hydrogen ion. The carboxyl group then becomes a carboxylate ion (—COO⁻). At the normal pH of body fluids (7.35–7.45), the carboxyl groups of most amino acids have already given up their hydrogen ions. (Proteins carry negative charges mainly for that reason.) However, some amino acids, notably *histidine* and *cysteine*, have R groups (side chains) that will donate hydrogen ions if the pH increases outside the normal range. Their buffering effects are very important in both the ECF and the ICF.

- In a neutral solution, an amino acid carries both + and charges. This state is called a *zwitterion*. The term is derived from German meaning *hybrid ion*.
- If pH decreases, the carboxylate ion and the amino group (--NH₂) can act as weak bases and accept additional hydrogen ions, forming a carboxyl group (--COOH) and an amino ion (--NH₃⁺), respectively. In free amino acids, both the main structural chain and the side chain can act as buffers. In a protein, most of the carboxyl and amino groups in the main chain are tied up in peptide bonds. Only the exposed amino group and carboxyl group at either end of a protein are available as buffers. So most of the buffering capacity of proteins is provided by the R groups of amino acids.

Plasma proteins contribute to the buffering capabilities of blood. Interstitial fluid contains extracellular protein fibers and dissolved amino acids that also assist in regulating pH. In the ICF of active cells, structural and other proteins provide an extensive buffering capability. Their buffering prevents destructive changes in pH when cellular metabolism produces organic acids, such as lactic acid or pyruvic acid.

The protein buffer system can also help stabilize the pH of the ECF, because exchange occurs between the ECF and the ICF. For example, when the pH of the ECF decreases, cells pump H^+ out of the ECF and into the ICF, where intracellular proteins can buffer them. When the pH of the ECF increases, pumps in plasma membranes move H^+ out of the ICF and into the ECF.

These mechanisms can assist in buffering the pH of the ECF, but the process is slow. Hydrogen ions must be individually transported across the plasma membrane. For this reason, the protein buffer system in most cells cannot make rapid, large-scale adjustments in the pH of the ECF.

Figure 27–11 The Role of Amino Acids in Protein Buffer Systems. Depending on the pH of their surroundings, amino acids either donate a hydrogen ion (as at left) or accept a hydrogen ion (as at right). An amino acid in solution is a zwitterion and has both a negative and positive charge. Additionally, several different R groups may release or absorb H⁺.

The Hemoglobin Buffer System. The situation is somewhat different for red blood cells. These cells, which contain approximately 5.5 percent of the ICF, are normally suspended in the plasma. They are densely packed with hemoglobin, and their cytoplasm contains large amounts of carbonic anhydrase. Red blood cells have a significant effect on the pH of the ECF, because they absorb carbon dioxide from the plasma and convert it to carbonic acid. Carbon dioxide can diffuse across the RBC membrane very quickly, so no transport mechanism is needed. As the carbonic acid dissociates within an RBC, the bicarbonate ions diffuse into the plasma in exchange for chloride ions, a swap known as the *chloride shift*. **D p**. 864 Hemoglobin molecules buffer the hydrogen ions (Figure 23-23, p. 865). In the lungs, the entire reaction sequence diagrammed in Figure 23-23 proceeds in reverse. This mechanism is known as the hemoglobin buffer system.

The hemoglobin buffer system is the only intracellular buffer system that can have an immediate effect on the pH of the ECF. The hemoglobin buffer system helps prevent drastic changes in pH when the plasma P_{CO_2} is increasing or decreasing.

The Carbonic Acid–Bicarbonate Buffer System

Body cells generate carbon dioxide virtually 24 hours a day. (Exceptions are red blood cells, some cancer cells, and tissues temporarily deprived of oxygen.) As we have seen, most of the carbon dioxide is converted to carbonic acid, which then

dissociates into a hydrogen ion and a bicarbonate ion. The carbonic acid and its dissociation products form the **carbonic acid–bicarbonate buffer system**. The primary role of this buffer system is to prevent changes in pH caused by organic acids and fixed acids in the ECF.

The carbonic acid-bicarbonate buffer system consists of the reaction introduced in our discussion of volatile acids (Figure 27–12a):

CO_2	+	H_2O	\rightleftharpoons	H ₂ CO ₃	\rightleftharpoons	H^+	+	HCO_3^-
carbon		water		carbonic		hydrogen		bicarbonate
dioxide				acid		ion		ion

Because the reaction is freely reversible, a change in the concentration of any one participant affects the concentrations of all others. For example, if hydrogen ions are added, most of them will be removed by interactions with HCO_3^- , forming H_2CO_3 (carbonic acid). In the process, the HCO_3^- acts as a weak base that buffers the excess H^+ . The H_2CO_3 formed in this way in turn dissociates into CO_2 and H_2O (Figure 27–12b). The lungs can then excrete the extra CO_2 . In effect, this reaction takes the H^+ released by a strong organic or fixed acid and generates a volatile acid that can easily be eliminated.

The carbonic acid-bicarbonate buffer system can also protect against increases in pH, although such changes are rare. If hydrogen ions are removed from the plasma, the reaction is

driven to the right: The P_{CO_2} decreases, and H_2CO_3 dissociates to replace the missing H^+ .

The carbonic acid–bicarbonate buffer system has three important limitations:

- It cannot protect the ECF from changes in pH that result from increased or decreased levels of CO₂. A buffer system cannot protect against changes in the concentration of its own weak acid. As Figure 27–12a indicates, an equilibrium exists among the components of this buffer system. Thus, in this system, the addition of excess H⁺ from an outside source would drive the reaction to the left. But the addition of excess CO₂ would form H₂CO₃ and drive the reaction to the right. The dissociation of H₂CO₃ would release H⁺ and HCO₃⁻, decreasing the pH of the plasma.
- 2. It can function only when the respiratory system and the respiratory control centers are working normally. Normally, the increase in P_{CO_2} that occurs when fixed acids or organic acids are buffered stimulates an increase in the respiratory rate. This increase accelerates the removal of CO_2 by the lungs. The efficiency of the buffer system will be reduced if the respiratory passageways are blocked, or blood flow to the lungs is impaired, or the respiratory centers do not respond normally. This buffer system cannot eliminate H⁺ and remove the threat to homeostasis unless the respiratory system is functioning normally.
- **3.** *The ability to buffer acids is limited by the availability of bicarbonate ions.* Every time a hydrogen ion is removed from the plasma, a bicarbonate ion goes with it. When all the bicarbonate ions have been tied up, buffering capabilities are lost.

Problems due to a lack of bicarbonate ions are rare, for several reasons. First, body fluids contain a large reserve of HCO_3^- , mostly in the form of dissolved molecules of the weak base *sodium bicarbonate* (NaHCO₃). This readily available supply of HCO_3^- is known as the **bicarbonate reserve**. The reaction involved (Figure 27–12a) is

> $Na^+ + HCO_3^- \rightleftharpoons NaHCO_3$ bicarbonate sodium ion bicarbonate

When hydrogen ions enter the ECF, the bicarbonate ions tied up in H_2CO_3 molecules are replaced by HCO_3^- from the bicarbonate reserve (Figure 27–12b).

Second, additional HCO_3^- can be generated by the kidneys, through mechanisms described in Chapter 26 (Figure 26–14c, p. 999). In the distal convoluted tubule and collecting system, carbonic anhydrase converts CO_2 within tubular cells into H_2CO_3 , which then dissociates. The hydrogen ion is pumped into tubular fluid in exchange for a sodium ion, and the bicarbonate ion is transported into peritubular fluid in exchange for a chloride ion. In effect, tubular cells remove HCl from peritubular fluid in exchange for NaHCO₃.

Maintenance of Acid–Base Balance

Buffer systems can tie up excess H^+ , but they provide only a temporary solution to an acid–base imbalance. The hydrogen ions are merely rendered harmless. They are not eliminated. To preserve homeostasis, the captured H^+ must ultimately be either permanently tied up in water molecules, through the removal of carbon dioxide by the lungs, or removed from body fluids, through secretion by the kidneys.

The underlying problem is that the body's supply of buffer molecules is limited. Suppose that a buffer molecule prevents a change in pH by binding a hydrogen ion that enters the ECF. That buffer molecule is then tied up, reducing the capacity of the ECF to cope with any additional H^+ . Eventually, all the buffer molecules are bound to H^+ , and further pH control becomes impossible.

The situation can be resolved only by removing H^+ from the ECF (thereby freeing the buffer molecules) or by replacing the buffer molecules. Similarly, if a buffer provides a hydrogen ion to maintain normal pH, homeostatic conditions will return only when either another hydrogen ion has been obtained or the buffer has been replaced.

The maintenance of acid–base balance thus includes balancing H^+ gains and losses. This "balancing act" involves coordinating the actions of buffer systems with respiratory mechanisms and renal mechanisms. These mechanisms support the buffer systems by (1) secreting or absorbing H^+ , (2) controlling the excretion of acids and bases, and, when necessary, (3) generating additional buffers. As we have noted, it is the combination of buffer systems and these respiratory and renal mechanisms that maintains body pH within narrow limits.

Respiratory Compensation

Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Respiratory compensation takes place whenever body pH strays outside normal limits. Such compensation works because respiratory activity has a direct effect on the carbonic acid–bicarbonate buffer system. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO_2} . When the P_{CO_2} increases, the pH decreases, because the addition of CO₂ drives the carbonic acid–bicarbonate buffer system to the right. When the P_{CO_2} falls, the pH increases because the removal of CO₂ drives that buffer system to the left.

We described the mechanisms responsible for the control of respiratory rate in Chapter 23. Here we present only a brief summary. (For a review, see **Spotlight Figure 23–25** and **Figure 23–26**, pp. 868, 871.) Chemoreceptors of the carotid and aortic bodies are sensitive to the P_{CO_2} of circulating blood. Other receptors, located on the ventrolateral surfaces of the medulla oblongata, monitor the P_{CO_2} of the CSF. A rise in P_{CO_2} stimulates the chemoreceptors, leading to an increase in the respiratory rate. As the rate of respiration increases, more CO_2 is lost at the lungs, so the P_{CO_2} returns to normal levels. Conversely, when the P_{CO_2} of the blood or CSF decreases, the chemoreceptors are inhibited. Respiratory activity becomes depressed and the breathing rate decreases, causing an elevation of the P_{CO_2} in the ECF.

Renal Compensation

Renal compensation is a change in the rates of H^+ and HCO_3^- secretion or reabsorption by the kidneys in response to changes in plasma pH. Under normal conditions, the body generates enough organic and fixed acids to add about 100 mEq of H^+ to the ECF each day. An equivalent number of hydrogen ions must be excreted in urine to maintain acid–base balance. In addition, the kidneys assist the lungs by eliminating any CO_2 that either enters the renal tubules during filtration or diffuses into the tubular fluid as it travels toward the renal pelvis.

Hydrogen ions are secreted into the tubular fluid along the proximal convoluted tubule (PCT), the distal convoluted tubule (DCT), and the collecting system. The basic mechanisms involved are shown in Figures 26–12 and 26–14c (pp. 993, 999). The ability to eliminate a large number of hydrogen ions in a normal volume of urine depends on the presence of buffers in the urine. The secretion of H⁺ can continue only until the pH of the tubular fluid reaches 4.0–4.5. (At that point, the H⁺ concentration gradient is so great that hydrogen ions leak out of the tubule as fast as they are pumped in.)

If the tubular fluid lacked buffers to absorb the hydrogen ions, the kidneys could secrete less than 1 percent of the acid produced each day before the pH reached this limit. To maintain acid balance under these conditions, the kidneys would have to produce about 1000 liters of urine each day just to keep pace with the generation of H^+ in the body! Buffers in tubular fluid are extremely important, because they keep the pH high enough for H^+ secretion to continue. Metabolic acids are being generated continuously. Without these buffering mechanisms, the kidneys could not maintain homeostasis.

Figure 27–13 diagrams the primary routes of H⁺ secretion and the buffering mechanisms that stabilize the pH of tubular fluid. The three major buffers involved are the carbonic acid– bicarbonate buffer system, the phosphate buffer system, and the ammonia buffer system (**Figure 27–13a**). Glomerular filtration puts components of the carbonic acid–bicarbonate buffer system and the phosphate buffer system into the filtrate. Tubule cells (mainly those of the PCT) generate ammonia. Figure 27–13a shows the secretion of H^+ , which relies on carbonic anhydrase activity within tubular cells. The hydrogen ions generated may be pumped into the lumen in exchange for sodium ions, individually or together with chloride ions. The net result is the secretion of H^+ , accompanied by the removal of CO_2 (from the tubular fluid, the tubule cells, and the ECF), and the release of sodium bicarbonate into the ECF.

Figure 27–13b shows the generation of ammonia within the tubules. As tubule cells use the enzyme *glutaminase* to break down the amino acid *glutamine*, amino groups are released as either ammonium ions (NH_4^+) or ammonia (NH_3) . The ammonium ions are transported into the lumen in exchange for Na⁺ in the tubular fluid. The NH₃, which is highly volatile and also toxic to cells, diffuses rapidly into the tubular fluid. There it reacts with a hydrogen ion, forming NH₄⁺.

This reaction buffers the tubular fluid and removes a potentially dangerous compound from body fluids. The carbon chains of the glutamine molecules are ultimately converted to HCO_3^- , which is cotransported with Na⁺ into the ECF. The generation of ammonia by tubule cells ties up H⁺ in the tubular fluid and releases sodium bicarbonate into the ECF, where it contributes to the bicarbonate reserve. These mechanisms of H⁺ secretion and buffering are always functioning, but their levels of activity vary widely with the pH of the ECF.

The Renal Responses to Acidosis and Alkalosis. Acidosis (low blood pH) develops when the normal plasma buffer mechanisms are stressed by excessive hydrogen ions. The kidney tubules do not distinguish among the various acids that may cause acidosis. Whether the decrease in pH results from the production of volatile, fixed, or organic acids, the renal contribution remains limited to (1) the secretion of H⁺, (2) the activity of buffers in the tubular fluid, (3) the removal of CO₂, and (4) the reabsorption of NaHCO₃.

Tubule cells thus bolster the capabilities of the carbonic acid–bicarbonate buffer system. They do so by increasing the concentration of bicarbonate ions in the ECF, replacing those already used to remove hydrogen ions from solution. In a starving person, tubule cells break down amino acids, yielding ammonium ions that are pumped into the tubular fluid, bicarbonates to help buffer ketone bodies in the blood, and carbon chains for catabolism (Figure 27–13b).

When alkalosis (high blood pH) develops, (1) the rate of H^+ secretion by the kidneys declines, (2) tubule cells do not reclaim the bicarbonates in tubular fluid, and (3) the collecting system transports HCO_3^- into tubular fluid while releasing a strong acid (HCl) into peritubular fluid (Figure 27–13c). The concentration of HCO_3^- in blood decreases, promoting the dissociation of H_2CO_3 and the release of hydrogen ions. The additional H^+ generated by the kidneys helps return the pH to normal levels.

27

CHECKPOINT

- 12. Identify the body's three major buffer systems.
- 13. What effect would a decrease in the pH of body fluids have on the respiratory rate?
- 14. Why must tubular fluid in nephrons be buffered?

See the blue Answers tab at the back of the book.

27-6 Respiratory acidosis/alkalosis and metabolic acidosis/alkalosis are classes of acid–base balance disturbances

Learning Outcome Identify the most frequent disturbances of acidbase balance, and explain how the body responds when the pH of body fluids varies outside normal limits.

Figure 27–14 summarizes the interactions among buffer systems, respiration, and renal function in maintaining normal acid–base balance. In combination, these mechanisms can generally control pH very precisely, so the pH of the ECF seldom varies more than 0.1 pH unit, from 7.35 to 7.45. When buffering mechanisms are severely stressed, however, the pH drifts outside these limits, producing signs and symptoms of alkalosis or acidosis.

For anyone considering a career in a health-related field, an understanding of acid–base dynamics is essential for clinical diagnosis and patient management under a variety of conditions. Temporary shifts in the pH of body fluids occur frequently. Rapid and complete recovery involves a combination of buffer system activity and the respiratory and renal responses. More serious and prolonged disturbances of acid–base balance can result under the following circumstances:

- Any Disorder Affecting Circulating Buffers, Respiratory Performance, or Renal Function. Several conditions, including emphysema and renal failure, are associated with dangerous changes in pH. ⁽⁾ pp. 875, 1008
- *Cardiovascular Conditions*. Conditions such as *heart failure* or *hypotension* can affect the pH of internal fluids by causing fluid shifts and by changing glomerular filtration rates and respiratory efficiency. **D pp.** 710, 738
 - Conditions Affecting the Central Nervous System. Neural damage or disease that affects the CNS can affect the respiratory and cardiovascular reflexes that are essential to normal pH regulation.

Serious abnormalities in acid–base balance generally have an initial *acute phase*, in which the pH moves rapidly out of the normal range. If the condition persists, physiological adjustments take place. The person then enters the *compensated phase*. Unless the underlying problem is corrected, compensation cannot be completed, and blood chemistry will remain abnormal. The pH typically remains outside normal limits even after compensation has occurred. Even if the pH is within the normal range, the P_{CO_3} or HCO_3^- concentrations can be abnormal.

The name given to the resulting condition usually indicates the primary source of the problem:

- *Respiratory acid–base disorders* result from a mismatch between carbon dioxide generation in peripheral tissues and carbon dioxide excretion by the lungs. When a respiratory acid–base disorder is present, the carbon dioxide level of the ECF is abnormal.
- Metabolic acid-base disorders are caused by the generation of organic acids or fixed acids or by conditions affecting the concentration of HCO₃⁻ in the ECF.

Respiratory compensation alone may restore normal acidbase balance in persons with respiratory acid-base disorders. In contrast, compensation mechanisms for metabolic acid-base disorders may be able to stabilize pH, but other aspects of acid-base balance (buffer system function, bicarbonate and P_{CO_2} levels) remain abnormal until the underlying metabolic cause is corrected.

We subdivide the respiratory and metabolic categories into four major classes of acid–base disturbances: (1) *respiratory acidosis*, (2) *respiratory alkalosis*, (3) *metabolic acidosis*, and (4) *metabolic alkalosis*.

Respiratory Acidosis

Respiratory acidosis develops when the respiratory system cannot eliminate all the carbon dioxide generated by peripheral tissues. The primary sign is low blood pH due to **hypercapnia**, an increased blood P_{CO_2} . The usual cause is hypoventilation, an abnormally low respiratory rate. When the P_{CO_2} in the ECF rises, H⁺ and HCO₃⁻ concentrations also begin rising as H₂CO₃ forms and dissociates. Other buffer systems can tie up some of the H⁺, but once the combined buffering capacity has been exceeded, the pH begins to fall rapidly. The effects are diagrammed in Figure 27–15a.

Respiratory acidosis is the most common challenge to acid–base equilibrium. Body tissues generate carbon dioxide rapidly. Even a few minutes of hypoventilation can cause acidosis, reducing the pH of the ECF to as low as 7.0. Under normal circumstances, the chemoreceptors that monitor the P_{CO_2} of blood and of cerebrospinal fluid (CSF) eliminate the problem by stimulating an increase in breathing rate.

If the chemoreceptors do not respond, if the breathing rate cannot be increased, or if the circulatory supply to the lungs is inadequate, pH will continue to decrease. If the decline is severe, **acute respiratory acidosis** develops. Acute respiratory acidosis is an immediate, life-threatening condition. It is especially dangerous in people whose tissues are generating large amounts of carbon dioxide, or in people who are incapable of normal respiratory activity. For this reason, the reversal of acute

in the Regulation of Plasma pH. The central role of the carbonic acid-bicarbonate buffer system is highlighted.

respiratory acidosis is probably the major goal in the resuscitation of cardiac arrest or drowning victims. Thus, first-aid, CPR, and lifesaving courses always stress the "ABCs" of emergency care: Airway, Breathing, and Circulation.

Chronic respiratory acidosis develops when normal respiratory function has been compromised, but the compensatory mechanisms have not failed completely. For example, normal respiratory compensation may not occur in response to chemoreceptor stimulation in persons with CNS injuries and those whose respiratory centers have been desensitized by drugs such as alcohol or barbiturates. As a result, these people are prone to developing acidosis due to chronic hypoventilation.

Even when respiratory centers are intact and functional, damage to some parts of the respiratory system can prevent increased pulmonary exchange. Examples of conditions fostering chronic respiratory acidosis include emphysema, congestive heart failure, and pneumonia (which typically cause alveolar damage or blockage). Pneumothorax and respiratory muscle paralysis have a similar effect, because they, too, limit adequate breathing rate.

When a normal pulmonary response does not take place, the kidneys respond by increasing the rate of H⁺ secretion into tubular fluid. This response slows the rate of pH change. However, renal mechanisms alone cannot return the pH to normal until the underlying respiratory or circulatory problems are corrected.

The primary problem in respiratory acidosis is that the rate of pulmonary exchange is inadequate to keep the arterial P_{CO_2} within normal limits. Breathing efficiency can typically be improved temporarily by inducing bronchodilation or by using mechanical aids that provide air under positive pressure. If breathing has stopped, artificial respiration or a mechanical ventilator is required. These measures may restore normal pH if the respiratory acidosis was not severe or prolonged. Treatment of acute respiratory acidosis is complicated by the fact that, as we will soon see, it causes a complementary *metabolic acidosis* as oxygen-starved tissues generate lactic acid.

Respiratory Alkalosis

Problems resulting from **respiratory alkalosis** are fairly uncommon (**Figure 27–15b**). Respiratory alkalosis develops when respiratory activity lowers blood P_{CO_2} to below-normal levels, a condition called **hypocapnia** (*-capnia*, presence of carbon dioxide). A temporary hypocapnia can be produced by *hyperventilation* when increased respiratory activity leads to a reduction in the arterial P_{CO_2} . Continued hyperventilation can increase the pH to levels as high as 8.0. This condition generally corrects itself, because the reduction in P_{CO_2} halts the stimulation of the chemoreceptors, so the urge to breathe fades until carbon dioxide levels have returned to normal. Respiratory alkalosis caused by hyperventilation seldom lasts long enough to cause a clinical emergency.

Common causes of hyperventilation include physical stresses such as pain, or psychological stresses such as extreme anxiety. Hyperventilation gradually increases the pH of the cerebrospinal fluid, and central nervous system function is affected. The initial symptoms involve tingling sensations in the hands, feet, and lips. The person may also feel light-headed. If hyperventilation continues, the person may lose consciousness. Unconsciousness removes any contributing psychological stimuli, and the breathing rate decreases. The P_{CO_2} then increases until pH returns to normal.

A simple treatment for respiratory alkalosis caused by hyperventilation is to have the person rebreathe air exhaled into a small paper bag. As the P_{CO_2} in the bag increases, so do the person's alveolar and arterial CO_2 concentrations. This change eliminates the problem and restores the pH to normal levels. Other problems with respiratory alkalosis are rare and involve primarily (1) persons adapting to high altitudes, where the low P_{O_2} promotes hyperventilation; (2) patients on mechanical respirators; or (3) persons whose brain stem injuries render them incapable of responding to shifts in plasma CO_2 concentrations.

Metabolic Acidosis

Metabolic acidosis is the second most common type of acidbase imbalance. It has three major causes:

- The most widespread cause of metabolic acidosis is the production of a large number of fixed acids or organic acids. The hydrogen ions released by these acids overload the carbonic acid-bicarbonate buffer system, so pH begins to decrease (Figure 27–16a). We considered two examples of metabolic acidosis earlier:
 - Lactic acidosis can develop after strenuous exercise or prolonged tissue hypoxia (oxygen starvation) as active cells rely on anaerobic respiration (see Figure 10–20, p. 319).
 - **Ketoacidosis** results from the generation of large quantities of ketone bodies during the postabsorptive state of metabolism. Ketoacidosis is a problem in starvation, and a potentially lethal complication of poorly controlled diabetes mellitus. In either case, peripheral tissues cannot obtain adequate glucose from the bloodstream and they begin metabolizing lipids and ketone bodies.
- A less common cause of metabolic acidosis is an impaired ability to excrete H⁺ by the kidneys (Figure 27–16a). For example, conditions marked by severe kidney damage, such as *glomerulonephritis*, typically result in severe metabolic acidosis. ⊃ p. 982 Diuretics that "turn off" the sodium–hydrogen transport system in the kidney tubules also cause metabolic acidosis. The secretion of H⁺ is linked to the reabsorption of Na⁺. When Na⁺ reabsorption stops, so does H⁺ secretion.
- **3.** Metabolic acidosis occurs after severe bicarbonate loss (Figure 27–16b). The carbonic acid–bicarbonate buffer system relies on bicarbonate ions to balance hydrogen ions that threaten pH balance. A decrease in the HCO₃⁻ concentration in the ECF makes this buffer system less effective, and acidosis soon develops. The most common cause of HCO₃⁻ depletion is chronic diarrhea. Under normal conditions, most of the bicarbonate ions secreted into the digestive tract in pancreatic, hepatic, and mucous secretions are reabsorbed before the feces are eliminated. In diarrhea, these bicarbonates are lost, so the HCO₃⁻ concentration of the ECF decreases.

The nature of the problem must be understood before treatment can begin. Potential causes are so varied that clinicians must piece together relevant clues to make a diagnosis. In some cases, the diagnosis is straightforward. For example, a patient with metabolic acidosis after a bicycle race probably has lactic acidosis. In other cases, clinicians must be detectives.

Compensation for metabolic acidosis generally involves a combination of respiratory and renal mechanisms. Hydrogen ions interacting with bicarbonate ions form carbon dioxide molecules that are eliminated by the lungs. The kidneys excrete additional hydrogen ions into the urine and generate bicarbonate ions that are released into the ECF.

Figure 27–16 Responses to Metabolic Acidosis.

Combined Respiratory and Metabolic Acidosis

Respiratory acidosis and metabolic acidosis are typically linked, because oxygen-starved tissues generate large quantities of lactic acid, and because sustained hypoventilation leads to decreased arterial P_{O_2} . The problem can be especially serious in cases of near drowning, in which body fluids have high P_{CO_2} , low P_{O_2} , and large amounts of lactate generated by the muscles of the struggling person. (Lactate ions—and hydrogen ions—are released by the dissociation of lactic acid.) Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance, coupled with intravenous infusion of an isotonic solution that contains sodium lactate, sodium gluconate, or sodium bicarbonate.

Metabolic Alkalosis

Metabolic alkalosis occurs when HCO_3^- concentrations are elevated (Figure 27–17). The bicarbonate ions then interact with hydrogen ions in solution, forming H_2CO_3 . The resulting decrease in H^+ concentrations causes signs of alkalosis.

Metabolic alkalosis is rare, but we noted one interesting cause in Chapter 24. \bigcirc p. 900 The phenomenon known as the *alkaline tide* is due to the influx into the ECF of large numbers of

bicarbonate ions associated with the secretion of hydrochloric acid (HCl) by the gastric mucosa. The alkaline tide temporarily increases the HCO_3^- concentration in the ECF during meals. But bouts of repeated vomiting may bring on serious metabolic alkalosis, because the stomach continues to generate stomach acids to replace those that are lost. As a result, the HCO_3^- concentration of the ECF continues to increase.

Compensation for metabolic alkalosis involves a decrease in the breathing rate, coupled with an increased loss of $HCO_3^$ in urine. Treatment of mild cases typically addresses the primary cause—generally by controlling the vomiting—and may involve administering solutions that contain NaCl or KCl.

Treatment of acute cases of metabolic alkalosis may involve administering ammonium chloride (NH_4Cl). Metabolism of the ammonium ion in the liver liberates a hydrogen ion, so in effect the introduction of NH_4Cl leads to the internal generation of HCl, a strong acid. As the HCl diffuses into the bloodstream, pH falls toward normal levels.

The Detection of Acidosis and Alkalosis

Spotlight Figure 27–18 and **Table 27–4** indicate the patterns that characterize the four major categories of acid–base disorders.

Figure 27–17 Metabolic Alkalosis. Metabolic alkalosis most commonly results from the loss of acids, especially stomach acid lost through vomiting. As replacement gastric acid is produced, the alkaline tide introduces many bicarbonate ions into the blood-stream, so pH increases.

SPOTLIGHT Figure 27–18 The Diagnosis of Acid–Base Disorders

ACID-BASE DISORDERS

Virtually anyone who has a problem that affects the cardiovascular, respiratory, urinary, digestive, or nervous system may develop potentially dangerous acid–base imbalances. For this reason, an arterial blood gas test is done to evaluate the body's acid–base balance. Standard tests measure arterial blood pH, partial pressure of carbon dioxide (P_{CO_2}), partial pressure of oxygen (P_{O_2}), and bicarbonate (HCO₃⁻) levels. These measurements make diagnosing acid–base disorders relatively straightforward. The flowchart below shows the diagnostic steps used to determine whether a person has an acid–base disorder, and to further determine what type of acidosis or alkalosis exists.

Table 27–4	Changes	Changes in Blood Chemistry Associated with the Major Classes of Acid–Base Disorders							
Disorder	pH (normal 7.35–7.45)	HCO ₃ (mEq/L) (normal = 21-28)	P _{CO2} (mm Hg) (normal = 35–45)	Remarks	Treatments				
Respiratory acidosis	Decreased (below 7.35)	Acute: normal Compensated: increased (above 28)	Increased (above 45)	Generally caused by hypoventilation and CO ₂ buildup in tissues and blood	Improve ventilation; in some cases, with bronchodilation and mechanical assistance				
Metabolic acidosis	Decreased (below 7.35)	Decreased (below 24)	Acute: normal Compensated: decreased (below 35)	Caused by buildup of organic or fixed acid, impaired H^+ elimination at kidneys, or HCO_3^- loss in urine or feces	Administration of bicarbonate (gradual), with other steps as needed to correct primary cause				
Respiratory alkalosis	Increased (above 7.45)	Acute: normal Compensated: decreased (below 24)	Decreased (below 35)	Generally caused by hyperventilation and reduction in plasma CO ₂ levels	Reduce respiratory rate, allow rise in P_{CO_2}				
Metabolic alkalosis	Increased (above 7.45)	Increased (above 28)	Increased (above 45)	Generally caused by prolonged vomiting and associated acid loss	pH below 7.55: no treatment; pH above 7.55: may require administration of NH₄Cl				

Additional steps can help in identifying possible causes of the problem and in distinguishing compensated from uncompensated conditions. These steps may include determining the *anion gap*, plotting blood test results on a numerical graph called a *nomogram*, or using a diagnostic chart.

- CHECKPOINT

- 15. How would a prolonged fast affect the body's pH?
- 16. Why can prolonged vomiting produce metabolic alkalosis?
- See the blue Answers tab at the back of the book.

27-7 Aging affects several aspects of fluid, electrolyte, and acid–base balance

Learning Outcome Describe the effects of aging on fluid, electrolyte, and acid–base balance.

Fetuses and infants have very different requirements for maintaining fluid, electrolyte, and acid–base balance than do adults. A fetus obtains the water, organic nutrients, and electrolytes it needs from the maternal bloodstream. Buffers in the fetal bloodstream provide short-term pH control, and the maternal kidneys eliminate the H⁺ generated. A newborn's body water content is high: At birth, water makes up about 75 percent of body weight, compared with 50–60 percent in adults. Basic aspects of electrolyte balance are the same in newborns as in adults, but the effects of fluctuations in the diet are much more immediate in newborns because their reserves of minerals and energy sources are much smaller.

The descriptions of fluid, electrolyte, and acid-base balance in this chapter were based on the responses of normal, healthy adults under age 40. Aging affects many aspects of fluid, electrolyte, and acid-base balance, including the following:

- Total body water content gradually decreases with age. Between ages 40 and 60, average total body water content declines slightly, to 55 percent for males and 47 percent for females. After age 60, the values decline further, to about 50 percent for males and 45 percent for females. Among other effects, each decrease reduces the dilution of wastes, toxins, and any drugs that have been administered.
- A decrease in the glomerular filtration rate and in the number of functional nephrons reduces the body's ability to regulate pH through renal compensation.
- The body's ability to concentrate urine declines, so more water is lost in urine. In addition, the rate of insensible perspiration increases as the skin becomes thinner and more delicate. Maintaining fluid balance therefore requires a higher daily water intake. A reduction in ADH and aldosterone sensitivity makes older people less able than younger people to conserve body water when losses exceed gains.
- Many people over age 60 experience a net loss in body mineral content as muscle mass and skeletal mass decrease. This loss can be prevented, at least in part, by a combination of exercise and an increased dietary mineral supply.
- The reduction in vital capacity that accompanies aging reduces the body's ability to perform respiratory compensation, increasing the risk of respiratory acidosis. This

problem can be compounded by arthritis, which can reduce vital capacity by limiting rib movements, and by emphysema, another condition that, to some degree, develops with aging.

 Disorders affecting major systems become more common with increasing age. Most, if not all, of these disorders have some effect on fluid, electrolyte, and/or acid-base balance.

CHECKPOINT

- **17**. As a person ages, the glomerular filtration rate and the number of functional nephrons decreases. What effect would these changes have on pH regulation?
- **18**. After the age of 40, does the total body water content increase or decrease?
- See the blue Answers tab at the back of the book.

Related Clinical Terms

antacid: A substance used to counteract or neutralize stomach acid. **bicarbonate loading:** In sports, the act of ingesting bicarbonates prior to an athletic event to neutralize the lactic acid produced during strenuous physical activity.

- **enema:** A procedure in which a liquid or gas is injected into the rectum, usually with the intention of having the rectum dispel its contents, but sometimes used as a way to introduce drugs or to permit x-ray imaging.
- **fluid replacement therapy:** Procedure conducted with the intent to replace body fluids lost due to disease or restricted intake; or to maintain a higher-than-normal rate of fluid excretion to ensure the removal of toxins; or possibly to administer therapeutic or anesthetic agents slowly over time.
- **potassium adaptation:** The tolerance to increasing amounts of potassium.
- **syndrome of inappropriate secretion of ADH (SIADH):** A condition associated with excessive ADH secretion that results in the excretion of concentrated urine. It disturbs fluid and electrolyte balance, and causes nausea, vomiting, muscle cramps, confusion, and convulsions. This syndrome can occur with some forms of cancer, such as oat-cell lung cancer, pancreatic cancer, prostate cancer, Hodgkin's disease, and possibly due to a number of other disorders.

total body water: The sum of fluids within all compartments.

- 27-1 Fluid balance, electrolyte balance, and acid-base balance are interrelated and essential to homeostasis p. 1016
 - 1. The maintenance of normal volume and composition of extracellular and intracellular fluids is vital to life. Three types of homeostasis are involved: **fluid balance**, **electrolyte balance**, and **acid–base balance**.
- **27-2** The ECF and ICF make up the fluid compartments, which also contain cations and anions p. 1017
- 2. The **intracellular fluid (ICF)** contains nearly two-thirds of the total body water. The **extracellular fluid (ECF)** contains the rest. Exchange occurs between the ICF and the ECF, but the

two **fluid compartments** retain their distinctive characteristics. (*Figures 27–1, 27–2*)

- **3.** Homeostatic mechanisms that monitor and adjust the composition of body fluids respond to changes in the ECF.
- 4. No receptors directly monitor fluid or electrolyte balance. Receptors involved in fluid balance and in electrolyte balance respond to changes in plasma volume and osmotic concentration.
- Body cells cannot move water molecules by active transport. All movements of water across plasma membranes and epithelia occur passively, in response to osmotic gradients.
- 6. The body's content of water or electrolytes will increase if intake exceeds outflow and will decrease if losses exceed gains.
- 7. ADH encourages water reabsorption by the kidneys and stimulates thirst. Aldosterone increases the rate of sodium reabsorption by the kidneys. Natriuretic peptides (ANP and BNP) oppose those actions and promote fluid and electrolyte losses in urine.
- 8. The regulatory mechanisms of fluid balance and electrolyte balance are quite different, and the distinction is clinically important.
- 27-3 Hydrostatic and osmotic pressures regulate the movement of water and electrolytes to maintain fluid balance p. 1021
- 9. Water circulates freely within the ECF compartment.
- **10.** Water losses are normally balanced by gains through eating, drinking, and **metabolic generation**. (*Figure 27–3; Table 27–1*)

- - P

11. Water movement between the ECF and ICF is called a **fluid shift**. If the ECF becomes hypertonic relative to the ICF, water will move from the ICF into the ECF until osmotic equilibrium has been restored. If the ECF becomes hypotonic relative to the ICF, water will move from the ECF into the cells, and the volume of the ICF will increase. (*Figure 27–4*)

27-4 Sodium, potassium, calcium, magnesium, phosphate, and chloride balance is essential for maintaining homeostasis p. 1024

- **12.** An **equivalent** is the amount of a positive ion or negative ion that supplies one mole of electrical charge, and 1 equivalent = 1000 milliequivalents (mEq).
- **13.** Problems with electrolyte balance generally result from a mismatch between gains and losses of sodium. Problems with potassium balance are less common, but more dangerous.
- 14. The rate of sodium uptake across the digestive epithelium is directly proportional to the amount of sodium in the diet. Sodium losses occur mainly in urine and through perspiration. (*Figure 27–5*)
- **15.** Shifts in sodium balance result in expansion or contraction of the ECF. Large variations in ECF volume are corrected by homeostatic mechanisms triggered by changes in blood volume. If the volume becomes too low, ADH and aldosterone are secreted; if the volume becomes too high, natriuretic peptides (ANP and BNP) are secreted. (*Figure 27–6*)
- **16.** Potassium ion concentrations in the ECF are very low and not as closely regulated as are sodium ion concentrations. Potassium excretion increases as ECF concentrations rise, under aldosterone stimulation, and when the pH increases. Potassium retention occurs when the pH decreases. (*Figure 27–7*)
- **17.** ECF concentrations of other electrolytes, such as calcium, magnesium, phosphate, and chloride, are also regulated. (*Table 27–2*)
- 27-5 In acid–base balance, regulation of hydrogen ions in body fluids involves buffer systems and respiratory and renal compensatory mechanisms p. 1030
- 18. Acids and bases are either strong or weak. (Table 27-3)
- **19.** The pH of normal body fluids ranges from 7.35 to 7.45. Variations outside this relatively narrow range produce symptoms of **acidosis** or **alkalosis**.
- 20. Volatile acids can leave solution and enter the atmosphere. Fixed acids remain in body fluids until excreted by the kidneys. Organic acids are participants in, or are byproducts of, aerobic metabolism. (*Figure 27–8*)
- **21.** Carbonic acid, a volatile acid, is the most important factor affecting the pH of the ECF. In solution, CO_2 reacts with water to form carbonic acid. An inverse relationship exists between pH and the concentration of CO_2 . (*Figure 27–9*)
- **22.** Sulfuric acid and phosphoric acid, the most important fixed acids, are generated during the catabolism of amino acids and compounds containing phosphate groups.
- **23.** Organic acids include metabolic products such as lactic acid and ketone bodies.
- 24. A buffer system typically consists of a weak acid and the anion released by its dissociation. The anion functions as a weak base that can absorb H⁺. The three major buffer systems are (1) the phosphate buffer system in the ICF and urine; (2) protein buffer systems in the ECF and ICF; and (3) the carbonic acid-bicarbonate buffer system, most important in the ECF. (*Figure 27-10*)

- **25.** The phosphate buffer system plays a supporting role in regulating the pH of the ECF, but it is important in buffering the pH of the ICF and of urine.
- **26.** In protein buffer systems, the initial, final, and R groups of component amino acids respond to changes in pH by accepting or releasing hydrogen ions. The **hemoglobin buffer system** is a protein buffer system that helps prevent drastic changes in pH when the P_{CO_2} is increasing or decreasing. (*Figure 27–11*)
- 27. The carbonic acid–bicarbonate buffer system prevents pH changes caused by organic acids and fixed acids in the ECF. The readily available supply of bicarbonate ions is the **bicarbonate reserve**. (*Figure 27–12*)
- **28.** The lungs help regulate pH by affecting the carbonic acid– bicarbonate buffer system. A change in respiratory rate can raise or lower the P_{CO_2} of body fluids, affecting the body's buffering capacity. This process is called **respiratory compensation**.
- **29.** In **renal compensation**, the kidneys vary their rates of hydrogen ion secretion and bicarbonate ion reabsorption, depending on the pH of the ECF. (*Figure 27–13*)
- 27-6 Respiratory acidosis/alkalosis and metabolic acidosis/ alkalosis are classes of acid-base balance disturbances p. 1038
- **30.** Interactions among buffer systems, respiration, and renal function normally maintain tight control of the pH of the ECF, generally within a range of 7.35–7.45. (*Figure 27–14*)
- **31.** *Respiratory acid–base disorders* result when abnormal respiratory function causes an extreme increase or decrease in CO₂ levels in the ECF. *Metabolic acid–base disorders* are caused by the generation of organic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF.
- **32. Respiratory acidosis** results from excessive levels of CO_2 in body fluids. (*Figure 27–15a*)
- **33. Respiratory alkalosis** is a relatively rare condition associated with hyperventilation. (*Figure 27–15b*)
- 34. **Metabolic acidosis** results from the depletion of the bicarbonate reserve, caused by an inability to excrete hydrogen ions by the kidneys, the production of large numbers of fixed and organic acids, or bicarbonate loss that accompanies chronic diarrhea. (*Figure 27–16*)
- 35. **Metabolic alkalosis** results when bicarbonate ion concentrations become elevated, as occurs during extended periods of vomiting. (*Figure 27–17*)
- **36.** An arterial blood gas test evaluates blood pH, P_{CO_2} , P_{O_2} , and HCO_3^- levels to recognize and classify acidosis and alkalosis as either respiratory or metabolic in nature. (*Spotlight Figure* 27–18; *Table* 27–4)

27-7 Aging affects several aspects of fluid, electrolyte, and acid-base balance p. 1045

37. Age-related changes that affect fluid, electrolyte, and acid–base balance include (1) reduced total body water content, (2) impaired ability to perform renal compensation, (3) increased water demands due to decreased ability to concentrate urine and reduced sensitivity to ADH and aldosterone, (4) a net loss of minerals, (5) reductions in respiratory efficiency that affect respiratory compensation, and (6) increased incidence of conditions that secondarily affect fluid, electrolyte, or acid–base balance.

Review Questions

LEVEL 1 Reviewing Facts and Terms

- 1. The primary components of the extracellular fluid are (a) lymph and cerebrospinal fluid, (b) plasma and serous fluids, (c) interstitial fluid and plasma, (d) all of these.
- The principal anions in the ICF are (a) phosphate and proteins (Pr⁻),
 (b) phosphate and bicarbonate, (c) sodium and chloride, (d) sodium and potassium.
- **3.** Osmoreceptors in the hypothalamus monitor the osmotic concentration of the ECF and secrete ______ in response to higher osmotic concentrations. (a) BNP, (b) ANP, (c) aldosterone, (d) ADH.
- 4. Write the missing names and molecular formulas for the following reactions between the carbonic acid–bicarbonate buffer system and the bicarbonate reserve.

- (a) _____
- (b) _____
- (c) _____
- Calcium homeostasis primarily reflects (a) a balance between absorption in the gut and excretion by the kidneys, (b) careful regulation of blood calcium levels by the kidneys, (c) an interplay between parathormone and aldosterone, (d) an interplay among reserves in the bones, the rate of absorption, and the rate of excretion, (e) hormonal control of calcium reserves in the bones.
- 6. The *most* important factor affecting the pH of body tissues is the concentration of (a) lactic acid, (b) ketone bodies, (c) organic acids, (d) carbon dioxide, (e) hydrochloric acid.
- Changes in the pH of body fluids are compensated for by all of the following *except* (a) an increase in urine output, (b) the carbonic acid–bicarbonate buffer system, (c) the phosphate buffer system, (d) changes in the rate and depth of breathing, (e) protein buffers.
- Respiratory acidosis develops when the blood pH is (a) increased due to a decreased blood P_{CO2} level, (b) decreased due to an increased blood P_{CO2} level, (c) increased due to an increased blood P_{CO2} level, (d) decreased due to a decreased blood P_{CO2} level.
- Metabolic alkalosis occurs when (a) bicarbonate ion concentrations become elevated, (b) a severe bicarbonate loss occurs, (c) the kidneys fail to excrete hydrogen ions, (d) ketone bodies are generated in abnormally large quantities.
- **10.** Identify four hormones that mediate major physiological adjustments affecting fluid and electrolyte balance. What are the primary effects of each hormone?

LEVEL 2 Reviewing Concepts

11. Drinking a solution hypotonic to the ECF causes the ECF to **(a)** increase in volume and become hypertonic to the ICF, **(b)** decrease in volume and become hypertonic to the ICF, **(c)** decrease in volume and become hypotonic to the ICF, **(d)** increase in volume and become hypotonic to the ICF.

See the blue Answers tab at the back of the book.

- **12.** The osmotic concentration of the ECF decreases if an individual gains water without a corresponding (a) gain of electrolytes, (b) loss of water, (c) fluid shift from the ECF to the ICF, (d) a, b, and c.
- **13.** When the pH of body fluids begins to *decrease*, free amino acids and proteins will **(a)** release a hydrogen from the carboxyl group, **(b)** release a hydrogen from the amino group, **(c)** release a hydrogen at the carboxyl group, **(d)** bind a hydrogen at the amino group.
- 14. In a protein buffer system, if the pH increases, (a) the protein acquires a hydrogen ion from carbonic acid, (b) hydrogen ions are buffered by hemoglobin molecules, (c) a hydrogen ion is released and a carboxylate ion is formed, (d) a chloride shift occurs.
- **15.** Differentiate among fluid balance, electrolyte balance, and acid-base balance, and explain why each is important to homeostasis.
- **16.** What are fluid shifts? What is their function, and what factors can cause them?
- 17. Why should a person with a fever drink plenty of fluids?
- **18.** Define and give an example of (a) a volatile acid, (b) a fixed acid, and (c) an organic acid. Which represents the greatest threat to acid–base balance? Why?
- **19.** What are the three major buffer systems in body fluids? How does each system work?
- 20. How do respiratory and renal mechanisms support the buffer systems?
- **21.** Differentiate between respiratory compensation and renal compensation.
- **22.** Distinguish between respiratory and metabolic disorders that disturb acid–base balance.
- **23.** What is the difference between metabolic acidosis and respiratory acidosis? What can cause these conditions?
- 24. The most recent advice from medical and nutritional experts is to monitor one's intake of salt so that it does not exceed the amount needed to maintain a constant ECF volume. What effect does excessive salt ingestion have on blood pressure?
- **25.** Exercise physiologists recommend that adequate amounts of fluid be ingested before, during, and after exercise. Why is fluid replacement during extensive sweating important?

LEVEL 3 Critical Thinking and Clinical Applications

- **26.** After falling into an abandoned stone quarry filled with water and nearly drowning, a young boy is rescued. In assessing his condition, rescuers find that his body fluids have high P_{CO_2} and lactate levels, and low P_{O_2} levels. Identify the underlying problem and recommend the necessary treatment to restore homeostatic conditions.
- 27. Dan has been lost in the desert for two days with very little water. As a result of this exposure, you would expect to observe which of the following? (a) increased ADH levels, (b) decreased blood osmolarity, (c) normal urine production, (d) increased blood volume, (e) cells enlarged with fluid.
- **28.** Mary, a nursing student, has been caring for burn patients. She notices that they consistently show elevated levels of potassium in their urine and wonders why. What would you tell her?
- **29.** While visiting a foreign country, Milly inadvertently drinks some water, even though she had been advised not to. She contracts an intestinal disease that causes severe diarrhea. How would you expect her condition to affect her blood pH, urine pH, and pattern of ventilation?

- **30.** Yuka is dehydrated, so her physician prescribes intravenous fluids. The attending nurse becomes distracted and erroneously gives Yuka a hypertonic glucose solution instead of normal saline. What effect will this mistake have on Yuka's plasma ADH levels and urine volume?
- **31.** Refer to the diagnostic flowchart in Spotlight Figure 27–18. Use information from the blood test results in the accompanying table to categorize the suspected acid–base disorders of the patients represented in the table.

Results	Patient 1	Patient 2	Patient 3	Patient 4
рН	7.5	7.2	7.0	7.7
P _{CO2} (mmHg)	32	45	60	50
Na [–] (mEq/L)	138	140	140	136
HCO ₃ ⁻ (mEq/L)	22	20	28	34
Cl [–] (mEq/L)	106	102	101	91
Anion gap* (mEq/L)	10	18	12	11

*Anion gap = Na^+ concentration – (HCO₃⁻ concentration + CI⁻ concentration).

CLINICAL CASE

When Treatment Makes You Worse

"Your problem is a simple but critical electrolyte—potassium," the doctor tells Marquis.

Marquis had been in a state of electrolyte balance, in which the rates of gain and loss for each electrolyte are equal every day, but he had high blood pressure before beginning treatment. The hydrochlorothiazide diuretic he is taking works by inhibiting reabsorption of Na⁺ and K⁺ in the distal convoluted tubules. Recall that "water follows salt." The increased excretion of Na⁺ and K⁺ causes increased excretion of water, which reduces blood volume and therefore decreases pressure on the arterial walls. Ninetyeight percent of the body's potassium is in the ICF, leaving only a small amount in the ECF that is critically controlled. The fecal loss of K⁺ is usually negligible, but diarrhea causes significant K⁺ loss. Three days of diarrhea, on top of the new "potassium wasting" diuretic, have pushed Marquis into a state of hypokalemia. His blood K⁺ measures only 2.5 mEq/L (normal 3.5–5.0 mEq/L). Potassium is critical for a variety of cell functions, particularly in electrically active cells in the nervous system, skeletal muscle, and cardiac muscle. When blood K⁺ levels are low, cells cannot repolarize and are unable to fire repeatedly. This causes muscle weakness, aching, and cramping. In cardiac muscle, hypokalemia increases the resting membrane potential and

Wrap-Up

increases both the duration of the action potential and the duration of the refractory period, leading to cardiac arrhythmias.

- 1. How do you think Marquis's hypokalemia should be treated?
- 2. What is happening when Marquis complains of a sensation of a "frog jumping around" in his chest that is accompanied by dizziness?

See the blue Answers tab at the back of the book.

The Reproductive System

Learning Outcomes

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **28-1** List the basic structures of the human reproductive system, and summarize the functions of each.
- 28-2 Describe the structures of the male reproductive system and the roles played by the reproductive tract and accessory glands in producing spermatozoa; specify the composition of semen; and summarize the hormonal mechanisms that regulate male reproductive functions.
- 28-3 Describe the structures of the female reproductive system and the ovarian roles in oogenesis; explain the complete ovarian and uterine cycles; outline the histology, anatomy, and functions of the vagina; and summarize all aspects of the female reproductive cycle.
- **28-4** Discuss the physiology of sexual intercourse in males and females.
- **28-5** Describe the reproductive system changes that occur with aging.
- **28-6** Give examples of interactions between the reproductive system and each of the other organ systems.

SPOTLIGHTS

- Regulation of Male Reproduction p. 1067

- Breast Cancer p. 1083

CLINICAL CASE

A Post-Game Mystery

Dan and his high school football team have just beaten their archrivals in an exciting homecom-

ing game, and they are looking forward to celebrating their victory at tonight's dance. Dan heads to the locker room. While showering, he starts to feel pain in the left side of his scrotum. He cannot recall getting hit there during the game. He does not see any bruising or swelling. However, his left testicle appears to be higher than his right, and is so tender to touch and movement that he can barely get dressed. Dan leaves the locker room hunched over in pain and feeling nauseous.

The coach notices Dan's odd posture and watches him stop to vomit in a trash can. He catches up to Dan and asks him what's going on. "I'm feeling a little sick to my stomach," says Dan. "And this is embarrassing, but my left testicle is killing me. I don't remember getting hit there, but it is so painful I can't touch it or stand up straight."

"Dan, I don't think you'll make it to the homecoming dance tonight," says Coach. "You're going straight to the

emergency room." Why is Coach so concerned about Dan's condition? To find out, turn to the Clinical Case Wrap-Up on p. 1094.

An Introduction to the Reproductive System

Approximately 7.1 billion people currently live on the Earth. This is an astonishing number given that our reproductive system is the only system that is not essential to the life of an individual. Its activities do, however, affect other systems. In this chapter we discuss how the male and female reproductive organs produce and store specialized reproductive cells that combine to form new individuals. We also look at how various reproductive organs secrete hormones that play major roles in maintaining normal sexual function.

28-1 Basic reproductive system structures are gonads, ducts, accessory glands and organs, and external genitalia

Learning Outcome List the basic structures of the human reproductive system, and summarize the functions of each.

The human **reproductive system** ensures the continued existence of the human species—by producing, storing, nourishing, and transporting functional male and female reproductive cells. These cells are called **gametes** (GAM-ēts).

The reproductive system includes the following basic components:

- **Gonads** (GO-nadz; *gone*, seed, generation), or reproductive organs that produce gametes and hormones.
- Ducts that receive and transport the gametes.
- Accessory glands and organs that secrete fluids into the ducts of the reproductive system or into other excretory ducts.
- Perineal structures that are collectively known as the external genitalia (jen-i-TĀ-lē-uh).

In both males and females, the ducts are connected to chambers and passageways that open to the outside. The structures involved make up the *reproductive tract*. The male and female reproductive systems are functionally quite different, however.

In adult males, the **testes** (TES-tēz; singular, *testis*), or *testicles*, are male gonads that secrete sex hormones called androgens. The main androgen is *testosterone*, which was introduced in Chapter 18. \bigcirc **p**. 641 The testes also produce the male gametes, called **spermatozoa** (sper-ma-tō-ZŌ-uh; singular, *spermatozoon*), or *sperm*. Males produce about one-half billion sperm each day. During *emission*, mature spermatozoa travel along a lengthy duct system, where they are mixed with the secretions of accessory glands. The mixture created is known as **semen** (SĒ-men). During *ejaculation*, semen is expelled from the body.

In adult females, the **ovaries**, or female gonads, release only one immature gamete, called an **oocyte**. Normally only one oocyte is released each month. This oocyte travels along one of two short *uterine tubes*, which end in the muscular organ called the *uterus* (Ū-ter-us). If a sperm reaches the oocyte and starts the process of *fertilization*, the oocyte matures into an **ovum** (plural, *ova*). A short passageway, the *vagina* (va-JĪ-nuh), connects the uterus with the exterior.

During *sexual intercourse*, ejaculation introduces semen into the vagina, and the spermatozoa then ascend the female reproductive tract. If fertilization takes place, the uterus will enclose and support a developing *embryo* as it grows into a *fetus* and prepares for birth.

Next we examine the anatomy of the male and female reproductive systems. We will consider the physiological and hormonal mechanisms that regulate reproductive function. Earlier chapters introduced the anatomical reference points used in the discussions that follow. You may find it helpful to review the figures on the pelvic girdle (Figure 8–7 and Figure 8–8, pp. 251, 252), perineal musculature (Figure 11–13, p. 356),

pelvic innervation (Figure 13–12, p. 446), and regional blood supply (Figures 21–24 and 21–28, pp. 762, 768).

CHECKPOINT

- 1. Define gamete.
- 2. List the basic structures of the reproductive system.
- 3. Define gonads.

- See the blue Answers tab at the back of the book.

28-2 Spermatogenesis occurs in the testes, and hormones from the hypothalamus, anterior lobe of the pituitary gland, and testes control male reproductive functions

Learning Outcome Describe the structures of the male reproductive system and the roles played by the reproductive tract and accessory glands in producing spermatozoa; specify the composition of semen; and summarize the hormonal mechanisms that regulate male reproductive functions.

Figure 28–1 shows the main structures of the male reproductive system. Starting from a testis, the spermatozoa travel within the *epididymis* (ep-i-DID-i-mus); the *ductus deferens* (DUK-tus DEF-e-renz; plural, *ductus deferentia*), also called the *vas deferens*; the *ejaculatory duct*; and the *urethra* before leaving the body. Accessory organs—the *seminal* (SEM-i-nal) *glands* (seminal vesicles), the *prostate* (PROS-tāt) *gland*, and the *bulbourethral* (bul-bō-ū-RĒ-thral) *glands*—secrete various fluids into the ejaculatory ducts and urethra. The external genitalia consist of the *scrotum* (SKRŌ-tum), which encloses the testes, and the *penis* (PĒ-nis), an erectile organ. The distal portion of the urethra passes through the penis.

The Testes

Each testis is about 5 cm (2 in.) long, 3 cm (1.2 in.) wide, and 2.5 cm (1 in.) thick. Each weighs 10–15 g (0.35–0.53 oz). The testes hang within the **scrotum**, a fleshy pouch suspended inferior to the perineum. The scrotum is anterior to the anus, and posterior to the base of the penis (Figure 28–1). ATLAS: Embryology Summary 21: The Development of the Reproductive System

Descent of the Testes

During fetal development, the testes form inside the body cavity adjacent to the kidneys. A bundle of connective tissue fibers—called the **gubernaculum testis** (goo-bur-NAK-ū-lum TES-tis)—extends from each testis to the posterior wall of a small anterior and inferior pocket of the peritoneum (Figure 28–2a).

Figure 28–1 The Male Reproductive System. A sagittal section of the male reproductive structures. ATLAS: Plate 64

the formation of the spermatic cords.

As the fetus grows, the gubernacula do not get any longer, so they lock the testes in position. As a result, the position of each testis changes as the body enlarges. The testis gradually moves inferiorly and anteriorly toward the anterior abdominal wall. During the seventh developmental month, fetal growth continues rapidly, and circulating hormones stimulate a contraction of the gubernaculum testis. During this time, each testis moves through the abdominal musculature, along with small pockets of the peritoneal cavity. This process is called the **descent of the testes** into the scrotum (Figure 28–2).

In *cryptorchidism* (krip-TOR-ki-dizm; *crypto*, hidden + *or-chis*, testis), one or both of the testes have not descended into the scrotum by the time of birth. Typically, the cryptorchid (ab-dominal) testes are lodged in the abdominal cavity or within the inguinal canal. Cryptorchidism occurs in about 3 percent

of full-term deliveries and in about 30 percent of premature births. In most instances, normal descent takes place a few weeks later.

The condition can be surgically corrected if it persists. Corrective measures should be taken before *puberty* (sexual maturation), because a cryptorchid testis will not produce spermatozoa. If both testes are cryptorchid, the male will be *sterile* (*infertile*) and unable to father children. If the testes cannot be moved into the scrotum, they will usually be removed. This surgical procedure to remove the testes is called an *orchiectomy* (or-kē-EK-tō-mē). About 10 percent of males with uncorrected cryptorchid testes eventually develop testicular cancer.

As each testis moves through the body wall, the ductus deferens and the testicular blood vessels, nerves, and lymphatic vessels accompany it. Together, these structures form the body of the spermatic cord, which we discuss next.

The Spermatic Cords

The **spermatic cords** are paired structures extending between the abdominopelvic cavity and the testes (Figure 28–3). Each spermatic cord begins at the entrance to the *inguinal canal* (a passageway through the abdominal musculature). After passing through the inguinal canal, the spermatic cord descends into the scrotum.

Each spermatic cord consists of layers of fascia and muscle enclosing the ductus deferents and the blood vessels, nerves, and lymphatic vessels that supply the testes. The blood vessels include the *deferential artery*, a *testicular artery*, and the **pampiniform** (pam-PIN-i-form; *pampinus*, tendril + *forma*, form) **plexus** of a testicular vein. Branches of the *genitofemoral nerve* from the lumbar plexus provide innervation.

The inguinal canals form during development as the testes descend into the scrotum. At that time, these canals link the scrotal cavities with the peritoneal cavity. In normal adult males, the inguinal canals are closed, but the presence of the spermatic cords creates weak points in the abdominal wall that remain throughout life. As a result, *inguinal hernias* protrusions of visceral tissues or organs into the inguinal canal—are fairly common in males. The inguinal canals in females are very small, containing only the *ilioinguinal nerves* and the *round ligaments* of the uterus. The abdominal wall is nearly intact, so inguinal hernias in women are very rare.

The Scrotum and the Position of the Testes

The scrotum is divided internally into two chambers. A raised thickening in the scrotal surface known as the **raphe** (RĀ-fē) divides it in two (Figure 28–3). Each testis lies in a separate chamber, or **scrotal cavity**. Because the scrotal cavities are separated by a partition, infection or inflammation of one testis does not normally spread to the other.

A narrow space separates the inner surface of the scrotum from the outer surface of the testis. The **tunica vaginalis** (TU-ni-ka vaj-i-NAL-is), a serous membrane, lines the scrotal cavity and reduces friction between the opposing parietal (scrotal) and visceral (testicular) surfaces. The tunica vaginalis is an isolated portion of the peritoneum that lost its connection with the peritoneal cavity after the testes descended, when the inguinal canal closed.

The scrotum consists of a thin layer of skin and the underlying superficial fascia. The dermis contains a layer of smooth muscle, the **dartos** (DAR-tōs) **muscle**. Resting muscle tone in the dartos muscle elevates the testes and causes the characteristic wrinkling of the scrotal surface.

A layer of skeletal muscle, the **cremaster** (krē-MAS-ter) **muscle**, lies deep to the dermis. When the cremaster muscle contracts during sexual arousal or in response to decreased temperature, it tenses the scrotum and pulls the testes closer to the body. The cremasteric reflex can be initiated by stroking the skin on the upper thigh, causing the scrotum to move the testes closer to the body.

For spermatozoa to develop normally in the testes, the temperature must be about 1.1°C (2°F) lower than elsewhere in the body. The cremaster and dartos muscles relax or contract to move the testes away from or toward the body as needed to maintain acceptable testicular temperatures. When air or body temperature rises, these muscles relax and the testes move away from the body. When the scrotum cools suddenly, as happens when jumping into a cold swimming pool, these muscles contract to pull the testes closer to the body and keep testicular temperatures from falling.

Structure of the Testes

Deep to the tunica vaginalis covering the testis is the **tunica albuginea** (al-bū-JIN- \bar{e} -uh), a dense layer of connective tissue rich in collagen fibers (**Figure 28–4a**). These fibers are continuous with those surrounding the adjacent epididymis and extend into the testis. There they form fibrous partitions, or *septa*, that converge toward the region nearest the entrance to the epididymis. The connective tissues in this region support the blood vessels and lymphatic vessels that supply and drain the testis, and the *efferent ductules*, which transport spermatozoa to the epididymis.

Histology of the Testes

The septa subdivide the testis into a series of **lobules** (Figure 28–4a). Distributed among the lobules are approximately 800 slender, tightly coiled **seminiferous** (sem-i-NIFer-us) **tubules** (Figures 28–4 and 28–5). Each tubule averages about 80 cm (32 in.) in length. A typical testis contains nearly one-half mile of seminiferous tubules. Sperm production takes place within these tubules.

Each lobule contains several seminiferous tubules that merge into **straight tubules** that enter the mediastinum of the testis. Straight tubules are extensively interconnected, forming **Figure 28–3** The Male Reproductive System in Anterior View. In the anatomical position, the penis is erect, and the dorsal surface is closest to the navel. In a flaccid state, the dorsal surface is facing anteriorly.

a maze of passageways known as the **rete** (RĒ-tē; rete, a net) **testis** (Figure 28–4). Fifteen to 20 large **efferent ductules** connect the rete testis to the epididymis.

Because the seminiferous tubules are tightly coiled, most tissue slides show them in transverse section (Figure 28–5a). A delicate connective tissue capsule surrounds each tubule, and areolar tissue fills the spaces between the tubules (Figure 28–5b). Within those spaces are numerous blood vessels and large interstitial cells (*Leydig cells*). Interstitial cells produce *androgens* (androsterone and testosterone), the dominant sex hormones in males. *Testosterone* is the most important androgen.

Spermatogenesis (sper-ma-tō-JEN-e-sis) is the process of spermatozoa formation. It begins at the outermost layer of cells in the seminiferous tubules and proceeds toward the lumen (**Figure 28–5c,d**). At each step in this process, the daughter cells move closer to the lumen.

First, stem cells called **spermatogonia** (sper-ma-tō-GOnē-uh) divide by mitosis to produce two daughter cells. One daughter cell remains at that location as a spermatogonium while the other differentiates into a primary spermatocyte. **Primary spermatocytes** (sper-MA-tō-sīts) are the cells that begin *meiosis*, a specialized form of cell division involved only in the production of gametes (spermatozoa in males, oocytes in females). Primary spermatocytes give rise to **secondary spermatocytes** that divide and differentiate into **spermatids** (SPERma-tidz)—immature gametes that subsequently differentiate into spermatozoa. The spermatozoa lose contact with the wall of the seminiferous tubule and enter the fluid in the lumen.

Each seminiferous tubule contains spermatogonia, spermatocytes at various stages of meiosis, spermatids, spermatozoa, and large **nurse cells.** Nurse cells are also known as *sustentacular* (sus-ten-TAK-ū-lar) cells or *Sertoli cells*. They provide a microenvironment that supports spermatogenesis (Figure 28–5b,d).

Spermatogenesis

Spermatogenesis begins at puberty and continues until relatively late in life (past age 70). It is a continuous process. All stages of meiosis are seen within the seminiferous tubules.

The complete process of spermatogenesis takes about 64 days. It involves three integrated processes:

- Mitosis. Spermatogonia are stem cells that undergo cell divisions throughout adult life. (You can review the description of mitosis and cell division in Chapter 3. > pp. 104-105) One daughter cell from each division remains in place while the other is pushed toward the lumen (space) of the seminiferous tubule. The displaced cells differentiate into primary spermatocytes, which prepare to begin meiosis.
- Meiosis. Meiosis (mī-Ō-sis) is a special form of cell division involved in gamete production. In humans, gametes

contain 23 chromosomes, half the amount found in somatic cells. As a result, the fusion of the nuclei of a male gamete and a female gamete produces a cell that has the normal number of chromosomes (46), rather than twice that number. In the seminiferous tubules, meiotic divisions that begin with primary spermatocytes produce spermatids, the undifferentiated male gametes.

3. *Spermiogenesis.* Spermatids are small, unspecialized cells. In *spermiogenesis,* spermatids differentiate into physically mature spermatozoa, which are among the most highly specialized cells in the body. Spermiogenesis involves major changes in a spermatid's internal and external structures.

Mitosis and Meiosis

Mitosis and meiosis differ significantly in terms of the events that take place in the nucleus. Recall from Chapter 3 that human somatic cells contain 23 pairs of chromosomes, or 46 chromosomes altogether. Each pair consists of one chromosome provided by the father, and another provided by the mother, at the time of fertilization.

Mitosis is part of the process of somatic cell division, producing two daughter cells each containing identical numbers and pairs of chromosomes. The pattern is illustrated in Figure 28–6a. Because daughter cells contain both members of each chromosome pair (for a total of 46 chromosomes), they are called **diploid** (DIP-loyd; *diplo*, double) (2n) cells.

In contrast, meiosis follows the pattern in Figure 28–6b. It involves two cycles of cell division (*meiosis I* and *meiosis II*) and produces four cells, each containing 23 *individual* chromosomes (n=23). These cells are called **haploid** (HAP-loyd; *haplo*, single) (n) cells and contain only one member of each pair of chromosomes. The events in the nucleus shown in Figure 28–6b are the same for the formation of spermatozoa or oocytes.

As a cell prepares to begin meiosis, DNA replication occurs within the nucleus just as it does in a cell preparing for mitosis. The duplicated chromosomes condense and become visible with a light microscope. As in mitosis, each chromosome now consists of two duplicate *chromatids*.

At this point, the close similarities between meiosis and mitosis end. In meiosis, the corresponding maternal (inherited from the mother) and paternal (inherited from the father) chromosomes now come together in an event known as **synapsis** (si-NAP-sis). Synapsis involves 23 pairs of chromosomes, and each member of each pair consists of two chromatids. A matched set of four chromatids is called a **tetrad** (TET-rad; *tetras*, four) (Figure 28–6b). Some genetic material can be exchanged between the chromatids of a chromosome pair at this stage of meiosis. Such an exchange, called *crossing over*, increases genetic variation among offspring. We discuss genetics in Chapter 29.

Figure 28–5 The Seminiferous Tubules.

support the developing spermatocytes and spermatids.

d Stages in spermatogenesis in the wall of a seminiferous tubule.

28

Meiosis includes two division cycles, referred to as **meiosis I** and **meiosis II**. We identify the stages within each cycle with I or II, for example as prophase I, metaphase II, and so on. The nuclear envelope disappears at the end of prophase I. As metaphase I begins, the tetrads line up along the metaphase plate. As anaphase I begins, the tetrads break up—the maternal and paternal chromosomes separate. This is a major difference between mitosis and meiosis: In mitosis, each daughter cell receives a copy of every chromosome, maternal and paternal, but in meiosis I, each daughter cell receives two copies of *either* the maternal chromosome *or* the paternal chromosome. (Compare the two parts of Figure 28–6.)

As anaphase I proceeds, the maternal and paternal components are randomly and independently distributed. That is, as each tetrad splits, we cannot predict which daughter cell will receive copies of the maternal chromosome, and which will receive copies of the paternal chromosome. As a result, telophase I ends with the formation of two daughter cells containing unique combinations of maternal and paternal chromosomes. Both cells contain 23 chromosomes.

The first meiotic division is called a **reductional division** because it reduces the number of chromosomes from 46 to 23. Each of these chromosomes still consists of two duplicate chromatids. The duplicates will separate during meiosis II.

The interphase between meiosis I and meiosis II is very brief. No DNA is replicated during that period. Each cell then proceeds through prophase II, metaphase II, and anaphase II. During anaphase II, the duplicate chromatids separate. Telophase II yields *four haploid cells*, each containing 23 chromosomes. Because the number of chromosomes has not changed, meiosis II is an **equational division**.

The chromosomes are evenly distributed among the four cells, but the cytoplasm may not be. In males, meiosis produces four immature gametes that are identical in size. Each will develop into a functional sperm. In females, meiosis produces one relatively huge oocyte and three tiny, nonfunctional polar bodies. (If fertilization takes place, the oocyte completes meiosis II, yielding an ovum.) We examine the details of spermatogenesis here (Figure 28–7). We will consider oogenesis in a later section.

Spermiogenesis

The four spermatids initially remain interconnected by bridges of cytoplasm because cytokinesis (cytoplasmic division) is not completed in meiosis I or meiosis II. These connections assist in transferring nutrients and hormones between the cells, helping ensure that the cells develop in synchrony. The bridges are not broken until the last stages of physical maturation.

In **spermiogenesis**, the last step of spermatogenesis, each spermatid matures into a single spermatozoon, or *sperm* (Figure 28–7). Developing spermatocytes undergoing meiosis, and spermatids undergoing spermiogenesis, are not free in Figure 28–7 Spermatogenesis. The events depicted occur in the seminiferous tubules. The fates of three representative chromosome pairs are shown; for clarity, maternal and paternal chromatids are not identified.

the seminiferous tubules. Instead, they are surrounded by the cytoplasm of adjacent nurse cells. As spermiogenesis proceeds, the spermatids gradually develop into mature spermatozoa. At spermiation, a spermatozoon loses its attachment to the nurse cell and enters the lumen of the seminiferous tubule.

Nurse Cells. Nurse cells play a key role in spermatogenesis. These cells have six important functions that directly or indirectly affect mitosis, meiosis, and spermiogenesis within the seminiferous tubules:

1. Maintenance of the Blood-Testis Barrier. A blood-testis **barrier** isolates the seminiferous tubules from the general circulation. This barrier is comparable in function to the blood-brain barrier. **D** p. 469 Nurse cells are joined by

tight junctions. They form a layer that divides the seminiferous tubule into an outer basal compartment and an inner luminal compartment. The basal compartment contains the spermatogonia. Meiosis and spermiogenesis occur in the *luminal compartment* (Figure 28–5d). Transport across the nurse cells is tightly regulated, so conditions in the luminal compartment remain very stable.

The nurse cells produce the fluid in the lumen of 28a seminiferous tubule. They also regulate the fluid's composition. This luminal fluid is very different from the surrounding interstitial fluid. It is high in androgens, estrogens, potassium, and amino acids. The blood-testis barrier is essential to preserving the differences between the luminal fluid and the interstitial fluid.

In addition, this barrier prevents immune system cells from detecting and attacking the developing spermatozoa. The plasma membranes of spermatozoa contain spermspecific antigens not found in somatic cell membranes, so they might be identified as "foreign."

- 2. Support of Mitosis and Meiosis. Circulating follicle-stimulating hormone (FSH) and testosterone stimulate nurse cells. These stimulated nurse cells then promote the division of spermatogonia and the meiotic divisions of spermatocytes.
- **3.** *Support of Spermiogenesis.* Spermiogenesis requires the presence of nurse cells. These cells surround and enfold the spermatids, providing nutrients and chemical stimuli that promote their development. Nurse cells also phagocytize cytoplasm that is shed by spermatids as they develop into spermatozoa.
- 4. Secretion of Inhibin. Nurse cells secrete the peptide hormone inhibin (in-HIB-in) in response to factors released by developing spermatozoa. Inhibin depresses the pituitary production of FSH, and perhaps the hypothalamic secretion of gonadotropin-releasing hormone (GnRH). The faster the rate of sperm production, the more inhibin is secreted. By regulating FSH and GnRH secretion, nurse cells provide feedback control of spermatogenesis.
- 5. Secretion of Androgen-Binding Protein. Androgen-binding protein (ABP) binds androgens (primarily testosterone) in the

luminal fluid of the seminiferous tubules. This protein is thought to be important in both elevating the concentration of androgens within the seminiferous tubules and stimulating spermiogenesis. FSH stimulates the production of ABP.

6. Secretion of Müllerian-Inhibiting Factor. In the developing testes, nurse cells secrete Müllerian-inhibiting factor (MIF). This hormone causes regression of the fetal Müllerian (paramesonephric) ducts, passageways that form the uterine tubes and the uterus in females. In males, inadequate MIF production during fetal development causes retention of these ducts and the failure of the testes to descend into the scrotum.

The Anatomy of a Spermatozoon

Each spermatozoon has four distinct regions: head, neck, middle piece, and tail (Figure 28–8). The **head** is a flattened ellipse containing a nucleus with densely packed chromosomes. At the tip of the head is the **acrosome** (ak-rō-SŌM), or *acrosomal cap*, a membranous compartment containing enzymes essential to fertilization. During spermiogenesis, saccules of the spermatid's Golgi apparatus fuse and flatten into an *acrosomal vesicle*, which ultimately forms the acrosome.

A short **neck** attaches the head to the **middle piece**. The neck contains both centrioles of the original spermatid. The microtubules of the distal centriole are continuous with

Figure 28-8 Spermiogenesis and Spermatozoon Structure. ATLAS: Plate 60a

those of the middle piece and tail. Mitochondria in the middle piece are arranged in a spiral around the microtubules. Mitochondria provide the ATP required to move the tail.

The **tail** is the only flagellum in the human body. A *flagellum* is a whiplike organelle that moves a cell from one place to another. Cilia beat in a predictable, wavelike fashion, but the flagellum of a spermatozoon has a whiplike, corkscrew motion.

Unlike other, less specialized cells, a mature spermatozoon lacks an endoplasmic reticulum, a Golgi apparatus, lysosomes, peroxisomes, inclusions, and many other organelles. The loss of these organelles reduces the cell's size and mass. A sperm is essentially a mobile carrier for chromosomes, and extra weight would slow it down. Because a spermatozoon lacks glycogen or other energy reserves, it must absorb nutrients (primarily fructose) from the surrounding fluid.

The Male Reproductive Tract

The testes produce physically mature spermatozoa that are not yet capable of successfully fertilizing an oocyte. The other portions of the male reproductive system are responsible for the functional maturation, nourishment, storage, and transport of spermatozoa.

The Epididymis

Late in their development, spermatozoa detach from the nurse cells and lie within the lumen of the seminiferous tubule. They have most of the physical characteristics of mature spermatozoa, but are functionally immature and incapable of coordinated locomotion or fertilization. Fluid currents, created by cilia lining the efferent ductules, transport these immobile gametes into the epididymis (Figure 28–4a). The **epididymis** (ep-i-DID-i-mis; *epi*, on + *didymos*, twin) is the start of the male reproductive tract. It is a coiled tube bound to the posterior border of each testis.

The epididymides (ep-i-DID-i-mi-dēz) can be felt through the skin of the scrotum. Each epididymis is almost 7 m (23 ft) long, but it is coiled and twisted so it takes up very little space. It has a head, a body, and a tail (**Figure 28–9a,c**). The superior **head** is the portion of the epididymis proximal to the testis. The head receives spermatozoa from the efferent ductules.

The **body** begins distal to the last efferent ductule and extends inferiorly along the posterior margin of the testis. Near the inferior border of the testis, the number of coils decreases, marking the start of the **tail**. The tail re-curves and ascends to its connection with the ductus deferens. Spermatozoa are stored primarily within the tail of the epididymis.

Figure 28–9 The Epididymis. ATLAS: Plate 60a

The epididymis has three functions:

- It monitors and adjusts the composition of the fluid produced by the seminiferous tubules. The pseudostratified columnar epithelial lining of the epididymis has distinctive stereocilia (Figure 28–9b). These stereocilia increase the surface area available for absorption from, and secretion into, the fluid in the tubule.
- 2. It acts as a recycling center for damaged spermatozoa. Cellular debris and damaged spermatozoa are absorbed in the epididymis. The products of enzymatic breakdown are released into the surrounding interstitial fluids for pickup by the epididymal blood vessels.
- 3. It stores and protects spermatozoa and facilitates their functional *maturation*. A spermatozoon passes through the epididymis and completes its functional maturation. Over this time, spermatozoa exist in a sheltered environment that is precisely regulated by the surrounding epithelial cells.

Spermatozoa leaving the epididymis are mature but immobile. To become *motile* (actively swimming) and fully functional, they must undergo a process called **capacitation**. Capacitation normally takes place in two steps: (1) Spermatozoa become motile when they are mixed with secretions of the seminal glands, and (2) they become capable of successful fertilization when exposed to conditions in the female reproductive tract. The epididymis secretes a substance (as yet unidentified) that prevents premature capacitation.

Transport along the epididymis involves a combination of fluid movement and peristaltic contractions of smooth muscle in the epididymis. After passing along the tail of the epididymis, the spermatozoa enter the ductus deferens.

The Ductus Deferens

Each **ductus deferens**, or *vas deferens*, is 40–45 cm (16–18 in.) long. It begins at the tail of the epididymis (Figure 28–9a,c). As part of the spermatic cord, it ascends through the inguinal canal (Figure 28–3). Inside the abdominal cavity, the ductus deferens passes posteriorly, curving inferiorly along the lateral surface of the urinary bladder toward the superior and posterior margin of the prostate gland (Figure 28–1). Just before the ductus deferens reaches the prostate gland and seminal glands, its lumen enlarges. This expanded portion is known as the **ampulla** (am-PUL-luh) of the ductus deferens (Figure 28–10a).

The wall of the ductus deferens contains a thick layer of smooth muscle (Figure 28–10b). Peristaltic contractions in this layer propel spermatozoa and fluid along the duct, which is lined by a pseudostratified ciliated columnar epithelium. In addition to transporting spermatozoa, the ductus deferens can store spermatozoa for several months. During this time, the spermatozoa remain in a temporary state of inactivity with low metabolic rates.

The junction of the ampulla with the duct of the seminal gland marks the start of the **ejaculatory duct**. This short passageway is 2 cm, or less than 1 inch. It penetrates the muscular wall of the prostate gland and empties into the urethra (Figures 28–1 and 28–10a).

The Urethra

In males, the **urethra** is a passageway that extends 18–20 cm (7–8 in.) from the urinary bladder to the tip of the penis (Figure 28–1). It is divided into *prostatic, membranous,* and *spongy* regions. The male urethra is used by both the urinary and reproductive systems.

The Accessory Glands

The fluids secreted by the seminiferous tubules and the epididymis account for only about 5 percent of the volume of semen. The fluid component of semen is a mixture of secretions—each with distinctive biochemical characteristics—from many glands. Important glands include the *seminal glands*, the *prostate gland*, and the *bulbourethral glands*. All of these occur only in males.

Among the major functions of these glands are (1) activating spermatozoa; (2) providing the nutrients spermatozoa need for motility; (3) propelling spermatozoa and fluids along the reproductive tract, mainly by peristaltic contractions; and (4) producing buffers that counteract the acidity of the urethral and vaginal environments.

The Seminal Glands (Seminal Vesicles)

The ductus deferens on each side ends at the junction between the ampulla and the duct that drains the seminal gland (Figure 28–10a). The **seminal glands**, also called the **seminal vesicles**, are tubular glands embedded in connective tissue on either side of the midline, sandwiched between the posterior wall of the urinary bladder and the rectum. Each seminal gland is about 15 cm (6 in.). The body of the gland has many short side branches. The entire assemblage is coiled and folded into a compact, tapered mass roughly 5 cm \times 2.5 cm (2 in. \times 1 in.).

Seminal glands are very active secretory glands with an epithelial lining that contains extensive folds (Figure 28–10c). The seminal glands secrete about 60 percent of the volume of semen. The glandular fluid generally has the same osmotic concentration as that of blood plasma, but the compositions of the two fluids are quite different. In particular, the secretion of the seminal glands contains (1) higher concentrations of fructose, which is easily metabolized by spermatozoa; (2) prostaglandins, which can stimulate smooth muscle contractions along the male and female reproductive tracts; and (3) fibrinogen, which after ejaculation forms a temporary semen clot within the vagina. The secretions of the seminal glands are slightly alkaline, helping to neutralize acids in the

secretions of the prostate gland and within the vagina. When mixed with the secretions of the seminal glands, spermatozoa undergo the first step in capacitation and begin beating their flagella, becoming highly motile.

The secretions of the seminal glands are discharged into the ejaculatory duct at *emission*, when peristaltic contractions are under way in the ductus deferens, seminal glands, and prostate gland. These contractions are under the control of the sympathetic nervous system.

The Prostate Gland

The **prostate gland** is a small, muscular, rounded organ about 4 cm (1.6 in.) in diameter. The prostate gland encircles the proximal portion of the urethra as it leaves the urinary bladder (Figure 28–10a). The glandular tissue of the prostate consists of a cluster of 30–50 compound tubuloalveolar glands (Figure 28–10d). \supset p. 125 These glands are surrounded by and wrapped in a thick blanket of smooth muscle fibers.

The prostate gland produces **prostatic fluid**, a slightly acidic solution that makes up 20–30 percent of the volume of semen. In addition to several other compounds, prostatic secretions contain **seminalplasmin** (sem-i-nal-PLAZ-min), a protein with antibiotic properties that may help prevent urinary tract infections in males. These secretions are ejected into the prostatic urethra by peristaltic contractions of the muscular prostate wall.

Prostatic inflammation, or **prostatitis** (pros-ta-TĪ-tis), can occur in males at any age, but it most commonly afflicts older men. Prostatitis can result from bacterial infections but also occurs in the apparent absence of pathogens. Signs and symptoms can resemble those of prostate cancer. Individuals with prostatitis may complain of pain in the lower back, perineum, or rectum. In some cases, the symptoms are accompanied by painful urination and the discharge of mucus from the external urethral orifice. Antibiotic therapy is effective in treating most cases caused by bacterial infection.

The Bulbourethral Glands

The paired **bulbourethral glands**, or *Cowper's glands*, are compound tubular mucous glands located at the base of the penis (Figures 28–10a and 28–11a). They are covered by the fascia of the urogenital diaphragm. These glands are round, with diameters nearly 10 mm (less than 0.5 in.). The duct of each gland travels alongside the penile urethra for 3–4 cm (1.2–1.6 in.) before emptying into the urethral lumen. The bulbourethral glands secrete thick, alkaline mucus (Figure 28–10e). The secretion helps neutralize any urinary acids that may remain in the urethra, and it lubricates the *glans penis*, or tip of the penis.

Semen

A typical ejaculation releases 2–5 mL of semen. An abnormally low volume may indicate problems with the prostate gland or

seminal glands. When sampled for analysis, semen is collected after a 36-hour period of sexual abstinence. The volume of fluid produced by an ejaculation, called the **ejaculate**, typically contains the following:

- *Spermatozoa.* The normal **sperm count** ranges from 20 million to 100 million spermatozoa per milliliter of semen. Most individuals with lower sperm counts are infertile, because too few spermatozoa survive the ascent of the female reproductive tract to perform fertilization. A low sperm count may reflect inflammation of the epididymis, ductus deferens, or prostate gland. In a fertile male, at least 60 percent of the spermatozoa in the sample are normal in appearance. Common abnormalities are malformed heads and "twin" spermatozoa that did not separate at the time of spermiation. Normal sperm will be actively swimming.
- *Seminal Fluid.* **Seminal fluid**, the fluid component of semen, is a mixture of glandular secretions with a distinct ionic and nutrient composition. A typical sample of seminal fluid contains the combined secretions of the seminal glands (60 percent), the prostate gland (30 percent), the nurse cells and epididymis (5 percent), and the bulboure-thral glands (less than 5 percent).
- *Enzymes*. Several important enzymes are in seminal fluid, including (1) a protease that may help dissolve mucus in the vagina; (2) seminalplasmin, a prostatic enzyme that kills a variety of bacteria, including *Escherichia coli*; (3) a prostatic enzyme that coagulates the semen within a few minutes after ejaculation by converting fibrinogen to fibrin; and (4) *fibrinolysin*, which liquefies the clotted semen after 15–30 minutes.

A complete chemical analysis of semen appears in the Appendix.

The External Genitalia

The male external genitalia consist of the scrotum and penis. We have already described the structure of the scrotum. The **penis** is a tubular organ containing the distal portion of the urethra (Figure 28–11a). It conducts urine to the exterior and introduces semen into the female's vagina during sexual intercourse.

The penis has three main regions: the root, the body, and the glans penis (Figure 28–11c). The **root** is the fixed portion that attaches the penis to the body wall. This connection occurs within the urogenital triangle immediately inferior to the pubic symphysis. The **body (shaft)** of the penis is the tubular, movable portion of the organ. The **glans penis** is the expanded distal end that surrounds the external urethral orifice. The *neck* is the narrow portion of the penis between the shaft and the glans penis.

The skin overlying the penis resembles that of the scrotum. The dermis contains a layer of smooth muscle that is a continuation of the dartos muscle of the scrotum. The underlying

Corpus spongiosum

Corpora cavernosa

Scrotum

Figure 28–11 The Penis. ATLAS: Plate 60b

areolar tissue allows the thin skin to move without distorting underlying structures. The subcutaneous layer also contains superficial arteries, veins, and lymphatic vessels.

A fold of skin called the **prepuce** (PRE-poos), or *foreskin*, surrounds the tip of the penis. The prepuce attaches to the relatively narrow neck of the penis and continues over the glans penis. Preputial (prē-PŪ-shē-al) glands in the skin of the neck and the inner surface of the prepuce secrete a waxy material known as **smegma** (SMEG-ma). Unfortunately, smegma can be an excellent nutrient source for bacteria. Mild inflammation and infections in this area are common, especially if the area is not washed thoroughly and frequently. One way to avoid such problems is **circumcision** (ser-kum-SIZH-un), the surgical removal of the prepuce. In Western societies (especially the United States), this procedure is generally performed shortly after birth. Circumcision lowers the risks of developing urinary tract infections, HIV infection, and penile cancer. Because it is a surgical procedure with risk of bleeding, infection, and other complications, the practice remains controversial.

Deep to the areolar tissue, a dense network of elastic fibers encircles the internal structures of the penis. Most of the body of the penis consists of three cylindrical columns of **erectile tissue** (Figure 28–11b). Erectile tissue consists of a three-dimensional maze of vascular channels incompletely separated by partitions of elastic connective tissue and smooth muscle fibers. In the resting state, the arterial branches are constricted and the muscular partitions are tense. This combination restricts blood flow into the erectile tissue. During **erection** the penis stiffens and elevates to an upright position, but the flaccid (nonerect) penis hangs inferior to the pubic symphysis and anterior to the scrotum.

 An anterior and lateral view of the penis, showing positions of the erectile tissues

How does erection of the penis occur? The parasympathetic innervation of the penile arteries involves neurons that release nitric oxide at their axon terminals. The smooth muscles in the arterial walls relax when nitric oxide is released. At that

Neck of penis

Glans penis

External

urethral orifice

time, the vessels dilate, blood flow increases, and the vascular channels become engorged with blood.

The anterior surface of the flaccid penis covers two cylindrical masses of erectile tissue: the **corpora cavernosa** (KOR-poruh ka-ver-NŌ-suh; singular, *corpus cavernosum*). The two are separated by a thin septum and encircled by a dense collagenous sheath (**Figure 28–11b**). The corpora cavernosa diverge at their bases, forming the **crura** (*crura*, legs; singular, *crus*) of the penis (**Figure 28–11a**). Each crus is bound to the ramus of the ischium and pubis by tough connective tissue ligaments. The corpora cavernosa extend along the length of the penis as far as its neck. The erectile tissue within each corpus cavernosum surrounds a central artery, or deep artery of the penis (**Figure 28–11b**).

The relatively slender **corpus spongiosum** (spon-jē-Ōsum) surrounds the penile urethra (Figure 28–11a,b). This erectile body extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans penis. The sheath surrounding the corpus spongiosum contains more elastic fibers than does that of the corpora cavernosa, and the erectile tissue contains a pair of small arteries.

Hormones and Male Reproductive Function

The hormonal interactions that regulate male reproductive function are diagrammed in **Spotlight Figure 28–12**. We introduced major reproductive hormones in Chapter 18. **Dp. 641** The anterior lobe of the pituitary gland releases *folliclestimulating hormone* **(FSH)** and *luteinizing hormone* **(LH)**. The pituitary releases these hormones in response to *gonadotropinreleasing hormone* **(GnRH)**. This peptide is synthesized in the hypothalamus and carried to the anterior lobe by the hypophyseal portal system.

The hormone GnRH is secreted in pulses rather than continuously. In adult males, small pulses occur at 60- to 90-minute intervals. As levels of GnRH change, so do the rates of secretion of FSH and LH (and testosterone, which is released in response to LH). The GnRH pulse frequency in adult males remains relatively steady from hour to hour, day to day, and year to year, unlike the situation in women, as we will see later in the chapter. As a result, plasma levels of FSH, LH, and testosterone remain within a relatively narrow range until relatively late in a man's life.

Testosterone plays a major role in maintaining male sexual function (Spotlight Figure 28–12). Testosterone functions like other steroid hormones, circulating in the bloodstream while bound to one of two types of transport proteins. These proteins are (1) *gonadal steroid-binding globulin* (GBG), which carries about two-thirds of the circulating testosterone, and (2) the albumins, which bind the remaining one-third. Testosterone diffuses across the plasma membrane of target cells and binds to an intracellular receptor. The hormone–receptor complex then binds to the DNA in the nucleus.

In many target tissues, some of the arriving testosterone is converted to **dihydrotestosterone (DHT)**. A small amount

Clinical Note

Dehydroepiandrosterone (DHEA) *Dehydroepiandrosterone*, or **DHEA**, is the primary androgen secreted by the zona reticularis of the adrenal cortex. \bigcirc **p.** 634 As noted in Chapter 18, these androgens, which are secreted in small amounts, are converted to testosterone (or estrogens) by other tissues. The significance of this small adrenal androgen secretion in both sexes remains unclear, but DHEA is being promoted as a wonder drug for increasing vitality, strength, and muscle mass. The effects of long-term high doses of DHEA remain largely unknown. However, high levels of DHEA in women have been linked to an increased risk of ovarian cancer as well as to masculinization, due to the conversion of DHEA to testosterone. The IOC (International Olympic Committee), NCAA, MLB, and NFL have banned the use of DHEA.

of DHT diffuses back out of the cell and into the bloodstream, and DHT levels are usually about 10 percent of circulating testosterone levels. Dihydrotestosterone can also enter peripheral cells and bind to the same hormone receptors targeted by testosterone. In addition, some tissues (notably those of the external genitalia) respond to DHT rather than to testosterone. Other tissues (including the prostate gland) are more sensitive to DHT than to testosterone.

Testosterone production begins around the seventh week of fetal development and reaches a prenatal peak after six months. Over this period, the developing nurse cells secrete Müllerian-inhibiting factor, which leads to the regression of the Müllerian ducts. The early surge in testosterone levels stimulates the differentiation of the male duct system and accessory organs and affects CNS development.

The best-known CNS effects occur in the developing hypothalamus. There, testosterone apparently programs the hypothalamic centers that are involved with (1) GnRH production and the regulation of pituitary FSH and LH secretion, (2) sexual behaviors, and (3) sexual drive. As a result of this prenatal exposure to testosterone, the hypothalamic centers will respond appropriately when the individual becomes sexually mature. The factors responsible for regulating the fetal production of testosterone are not known.

Testosterone levels are low at birth. Until puberty, background testosterone levels are relatively low, but they are higher in males than in females. Testosterone secretion accelerates markedly at puberty, initiating sexual maturation and the appearance of secondary sex characteristics. In adult males, negative feedback controls the level of testosterone production. Above-normal testosterone levels inhibit the release of GnRH by the hypothalamus, causing a reduction in LH secretion and lowering testosterone levels (Spotlight Figure 28–12).

SPOTLIGHT Figure 28–12 Regulation of Male Reproduction

Male reproductive function is regulated by the complex interaction of hormones from the hypothalamus, anterior lobe of the pituitary gland, and the testes. Negative feedback systems keep testosterone levels within a relatively narrow range until late in life.

HYPOTHALAMUS

Clinical Note

Prostatic Hypertrophy and Prostate Cancer Enlargement of the prostate gland, or **benign prostatic hypertrophy**, typically occurs spontaneously in men over age 50. The increase in size happens as testosterone production by the interstitial cells decreases. For unknown reasons, small masses called prostatic concretions may form within the glands. At the same time, the interstitial cells begin releasing small quantities of estrogens into the bloodstream. The combination of lower testosterone levels and the presence of estrogens probably stimulates prostatic growth. In severe cases, prostatic swelling constricts and blocks the urethra and constricts the rectum. If not corrected, the urinary obstruction can cause permanent kidney damage. Partial surgical removal is the most effective treatment. In the procedure known as a TURP (transurethral prostatectomy) an instrument pushed along the urethra restores normal function by cutting away the swollen prostatic tissue. Most of the prostate gland remains in place, and no external scars result.

Prostate cancer, a malignancy of the prostate gland, is the second most common cancer and the second most common cause of cancer deaths in males. The American Cancer Society estimates that approximately 239,000 new prostate cancer cases in 2013 will result in about 30,000 deaths. Most patients are elderly. (The average age at diagnosis is 72.) For reasons that are poorly understood, prostate cancer rates for Asian American males are relatively low compared with those of either Caucasian Americans or African Americans. For all age and ethnic groups, the rates of prostate cancer are rising

The plasma of adult males also contains relatively small amounts of the estrogenic hormone estradiol (2 ng/dL versus 525 ng/dL of testosterone). Seventy percent of the estradiol is formed from circulating testosterone. Interstitial cells and nurse cells of the testes secrete the rest. An enzyme called aromatase converts testosterone to estradiol. For unknown reasons, estradiol production increases in older men.

CHECKPOINT

- 4. Name the male reproductive structures.
- 5. On a warm day, would the cremaster muscle be contracted or relaxed? Why?
- 6. What happens when the arteries within the penis dilate?
- 7. What effect would low FSH levels have on sperm production?
- 8. Trace the pathway that a sperm travels from the site of its production to outside the body.

See the blue Answers tab at the back of the book.

sharply. The reason for the increase is not known. Aggressive diagnosis and treatment of localized prostate cancer in elderly patients is controversial because many of these men have nonmetastatic tumors, and even if untreated are more likely to die of some other disease.

Prostate cancer normally originates in one of the secretory glands. As the cancer progresses, it produces a nodular lump or swelling on the surface of the prostate gland. Palpation of this gland through the rectal wall—a procedure known as a *digital rectal exam* (DRE)—is the easiest diagnostic screening procedure. *Transrectal prostatic ultrasound* (TRUS) is used to obtain more detailed information about the status of the prostate. Blood tests are also used for screening purposes. The most sensitive is a blood test for **prostate-specific antigen** (**PSA**). Elevated levels of this antigen, normally present in low concentrations, may indicate the presence of prostate cancer. Once prostrate cancer is detected, treatment decisions vary depending on how rapidly PSA levels are rising. Screening with periodic PSA tests is now being recommended for men over age 50.

If cancer is detected before it has spread to other organs, and the patient is elderly or has other serious health problems, "watchful waiting" is an option. In other cases, the usual treatment is localized radiation or surgical removal of the prostate gland. This operation, a **prostatectomy** (pros-ta-TEKtō-mē), can be effective in controlling the condition. Both surgery and radiation can have undesirable side effects, including urinary incontinence and loss of sexual function.

28–3 Oogenesis occurs in the ovaries, and hormones from the pituitary gland and gonads control female reproductive functions

Learning Outcome Describe the structures of the female reproductive system and the ovarian roles in oogenesis; explain the complete ovarian and uterine cycles; outline the histology, anatomy, and functions of the vagina; and summarize all aspects of the female reproductive cycle.

A woman's reproductive system produces sex hormones and functional gametes. It must also be able to protect and support a developing embryo and nourish a newborn infant. The main organs of the female reproductive system are the *ovaries*, the *uterine tubes*, the *uterus*, the *vagina*, and the components of the external genitalia (Figure 28–13). As in males, a variety of accessory glands release secretions into the female reproductive tract.

The ovaries, uterine tubes, and uterus are enclosed within an extensive mesentery known as the **broad ligament.** The uterine tubes run along the superior border of the broad

Figure 28–13 The Female Reproductive System. A sagittal section of the female reproductive structures. ATLAS: Plate 65

ligament and open into the pelvic cavity lateral to the ovaries. The **mesovarium** (mez-ō-VĀ-rē-um), a thickened fold of mesentery, supports and stabilizes the position of each ovary (**Figure 28–14a**). The broad ligament attaches to the sides and floor of the pelvic cavity, where it becomes continuous with the parietal peritoneum.

The broad ligament subdivides this part of the peritoneal cavity. The pocket formed between the posterior wall of the uterus and the anterior surface of the colon is the **rectouterine** (rek-tō-Ū-ter-in) **pouch** (Figure 28–13). The pocket formed between the uterus and the posterior wall of the bladder is the **vesicouterine** (ves-i-kō-Ū-ter-in) **pouch**. These subdivisions are easily seen in sagittal section.

Several other ligaments assist the broad ligament in supporting and stabilizing the uterus and associated reproductive organs. These ligaments lie within the mesentery sheet of the broad ligament and are connected to the ovaries or uterus. The broad ligament limits side-to-side movement and rotation, and the other ligaments (described in our discussion of the ovaries and uterus) prevent superior–inferior movement.

The Ovaries

The paired ovaries are small, lumpy, almond-shaped organs near the lateral walls of the pelvic cavity (Figure 28–14). The ovaries perform three main functions. They (1) produce immature female gametes, or oocytes; (2) secrete female sex hormones, including estrogens and progesterone; and (3) secrete inhibin, involved in the feedback control of pituitary FSH production.

Each ovary is stabilized by the mesovarium and by a pair of supporting ligaments: the ovarian ligament and the suspensory (infundibulopelvic) ligament (Figure 28–14a). The **ovarian ligament** extends from the uterus, near the attachment of the uterine tube, to the medial surface of the ovary. The **suspensory ligament** extends from the lateral surface of the ovary

past the open end of the uterine tube to the pelvic wall. The suspensory ligament contains the major blood vessels of the ovary: the **ovarian artery** and **ovarian vein**. These vessels are connected to the ovary at the **ovarian hilum**, where the ovary attaches to the mesovarium (Figure 28–14b).

A typical ovary is about 5 cm long, 2.5 cm wide, and 8 mm thick (2 in. \times 1 in. \times 0.33 in.). It weighs 6–8 g (about 0.25 oz). An ovary is pink or yellowish and has a nodular consistency. The visceral peritoneum, or *germinal epithelium*, covers the surface of each ovary and consists of a layer of columnar epithelial cells that overlies a dense connective tissue layer called the **tunica albuginea** (Figure 28–14b). We divide the interior tissues, or **stroma**, of the ovary into a superficial *cortex* and a deeper *medulla*. Gametes are produced in the cortex.

Oogenesis

Ovum production, or **oogenesis** (ō-ō-JEN-e-sis; *oon*, egg), begins before a woman's birth, accelerates at puberty, and ends at *menopause.* Between puberty and menopause, oogenesis occurs on a monthly basis as part of the *ovarian cycle*.

hilum

nest

b A sectional view of the ovary, uterine

tube, and associated mesenteries

epithelium

follicle

Oogenesis is summarized in **Figure 28–15**. Female reproductive stem cells produce *primary oocytes* by mitosis before birth. Then these cells proceed as far as prophase of meiosis I, and remain in that state until the individual reaches puberty.

Not all primary oocytes produced during fetal development survive until puberty. The ovaries have approximately 2 million *primordial follicles* at birth, each containing a primary oocyte. By puberty, the number has dropped to about 400,000. The rest of the primordial follicles degenerate in a process called **atresia** (a-TRĒ-zē-uh).

Figure 28–15 Oogenesis. For clarity, maternal and paternal chromatids are not identified.

cytoplasm, and two or three **polar bodies**, nonfunctional cells that later disintegrate.

2. The ovary releases a **secondary oocyte** rather than a mature ovum. The secondary oocyte is suspended in metaphase of meiosis II. Meiosis will not be completed unless fertilization occurs.

The Ovarian Cycle

Ovarian follicles are specialized structures in the cortex of the ovaries where both oocyte growth and meiosis I occur. We can divide the ovarian cycle into a follicular phase, or preovulatory phase, and a luteal phase, or postovulatory phase. Important steps in the ovarian cycle are summarized in Figure 28–16. (The drawing of the ovary illustrates the sequence and relative sizes of the various stages of the development, ovulation, and degeneration of an ovarian follicle. Follicles do not physically move around the cortex of the ovary.)

1 Primordial Follicles in Egg Nest. Primary oocytes are located in the outer portion of the ovarian cortex, near the tunica albuginea, in clusters called egg nests. A single squamous layer of follicle cells surrounds each primary oocyte within an egg nest. The primary oocyte and its follicle cells form a primordial follicle. Beginning at puberty, primordial follicles are continuously activated to join other follicles already in development. The activating mechanism is unknown, but local hormones or

The nuclear events in the ovaries during meiosis are the same as those in the testes, but the process differs in two important details:

1. The cytoplasm of the primary oocyte is unevenly distributed during the two meiotic divisions. Oogenesis produces one secondary oocyte, which contains most of the original growth factors within the ovary may be involved. The activated primordial follicle will either mature and be released as a secondary oocyte or degenerate (atresia). This monthly process is known as the **ovarian cycle**.

2 *The Formation of Primary Follicles.* The preliminary steps in follicle development vary in length but may take almost

a year to complete. Follicle development begins with the activation of primordial follicles into **primary follicles**. The follicular cells enlarge, divide, and form several layers of cells around the growing primary oocyte. These follicle cells, which become rounded in appearance, are now called **granulosa cells**. Microvilli from the surrounding follicular cells intermingle with microvilli from the surface of the oocyte. This glycoprotein-rich region is called the **zona pellucida** (ZŌ-na pe-LŪ-sid-uh; *pellucidus*, translucent). The microvilli increase the surface area available for transferring materials from the follicular cells to the growing oocyte. As the granulosa cells enlarge and multiply, adjacent cells in the ovarian stroma form a layer of **thecal cells** (*theca*, a box) around the follicle. Thecal cells and granulosa cells work together to produce sex hormones called *estrogens*.

3 *The Formation of Secondary Follicles.* Many primordial follicles develop into primary follicles, but only a few of the primary follicles mature further. This process is apparently under the control of a growth factor produced by the oocyte. The transformation begins as the wall of the follicle thickens and the deeper follicular cells begin secreting small amounts of fluid. This **follicular fluid**, or *liquor folliculi*, accumulates in small pockets that gradually expand and separate the inner and outer layers of the follicle. At this stage, the complex is known as a **secondary follicle**. The primary oocyte continues to grow slowly, while the follicle as a whole enlarges rapidly as follicular fluid accumulates.

4 The Formation of a Tertiary Follicle. Eight to 10 days after the start of the ovarian cycle, the ovaries generally contain only a single secondary follicle destined for further development. By the 10th to the 14th day of the cycle, that follicle has become a **tertiary follicle**, or *mature graafian* (GRAH-fē-an) *follicle*, roughly 15 mm in diameter. This complex spans the entire width of the ovarian cortex and distorts the ovarian capsule, creating a prominent bulge in the surface of the ovary. The oocyte projects into the **antrum** (AN-trum), or expanded central chamber of the follicle. The antrum is surrounded by a mass of granulosa cells.

Until this time, the primary oocyte has been suspended in prophase of meiosis I. As the development of the tertiary follicle ends, LH levels begin rising, prompting the primary oocyte to complete meiosis I. Instead of producing two secondary oocytes, the first meiotic division yields a secondary oocyte and a small, nonfunctional polar body. The secondary oocyte then enters meiosis II, but stops once again at metaphase. Meiosis II will not be completed unless fertilization occurs.

Generally, on day 14 of a 28-day cycle, the secondary oocyte and the attached granulosa cells lose their connections with the follicular wall and drift free within the antrum. The granulosa cells still associated with the secondary oocyte form a protective layer known as the **corona radiata** ($k\bar{o}$ - $R\bar{O}$ - nuh r \bar{a} - $d\bar{e}$ -AH-tuh).

Ovulation. At **ovulation**, the tertiary follicle releases the secondary oocyte. The distended follicular wall suddenly ruptures, ejecting the follicular contents, including the secondary oocyte and corona radiata, into the pelvic cavity. The sticky follicular fluid keeps the corona radiata (and the oocyte) attached to the surface of the ovary. The oocyte is then moved into the uterine tube by contact with the fimbriae that extend from the tube's funnel-like opening (Figure 28–14a), or by fluid currents produced by the cilia that line the tube. Ovulation marks the end of the **follicular phase** of the ovarian cycle and the start of the **luteal phase**.

6 The Formation of the Corpus Luteum. The empty tertiary follicle initially collapses, and ruptured vessels bleed into the antrum. The remaining granulosa cells then invade the area. They proliferate to create an endocrine structure known as the **corpus luteum** (LOO-tē-um; *lutea*, yellow), named for its yellow color. LH stimulates this process.

The cholesterol contained in the corpus luteum is used to manufacture the steroid hormone **progesterone** (prō-JESter-ōn). Progesterone is the main hormone in the luteal phase. Progesterone's primary function is to prepare the uterus for pregnancy by stimulating the maturation of the uterine lining and the secretions of uterine glands. The corpus luteum also secretes moderate amounts of estrogens, but levels are not as high as they were at ovulation.

TIPS&TRICKS

Progesterone literally means a steroid (-**one**) that favors (**pro**-) gestation (-**gest**).

Formation of the Corpus Albicans. The corpus luteum begins to degenerate about 12 days after ovulation (unless fertilization takes place). Progesterone and estrogen levels then fall markedly. Fibroblasts invade the nonfunctional corpus luteum, producing a knot of pale scar tissue called a **corpus albicans** (AL-bi-kanz). The disintegration, or *involution*, of the corpus luteum marks the end of the ovarian cycle. A new ovarian cycle then begins with the activation of another group of primordial follicles.

Age and Oogenesis

Generally only a single oocyte is released into the pelvic cavity at ovulation, although many primordial follicles may have developed into primary follicles, and several primary follicles may have been converted to secondary follicles. These undergo atresia. At puberty, each ovary contains about 200,000 primordial follicles. Forty years later, few if any follicles remain, although only about 500 secondary oocytes will have been ovulated.

Ovarian Cancer A woman in the United States has a 1-in-70 chance of developing **ovarian cancer** in her lifetime. In 2013, an estimated 22,240 ovarian cancer cases will be diagnosed, and about 12,340 deaths will occur as a result of this condition. Although ovarian cancer is the third most common reproductive cancer among women, it is the most dangerous because it is seldom diagnosed in its early stages. The prognosis is relatively good for cancers that originate in the general ovarian tissues or from abnormal oocytes. These cancers respond well to some combination of chemotherapy, radiation, and surgery. However, 85 percent of ovarian cancers develop from epithelial cells, and sustained remission occurs in only about one-third of these cases.

The Uterine Tubes

Each **uterine tube** (*Fallopian tube* or *oviduct*) is a hollow, muscular cylinder measuring roughly 13 cm (5.2 in.) in length (**Figures 28–13** and **28–14**). We divide each uterine tube into three segments (**Figure 28–17a**):

 The Infundibulum. The end closest to the ovary forms an expanded funnel, or **infundibulum**, with numerous fingerlike projections that extend into the pelvic cavity. The projections are called **fimbriae** (FIM-brē-ē). Fimbriae drape over the surface of the ovary, but there is no physical connection between the two structures. The inner surfaces of the infundibulum are lined with cilia that beat toward the middle segment of the uterine tube, called the *ampulla*.

- 2. *The Ampulla*. The **ampulla** is the middle region of the uterine tube. The thickness of its smooth muscle layers gradually increases as the tube approaches the uterus.
- **3.** *The Isthmus.* The ampulla leads to the **isthmus** (IS-mus), a short segment connected to the uterine wall.

Histology of the Uterine Tube

The epithelium lining the uterine tube is composed of ciliated columnar epithelial cells with scattered mucin-secreting cells (Figure 28–17c). Concentric layers of smooth muscle surround the mucosa (Figure 28–17b). Oocytes are transported by a combination of ciliary movement and peristaltic contractions in the walls of the uterine tube. A few hours before ovulation, sympathetic and parasympathetic nerves from the hypogastric plexus "turn on" this beating pattern and initiate peristalsis. It normally takes three to four days for an oocyte to travel from the infundibulum to the *uterine cavity*. If fertilization is to occur, the secondary oocyte must encounter spermatozoa during the first 12–24 hours of its passage. Fertilization typically takes place near the boundary between the ampulla and isthmus of the uterine tube.

In addition to its transport function, the uterine tube provides a nutrient-rich environment that contains lipids and glycogen. This mixture nourishes both spermatozoa and a developing *pre-embryo* (the cell cluster produced by the initial cell

Figure 28–17 The Uterine Tubes.

divisions following fertilization and before implantation in the uterine wall). Unfertilized oocytes degenerate in the terminal portions of the uterine tubes or within the uterus without completing meiosis.

In addition to ciliated cells, the epithelium lining the uterine tubes contains *peg cells* and scattered mucin-secreting cells. The peg cells project into the lumen of the uterine tube. They secrete a fluid that both completes the capacitation of spermatozoa and supplies nutrients to spermatozoa and the pre-embryo.

The Uterus

The **uterus** protects, nourishes, and removes wastes for the developing *embryo* (weeks 1–8) and *fetus* (week 9 through delivery). In addition, contractions of the muscular uterus are important in expelling the fetus at birth.

The uterus is a small, pear-shaped organ (Figure 28–18a,b,c). It is about 7.5 cm (3 in.) long with a maximum diameter of 5 cm (2 in.). It weighs 50–100 g (1.75–3.5 oz). In its normal position, the uterus bends anteriorly near its base, a condition known as *anteflexion* (an-tē-FLEK-shun) (Figure 28–13). In this position, the uterus covers the superior and posterior surfaces of the urinary bladder. If the uterus bends backward toward the sacrum, the condition is termed *retroflexion* (re-trō-FLEK-shun). Retroflexion occurs in about 20 percent of adult women and has no clinical significance. (A retroflexed uterus generally becomes anteflexed spontaneously during the third month of pregnancy.)

Suspensory Ligaments of the Uterus

In addition to the broad ligament, three pairs of suspensory ligaments stabilize the uterus and limit its range of movement (Figure 28–18b). The **uterosacral** (ū-te-rō-SĀ-krul) **ligaments** extend from the lateral surfaces of the uterus to the anterior face of the sacrum, keeping the body of the uterus from moving inferiorly and anteriorly. The **round ligaments** arise on the lateral margins of the uterus just posterior and inferior to the attachments of the uterine tubes. These ligaments extend through the inguinal canal and end in the connective tissues of the external genitalia. The round ligaments restrict posterior movement of the uterus. The **cardinal** (*lateral*) **ligaments** extend from the base of the uterus and vagina to the lateral walls of the pelvis. These ligaments tend to prevent inferior movement of the uterus. The muscles and fascia of the pelvic floor provide additional mechanical support.

Internal Anatomy of the Uterus

We divide the uterus into anatomical regions (Figure 28–18a). The uterine **body** is the largest portion of the uterus. The **fundus** is the rounded portion of the body superior to the attachment of the uterine tubes. The body ends at a constriction known as the **isthmus** of the uterus. The **cervix** (SER-viks) is the inferior portion of the uterus that extends from the isthmus to the vagina.

The tubular cervix projects about 1.25 cm (0.5 in.) into the vagina. Within the vagina, the distal end of the cervix forms a curving surface that surrounds the **external os** (*os*, an opening or mouth) of the uterus. The external os leads into the **cervical canal**, a constricted passageway that opens into the **uterine cavity** of the body at the **internal os**.

The uterus receives blood from branches of the **uterine arteries**. These vessels arise from branches of the *internal iliac arteries*, and from the *ovarian arteries*, which arise from the abdominal aorta inferior to the renal arteries. The arteries to the uterus are extensively interconnected, ensuring a reliable flow of blood to the organ despite changes in its position and shape during pregnancy. Numerous veins and lymphatic vessels also drain each portion of the uterus.

The organ is innervated by autonomic fibers from the hypogastric plexus (sympathetic) and from sacral segments S_3 and S_4 (parasympathetic). Sensory information reaches the central nervous system within the dorsal roots of spinal nerves T_{11} and T_{12} . The most delicate anesthetic procedures used during labor and delivery, known as *segmental blocks*, target only spinal nerves T_{10} – L_1 .

The Uterine Wall

The dimensions of the uterus are highly variable. In women of reproductive age who have not given birth, the uterine wall is about 1.5 cm (0.6 in.) thick. The wall has a thick, middle, muscular **myometrium** (mī- \bar{o} -MĒ-trē-um; *myo-*, muscle + *metra*, uterus) and a thin, inner, glandular **endometrium** (en- $d\bar{o}$ -MĒ-trē-um) (Figure 28–19). The fundus and the posterior surface of the uterine body and isthmus are covered by an outer serous membrane that is continuous with the peritoneal lining. This incomplete serosa is called the **perimetrium**.

The endometrium makes up about 10 percent of the mass of the uterus. The glandular and vascular tissues of the

Clinical Note

Cervical Cancer Cervical cancer is the most common cancer of the reproductive system in women ages 15–34. Each year roughly 12,340 U.S. women are diagnosed with invasive cervical cancer, and approximately one-third of them eventually die from the condition. Another 35,000 women are diagnosed with a less aggressive form of cervical cancer. *Gardisil* is a vaccine that protects against four types of human papillomavirus (HPV) that cause most cervical cancers.

Figure 28–18 The Uterus. ATLAS: Plates 66; 67

the position of the uterus in the pelvic cavity.

bladder cannot be seen because it is covered by peritoneum.

endometrium support the physiological demands of the growing fetus. Vast numbers of uterine glands open onto the endometrial surface and extend deep into the lamina propria, almost to the myometrium. Under the influence of estrogens, the uterine glands, blood vessels, and epithelium change with the phases of the monthly *uterine cycle*.

The myometrium is the thickest portion of the uterine wall. It makes up almost 90 percent of the mass of the uterus. Smooth muscle in the myometrium is arranged into longitudinal, circular, and oblique layers. The smooth muscle tissue of the myometrium provides much of the force needed to move a fetus out of the uterus and into the vagina.

Histology of the Uterus. We divide the endometrium into a **functional zone**—the layer closest to the uterine cavity—and a **basilar zone**, adjacent to the myometrium (Figure 28–19b). The functional zone contains most of the **uterine glands** and contributes most of the endometrial thickness. This zone undergoes dramatic changes in thickness and structure during the menstrual cycle. The basilar zone attaches the endometrium to the myometrium and contains the terminal branches of the tubular uterine glands.

Within the myometrium, branches of the uterine arteries form **arcuate arteries**, which encircle the endometrium (Figure 28–19a). Radial arteries supply straight arteries, which deliver blood to the basilar zone of the endometrium, and **spiral arteries**, which supply the functional zone.

The structure of the basilar zone remains fairly constant over time, but the functional zone undergoes cyclical changes in response to sex hormone levels. These cyclical changes produce the characteristic histological features of the uterine cycle.

The Uterine Cycle

The **uterine cycle**, or *menstrual* (MEN-strū-ul) *cycle*, is a repeating series of changes in the structure of the endometrium (**Figure 28–20**). The uterine cycle averages 28 days in length, but it can range from 21 to 35 days in healthy women of reproductive age.

We divide the uterine cycle into three phases: (1) *menses*, (2) the *proliferative phase*, and (3) the *secretory phase*. The phases take place in response to hormones associated with the regulation of the ovarian cycle. Menses and the proliferative phase occur during the follicular phase of the ovarian cycle. The secretory phase corresponds to the luteal phase of the ovarian cycle. We consider the regulatory mechanism involved in a later section.

Menses. The uterine cycle begins with the onset of **menses** (MEN-sēz), an interval marked by the degeneration of the functional zone of the endometrium (Figure 28–20a). This

degeneration occurs in patches. It is caused by constriction of the spiral arteries, which reduces blood flow to areas of endometrium. Deprived of oxygen and nutrients, the secretory glands and other tissues in the functional zone begin to deteriorate. Eventually, the weakened arterial walls rupture, and blood pours into the connective tissues of the functional zone. Blood cells and degenerating tissues then break away and enter the uterine cavity, to be lost as they pass through the external os and into the vagina. Only the functional zone is affected, because the deeper, basilar layer receives blood from the straight arteries, which remain unconstricted.

The sloughing off, or shedding, of tissue is gradual. At each site repairs begin almost at once. Nevertheless, before menses has ended, the entire functional zone has been lost. The process of endometrial sloughing, called **menstruation** (men-strū- \bar{A} -shun), generally lasts from one to seven days. During this time about 35 to 50 mL (1.2–1.7 oz) of blood are lost.

The process can be relatively painless. Painful menstruation, or **dysmenorrhea**, can result from uterine inflammation, myometrial contractions ("cramps"), or from conditions involving adjacent pelvic structures.

The Proliferative Phase. The basilar zone, including the basal parts of the uterine glands, survives menses intact. In the days after menses, the epithelial cells of the uterine glands multiply and spread across the endometrial surface, restoring the uterine epithelium (Figure 28–20b). Further growth and vascularization completely restore the functional zone.

During this reorganization, the endometrium is in the **proliferative phase**. Restoration takes place at the same time as the primary and secondary follicles enlarge in the ovary. Estrogens secreted by the developing ovarian follicles stimulate and sustain the proliferative phase.

By the time ovulation occurs, the functional zone is several millimeters thick. Prominent mucous glands extend to its border with the basilar zone. At this time, the uterine glands are manufacturing mucus that is rich in glycogen. This specialized mucus appears to be essential for the survival of the fertilized ovum through its earliest developmental stages. (We will consider these stages in Chapter 29.) The entire functional zone is highly vascularized, with small arteries spiraling toward the endometrial surface from larger arteries in the myometrium.

The Secretory Phase. During the **secretory phase** of the uterine cycle, the uterine glands enlarge, accelerating their rates of secretion. The arteries that supply the uterine wall elongate and spiral through the tissues of the functional zone (Figure 28–20c). This activity occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum. The secretory phase begins at the time of ovulation and persists as long as the corpus luteum remains intact.

Secretory activities peak about 12 days after ovulation. Over the next day or two, the glands become less active. The uterine cycle ends as the corpus luteum stops producing stimulatory hormones. A new uterine cycle then begins with the onset of menses and the disintegration of the functional zone.

The secretory phase generally lasts 14 days. For this reason, you can identify the date of ovulation by counting backward 14 days from the first day of menses.

Menarche and Menopause. The uterine cycle begins at puberty. The first cycle, known as **menarche** (me-NAR-kē; *men*,

Figure 28–21 The Histology of the Vagina.

month + *arche*, beginning), typically occurs at age 11–12. The cycles continue until **menopause** (MEN-ō-pawz), the termination of the uterine cycle, at age 45–55. Over the interim, the regular appearance of uterine cycles is interrupted only by circumstances such as illness, stress, starvation, or pregnancy.

If menarche does not appear by age 16, or if the normal uterine cycle of an adult woman is interrupted for six months or more, the condition of **amenorrhea** (ā-men-ō-RĒ-uh) exists. *Primary amenorrhea* is the failure to initiate menses. This condition may indicate developmental abnormalities, such as non-functional ovaries, the absence of a uterus, or an endocrine or genetic disorder. It can also result from malnutrition: Puberty is delayed if leptin levels are too low. $\supset p. 643$

Severe physical or emotional stresses can cause transient *secondary amenorrhea*. In effect, the reproductive system gets "switched off." Factors associated with amenorrhea include drastic weight loss, anorexia nervosa, and severe depression or grief. Amenorrhea has also been observed in marathon runners and other women engaged in training programs that require sustained high levels of exertion, which severely reduce body lipid reserves.

The Vagina

The **vagina** is an elastic, muscular tube extending between the cervix and the exterior. It opens into the *vestibule*, a space bounded by the female external genitalia (Figures 28–21 and 28–22). The vagina is typically 7.5–9 cm (3–3.6 in.) long. Its diameter varies because it is highly distensible.

28

At the proximal end of the vagina, the cervix projects into the **vaginal canal**. The shallow recess surrounding the cervical protrusion is known as the **fornix** (FOR-niks). The vagina lies parallel to the rectum, and the two are in close contact posteriorly. Anteriorly, the urethra extends along the superior wall of the vagina from the urinary bladder to the external urethral orifice, which opens into the vestibule.

The primary blood supply of the vagina is by the **vaginal branches** of the internal iliac (or uterine) arteries and veins. Innervation is from the hypogastric plexus, sacral nerves S_2-S_4 , and branches of the pudendal nerve. \bigcirc pp. 444, 763, 768

The vagina has three major functions. It (1) is a passageway for the elimination of menstrual fluids; (2) receives the penis during sexual intercourse, and holds spermatozoa prior to their passage into the uterus; and (3) forms the inferior portion of the *birth canal*, through which the fetus passes during delivery.

Anatomy and Histology of the Vagina

In sectional view, the lumen of the vagina appears constricted, forming a rough H-shape. The vaginal walls contain a network of blood vessels and layers of smooth muscle (Figure 28–21). The lining is moistened by secretions of the cervical glands and by the movement of water across the permeable epithelium. The **hymen** (HĪ-men) is an elastic epithelial fold of variable size that partially blocks the entrance to the vagina. An intact hymen is typically stretched or torn during first sexual intercourse, tampon use, pelvic examination, or physical activity.

The two *bulbospongiosus muscles* extend along either side of the vaginal entrance. Contractions of the bulbospongiosus muscles constrict the vagina. \bigcirc p. 356 These muscles cover the **vestibular bulbs**, masses of erectile tissue on either side of the vaginal entrance (Figure 28–22). The vestibular bulbs have the same embryonic origins as the corpus spongiosum of the penis in males.

The vaginal lumen is lined by a nonkeratinized stratified squamous epithelium (Figure 28–21). In the relaxed state, this epithelium forms folds called *rugae*. The underlying lamina propria is thick and elastic, and it contains small blood vessels, nerves, and lymph nodes. The vaginal mucosa is surrounded by an elastic *muscularis* layer consisting of layers of smooth muscle fibers arranged in circular and longitudinal bundles continuous with the uterine myometrium. The portion of the vagina adjacent to the uterus has a serosal covering that is continuous with the pelvic peritoneum. Along the rest of the vagina, the muscularis layer is surrounded by an *adventitia* of fibrous connective tissue.

The vagina contains a population of resident bacteria, usually harmless, supported by nutrients in the cervical mucus. The metabolic activity of these bacteria creates an acidic environment, which restricts the growth of many pathogens. Fungi, bacteria, or parasites can cause **vaginitis** (vaj-i-NĪ-tis), an inflammation of the vaginal canal. In addition to any discomfort

Figure 28–22 The Female External Genitalia.

that may result, the condition may affect the survival of spermatozoa and thereby reduce fertility. An acidic environment also inhibits the motility of sperm. For this reason, the buffers in semen are important to successful fertilization.

The hormonal changes associated with the ovarian cycle also affect the vaginal epithelium. By examining a *vaginal smear*—a sample of epithelial cells shed at the surface of the vagina—a clinician can estimate the corresponding stages in the ovarian and uterine cycles. This diagnostic procedure is an example of *exfoliative cytology*. \supset p. 120

The External Genitalia

The area containing the female external genitalia is the **vulva** (VUL-vuh), or *pudendum* (pū-DEN-dum; **Figure 28–22**). The vagina opens into the **vestibule**, a central space surrounded by small folds known as the **labia minora** (LĀ-bē-uh mi-NOR-uh; singular, *labium minus*). The labia minora are covered with a smooth, hairless skin. The urethra opens into the vestibule just anterior to the vaginal entrance. The **paraurethral glands**, or *Skene's glands*, discharge into the urethra near the external urethral opening.

Anterior to this opening, the **clitoris** (KLIT-ō-ris) projects into the vestibule. A small, rounded tissue projection, the clitoris is derived from the same embryonic structures as the penis in males. Internally, it contains erectile tissue comparable to the corpora cavernosa of the penis. A small erectile *glans* sits atop it. The vestibular bulbs along the sides of the vestibule are comparable to the corpus spongiosum. These erectile tissues engorge with blood during sexual arousal. Extensions of the labia minora encircle the body of the clitoris, forming its **prepuce**, or *hood*. ATLAS: Embryology Summary 21: The Development of the Reproductive System

A variable number of small **lesser vestibular glands** discharge their secretions onto the exposed surface of the vestibule between the orifices of the vagina and urethra. During sexual arousal, the **greater vestibular glands** (*Bartholin's glands*), located on either side of the distal portion of the vagina, secrete into the vestibule. These mucous glands keep the area moist and lubricated. The vestibular glands have the same embryonic origins as the bulbourethral glands in males.

The outer margins of the vulva are formed by the mons pubis and the labia majora. The **mons pubis** is a pad of adipose tissue covering the pubic symphysis. Adipose tissue also accumulates within the **labia majora** (singular, *labium majus*), prominent folds of skin that encircle and partially conceal the labia minora and adjacent structures. The outer margins of the labia majora and the mons pubis are covered with coarse hair, but the inner surfaces of the labia majora are hairless. Sebaceous glands and scattered apocrine sweat glands secrete onto the inner surface of the labia majora, moistening and lubricating them.

The Mammary Glands

A newborn infant cannot fend for itself, and several of its key systems have yet to complete development. Over the initial period of adjustment to an independent existence, the infant is nourished from the milk secreted by the maternal **mammary glands**. Milk production, or **lactation** (lak-TĀ-shun), takes place in these glands. In females, mammary glands are specialized organs of the integumentary system that are controlled mainly by hormones of the reproductive system and by the *placenta*, a temporary structure that provides the embryo and fetus with nutrients.

On each side, a mammary gland lies in the subcutaneous tissue of the **pectoral fat pad** deep to the skin of the chest (**Figure 28–23a**). Each breast has a **nipple**, a small conical projection where the ducts of the underlying mammary gland open onto the body surface. The reddish-brown skin around each nipple is the **areola** (a-RĒ-ō-luh). Large sebaceous glands deep to the areolar surface give it a grainy texture.

The glandular tissue of a mammary gland consists of separate lobes, each containing several secretory lobules. Ducts leaving the lobules converge, giving rise to a single **lactiferous** (lak-TIF-er-us) **duct** in each lobe. Near the nipple, that lactiferous duct enlarges, forming an expanded chamber called a **lactiferous sinus**. Typically, 15–20 lactiferous sinuses open onto the surface of each nipple. Dense connective tissue surrounds the duct system and forms partitions that extend between the lobes and the lobules. These bands of connective tissue, the *suspensory ligaments of the breast*, originate in the dermis of the overlying skin. A layer of areolar tissue separates the mammary gland complex from the underlying pectoralis muscles. Branches of the *internal thoracic artery* supply blood to each mammary gland (Figure 21–20, p. 757).

Figure 28–23b,c compares the histological organizations of inactive and active mammary glands. An inactive, or *resting*, mammary gland is dominated by a duct system rather than by active glandular cells. The size of the mammary glands in a nonpregnant woman reflects primarily the amount of adipose tissue present, not the amount of glandular tissue. The secretory apparatus normally does not complete its development unless pregnancy occurs. An active mammary gland is a tubuloalveolar gland, consisting of multiple glandular tubes that end in secretory alveoli. We will discuss the hormonal mechanisms involved in lactation in Chapter 29.

Hormones and Female Reproductive Function

The female reproductive tract is under hormonal control that involves interplay between secretions of both the pituitary gland and the gonads. Circulating hormones control the **female reproductive cycle**, coordinating the ovarian and uterine cycles for proper reproductive function. If the two cycles are not properly coordinated, infertility results. We do not yet know many of the biochemical details of the female reproductive cycle because the processes are complex and difficult to study, but the general patterns are reasonably clear.

As in males, GnRH from the hypothalamus regulates reproductive function in females. However, in females, the GnRH pulse frequency and amplitude (amount secreted per pulse) change throughout the ovarian cycle. If the hypothalamus were a radio station, the pulse frequency would correspond to the radio frequency it is transmitting on, and the amplitude would be the volume. We will consider changes in pulse frequency, as their effects are both dramatic and reasonably well understood. Circulating levels of estrogens and progesterone primarily control changes in GnRH pulse frequency. Estrogens increase the GnRH pulse frequency, and progesterone decreases it.

The endocrine cells of the anterior lobe of the pituitary gland respond as if each group of endocrine cells is monitoring different frequencies. As a result, each group of cells is sensitive to some GnRH pulse frequencies and insensitive to others. For example, consider the *gonadotropes*, the cells that produce FSH and LH. At one pulse frequency, the gonadotropes respond preferentially and secrete FSH, but at another frequency, these cells release primarily LH. FSH and LH production also occurs in pulses that follow the rhythm of GnRH pulses. If GnRH is absent or is supplied at a constant rate (without pulses), FSH and LH secretion stops in a matter of hours.

Spotlight Figure 28–24 shows the changes in circulating hormone levels that accompany the ovarian and uterine cycles. Early in the follicular phase of the ovarian cycle and prior to day 10, estrogen levels are low and the GnRH pulse frequency is 16–24 per day (one pulse every 60–90 minutes). At this frequency, FSH is the dominant hormone released by the anterior lobe of the pituitary gland. The estrogens released by developing follicles inhibit LH secretion. As secondary follicles develop, FSH levels decrease due to the negative feedback effects of inhibin. Follicular development and maturation continue, however, supported by the combination of estrogens, FSH, and LH.

As one or more tertiary follicles begin forming, the concentration of circulating estrogens rises steeply. As a result, the GnRH pulse frequency increases to about 36 per day (one pulse every 30–60 minutes). The increased pulse frequency stimulates LH secretion. In addition, around day 10 of the cycle, the effect of estrogen on LH secretion changes from inhibition to stimulation. The switchover takes place only after estrogen levels have risen above a specific threshold value for about 36 hours. (The threshold value and the time required vary among individuals.) High estrogen levels also increase gonado-trope sensitivity to GnRH. At about day 14, the estrogen level has peaked, the gonadotropes are at maximum sensitivity, and the GnRH pulses are arriving about every 30 minutes. The result is a massive release of LH from the anterior lobe of the pituitary gland. This sudden surge in LH concentration triggers (1) the completion of meiosis I by the primary oocyte, (2) the forceful rupture of the follicular wall, and (3) ovulation. Typically, ovulation occurs 34–38 hours after the LH surge begins, roughly 9 hours after the LH peak.

Clinical Note

Breast Cancer The uterine cycle also influences cyclical changes in the mammary glands. The effects usually go unnoticed, but occasional discomfort or even inflammation of mammary gland tissues can occur late in the cycle. If inflamed lobules become walled off by scar tissue, **cysts** are created. Clusters of cysts can be felt in the breast as discrete masses, a condition known as **fibrocystic disease**. Because its symptoms are similar to those of breast cancer, biopsies may be needed to distinguish between this benign condition and breast cancer.

Breast cancer is a malignant, metastasizing tumor of the mammary gland. It is the leading cause of death in women between ages 35 and 45, but it is most common in women over age 50. An estimated 12.4 percent of U.S. women will develop breast cancer at some point in their lifetime. Of the total of about 208,000 newly reported cases in 2010, about 1900 will occur in males. The incidence is highest among Caucasian Americans, somewhat lower in African Americans, and lowest in Asian Americans and American Indians. Notable risk factors include (1) a family history of breast cancer, (2) a first pregnancy after age 30, and (3) early menarche or late menopause.

Despite repeated studies, no links have been proven between breast cancer and oral contraceptive use, fat consumption, or alcohol use. It appears likely that multiple factors are involved. In some families an inherited genetic variation has been linked to higher-than-normal risk of developing the disease. However, most women never develop breast cancer even women in families with a history of the disease. Mothers who breast-fed (nursed) their babies have a 20 percent lower incidence of breast cancer after menopause than do mothers who did not breast-feed. The reason is not known. Adding to the mystery, nursing does not appear to affect the incidence of premenopausal breast cancer. Early detection of breast cancer is the key to saving lives. For this reason the use of clinical screening techniques has increased in recent years. **Mammography** involves the use of x-rays to examine breast tissues. The radiation dosage can be low, because only soft tissues must be penetrated.

Treatment is more successful if breast cancer is identified while it is still a relatively small, localized tumor. Once it has grown larger than 2 cm (0.78 in.), the chances of long-term survival worsen. A poor prognosis also follows if cancer cells have spread through the lymphatic system to the axillary lymph nodes. If the nodes are not yet involved, the chances of five-year survival are about 92 percent, but if four or more nodes are involved, the survival rate drops to 25 percent. More than 90 percent of breast cancers are now diagnosed at the local or regional stage.

Treatment of breast cancer includes surgical removal of the tumor. Because in many cases cancer cells begin to spread before the condition is diagnosed, part or all of the affected mammary gland is surgically removed and usually the axillary lymph nodes on that side are biopsied.

- In a *lumpectomy*, only a portion of the breast is removed.
- In a total mastectomy, the entire breast is removed.
- In axillary lymph node dissection, one or more of the axillary lymph nodes (called sentinel nodes) are removed to check for metastatic cells. If there are no cancer cells in the nodes checked, the other lymph nodes may be left in place.

A combination of chemotherapy, radiation treatments, and hormone treatments may be used to supplement the surgical procedures.

Hormones and the Follicular Phase of the Ovarian Cycle

Follicular development begins under FSH stimulation. Each month some of the primordial follicles begin to develop into primary follicles. As the follicles enlarge, thecal cells start producing *androstenedione*, a steroid hormone that is a key intermediate in the synthesis of estrogens and androgens. The granulosa cells absorb androstenedione and convert it to estrogens. In addition, interstitial cells scattered throughout the ovarian stroma secrete small quantities of estrogens. Circulating estrogens are bound primarily to albumins, with lesser amounts carried by gonadal steroid-binding globulin (GBG).

Of the three estrogens circulating in the bloodstream estradiol, estrone, and estriol—**estradiol** (es-tra-DĪ-ol) is the most abundant and has the most pronounced effects on target tissues. It is the dominant hormone prior to ovulation. In estradiol synthesis, androstenedione is first converted to testosterone, which the enzyme aromatase converts to estradiol (Figure 28–25). The synthesis of both *estrone* and *estriol* proceeds directly from androstenedione.

Estrogens have multiple functions that affect the activities of many tissues and organs throughout the body. Among the important general functions of estrogens are (1) stimulating bone and muscle growth; (2) maintaining female secondary sex characteristics, such as body hair distribution and the location of adipose tissue deposits; (3) affecting central nervous system activity, especially in the hypothalamus, where estrogens increase the sexual drive; (4) maintaining functional accessory reproductive glands and organs; and (5) initiating the repair and growth of the endometrium.

The ovarian and uterine cycles must operate in synchrony to ensure proper reproductive function. If the two cycles are not properly coordinated, infertility results. A female who doesn't ovulate cannot conceive, even if her uterus is perfectly normal. A female who ovulates normally, but whose uterus is not ready to support an embryo, will also be infertile.

This illustration combines the key events in the ovarian and uterine cycles. The monthly hormonal fluctuations cause physiological changes that affect core body temperature. During the follicular phase—when estrogens are the dominant hormones—the **basal body temperature**, or the resting body temperature measured upon awakening in the morning, is about 0.3°C (0.5°F) lower than it is during the luteal phase, when progesterone dominates.

1086 UNIT 6 Continuity of Life

Figure 28–25 Pathways of Steroid Hormone Synthesis in Males and Females. All gonadal steroids are derived from cholesterol. In men, the pathway ends with the synthesis of testosterone, which may subsequently be converted to dihydrotestosterone. In women, an additional step after testosterone leads to estradiol synthesis. The synthesis of progesterone and estrogens other than estradiol involves alternative pathways.

Hormones and the Luteal Phase of the Ovarian Cycle

The high LH levels that trigger ovulation also promote progesterone secretion and the formation of the corpus luteum. As progesterone levels rise and estrogen levels fall, the GnRH pulse frequency decreases sharply, soon reaching 1–4 pulses per day. This frequency of GnRH pulses stimulates LH secretion more than it does FSH secretion, and the LH maintains the structure and secretory function of the corpus luteum.

The corpus luteum secretes moderate amounts of estrogens, but progesterone is the main hormone of the luteal phase. Its primary function is to continue the preparation of the uterus for pregnancy. Progesterone enhances the blood supply to the functional zone and stimulates the secretion of uterine glands. Progesterone levels remain high for the next week, but unless pregnancy occurs, the corpus luteum begins to degenerate.

Approximately 12 days after ovulation, the corpus luteum becomes nonfunctional, and progesterone and estrogen levels fall markedly. The blood supply to the functional zone is restricted, and the endometrial tissues begin to deteriorate. As progesterone and estrogen levels drop, the GnRH pulse frequency increases, stimulating FSH secretion by the anterior lobe of the pituitary gland, and the ovarian cycle begins again. The hormonal changes involved with the ovarian cycle in turn affect the activities of other reproductive tissues and organs. At the uterus, the hormonal changes maintain the uterine cycle.

Hormones and the Uterine Cycle

Spotlight Figure 28–24 also shows the changes in the endometrium during a single uterine cycle. Progesterone and estrogen levels decrease as the corpus luteum degenerates, resulting in menses. The shedding of endometrial tissue continues for several days, until rising estrogen levels stimulate the repair and regeneration of the functional zone of the endometrium. The proliferative phase then continues until rising progesterone levels mark the arrival of the secretory phase. The combination of estrogen and progesterone then causes the uterine glands to enlarge and increase their secretions.

Hormones and Body Temperature

At the time of ovulation, the basal body temperature (BBT) decreases noticeably, making the rise in temperature over the next day even more noticeable (Spotlight Figure 28–24). Urine tests that detect LH are available, and testing daily for several days before expected ovulation can detect the LH surge more

reliably than the BBT changes. This information can be important for individuals who wish to avoid or promote a pregnancy, because fertilization typically occurs within a day of ovulation. After that time, oocyte viability and the likelihood of successful fertilization decrease markedly.

CHECKPOINT

- 9. Name the structures of the female reproductive system.
- 10. What effect would blockage of both uterine tubes by scar tissue (resulting from an infection such as gonorrhea) have on a woman's ability to conceive?
- 11. What benefit does the acidic pH of the vagina provide?
- 12. Which layer of the uterus is sloughed off, or shed, during menstruation?
- 13. Would the blockage of a single lactiferous sinus interfere with the delivery of milk to the nipple? Explain.
- 14. What changes would you expect to observe in the ovarian cycle if the LH surge did not occur?
- **15**. What effect would a blockage of progesterone receptors in the uterus have on the endometrium?
- 16. What event in the uterine cycle occurs when the levels of estrogens and progesterone decrease?

See the blue Answers tab at the back of the book.

28-4 The autonomic nervous system influences male and female sexual function

Learning Outcome Discuss the physiology of sexual intercourse in males and females.

Sexual intercourse, also known as *coitus* (KŌ-i-tus) or *copulation*, introduces semen into the female reproductive tract. The process affects both the male and female reproductive systems.

Male Sexual Function

Complex neural reflexes coordinate sexual function in males. The reflex pathways utilize the sympathetic and parasympathetic divisions of the autonomic nervous system. During sexual **arousal**, erotic thoughts, the stimulation of sensory nerves in the genital region, or both lead to an increase in parasympathetic outflow over the pelvic nerves. This outflow in turn leads to **erection** of the penis (discussed on p. 1065). The skin covering the glans penis contains numerous sensory receptors, and erection tenses the skin and increases sensitivity. Subsequent stimulation can initiate the secretion of the bulbourethral glands, providing **lubrication** for the penile urethra and the surface of the glans penis.

During intercourse, the sensory receptors of the penis are rhythmically stimulated. This stimulation eventually results in the coordinated processes of emission and ejaculation. **Emission** occurs under sympathetic stimulation. The process begins when the peristaltic contractions of the ampulla push seminal fluid and spermatozoa into the prostatic urethra. The seminal glands then begin contracting, and the contractions increase in force and duration over the next few seconds. Peristaltic contractions also appear in the walls of the prostate gland. The combination moves the seminal mixture into the membranous and penile portions of the urethra. While the contractions are proceeding, sympathetic commands also cause the contraction of the urinary bladder and the internal urethral sphincter. The combination of elevated pressure inside the bladder and the contraction of the sphincter effectively prevent semen from passing into the bladder.

Ejaculation occurs as powerful, rhythmic contractions appear in the *ischiocavernosus* and *bulbospongiosus muscles*, two superficial skeletal muscles of the pelvic floor. The ischiocavernosus muscles insert along the sides of the penis. Their contractions serve primarily to stiffen that organ. The bulbospongiosus muscle wraps around the base of the penis. The contraction of this muscle pushes semen toward the external urethral opening. The contractions of both muscles are controlled by somatic motor neurons in the inferior lumbar and superior sacral segments of the spinal cord. (The positions of these muscles are shown in Figure 11–13b, p. 356.) Contraction of the smooth muscle within the prostate acts to pinch off the urethra, preventing urine from passing through the erect penis.

Ejaculation is associated with intensely pleasurable sensations associated with perineal muscle contraction, an experience known as male **orgasm** (OR-gazm). Several other noteworthy physiological changes take place at this time, including pronounced but temporary increases in heart rate and blood pressure. After ejaculation, blood begins to leave the erectile tissue, and the erection begins to subside. This subsidence, called **detumescence** (dē-tū-MES-ens), is mediated by the sympathetic nervous system.

In sum, arousal, erection, emission, and ejaculation are controlled by a complex interplay between the sympathetic and parasympathetic divisions of the autonomic nervous system. Higher centers, including the cerebral cortex, can facilitate or inhibit many of the important reflexes, modifying sexual function. Any physical or psychological factor that affects a single component of the system can result in male sexual dysfunction, also called *impotence*.

Impotence, or **erectile dysfunction (ED)**, is defined as an inability to achieve or maintain an erection. Various physical causes may be responsible for impotence, because erection involves vascular changes as well as neural commands. For example, low blood pressure in the arteries supplying the penis, due to a circulatory blockage such as a plaque, will reduce the ability to attain an erection. Drugs, alcohol, trauma, or illnesses that affect the autonomic nervous system or the central nervous
system can have the same effect. But male sexual performance can also be strongly affected by the psychological state of the individual. Temporary periods of impotence are fairly common in healthy individuals who are experiencing severe stresses or emotional problems. Depression, anxiety, and fear of impotence are examples of emotional factors that can result in sexual dysfunction. The prescription drugs Viagra, Levitra, and Cialis, which enhance and prolong the effects of nitric oxide on the erectile tissue of the penis, have proven useful in treating many cases of impotence.

Female Sexual Function

The events in female sexual function are largely comparable to those of male sexual function. During sexual arousal, parasympathetic activation leads to engorgement of the erectile tissues of the clitoris and the vestibular bulbs, and increased secretion from cervical mucous glands and the greater vestibular glands. Clitoral erection increases the receptors' sensitivity to stimulation, and the cervical and vestibular glands lubricate the vaginal walls. A network of blood vessels in the vaginal walls becomes filled with blood at this time, and the vaginal surfaces are also moistened by fluid that moves across the epithelium from underlying connective tissues. (This process accelerates during intercourse as the result of mechanical stimulation.) Parasympathetic stimulation also causes contraction of subcutaneous smooth muscle of the nipples, making them more sensitive to touch and pressure.

During sexual intercourse, rhythmic contact of the penis with the clitoris and vaginal walls—reinforced by touch sensations from the breasts and other stimuli (visual, olfactory, and auditory)—provides stimulation that leads to orgasm. Female orgasm is accompanied by peristaltic contractions of the uterine and vaginal walls and, through impulses traveling over the pudendal nerves, rhythmic contractions of the bulbospongiosus and ischiocavernosus muscles. The latter contractions give rise to the intensely pleasurable sensations of orgasm.

Sexual activity carries with it the risk of infection with a variety of microorganisms. The consequences of such an infection may range from merely inconvenient to potentially lethal. **Sexually transmitted diseases (STDs)**, also called **sexually transmitted infections (STIs)**, are transferred from individual to individual, primarily or exclusively by sexual intercourse. At least two dozen bacterial, viral, and fungal infections are currently recognized as STDs. The bacterium *Chlamydia* can cause **pelvic inflammatory disease (PID)** and infertility. AIDS, caused by a virus, is deadly.

The incidence of STDs has been increasing in the United States since 1984. An estimated 20 million new cases occur each year, almost 50 percent in persons aged 15–24. Poverty, intravenous drug use, prostitution, and the appearance of drug-resistant pathogens all contribute to the problem.

CHECKPOINT

- 17. List the physiological events of sexual intercourse in both sexes, and indicate those that occur in males but not in females.
- 18. An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with which part of the male sex act?
- **19**. What changes occur in females during sexual arousal as the result of increased parasympathetic stimulation?
- See the blue Answers tab at the back of the book.

28–5 With age, decreasing levels of reproductive hormones cause functional changes

Learning Outcome Describe the reproductive system changes that occur with aging.

Sex hormones have widespread effects on the body. They affect brain development and behavioral drives, muscle mass, bone mass and density, body proportions, and the patterns of hair and body fat distribution. As aging occurs, reductions in sex hormone levels affect appearance, strength, and a variety of physiological functions. The aging process affects all body systems, including the reproductive systems of both men and women. As noted earlier in the chapter, these systems become fully functional at puberty. Later on, the most striking age-related changes in the female reproductive system occur at menopause. Comparable age-related changes in the male reproductive system occur more gradually and over a longer period of time.

Menopause

Menopause is usually defined as the time when ovulation and menstruation cease. Menopause typically occurs at age 45–55, but in the years immediately preceding it, the ovarian and uterine cycles become irregular. This interval is called *perimenopause*. A shortage of primordial follicles is the underlying cause of the irregular cycles. It has been estimated that almost 7 million potential oocytes are in fetal ovaries after five months of development, but the number decreases to about 2 million at birth, and to a few hundred thousand at puberty. With the arrival of perimenopause, the number of primordial follicles responding each month begins to decrease markedly. As their numbers decrease, estrogen levels decrease and may not increase enough to trigger ovulation. By age 50, there are often no primordial follicles left to respond to FSH. In **premature menopause**, this depletion occurs before age 40.

Menopause is accompanied by a decrease in circulating concentrations of estrogens and progesterone, and a sharp and sustained increase in the production of GnRH, FSH, and LH. The decrease in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal epithelia. The decreased estrogen concentrations have also been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. A variety of neural effects are reported as well, including "hot flashes," anxiety, and depression. Hot flashes typically begin while estrogen levels are decreasing, and cease when estrogen levels reach minimal values. These intervals of increased body temperature are associated with surges in LH production. The hormonal mechanisms involved in other CNS effects of menopause are poorly understood. In addition, the risks of atherosclerosis and other forms of cardiovascular disease increase after menopause.

The majority of women experience only mild symptoms, but some individuals experience acutely unpleasant symptoms in perimenopause or during or after menopause. For most of those women, hormone replacement therapy (HRT) involving a combination of estrogens and progesterone can control the unpleasant neural and vascular changes associated with menopause. The hormones are administered as pills, by injection, or by transdermal "estrogen patches." However, recent studies suggest that taking estrogen replacement therapy for more than five years increases the risk of heart disease, breast cancer, Alzheimer's disease, blood clots, and stroke. HRT should be used only after a full discussion and assessment of the potential risks and benefits, and taken for as short a time as possible.

The Male Climacteric

Changes in the male reproductive system take place more gradually than do those in the female reproductive system. The period of declining reproductive function, which corresponds to perimenopause in women, is known as the **male climacteric** or *andropause*. Levels of circulating testosterone begin to decrease between the ages of 50 and 60, and levels of circulating FSH and LH increase. Although sperm production continues (men well into their 80s can father children), older men experience a gradual reduction in sexual activity. This decrease may be linked to declining testosterone levels. Some clinicians suggest the use of testosterone replacement therapy to enhance the libido (sexual drive) of elderly men, but this may increase the risk of prostate disease.

CHECKPOINT

- **20**. Define menopause.
- 21. Why does the level of FSH increase and remain high during menopause?
- 22. What is the male climacteric?
- See the blue Answers tab at the back of the book.

28-6 The reproductive system secretes hormones affecting growth and metabolism of all body systems

Learning Outcome Give examples of interactions between the reproductive system and each of the other organ systems.

Normal human reproduction is a complex process that involves multiple systems. The hormones discussed in this chapter play a major role in coordinating reproductive events (Table 28–1).

28

Table 28–1 Hormo	Hormones of the Reproductive System					
Hormone	Source	Regulation of Secretion	Primary Effects			
Gonadotropin-releasing hormone (GnRH)	Hypothalamus	<i>Males:</i> inhibited by testosterone and possibly by inhibin <i>Females:</i> GnRH pulse frequency increased by estrogens, decreased by progesterone	Stimulates FSH secretion and LH synthesis in males Stimulates FSH secretion and LH synthesis in females			
Follicle-stimulating hormone (FSH)	Anterior lobe of the pituitary gland	<i>Males:</i> stimulated by GnRH, inhibited by inhibin <i>Females:</i> stimulated by GnRH, inhibited by inhibin	<i>Males:</i> stimulates spermatogenesis and spermiogenesis through effects on nurse cells <i>Females:</i> stimulates follicle development, estrogen production, and oocyte maturation			
Luteinizing hormone (LH)	Anterior lobe of the pituitary gland	<i>Males:</i> stimulated by GnRH <i>Females:</i> production stimulated by GnRH, secretion by the combination of high GnRH pulse frequencies and high estrogen levels	<i>Males:</i> stimulates interstitial cells to secrete testosterone <i>Females:</i> stimulates ovulation, formation of corpus luteum, and progesterone secretion			
Androgens (primarily testosterone and dihydrotestosterone)	Interstitial cells of testes	Stimulated by LH	Establish and maintain male secondary sex characteristics and sexual behavior; promote maturation of spermatozoa; inhibit GnRH secretion			
Estrogens (primarily estradiol)	Granulosa and thecal cells of developing follicles; corpus luteum	Stimulated by FSH	Stimulate LH secretion (at high levels); establish and maintain female secondary sex characteristics and sexual behavior; stimulate repair and growth of endometrium; increase frequency of GnRH pulses			
Progesterone	Granulosa cells from midcycle through functional life of corpus luteum	Stimulated by LH	Stimulate endometrial growth and glandular secretion; reduce frequency of GnRH pulses			
Inhibin	Nurse cells of testes and granulosa cells of ovaries	Stimulated by factors released by developing spermatozoa (male) and developing follicles (female)	Inhibits secretion of FSH (and possibly of GnRH)			

effects on growth and metabolism.

Figure 28–26 diagrams the functional relationships between the reproductive system and the other body systems.

Physical factors also play a role. The man's sperm count must be adequate, the semen must have the correct pH and nutrients, and erection and ejaculation must occur in the proper sequence. The woman's ovarian and uterine cycles must be properly coordinated; ovulation and oocyte transport must occur normally. Her reproductive tract must provide a hospitable environment for the survival and movement of sperm, and for the subsequent fertilization of the oocyte. For these steps to occur, the reproductive, digestive, endocrine, nervous, cardiovascular, and urinary systems must all be functioning normally.

Even when all else is normal and fertilization occurs at the proper time and place, a healthy infant will not be produced unless the zygote—the union of an ovum with a sperm forming a single cell the size of a pinhead—manages to develop into a full-term fetus that typically weighs about 3 kg (6.6 lb). In Chapter 29 we will consider the process of development, focusing on the mechanisms that determine both the structure of the body and the distinctive characteristics of each individual.

Even though the reproductive system's primary function producing offspring—doesn't play a role in maintaining homeostasis, reproduction depends on a variety of physical, physiological, and psychological factors. Many of these factors require intersystem cooperation. In addition, the hormones that control and coordinate sexual function have direct effects on the organs and tissues of other systems. For example, testosterone and estradiol affect both muscular development and bone density. **Figure 28–26** summarizes the relationships between the reproductive system and other body systems.

CHECKPOINT

- **23**. Describe the interaction between the reproductive system and the cardiovascular system.
- 24. Describe the interaction between the reproductive system and the skeletal system.
- See the blue Answers tab at the back of the book.

Related Clinical Terms

- **cervical dysplasia:** Abnormal growth of epithelial cells in the uterine cervix; may progress to cancer.
- **endometriosis:** The growth of endometrial tissue outside the uterus. **genital herpes:** A sexually transmitted disease caused by a herpes
- virus and characterized by painful blisters in the genital area. **gonorrhea:** A sexually transmitted bacterial disease caused by
- Neisseria gonorrhoeae. Commonly called "the clap."
- **gynecology:** The branch of medicine that deals with the functions and diseases specific to women and girls affecting the reproductive system.
- **hydrocele:** The accumulation of serous fluid in any body sac, but especially in the tunica vaginalis of the testis or along the spermatic cord.
- hysterectomy: The surgical removal of the uterus.

menorrhagia: The condition of experiencing extremely heavy bleeding at menstruation.

oophorectomy: The surgical removal of one or both ovaries. **orchitis:** Inflammation of one or both testicles.

- **ovarian cyst:** A condition (usually harmless) in which fluid-filled sacs develop in or on the ovary.
- **premature ejaculation:** A common complaint of ejaculating semen sooner than the man desires while achieving orgasm during intercourse. An estimated 30 percent of men regularly experience the problem.
- **polycystic ovary syndrome (PCOS):** A condition in women that is characterized by irregular or no menstrual periods, acne, obesity, and excessive hair growth.

- **premenstrual dysphoric disorder (PMDD):** A collection of physical and emotional symptoms that occur 5 to 11 days before a woman's period begins, and goes away once menstruation starts. Over 150 signs and symptoms have been associated with the condition.
- **premenstrual syndrome:** A condition occurring in the last half of the menstrual cycle after ovulation that is a combination of physical and mood disturbances which normally end with the onset of the menstrual flow.

salpingitis: Inflammation of a uterine tube.

- **uterine fibroids (leiomyomas):** Benign tumors of the uterus composed of smooth muscle tissue that grows in the wall of the uterus of some women. While not usually dangerous they can cause problems such as very heavy menstrual periods and pain.
- **uterine prolapse:** Condition that occurs when a woman's pelvic floor muscles and ligaments stretch and weaken and provide inadequate support for the uterus, which then descends into the vaginal canal.
- **vasectomy:** The surgical removal of a segment of each ductus (vas) deferens, making it impossible for spermatozoa to reach the distal portions of the male reproductive tract.
- **vulvovaginal candidiasis:** A common female vaginal infection caused by the yeast *Candida*, usually *Candida albicans*.

 PhysioEx
- 28-1 Basic reproductive system structures are gonads, ducts, accessory glands and organs, and external genitalia p. 1051
 - The human **reproductive system** produces, stores, nourishes, and transports functional **gametes** (reproductive cells).
 Fertilization is the fusion of male and female gametes.
 - 2. The reproductive system includes **gonads (testes** or **ovaries)**, ducts, accessory glands and organs, and the **external genitalia**.
- **3.** In males, the testes produce **spermatozoa**, which are expelled from the body in **semen** during *ejaculation*. The ovaries of a sexually mature female produce **oocytes** (immature **ova**) that travel along *uterine tubes* toward the *uterus*. The *vagina* connects the uterus with the exterior of the body.
- **28-2** Spermatogenesis occurs in the testes, and hormones from the hypothalamus, anterior lobe of the pituitary gland, and testes control male reproductive functions p. 1052
- 4. Spermatozoa travel along the *epididymis*, the *ductus deferens*, the *ejaculatory duct*, and the *urethra* before leaving the body. Accessory organs (notably the *seminal glands*, *prostate gland*, and *bulbourethral glands*) secrete fluids into the ejaculatory ducts and the urethra. The *scrotum* encloses the testes, and the *penis* is an erectile organ. (*Figure 28–1*)
- The descent of the testes through the *inguinal canals* occurs during fetal development. The testes remain connected to internal structures by the spermatic cords. The raphe marks the boundary between the two chambers in the scrotum. (*Figures 28–2, 28–3*)
- 6. The **dartos** muscle tightens the scrotum, giving it a wrinkled appearance as it elevates the testes. The **cremaster muscles** are more substantial muscles that pull the testes close to the body.
- The tunica albuginea surrounds each testis. Septa extend from the tunica albuginea to the region of the testis closest to the entrance to the epididymis, creating a series of lobules. (*Figure 28–4*)
 - 8. Seminiferous tubules within each lobule are the sites of sperm production. From there, spermatozoa pass through the **rete testis**. Seminiferous tubules connect to a **straight tubule**. Efferent ductules connect the rete testis to the

epididymis. Between the seminiferous tubules are **interstitial cells**, which secrete sex hormones. (*Figures 28–4, 28–5*)

- 9. Seminiferous tubules contain **spermatogonia**, stem cells involved in **spermatogenesis** (the production of spermatozoa), and **nurse** (sustentacular or Sertoli) **cells**, which sustain and promote the development of spermatozoa. (*Figures 28–6, 28–7*)
- **10.** Each **spermatozoon** has a **head** capped by an **acrosome**, a **middle piece**, and a **tail**. (*Figure 28–8*)
- 11. From the testis, the spermatozoa enter the **epididymis**, an elongated tubule with **head**, **body**, and **tail** regions. The epididymis monitors and adjusts the composition of the fluid in the seminiferous tubules, serves as a recycling center for damaged spermatozoa, stores and protects spermatozoa, and facilitates their functional maturation. (*Figure 28–9*)
- 12. The **ductus deferens**, or *vas deferens*, begins at the epididymis and passes through the inguinal canal as part of the spermatic cord. Near the prostate gland, the ductus deferens enlarges to form the **ampulla**. The junction of the base of the seminal gland and the ampulla creates the **ejaculatory duct**, which empties into the urethra. (*Figures 28–9, 28–10*)
- **13.** The **urethra** extends from the urinary bladder to the tip of the penis. The urethra can be divided into *prostatic, membranous,* and *spongy regions.*
- 14. Each seminal gland (seminal vesicle) is an active secretory gland that contributes about 60 percent of the volume of semen. Its secretions contain fructose (which is easily metabolized by spermatozoa), bicarbonate ions, prostaglandins, and fibrinogen. The prostate gland secretes slightly acidic prostatic fluid. Alkaline mucus secreted by the bulbourethral glands has lubricating properties. (*Figures 28–10, 28–11*)
- **15.** A typical ejaculation releases 2–5 mL of semen **(ejaculate)**, which contains 20–100 million spermatozoa per milliliter. The fluid component of semen is **seminal fluid**.
- 16. The skin overlying the **penis** resembles that of the scrotum. Most of the **body** of the penis consists of three masses of **erectile tissue**. Beneath the superficial fascia are two **corpora cavernosa** and a single **corpus spongiosum**, which surrounds the urethra. Dilation of the blood vessels within the erectile tissue produces an **erection**. (*Figure 28–11*)
- 17. Important regulatory hormones include **FSH** (*follicle-stimulating hormone*), **LH** (*luteinizing hormone*), and **GnRH** (*gonadotropin-releasing hormone*). *Testosterone* is the most important androgen. (*Spotlight Figure 28–12*)

28-3 Oogenesis occurs in the ovaries, and hormones from the pituitary gland and gonads control female reproductive functions p. 1068

- **18.** Principal organs of the female reproductive system include the *ovaries, uterine tubes, uterus, vagina,* and external genitalia. (*Figure 28–13*)
- **19.** The ovaries, uterine tubes, and uterus are enclosed within the **broad ligament**. The **mesovarium** supports and stabilizes each ovary. (*Figure 28–14*)
- **20.** The ovaries are held in position by the **ovarian ligament** and the **suspensory ligament**. Major blood vessels enter the ovary at the **ovarian hilum**. Each ovary is covered by a **tunica albuginea**. (*Figure 28–14*)

- 21. **Oogenesis** (ovum production) occurs monthly in **ovarian follicles** as part of the **ovarian cycle**, which is divided into a **follicular** (*preovulatory*) **phase** and a **luteal** (*postovulatory*) **phase**. (*Figures* 28–15, 28–16)
- 22. As follicle development proceeds, **primary**, **secondary**, and **tertiary follicles** are produced in turn. At **ovulation**, a **secondary oocyte** and the attached follicular cells of the **corona radiata** are released through the ruptured ovarian wall. The follicular cells remaining within the ovary form the **corpus luteum**, which later degenerates into scar tissue called a **corpus albicans**. (*Figure 28–16*)
- **23.** Each **uterine tube** has an **infundibulum** with **fimbriae** (fingerlike projections), an **ampulla**, and an **isthmus**. Each uterine tube opens into the *uterine cavity*. For fertilization to occur, a secondary oocyte must encounter spermatozoa during the first 12–24 hours of its passage from the infundibulum to the uterus. (*Figure 28–17*)
- 24. *Peg cells* lining the uterine tube secrete a fluid that completes the capacitation of spermatozoa.
- 25. The uterus provides mechanical protection, nutritional support, and waste removal for the developing embryo and fetus. Normally, the uterus bends anteriorly near its base (*anteflexion*). The broad ligament, uterosacral ligaments, round ligaments, and lateral ligaments stabilize the uterus. (*Figure 28–18*)
- 26. Major anatomical landmarks of the uterus include the body, isthmus, cervix, external os (external orifice), uterine cavity, cervical canal, and internal os (internal orifice). The uterine wall consists of an inner endometrium, a muscular myometrium, and a superficial perimetrium (an incomplete serous layer). (Figures 28–18, 28–19)
- 27. A typical 28-day **uterine**, or *menstrual*, **cycle** begins with the onset of **menses** and the destruction of the **functional zone** of the endometrium. This process of **menstruation** continues from one to seven days. (*Figure 28–20*)
- 28. After menses, the **proliferative phase** begins, and the functional zone thickens and undergoes repair. The proliferative phase is followed by the **secretory phase**, during which uterine glands enlarge. Menstrual activity begins at **menarche** and continues until **menopause**. (*Figure 28–20*)
- **29.** The **vagina** is a muscular tube extending between the uterus and the external genitalia; it is lined by a nonkeratinized stratified squamous epithelium. A thin epithelial fold, the **hymen**, partially blocks the entrance to the vagina until physical distortion ruptures the membrane. (*Figures 28–21, 28–22*)

- **30.** The components of the **vulva** are the **vestibule**, **labia minora**, **paraurethral glands**, **clitoris**, **labia majora**, and **lesser** and **greater vestibular glands**. (*Figure 28–22*)
- **31.** A newborn infant is nourished from milk secreted by maternal **mammary glands**. (*Figure 28–23*)
- **32.** Hormonal regulation of the **female reproductive cycle** involves the coordination of the ovarian and uterine cycles. (*Spotlight Figure 28–24*)
- **33. Estradiol**, the most important *estrogen*, is the dominant hormone of the follicular phase. Ovulation occurs in response to a midcycle surge in LH. (*Spotlight Figure 28–24*, *Figure 28–25*)
- 34. The hypothalamic secretion of GnRH occurs in pulses that trigger the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian interstitial cells produce estrogens. High estrogen levels stimulate LH secretion, increase pituitary sensitivity to GnRH, and increase the GnRH pulse frequency. **Progesterone** is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. *(Spotlight Figure 28–24)*

28-4 The autonomic nervous system influences male and female sexual function p. 1087

- 35. During sexual **arousal** in males, erotic thoughts, sensory stimulation, or both lead to parasympathetic activity that produces erection. Stimuli accompanying **sexual intercourse** lead to **emission** and **ejaculation**. Contractions of the bulbospongiosus muscles are associated with **orgasm**.
- **36.** The events of female sexual function resemble those of male sexual function, with parasympathetic arousal and skeletal muscle contractions associated with orgasm.

28-5 With age, decreasing levels of reproductive hormones cause functional changes p. 1088

- **37.** Menopause (the time that ovulation and menstruation stop) typically occurs at ages 45–55. The production of GnRH, FSH, and LH rise, whereas circulating concentrations of estrogen and progesterone decrease.
- **38.** During the **male climacteric**, at ages 50–60, circulating testosterone levels decrease, and FSH and LH levels increase.

28-6 The reproductive system secretes hormones affecting growth and metabolism of all body systems p. 1089

39. Normal human reproduction depends on a variety of physical, physiological, and psychological factors, many of which require intersystem cooperation. (*Figure 28–26; Table 28–1*)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- 1. Developing spermatozoa are nourished by (a) interstitial cells, (b) the seminal glands, (c) nurse cells, (d) Leydig cells, (e) the epididymis.
- 2. The ovaries are responsible for (a) the production of female gametes,(b) the secretion of female sex hormones, (c) the secretion of inhibin,(d) all of these.
- 3. In females, meiosis II is not completed until (a) birth, (b) puberty, (c) fertilization occurs, (d) uterine implantation occurs.
- 4. A sudden surge in LH secretion causes the (a) onset of menses,
 (b) rupture of the follicular wall and ovulation, (c) beginning of the proliferative phase, (d) end of the uterine cycle.

See the blue Answers tab at the back of the book.

- 5. The main hormone of the postovulatory phase is (a) progesterone,(b) estradiol, (c) estrogen, (d) luteinizing hormone.
- 6. Which accessory structures contribute to the composition of semen? What are the functions of each structure?
- 7. What types of cells in the testes are responsible for functions related to reproductive activity? What are the functions of each cell type?
- 8. Identify the three regions of the male urethra.
- 9. List the functions of testosterone in males.
- 10. List and summarize the important steps in the ovarian cycle.
- 11. Describe the histological composition of the uterine wall.
- 12. What is the role of the clitoris in the female reproductive system?

- 13. Trace the path of milk flow from its site of production to outside the female
- 14. Identify the main structures of the male reproductive system in the diagram below.

(a)	 (b)	
(c)	 (d)	
(e)	 (f)	
(g)	 (h)	
(i)	 (j)	
(k)	 (1)	

LEVEL 2 Reviewing Concepts

- 15. In the follicular phase of the ovarian cycle, the ovary (a) undergoes atresia, (b) forms a corpus luteum, (c) releases a mature ovum, (d) secretes progesterone, (e) matures a follicle.
- 16. Summarize the roles of the hormones in the ovarian and uterine cycles.
- 17. What are the main differences in gamete production between males and females?
- 18. Describe the erectile tissues of the penis. How does erection occur?
- 19. Describe each of the three phases of a typical 28-day uterine cycle.
- 20. Describe the hormonal events associated with the ovarian cycle.
- 21. Describe the hormonal events associated with the uterine cycle.
- 22 Summarize the events that occur in sexual arousal and orgasm. Do these processes differ in males and females?
- 23. How does the aging process affect the reproductive systems of men and women?

LEVEL 3 Critical Thinking and Clinical Applications

- 24. Diane has peritonitis (an inflammation of the peritoneum), which her physician says resulted from a urinary tract infection. Why might this condition occur more readily in females than in males?
- 25. In a condition known as endometriosis, endometrial cells are believed to migrate from the body of the uterus into the uterine tubes or by way of the uterine tubes into the peritoneal cavity, where they become established. A major symptom of endometriosis is periodic pain. Why does such pain occur?
- 26. Contraceptive pills contain estradiol and progesterone, or progesterone alone, administered at programmed doses during the ovarian cycle to prevent follicle maturation and ovulation. Explain how such pills are effective.
- 27. Female bodybuilders and women with eating disorders such as anorexia nervosa commonly experience amenorrhea. What does this fact suggest about the relation between body fat and menstruation? What effect would amenorrhea have on achieving a successful pregnancy?

CLINICAL CASE

A Post-Game Mystery

The emergency room doctor examines Dan and notes how uncomfortable he is. Dan's left testis is extremely tender to the touch and is visibly higher than the right testis. It also appears swollen. The doctor further notes that the epididymis on the left testis is located anteromedially, near the scrotal raphe, instead of the normal posterior location. Dan's cremasteric reflex is intact on the right. But when the physician strokes Dan's inner left thigh, Dan's left testis does not retract toward his inguinal canal. His genitofemoral nerve is no longer working.

The doctor does a bedside ultrasonography, an imaging technique using high-frequency sound waves, and determines there is no blood supply to Dan's left testis. The doctor concludes that Dan is suffering from an acute testicular torsion. His left testis has twisted on its spermatic cord and cut off its blood supply,

Wrap-Up

including the deferential artery, the testicular artery, and the venous pampiniform plexus. This torsion has also twisted the genitofemoral nerve. Dan's left testis is infarcting, or dying from lack of blood.

the scene. "Sorry about ruining your homecoming night, Dan," she says. "But our best chance of saving your testis is to head straight to the operating room and untwist it."

- 1. What other structures in Dan's left spermatic cord are being twisted with this testicular torsion?
- 2. Epididymitis is a painful inflammation of the epididymis that can mimic the clinical signs and symptoms of testicular torsion. Do you think Dan's cremasteric reflex would be intact if he were suffering from epididymitis?

See the blue Answers tab at the back of the book.

Development and Inheritance

Learning Outcomes

79

These Learning Outcomes correspond by number to this chapter's sections and indicate what you should be able to do after completing the chapter.

- **29-1** Explain the relationship between differentiation and development, and specify the various stages of development.
- **29-2** Describe the process of fertilization, and explain how developmental processes are regulated.
- **29-3** List the three stages of prenatal development, and describe the major events of each.
- **29-4** Explain how the three germ layers are involved in forming the extraembryonic membranes, and discuss the importance of the placenta as an endocrine organ.
- **29-5** Describe the interplay between the maternal organ systems and the developing fetus, and discuss the structural and functional changes in the uterus during gestation.
- **29-6** List and discuss the events that occur during labor and delivery.
- **29-7** Identify the features and physiological changes of the postnatal stages of life.
- **29-8** Relate basic principles of genetics to the inheritance of human traits.

SPOTLIGHT

• Extraembryonic Membranes and Placenta Formation pp. 1104–1105

CLINICAL CASE

• The Twins That Looked Nothing Alike p. 1096

Clinical Notes

- Abortion p. 1114
- Chromosomal Abnormalities and Genetic Analysis p. 1130

CLINICAL CASE

The Twins That Looked Nothing Alike

Annie and her twin, Ruth, are in Twinsburg, Ohio, for the Twins Day Festival, the largest annual celebration of twins in the world. There are thousands of identical twins in attendance, and a healthy representation of fraternal twins as well. Annie and Ruth are amazed to see so many twins who not only look alike but also move alike, sound alike, and smile alike.

As they walk through the festival grounds, Annie and Ruth notice tents set up to recruit twins for everything from FBI facerecognition software development to fingerprint and handwriting analysis. The festival is a popular event for "nurture vs. nature" researchers who are looking for twins to enlist in their studies.

Another centerpiece of the festival is the awarding of medals to twins in various categories, including the oldest twins, the youngest twins, the "most-alike" twins, and the "least-alike" twins.

This year, the "least-alike" twins medals are awarded to two boys, one who is short and Caucasian, the other who is tall and of African descent. Annie elbows Ruth and asks, "What do you think is the story with these twins?" To find out, turn to the Clinical Case Wrap-Up on p. 1134.

An Introduction to Development and Inheritance

The physiological processes we have studied so far are relatively brief. Many last only a fraction of a second, and others may take hours. But some important processes are measured in months, years, or decades. A human being develops in the womb for nine months, grows to maturity in 15 to 20 years, and may live the better part of a century. During that time, he or she is always changing. Birth, growth, maturation, aging, and death are all parts of a single, continuous process. That process does not end with the individual, because humans can pass at least some of their characteristics on to their offspring. Each generation gives rise to a new generation that will repeat the cycle.

In this chapter, we explore how genetic programming, environmental factors, and various physiological processes affect the events following the union of male and female gametes sperm and oocytes. The explanation begins with prenatal development and continues through childhood and adolescence and into maturity and senescence, or aging.

29-1 Development, marked by various stages, is a continuous process that occurs from fertilization to maturity

Learning Outcome Explain the relationship between differentiation and development, and specify the various stages of development.

Time refuses to stand still. Today's infant will be tomorrow's adult. The gradual modification of anatomical structures and physiological characteristics during the period from fertilization to maturity is called **development**. The changes that

occur during development are truly remarkable. In a mere nine months, all the tissues, organs, and organ systems we have studied so far take shape and begin to function. What begins as a single cell slightly larger than the period at the end of this sentence becomes an individual like yourself whose body contains trillions of cells organized into a complex array of highly specialized structures. The formation of the different types of cells required in this process is called **differentiation**. Differentiation occurs through selective changes in genetic activity. As development proceeds, some genes are turned off and others are turned on. Exactly which genes are turned off and on varies from one type of cell to another, and the patterns change over time.

Development begins at **fertilization**, or **conception**, when the male and female gametes fuse. We divide development into stages characterized by specific anatomical changes. **Embryonic development** includes the events during the first two months after fertilization. The study of these events is called **embryology** (em-brē-OL-ō-jē). **Fetal development** begins at the start of the ninth week and continues until birth. Embryonic and fetal development are sometimes referred to collectively as **prenatal** (*natus*, birth) **development**, the primary focus of this chapter. **Postnatal development** begins at birth and continues to **maturity**, the state of full development or completed growth.

A basic understanding of human development gives important insights into anatomical structures. In addition, many of the mechanisms of development and growth are similar to those that repair injuries. In this chapter, we focus on major aspects of development. We consider highlights of the developmental process rather than examine the events in great detail. We also consider the regulatory mechanisms involved, and how developmental patterns can be modified for good or harm. Few topics in the biological sciences are All humans go through the same developmental stages, but differences in their genetic makeup produce distinctive individual characteristics. The term **inheritance** or **heredity** refers to the transfer of genetically determined characteristics from generation to generation. The study of the mechanisms responsible for inheritance is called **genetics**. In this chapter, we will consider basic genetics as it applies to inherited characteristics, such as sex, hair color, and various diseases.

- CHECKPOINT

- 1. Define differentiation.
- 2. What event marks the onset of development?
- **3**. Define inheritance.

See the blue Answers tab at the back of the book.

29-2 Fertilization—the fusion of a secondary oocyte and a spermatozoon—forms a zygote

Learning Outcome Describe the process of fertilization, and explain how developmental processes are regulated.

Fertilization involves the fusion of two haploid gametes, each containing 23 chromosomes, producing a zygote that contains 46 chromosomes, the normal diploid number in a human somatic cell. The functional roles and contributions of the male and female gametes are very different. The spermatozoon delivers the paternal (father's) chromosomes to the site of fertilization. It must travel a relatively long distance and is small, efficient, and highly streamlined. In contrast, the female oocyte provides all the cellular organelles and inclusions, nourishment, and genetic programming necessary to support development of the embryo for nearly a week after conception. For this reason, the volume of this gamete is much greater than that of the spermatozoon. Recall from Chapter 28 that ovulation releases a secondary oocyte suspended in metaphase of meiosis II. At fertilization, the diameter of the secondary oocyte is more than twice the entire length of the spermatozoon (Figure 29–1a). The ratio of their volumes is even more striking—approximately 2000:1.

The spermatozoa deposited in the vagina are already motile, as a result of contact with secretions of the seminal

glands—the first step of *capacitation*. **D** p. 1062 Capacitation involves the physical changes in the sperm coating and uncovering of receptors that allow it to penetrate and fertilize an oocyte. (An unidentified substance secreted by the epididymis appears to prevent premature capacitation.) The spermatozoa, however, cannot accomplish fertilization until they have been exposed to conditions in the female reproductive tract. Uterine tube peg cell secretions help with capacitation, but the exact mechanism responsible for capacitation remains unknown. Furthermore, how sperm "find" the oocyte remains a rich field of investigation. Fertilization typically takes place near the junction between the ampulla and isthmus of the uterine tube. It generally occurs within a day after ovulation. By this time, the secondary oocyte has traveled only a few centimeters, but spermatozoa must cover the distance between the vagina and the ampulla of the uterine tube. A spermatozoon can propel itself at speeds of only about 34 µm per second, or about 12.5 cm (5 in.) per hour. In theory it should take spermatozoa several hours to reach the upper portions of the uterine tubes. The actual time, however, ranges from two hours to as little as 30 minutes. Contractions of the uterine musculature and ciliary currents in the uterine tubes have been suggested as possibly helping the spermatozoa travel from the vagina to the site of fertilization.

Even with transport assistance, the passage is not easy. Of the nearly 200 million spermatozoa introduced into the vagina in a typical ejaculation, only about 10,000 enter the uterine tube, and fewer than 100 reach the isthmus. In general, a male with a sperm count below 20 million per milliliter is functionally sterile because too few spermatozoa survive to reach and fertilize an oocyte. While it is true that only one spermatozoon fertilizes an oocyte, dozens of spermatozoa are required for successful fertilization. The additional sperm are essential because one sperm does not contain enough acrosomal enzymes to disrupt the *corona radiata*, the layer of follicle cells that surrounds the oocyte.

The Oocyte at Ovulation

Ovulation takes place before the oocyte is completely mature. The secondary oocyte leaving the follicle is in metaphase of meiosis II. The cell's metabolic operations have been suspended as it awaits the stimulus for further development. If fertilization does not take place, the oocyte disintegrates without completing meiosis.

Fertilization is complicated by the fact that when the secondary oocyte leaves the ovary, it is surrounded by the corona radiata. Fertilization and the events that follow are diagrammed in **Figure 29–1b**. The cells of the corona radiata protect the secondary oocyte as it passes through the ruptured

Figure 29–1 Fertilization.

a A secondary oocyte and numerous sperm at the time of fertilization. Notice the difference in size between the gametes. follicular wall, across the surface of the ovary, and into the infundibulum of the uterine tube. The physical process of fertilization requires that only a single spermatozoon contact the oocyte membrane, but that spermatozoon must first penetrate the corona radiata. The acrosome of each sperm contains several enzymes, including **hyaluronidase** (hī-uh-lū-RON-i-dās). Hyaluronidase breaks down the bonds between adjacent follicle cells. Dozens of spermatozoa must release hyaluronidase before the connections between the follicle cells break down enough to allow an intact spermatozoon to reach the oocyte.

No matter how many spermatozoa slip through the gap in the corona radiata, only a single spermatozoon fertilizes and activates the oocyte (1, Figure 29–1b). That spermatozoon must have an intact acrosome. The first step is the binding of the spermatozoon to *sperm receptors* in the zona pellucida, a thick envelope surrounding the oocyte. This binding triggers the rupture of the acrosome. The hyaluronidase and **acrosin**, another protein-digesting enzyme, then digest a path through the zona pellucida toward the surface of the oocyte. When the sperm contacts that surface, the sperm and oocyte membranes begin to fuse. This step triggers *oocyte activation*, a complex process we discuss in the next section.

b Fertilization and the preparations for cleavage.

29

Oocyte Activation

Oocyte activation involves a series of changes in the metabolic activity of the oocyte. The trigger for activation is contact and fusion of the plasma membranes of the sperm and oocyte. This process is accompanied by the depolarization of the oocyte membrane due to an increased permeability to sodium ions. The entry of sodium ions in turn causes the release of calcium ions from the smooth endoplasmic reticulum. The sudden rise in Ca^{2+} levels has important effects, including the following:

- *Exocytosis of Vesicles Adjacent to the Oocyte Membrane.* This process, called the *cortical reaction*, releases enzymes called zonal inhibiting proteins, or ZIPs, that both inactivate the sperm receptors and harden the zona pellucida. This combination prevents **polyspermy**, or fertilization by more than one sperm, which would create a zygote that is incapable of normal development. (Prior to completion of the cortical reaction, depolarization of the oocyte membrane probably prevents fertilization by any other sperm cells that penetrate the zona pellucida.)
- Completion of Meiosis II and Formation of the Second Polar Body. The sperm enters the oocyte and loses its plasma membrane. Meiosis II, which began in the tertiary follicle, can now be completed because fertilization occurred. The fertilized oocyte is now called an *ovum*.
- Activation of Enzymes That Cause a Rapid Increase in the Cell's Metabolic Rate. The cytoplasm contains a large number of mRNA strands that have been inactivated by special proteins. The mRNA strands are now activated, so protein synthesis accelerates quickly. Most of the proteins synthesized are required for development to proceed.

After oocyte activation and the completion of meiosis, the nuclear material remaining within the ovum reorganizes as the **female pronucleus** (2), Figure 29–1b). While these changes are under way, the nucleus of the spermatozoon swells. As it forms the **male pronucleus**, the rest of the sperm cell breaks down (3). The male pronucleus then migrates toward the center of the cell, and spindle fibers form. The male and female pronuclei then fuse in a process called *amphimixis* (am-fi-MIK-sis) (4). The cell is now a **zygote** that contains the normal diploid complement of 46 chromosomes, and fertilization is complete. This is the "moment of conception." Almost immediately, the chromosomes line up along a metaphase plate, and the cell prepares to divide. This is the start of the process of *cleavage*, a series of cell divisions that produce an ever-increasing number of smaller and smaller daughter cells. The first cleavage division is completed about 30 hours after fertilization. It yields two daughter cells, each one-half the size of the original zygote (**5**). These cells are called *blastomeres* (BLAS-tō-mērz).

TIPS&TRICKS

Amphimixis means "both mixed together."

CHECKPOINT

- 4. Name two sperm enzymes important to secondary oocyte penetration.
- 5. How many chromosomes are contained within a human zygote?

See the blue Answers tab at the back of the book.

29–3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters

Learning Outcome List the three stages of prenatal development, and describe the major events of each.

During prenatal development, a single cell ultimately forms a 3–4 kg (6.6–8.8 lb) infant. In postnatal development, the infant will grow through adolescence and maturity toward old age and eventual death. One of the most fascinating aspects of development is its apparent order. Continuity exists at all levels and at all times. Nothing "leaps" into existence without apparent precursors. Differentiation and increasing structural complexity take place hand in hand.

Differentiation involves changes in the genetic activity of some cells but not others. A continuous exchange of information takes place between the nucleus and the cytoplasm in a cell. Activity in the nucleus varies in response to chemical messages that arrive from the surrounding cytoplasm. In turn, ongoing nuclear activity alters conditions within the cytoplasm by directing the synthesis of specific proteins. In this way, the nucleus can affect enzyme activity, cell structure, and membrane properties.

In development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. These changes in turn lead to further alterations in the cytoplasm, and the process continues in a sequence. But if all the cells of the embryo are derived from cell divisions of a zygote, how do the cytoplasmic differences originate? What sets the process in motion? The important first step occurs before fertilization, while the oocyte is in the ovary.

Before ovulation, the growing oocyte accepts amino acids, nucleotides, and glucose, as well as more complex materials such as phospholipids, mRNA molecules, and proteins, from the surrounding granulosa cells. The contents of the cytoplasm are not evenly distributed because not all follicle cells manufacture and deliver the same nutrients and instructions to the oocyte. After fertilization, the zygote divides into ever-smaller cells that differ from one another in cytoplasmic composition. These differences alter the genetic activity of each cell, creating cell lines with increasingly diverse fates.

As development proceeds, some of the cells release chemical substances, including RNA molecules, polypeptides, and small proteins that affect the differentiation of other embryonic cells. This type of chemical interplay among developing cells is called *induction* (in-DUK-shun). It works over very short distances, such as when two types of cells are in direct contact. It may also operate over longer distances, with the inducing chemicals functioning as hormones.

This type of regulation, which involves an integrated series of interacting steps, can control highly complex processes. The mechanism is not always error free, however. The appearance of an abnormal or inappropriate inducer can change the course of development.

The time spent in prenatal development is known as **gestation** (jes-TĀ-shun). For convenience, we usually think of the gestation period as three integrated **trimesters**, each lasting three months:

- 1. The **first trimester** is the period of embryonic and early fetal development. During this time, the beginnings of all the major organ systems appear.
- 2. The **second trimester** is dominated by the development of organs and organ systems. This process nears completion by the end of the sixth month. During this time, body shape and proportions change. By the end of this trimester, the fetus looks distinctively human.
- **3.** The **third trimester** is characterized by rapid fetal growth and deposition of adipose tissue. Early in the third trimester, most of the fetus's major organ systems become fully functional. An infant born one month or even two months prematurely has a reasonable chance of survival.

Martini's Atlas of the Human Body contains "Embryology Summaries" that introduce key steps in embryonic and fetal development. The summaries also trace the development of specific organ systems. We will refer to those summaries in the discussions that follow. As you proceed, reviewing the referenced material will help you understand the "big picture" as well as the specific details.

CHECKPOINT

- 6. Define gestation.
- 7. Characterize the key features of each trimester.

See the blue Answers tab at the back of the book.

29-4 Cleavage, implantation, placentation, and embryogenesis are critical events of the first trimester

Learning Outcome Explain how the three germ layers are involved in forming the extraembryonic membranes, and discuss the importance of the placenta as an endocrine organ.

At the moment of conception, the fertilized ovum is a single cell about 0.135 mm (0.005 in.) in diameter. It weighs approximately 150 μ g. By convention, pregnancies are clinically dated from the last menstrual period (LMP), which is usually two weeks before ovulation and conception. At the end of the first trimester (12 weeks from LMP, but only 10 developmental weeks), the fetus is almost 75 mm (3 in.) long and weighs perhaps 14 g (0.5 oz).

Many important and complex developmental events occur during the first trimester. Here we focus on four general processes: cleavage, implantation, placentation, and embryogenesis:

- 1. **Cleavage** (KLĒV-ij) is a sequence of cell divisions that begins immediately after fertilization (Figure 29–1b). During cleavage, the zygote becomes a **pre-embryo**, which develops into a multicellular complex known as a *blastocyst*. Cleavage ends when the blastocyst first contacts the uterine wall. Cleavage and blastocyst formation are introduced in the *Atlas*.
- Implantation begins when the blastocyst attaches to the endometrium of the uterus. The process continues as the blastocyst invades maternal tissues. Important events during implantation set the stage for the formation of vital embryonic structures.
- 3. **Placentation** (plas-en-TĀ-shun) occurs as blood vessels form around the periphery of the blastocyst, and as the placenta develops. The **placenta** is a complex organ that permits exchange between maternal and embryonic blood. It supports the fetus from its formation early in the first trimester until just after birth, when the placenta stops functioning and is expelled from the uterus. From that point on, the newborn is physically independent of the mother.
- Embryogenesis (em-brē-ō-JEN-e-sis) is the formation of a viable embryo. This process establishes the foundations for all major organ systems.

These processes are both complex and vital to the survival of the embryo. Perhaps because the events in the first trimester are so complex, it is the most dangerous prenatal stage. Only about 40 percent of conceptions produce embryos that survive the first trimester. For that reason, pregnant women are warned to avoid drugs, alcohol, tobacco, and other disruptive stresses during the first trimester, in the hope of preventing an error in the intricate processes that are under way.

Cleavage and Blastocyst Formation

Cleavage is a series of cell divisions that subdivides the cytoplasm of the zygote (Figures 29–1b and 29–2). The first cleavage produces a pre-embryo consisting of two identical cells. As noted earlier, cleavage divisions produce identical cells called **blastomeres**. After the first division is completed approximately 30 hours after fertilization, subsequent divisions take place at intervals of 10–12 hours. During the initial divisions, all the blastomeres divide simultaneously. As the number of blastomeres increases, the timing becomes less predictable.

After three days of cleavage, the pre-embryo is a solid ball of cells resembling a mulberry. This stage is called the **morula** (MOR- \bar{u} -luh; *morus*, mulberry). The morula typically reaches the uterus on day 4. Over the next two days, the blastomeres form a **blastocyst**, a hollow ball with an inner cavity known as the **blastocoele** (BLAS-t \bar{o} -s \bar{e} l). The blastomeres are now no longer identical in size and shape. The outer layer of cells is called the **trophoblast** (TR \bar{O} -f \bar{o} -blast). As the word *trophoblast* implies (*trophos*, food + *blast*, precursor), cells in this layer provide nutrients to the developing embryo. A second group of cells, the **inner cell mass**, lies clustered at one end of the blastocyst. These cells are exposed only to the blastocoele and insulated from contact with the outside uterine environment by the trophoblast. In time, the inner cell mass will form the embryo.

Implantation

During blastocyst formation, enzymes released by the trophoblast erode an opening in the zona pellucida, which is then shed in a process known as *hatching* (Figure 29–2). The blastocyst is now freely exposed to the fluid contents of the uterine cavity. The uterine glands secrete this glycogen-rich fluid. Throughout the previous few days, the pre-embryo and early blastocyst had been absorbing fluid and nutrients from its surroundings. The process now accelerates, and the blastocyst enlarges. When fully formed, the blastocyst contacts the endometrium, and implantation takes place (Figures 29–2 and 29–3).

Implantation begins as the surface of the blastocyst closest to the inner cell mass adheres to the uterine lining (see day 7 in **Figure 29–3**). At the point of contact, the trophoblast cells divide rapidly, making the trophoblast several layers thick. The cells closest to the interior of the blastocyst remain intact, forming a layer of **cellular trophoblast**, or *cytotrophoblast*. Near the endometrial wall, however, the plasma membranes separating the trophoblast cells disappear, creating a layer of cytoplasm

Figure 29–3 Stages in Implantation.

with multiple nuclei (day 8). This outer layer is called the **syncytial** (sin-SISH-ul) **trophoblast**, or *syncytiotrophoblast*.

The syncytial trophoblast erodes a path through the uterine epithelium by secreting hyaluronidase. This enzyme dissolves the proteoglycans between adjacent epithelial cells, just as hyaluronidase released by spermatozoa dissolved the connections between cells of the corona radiata. At first, the erosion creates a gap in the uterine lining, but maternal epithelial cells migrate and divide and soon repair the surface. By day 10 the repairs are complete, and the blastocyst has lost contact with the uterine cavity. Further development occurs entirely within the functional zone of the endometrium.

In most cases, implantation occurs in the fundus or in the body of the uterus. In an **ectopic pregnancy**, implantation occurs somewhere other than within the uterus, such as in one of the uterine tubes. Approximately 0.6 percent of pregnancies are ectopic pregnancies. They do not produce a viable embryo and can be life-threatening to the mother.

As implantation proceeds, the syncytial trophoblast continues to enlarge and spread into the surrounding endometrium (see day 9, Figure 29–3). The erosion of uterine glands releases nutrients that are absorbed by the syncytial trophoblast. They diffuse through the underlying cellular trophoblast to the inner cell mass. These nutrients provide the energy needed for the early stages of embryo formation. Trophoblastic extensions grow around endometrial capillaries. As the capillary walls are destroyed, maternal blood begins to percolate through trophoblastic channels known as **lacunae** (*lacuna*, singular). Fingerlike **villi** extend away from the trophoblast into the surrounding endometrium, gradually increasing in size and complexity until about day 21. As the syncytial trophoblast spreads, it begins breaking down larger endometrial veins and arteries, and blood flow through the lacunae accelerates.

Formation of the Amniotic Cavity

The inner cell mass has little apparent organization early in the blastocyst stage. Yet by the time of implantation, the inner cell mass has separated from the trophoblast. The separation gradually increases, creating a fluid-filled chamber called the **amniotic** (am-nē-OT-ik) **cavity** (see day 9 in Figure 29–3; details from days 10–12 are shown in Figure 29–4). The trophoblast will later be separated from the amniotic cavity by layers of cells that originate at the inner cell mass and line the amniotic cavity. These layers form the *amnion*, a membrane we will examine later in the chapter. When the amniotic cavity first appears, the cells of the inner cell mass are organized into an oval sheet that is two layers thick. A superficial layer faces the amniotic cavity, and a deeper layer is exposed to the fluid contents of the blastocoele.

Gastrulation and Germ Layer Formation

By day 12, a third layer of cells begins to form between the superficial and deep layers of the inner cell mass through a process

Figure 29–4 The Inner Cell Mass and Gastrulation.

Day 10: Yolk Sac Formation

called **gastrulation** (gas-trū-LĀ-shun) (day 12, Figure 29–4). Together, the three layers of cells are called *germ layers*. The layers are known as the *ectoderm*, *mesoderm*, and *endoderm*. Table 29–1 contains a listing of the contributions each germ layer makes to form the body systems described in earlier chapters. The formation of the mesoderm between the ectoderm and endoderm, and the developmental fates of the three germ layers are also summarized in the *Atlas*.

Formation of the Extraembryonic Membranes

The germ layers also form four **extraembryonic membranes**: the yolk sac, amnion, allantois, and chorion. **Spotlight Figure 29–5** illustrates and describes the processes involved in the development of these extraembryonic membranes. We'll focus on the chorion here because of its early role in the maternal–embryo exchange of nutrients, gases, and wastes. When implantation first occurs, the nutrients absorbed by the trophoblast can easily reach the inner cell mass by simple diffusion. But as the embryo and the trophoblast enlarge, the distance between them increases, so diffusion alone can no longer keep pace with the demands of the developing embryo. Blood vessels now begin to develop within the mesoderm of the chorion, creating a rapid-transit system for nutrients that links the embryo with the trophoblast.

Chorionic villi continue to enlarge and branch, creating an intricate network within the endometrium. Embryonic blood vessels develop within each villus. Blood flow through those chorionic vessels begins early in the third week of development,

SPOTLIGHT Figure 29–5 Extraembryonic Membranes and Placenta Formation

The germ layers introduced in Figure 29–4 also form four **extraembryonic membranes:** (1) The **yolk sac** (ectoderm and mesoderm), (2) the **amnion** (ectoderm and mesoderm), (3) the **allantois** (endoderm and mesoderm), and (4) the **chorion** (mesoderm and trophoblast). These membranes support embryonic and fetal development, but few traces of their existence remain in adults.

Yolk sac

The yolk sac begins as a layer of cells spreads out around the outer edges of the blastocoele to form a complete pouch. It is the primary nutrient source for early embryonic develoment, and becomes an important site for blood cell formation.

Amnion

Ectodermal cells spread over the inner surface of the amniotic cavity, soon followed by mesodermal cells. Amniotic fluid is produced, which cushions the developing embryo.

Week 2

Migration of mesoderm around the inner surface of the cellular trophoblast forms the chorion. Mesodermal migration around the outside of the amniotic cavity, between the ectodermal cells and the trophoblast, forms the amnion. Mesodermal migration around the endodermal pouch creates the yolk sac.

Week 3

2

The embryonic disc bulges into the amniotic cavity at the head fold. The allantois, an endodermal extension surrounded by mesoderm, extends toward the trophoblast.

3 Week 4

The embryo now has a head fold and a tail fold. Constriction of the connections between the embryo and the surrounding trophoblast narrows the yolk stalk and body stalk.

Amniotic cavity Head fold (containing of embryo amniotic fluid)

Allantois

The allantois begins as an outpocket of the endoderm near the base of the yolk sac. The free endodermal tip then grows toward the wall of the blastocyst, surrounded by a mass of mesodermal cells. The base of the allantois eventually gives rise to the urinary bladder.

Chorion

The mesoderm associated with the allantois spreads around the entire blastocyst, separating the cellular trophoblast from the blastocoele. The appearance of blood vessels in the chorion is the first step in the creation of a functional placenta. By the third week of development, the mesoderm extends along the core of each trophoblastic villus, forming chorionic villi in contact with maternal tissues and blood vessels. These villi continue to enlarge and branch forming the placenta, the exchange platform between mother and fetus for nutrients, oxygen, and wastes.

Week 5

The developing embryo and extraembryonic membranes bulge into the uterine cavity. The trophoblast pushing out into the uterine cavity remains covered by endometrium but no longer participates in nutrient absorption and embryo support. The embryo moves away from the placenta, and the body stalk and yolk stalk fuse to form an umbilical stalk.

Week 10

5

The amnion has expanded greatly, filling the uterine cavity. The fetus is connected to the placenta by an elongated umbilical cord that contains a portion of the allantois, blood vessels, and the remnants of the yolk stalk.

Table 29–1 The Fates of the Germ Layers				
ECTODERMAL CONTRIBUTIONS				
Integumentary system: epidermis, hair follicles and hairs, nails, and glands communicating with the skin (sweat glands, mammary glands, and sebaceous glands)				
Skeletal system: pharyngeal cartilages and their derivatives in adults (portion of sphenoid, the auditory ossicles, the styloid processes of the temporal bones, the cornu and superior rim of the hyoid bone)*				
Nervous system: all neural tissue, including brain and spinal cord				
Endocrine system: pituitary gland and adrenal medullae				
Respiratory system: mucous epithelium of nasal passageways				
Digestive system: mucous epithelium of mouth and anus, salivary glands				
MESODERMAL CONTRIBUTIONS				
Integumentary system: dermis and hypodermis				
Skeletal system: all structures except some pharyngeal derivatives				
Muscular system: all structures				
Endocrine system: adrenal cortex, endocrine tissues of heart, kidneys, and gonads				
Cardiovascular system: all structures				
Lymphatic system: all structures				
Urinary system: the kidneys, including the nephrons and the initial portions of the collecting system				
Reproductive system: the gonads and the adjacent portions of the duct systems				
Miscellaneous: the lining of the pleural, pericardial, and peritoneal cavities and the connective tissues that support all organ systems				
ENDODERMAL CONTRIBUTIONS				
Endocrine system: thymus, thyroid gland, and pancreas				
Respiratory system: respiratory epithelium (except nasal passageways) and associated mucous glands				
Digestive system: mucous epithelium (except mouth and anus), exocrine glands (except salivary glands), liver, and pancreas				
Urinary system: urinary bladder and distal portions of the duct system				
Reproductive system: distal portions of the duct system, stem cells that produce gametes				

*The neural crest is derived from ectoderm and contributes to the formation of the skull and the skeletal derivatives of the embryonic pharyngeal arches.

when the embryonic heart starts beating. The blood supply to the chorionic villi arises from the allantoic arteries and veins.

As the chorionic villi enlarge, more maternal blood vessels are eroded. Maternal blood now moves slowly through complex lacunae lined by the syncytial trophoblast. Chorionic blood vessels pass close by, and gases and nutrients diffuse between the embryonic and maternal circulations across the layers of the trophoblast. Recall that fetal hemoglobin has a higher affinity for oxygen than does maternal hemoglobin, enabling fetal hemoglobin to strip oxygen from maternal hemoglobin. **p.** 863 Maternal blood then reenters the venous system of the mother through the broken walls of small uterine veins. No mixing of maternal and fetal blood takes place, because layers of trophoblast always separate the two.

Placentation

At first, the entire blastocyst is surrounded by chorionic villi. The chorion continues to enlarge, expanding like a balloon within the endometrium. By week 4, the embryo, amnion, and yolk sac are suspended within an expansive, fluid-filled chamber (Spotlight Figure 29–5). The **body stalk**, the connection between embryo and chorion, contains the distal portions of the allantois and blood vessels that carry blood to and from the placenta. The narrow connection between the endoderm of the embryo and the yolk sac is called the **yolk stalk**. The formation of the yolk stalk and body stalk are illustrated in the *Atlas*.

The placenta does not continue to enlarge indefinitely. Regional differences in placental organization begin to develop as expansion of the placenta creates a prominent bulge in the endometrial surface. This relatively thin portion of the endometrium, called the **decidua capsularis** (dē-SID-ū-uh kap-sū-LA-ris; *deciduus*, a falling off), no longer exchanges nutrients, and the chorionic villi in the region disappear (**Spotlight Figure 29–5** [week 5] and **Figure 29–6a**). Placental functions are now concentrated in a disc-shaped area in the deepest portion of the endometrium, a region called the **decidua basalis** (bā-SĀ-lis). The rest of the uterine endometrium, which has no contact with the chorion, is called the **decidua parietalis**.

As the end of the first trimester approaches, the fetus moves farther from the placenta (see weeks 5 and 10, **Spotlight Figure 29–5**). The fetus and placenta remain connected by the **umbilical cord**, which contains the allantois, the placental blood vessels, and the yolk stalk.

TIPS&TRICKS

Like a deep-sea diver's air hose or a space-walking astronaut's tether, the umbilical cord supplies the fetus with life-sustaining substances and removes wastes.

Placental Circulation

Figure 29–6a illustrates circulation at the placenta near the end of the first trimester. Blood flows from the fetus to the placenta through the paired **umbilical arteries** and returns in a single **umbilical vein**. \bigcirc p. 772 The chorionic villi provide the surface area for active and passive exchanges of gases, nutrients, and wastes between the fetal and maternal bloodstreams. The blood in the umbilical arteries is deoxygenated and contains wastes generated by fetal tissues. At the placenta, oxygen supplies are replenished, organic nutrients added, and carbon dioxide and other organic wastes removed.

The placenta places a considerable demand on the maternal cardiovascular system, and blood flow to the uterus and placenta is extensive. If the placenta is torn or otherwise damaged, the consequences may prove fatal to both fetus and mother.

The Endocrine Placenta

In addition to its role in the nutrition of the fetus, the placenta acts as an endocrine organ. Several hormones—including *human chorionic gonadotropin, human placental lactogen, placental prolactin, relaxin, progesterone,* and *estrogens*—are synthesized by the syncytial trophoblast and released into the maternal bloodstream.

Human Chorionic Gonadotropin. The hormone **human chorionic gonadotropin (hCG)** appears in the maternal bloodstream soon after implantation. The presence of hCG in blood or urine samples is a reliable indication of pregnancy. Home pregnancy tests detect the presence of hCG in the urine.

In function, hCG resembles luteinizing hormone (LH), because it maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone. As a result, the endometrial lining remains perfectly functional, and menses does not normally occur. Without hCG, the pregnancy ends, because another uterine cycle begins and the functional zone of the endometrium disintegrates.

With hCG, the corpus luteum persists for three to four months before gradually decreasing in size and secretory function. The decrease in luteal function does not trigger the return of uterine cycles, because by the end of the first trimester, the placenta actively secretes both estrogens and progesterone.

Human Placental Lactogen and Placental Prolactin. Human placental lactogen (hPL) helps prepare the mammary glands for milk production. It also has a stimulatory effect on other maternal tissues comparable to that of growth hormone (GH), ensuring that glucose and protein are available for the fetus. At the mammary glands, the conversion from inactive to active status requires placental hormones (hPL, **placental prolactin**, estrogens, and progesterone) and several maternal hormones (GH, prolactin, and thyroid hormones). We consider the hormonal control of mammary gland function in a later section.

Relaxin. Relaxin is a peptide hormone secreted by the placenta and the corpus luteum during pregnancy. Relaxin (1) increases the flexibility of the pubic symphysis, permitting the pelvis to expand during delivery; (2) causes the cervix to dilate, making it easier for the fetus to enter the vaginal canal; and (3) suppresses the release of oxytocin by the hypothalamus and delays the onset of labor contractions.

Progesterone and Estrogens. After the first trimester, the placenta produces sufficient amounts of progesterone to maintain the endometrial lining and continue the pregnancy. As the end of the third trimester approaches, estrogen production by the placenta accelerates. As we will see in a later section, the increasing estrogen levels play a role in stimulating labor and delivery.

Embryogenesis

Shortly after gastrulation begins, the body of the embryo begins to separate itself from the rest of the embryonic disc. The body of the embryo and its internal organs now start to form. This process, called **embryogenesis**, begins as folding and differential growth of the embryonic disc produce a bulge that projects into the amniotic cavity (Spotlight Figure 29–5 2). This projection is known as the **head fold**. Similar movements lead to the formation of a **tail fold** (Spotlight Figure 29–5 3).

The embryo is now physically as well as developmentally distinct from the embryonic disc and the extraembryonic membranes. The definitive orientation of the embryo can now be seen, complete with dorsal and ventral surfaces and left and right sides.

a Week 2. An SEM of the superior surface of a monkey embryo at 2 weeks of development. A human embryo at this stage would look essentially the same.

 Week 8. Fiber-optic view of human development at week 8 (about 1.6 cm in size).

Table 29–2 provides an overview of the subsequent development of the major organs and body systems. The changes in proportions and appearance that occur between the second developmental week and the end of the first trimester are summarized in Figure 29–7.

The first trimester is a critical period for development, because events in the first 12 weeks establish the basis for **organogenesis**, the process of organ formation. The major features of organogenesis in each organ system are described in Embryology Summaries 4–21 in the *Atlas*. Important developmental milestones are indicated in Table 29–2.

b Week 4. Fiber-optic view of human development at week 4 (about 5 mm in size).

d Week 12. Fiber-optic view of human development at week 12 (about 5.4 cm in size).

CHECKPOINT

- 8. What is the developmental fate of the inner cell mass of the blastocyst?
- 9. Improper development of which of the extraembryonic membranes would affect the cardiovascular system?
- Sue's pregnancy test indicates the presence of elevated levels of the hormone hCG (human chorionic gonadotropin). Explain whether she is pregnant or not.
- 11. What are two important functions of the placenta?
- See the blue Answers tab at the back of the book.

29-5 During the second and third trimesters, maternal organ systems support the developing fetus, and the uterus undergoes structural and functional changes

Learning Outcome Describe the interplay between the maternal organ systems and the developing fetus, and discuss the structural and functional changes in the uterus during gestation.

The rudiments of all the major organ systems have formed by the end of the first trimester (Figure 29–7d). Over the next three months, the fetus grows to a weight of about 0.6 kg (1.32 lb). Encircled by the amnion, the fetus grows faster than the surrounding placenta during this second trimester. When the mesoderm on the outer surface of the amnion contacts the mesoderm on the inner surface of the chorion, these layers fuse, creating a compound *amniochorionic membrane*. Figure 29–8a shows a four-month-old fetus. Figure 29–8b shows a six-monthold fetus. During the third trimester, most of the organ systems become ready to perform their normal functions without maternal assistance. The rate of growth starts to slow, but in absolute terms this trimester sees the greatest weight gain. In the last three months of gestation, the fetus gains about 2.6 kg (5.7 lb), reaching a full-term weight of approximately 3.2 kg (7.05 lb). The Embryology Summaries in the *Atlas* illustrate organ system development in the second and third trimesters. Highlights are noted in Table 29–2.

At the end of gestation, a typical uterus has undergone a tremendous increase in size. Figure 29–9a,b,d shows the positions of the uterus, fetus, and placenta from 16 weeks to *full term* (nine months). When the pregnancy is at full term, the uterus and fetus push many of the maternal abdominal organs out of their normal positions (Figure 29–9d).

Pregnancy and Maternal Systems

The developing fetus is totally dependent on maternal organ systems for nourishment, respiration, and waste removal.

c A sectional view through the abdominopelvic cavity of a woman who is not pregnant.

d Pregnancy at full term. Note the positions of the uterus and full-term fetus within the abdomen, and the displacement of abdominal organs.

Maternal systems perform these functions in addition to their normal operations. For example, the mother must absorb enough oxygen, nutrients, and vitamins for herself *and* for her fetus, and she must eliminate all the wastes that are generated. This is not a burden over the initial weeks of gestation, but the demands placed on the mother become significant as the fetus grows. For the mother to survive under these conditions, maternal systems must compensate for changes introduced by the fetus. In practical terms, the mother must breathe, eat, and excrete for two. The major changes in maternal systems include the following:

- Maternal respiratory rate increases and tidal volume increases. As a result, the mother's lungs deliver the extra oxygen required, and remove the excess carbon dioxide generated by the fetus.
- *Maternal blood volume increases.* This increase occurs because blood flowing into the placenta decreases the volume in the rest of the systemic circuit, and because fetal metabolic activity both decreases blood P_{O2} and increases P_{CO2}. The latter combination stimulates the production of renin and erythropoietin, leading to an increase in maternal blood volume through mechanisms detailed in Chapter 21 (see **Figure 21–15**, ⊃ p. 748). By the end of gestation, maternal blood volume has increased by almost 50 percent.
- Maternal requirements for nutrients increase 10–30 percent.
 Pregnant women tend to have increased appetites because they must nourish both themselves and their fetus.
- *Maternal glomerular filtration rate increases by approximately 50 percent.* This increase corresponds to the increase in blood volume and accelerates the excretion of metabolic wastes generated by the fetus. Pregnant women need to urinate frequently because the volume of urine produced increases and the weight of the uterus presses down on the urinary bladder.
- The uterus undergoes a tremendous increase in size. Structural and functional changes in the expanding uterus are so important that we will discuss them in a separate section.
- The mammary glands increase in size, and secretory activity begins. Mammary gland development requires a combination of hormones, including human placental lactogen and placental prolactin from the placenta, and prolactin (PRL), estrogens, progesterone, GH, and thyroxine from maternal endocrine organs. By the end of the sixth month of pregnancy, the mammary glands are fully developed and begin to produce clear secretions that are stored in the duct system and may be expressed from the nipple.

Structural and Functional Changes in the Uterus

At the end of gestation, a typical uterus has grown from 7.5 cm (3 in.) in length and 30-40 g (1-1.4 oz) in weight to

Clinical Note

Abortion Abortion is the termination of a pregnancy. Most references distinguish among spontaneous, therapeutic, and induced abortions. Most spontaneous abortions, or miscarriages, result from developmental problems (such as chromosomal defects in the embryo) or from hormonal problems, including abnormally low LH production by the maternal pituitary gland, reduced LH sensitivity at the corpus luteum, insufficient progesterone sensitivity in the endometrium, or insufficient placental production of hCG. Spontaneous abortions occur in at least 15 percent of recognized pregnancies. Therapeutic **abortions** are performed when continued pregnancy poses a threat to the life of the mother. Induced abortions, or *elective abortions*, are performed at the woman's request. Induced abortions remain the focus of considerable controversy.

30 cm (12 in.) in length and 1100 g (2.4 lb) in weight. The uterus may then contain 2 liters of fluid, plus fetus and placenta, for a total weight of about 6-7 kg (13–15.4 lb). This remarkable expansion occurs through the enlargement (hypertrophy) of existing cells, especially smooth muscle fibers, rather than by an increase in the total number of cells.

The tremendous stretching of the uterus is associated with a gradual increase in the rate of spontaneous smooth muscle contractions in the myometrium. In the early stages of pregnancy, the contractions are weak, painless, and brief. Evidence indicates that progesterone released by the placenta has an inhibitory effect on uterine smooth muscle, preventing more extensive and more powerful contractions. Placental and fetal factors are involved in the initiation of labor and delivery (Figure 29–10).

Late in pregnancy, some women experience occasional spasms in the uterine musculature, but these contractions are not regular or persistent. Such contractions are called **false labor**. **True labor** begins when biochemical and mechanical factors reach a point of no return. After nine months of gestation, multiple factors interact to initiate true labor. Once **labor contractions** have begun in the myometrium, positive feedback ensures that they will continue until delivery has been completed.

When labor begins, the fetal pituitary gland secretes oxytocin, which is released into the maternal bloodstream at the placenta. This may be the actual trigger for the onset of true labor, as it increases myometrial contractions and prostaglandin production, on top of the priming effects of estrogens and maternal oxytocin.

Figure 29–10 Factors Involved in the Initiation of Labor and Delivery.

CHECKPOINT

- 12. Why do pregnant women experience breathing difficulty?
- 13. Identify three major factors opposing the calming action of progesterone on the uterus.
- 14. Why does a mother's blood volume increase during pregnancy?
- See the blue Answers tab at the back of the book.

29-6 Labor consists of the dilation, expulsion, and placental stages

Learning Outcome List and discuss the events that occur during labor and delivery.

The goal of labor is **parturition** (par-tū-RISH-un), or childbirth, the forcible expulsion of the fetus. During true labor, each contraction begins near the superior portion of the uterus and sweeps in a wave toward the cervix. The contractions are strong and occur at regular intervals. As parturition approaches, the contractions increase in force and frequency, changing the position of the fetus and moving it toward the cervical canal.

Stages of Labor

Labor has traditionally been divided into three stages: the dilation stage, the expulsion stage, and the placental stage (Figure 29–11).

The Dilation Stage

The **dilation stage** begins with the onset of true labor, as the **29** cervix dilates and the fetus begins to shift toward the cervical canal, moved by gravity and uterine contractions (Stage 1) in Figure 29–11). This stage is highly variable in length but typically lasts eight or more hours. At the start of the dilation stage, labor contractions last up to half a minute and occur once every 10-30 minutes. Their frequency increases steadily. Late in this

Figure 29–11 The Stages of Labor.

stage, the amniochorionic membrane ruptures, an event sometimes referred to as the woman having her "water break." If this event occurs before other events of the dilation stage, the life of the fetus may be at risk from infection. If the risk is sufficiently great, labor can be induced.

The Expulsion Stage

The **expulsion stage** begins as the cervix, pushed open by the approaching fetus, completes its dilation to about 10 cm (4 in.) (**Stage 2** in Figure 29–11). In this stage, contractions reach maximum intensity. They occur at perhaps two- or three-minute intervals and last a full minute. Expulsion continues until the fetus has emerged from the vagina. In most cases, the expulsion stage lasts less than two hours. The arrival of the newborn infant into the outside world is **delivery**, or birth.

If the vaginal canal is too small to permit the passage of the fetus, posing acute danger of perineal tearing, a clinician may temporarily enlarge the passageway by performing an **episiotomy** (e-piz-ē-OT-ō-mē), an incision through the perineal musculature. After delivery, this surgical cut is repaired with sutures, a much simpler procedure than suturing the jagged edges associated with an extensive perineal tear.

If complications arise during the dilation or expulsion stage, the infant can be delivered by **cesarean section**, or *"C-section."* In such cases, an incision is made through the abdominal wall, and the uterus is opened just enough to allow passage of the infant's head. The cesarean delivery rate had been

steadily increasing in the United States for the past 12 years. However, data released from the CDC's National Vital Statistics System showed that between 2009 and 2011 the cesarean delivery rate was unchanged and accounted for 31.3 percent of all live singleton births.

Immediately after birth, clinicians assess the newborn's health in five areas: heart rate, breathing, skin color, muscle tone, and reflex response. This assessment is called an **Apgar score**. Each criterion is scored from 0 to 2, with 8–10 indicating a healthy baby.

The Placental Stage

During the **placental stage** of labor, muscle tension builds in the walls of the partially empty uterus, which gradually decreases in size (**Stage 3** in Figure 29–11). This uterine contraction tears the connections between the endometrium and the placenta. In general, within an hour of delivery, the placental stage ends with the ejection of the placenta, or *afterbirth*. The disruption of the placenta is accompanied by a loss of blood, but associated uterine contraction compresses the uterine vessels and usually restricts this flow. Because maternal blood volume has increased greatly during pregnancy, the blood loss can normally be tolerated without difficulty.

Premature Labor

Premature labor occurs when true labor begins before the fetus has completed normal development. The newborn's chances of surviving are directly related to its body weight at delivery. Even with massive supportive efforts, newborns weighing less than 400 g (14 oz) at birth will not survive, primarily because their respiratory, cardiovascular, and urinary systems are unable to support life without aid from maternal systems. As a result, the dividing line between spontaneous abortion and **immature delivery** is usually set at 500 g (17.6 oz), the normal weight near the end of the second trimester.

Most fetuses born at 25–27 weeks of gestation (a birth weight under 600 g or 21.1 oz) die despite intensive neonatal care. Survivors have a high risk of developmental abnormalities. **Premature delivery** usually refers to birth at 28–36 weeks (a birth weight over 1 kg or 2.2 lb). With care, these newborns have a good chance of surviving and developing normally.

Difficult Deliveries

By the end of gestation in most pregnancies, the fetus has rotated within the uterus to transit the birth canal headfirst, facing the mother's sacrum. In about 6 percent of deliveries, the fetus faces the mother's pubis instead. These babies can be delivered normally, given enough time, but risks to infant and mother are reduced by a *forceps delivery*. Forceps resemble large, curved salad tongs that can be separated for insertion into the vaginal canal, one side at a time. Once in place, they are reunited and used to grasp the head of the fetus. An intermittent pull is applied, so that the forces on the head resemble those of normal delivery.

In 3–4 percent of deliveries, the legs or buttocks of the fetus enter the vaginal canal first. Such deliveries are **breech births**. Risks to the fetus are higher in breech births than in normal deliveries, because the umbilical cord can become constricted, cutting off placental blood flow.

The head is normally the widest part of the fetus. The mother's cervix may dilate enough to pass the baby's legs and body, but not the head. This entrapment compresses the umbilical cord, prolongs delivery, and subjects the fetus to severe distress and potential injury. If attempts to reposition the fetus or promote further dilation are unsuccessful over the short term, delivery by cesarean section may be required.

Multiple Births

Multiple births (twins, triplets, quadruplets, and so forth) can take place for several reasons. The ratio of twin births to single births in the U.S. population is nearly 1:89. "Fraternal twins," or **dizygotic twins** (dī-zī-GOT-ik), develop when two separate oocytes are ovulated and fertilized. Because chromosomes are shuffled during meiosis, the odds against any two zygotes from the same parents having identical genes exceed 1 in 8.4 million. Seventy percent of twins are dizygotic.

"Identical twins" or **monozygotic twins**, result either from the separation of blastomeres early in cleavage or from the splitting of the inner cell mass before gastrulation. In either event, the genetic makeup of the twins is identical because both formed from the same pair of gametes.

Triplets, quadruplets, and larger multiples can result from multiple ovulations, blastomere splitting, or some combination of the two. For unknown reasons, the rates of naturally occurring multiple births fall into a pattern: Twins occur in 1 of every 89 births, triplets in 1 of every 89² (or 7921) births, quadruplets in 1 of every 89³ (704,969) births, and so forth. Taking fertility drugs that stimulate the maturation of abnormally high numbers of follicles can increase the incidence of multiple births.

Pregnancies with multiple fetuses pose special problems because the strains on the mother are multiplied. The chances of premature labor are increased, and the risks to the mother are higher than for single births. Increased risks also extend to the fetuses during gestation, and to the newborns, because even at full term such newborns have lower-than-average birth weights. They are also more likely to have problems during delivery. For example, in more than half of twin deliveries, one or both fetuses enter the vaginal canal in an abnormal position.

If the splitting of the blastomeres or of the embryonic disc is not complete, **conjoined** (*Siamese*) **twins** may develop.

These genetically identical twins typically share some skin, a portion of the liver, and perhaps other internal organs as well. When the fusion is minor, the infants can be surgically separated with some success. Most conjoined twins with more extensive fusions fail to survive delivery.

CHECKPOINT

- 15. Name the three stages of labor.
- **16**. Differentiate between immature delivery and premature delivery.
- **17**. Give the biological terms for fraternal twins and identical twins.

See the blue Answers tab at the back of the book.

29-7 Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence

Learning Outcome Identify the features and physiological changes of the postnatal stages of life.

Developmental processes do not stop at delivery. Newborns have few of the anatomical, functional, or physiological characteristics of mature adults. The course of postnatal development typically includes five **life stages**: (1) the *neonatal period*, (2) *infancy*, (3) *childhood*, (4) *adolescence*, and (5) *maturity*. Each stage is typified by a distinctive combination of characteristics and abilities. These stages are familiar parts of human experience. Each stage has distinctive features, but the transitions between them are gradual, and the boundaries indistinct. At maturity, development ends and the process of aging, or *senescence*, begins.

The Neonatal Period, Infancy, and Childhood

The **neonatal period** extends from birth to one month of age. **Infancy**, or babyhood, then continues through the first year of life. **Childhood** lasts from infancy until **adolescence** (puberty), the period of sexual and physical maturation. Two major events are under way during these developmental stages:

- 1. The organ systems (except those associated with reproduction) become fully operational and gradually acquire the functional characteristics of adult structures.
- 2. The individual grows rapidly, and body proportions change significantly.

Pediatrics is the medical specialty that focuses on postnatal development from infancy through adolescence. Infants and young children cannot clearly describe the problems they are experiencing, so pediatricians and parents must be skilled observers. Standardized tests are used to assess developmental progress relative to average values.

The Neonatal Period

Physiological and anatomical changes take place as the fetus completes the transition to the status of newborn, or **neonate**. The neonatal period is the time from birth through 28 days. Before delivery, dissolved gases, nutrients, wastes, hormones, and antibodies were transferred across the placenta. At birth, the neonate must become relatively self-sufficient, performing respiration, digestion, and excretion using its own specialized organs and organ systems. The transition from fetus to neonate can be summarized as follows:

- At birth, the lungs are collapsed and filled with fluid.
 Filling them with air requires a massive and powerful inhalation. D p. 872
- When the lungs expand, the pattern of cardiovascular circulation changes due to alterations in blood pressure and flow rates. The ductus arteriosus closes, isolating the pulmonary and systemic trunks. Closure of the foramen ovale separates the atria of the heart, completing the separation of the pulmonary and systemic circuits. ⊃ p. 772
- The typical neonatal heart rate (120–140 beats per minute) and respiratory rate (30 breaths per minute) are considerably higher than in adults. In addition, the metabolic rate per unit of body weight in neonates is approximately twice that of adults.
- Before birth, the digestive system is relatively inactive, although it does accumulate a mixture of bile secretions, mucus, and epithelial cells. This collection of debris, called *meconium*, is excreted during the first few days of life. During that period, the newborn begins to nurse.
- As wastes build up in the arterial blood, the kidneys excrete them. Glomerular filtration is normal, but the neonate's kidneys cannot concentrate urine to any significant degree. As a result, urinary water losses are high, and neonatal fluid requirements are proportionally much greater than those of adults.
- The neonate has little ability to control its body temperature, particularly in the first few days after delivery. As the infant grows larger and its insulating subcutaneous adipose "blanket" gets thicker, its metabolic rate also increases. Daily and even hourly shifts in body temperature continue throughout childhood. D p. 967

Over the entire neonatal period, the newborn is dependent on nutrients contained in milk, typically breast milk secreted by the mother's mammary glands.

Lactation and the Mammary Glands. By the end of the sixth month of pregnancy, the mammary glands are fully developed,

and the gland cells begin to secrete **colostrum** (ko-LOS-trum). Ingested by the infant during the first two or three days of life, colostrum contains more proteins and far less fat than breast milk. Many of the proteins are antibodies that may help the infant ward off infections until its own immune system becomes fully functional. In addition, the mucins present in both colostrum and milk can inhibit the replication of a family of viruses (rotaviruses) that can cause dangerous forms of gastroenteritis and diarrhea in infants.

vert to milk production. Breast milk consists of water, proteins, amino acids, lipids, sugars, and salts. It also contains large quantities of *lysozyme*—an enzyme with antibiotic properties. In terms of energy, human milk provides about 750 kilocalories per liter. The secretory rate varies with the demand, but a 5-6-kg (11-13-lb) infant usually requires about 850 mL (3.6 cups) of milk per day. (Maternal milk production throughout this period is maintained through the combined actions of several hormones, as detailed in Chapter 18. **D p. 622**)

down (milk-ejection) reflex (Figure 29-12). This reflex continues to function until weaning, withdrawing mother's milk, typically one to two years after birth. Milk production stops soon after, and the mammary glands gradually return to a resting state. Earlier weaning is a common practice in the United States, where women take advantage of commercially prepared milk- or soy-based infant formulas that closely approximate the composition of natural breast milk. The major difference between such substitutes and natural milk is that the substitutes lack antibodies and lysozyme, which play important roles

in maintaining the health of the infant. Consequently, early weaning is associated with an increased risk of infections and allergies in the infant.

Infancy and Childhood

The most rapid growth occurs during prenatal development, and the growth rate decreases after delivery. Growth during infancy and childhood occurs under the direction of circulating hormones, notably growth hormone, adrenal steroids, and thyroid hormones. These hormones affect each tissue and organ in specific ways, depending on the sensitivities of the individual cells. As a result, growth does not occur uniformly, so body proportions gradually change. The head, for example, is relatively large at birth but decreases in proportion to the rest of the body as the child grows to adulthood (Figure 29–13).

Adolescence and Maturity

Adolescence begins at **puberty**, the period of sexual maturation, and ends when growth is completed. Three major hormonal events interact at the onset of puberty:

- 1. The hypothalamus increases its production of gonadotropinreleasing hormone (GnRH). Evidence indicates that this increase is dependent on adequate levels of *leptin*, a hormone released by adipose tissues. ⊃ p. 643
- **2.** Endocrine cells in the anterior lobe of the pituitary gland become more sensitive to the presence of GnRH, so circulating levels of FSH and LH increase rapidly.
- **3.** Ovarian or testicular cells become more sensitive to FSH and LH. These cells initiate (1) gamete production; (2) the secretion of sex hormones that stimulate the appearance of secondary sex characteristics and behaviors; and (3) a sudden acceleration in the growth rate, ending with closure of the epiphyseal cartilages.

The age at which puberty begins varies. In the United States today, puberty generally starts at about age 12 in boys and 11 in girls, but the normal ranges are broad (10–15 in boys, 9–14 in girls). Sex-specific differences in structure and function develop as many body systems alter their activities in response to circulating sex hormones and to the presence of growth hormone, thyroid hormones, prolactin, and adrenocortical hormones. At puberty, endocrine system changes induce characteristic changes in various body systems:

Integumentary System. Testosterone stimulates the development of terminal hairs on the face and chest of males.
 p. 165 Under estrogen stimulation those follicles continue to produce fine hairs in females. The hairline recedes under testosterone stimulation. Both testosterone and estrogen stimulate terminal hair growth in the axillae and

in the genital area. Androgens, which are present in both sexes, also stimulate sebaceous gland secretion and may cause acne. Adipose tissues respond differently to testosterone than to estrogens, and this difference produces changes in the distribution of subcutaneous body fat. In women, the combination of estrogens, prolactin, growth hormone, and thyroid hormones promotes the initial development of the mammary glands. The duct system becomes more elaborate, but true secretory alveoli do not yet develop. Much of the growth of the breasts during this period reflects increased deposition of fat rather than glandular tissue.

- *Skeletal System.* Both testosterone and estrogen accelerate bone deposition and skeletal growth. In the process, they promote closure of the epiphyseal cartilages and thus place a limit on growth in height. Girls generally do not grow as tall as boys because estrogens cause more rapid epiphyseal cartilage closure than does testosterone, and the period of skeletal growth ends at an earlier age in girls than in boys. Girls grow most rapidly between ages 10 and 13, whereas boys grow most rapidly between ages 12 and 15.
- Muscular System. Sex hormones stimulate the growth of skeletal muscle fibers, increasing strength and endurance. The effects of testosterone greatly exceed those of the estrogens, and the increased muscle mass accounts for significant sex differences in body mass, even for males and females of the same height. The stimulatory effects of testosterone on muscle mass has led to the use of anabolic steroids among competitive athletes of both sexes.
- Nervous System. Sex hormones affect central nervous system centers concerned with sexual drive and sexual behaviors. These centers differentiated in sex-specific ways during the second and third trimesters, when the fetal gonads secrete either testosterone (in males) or estrogens (in females). The surge in sex hormone secretion at puberty activates the CNS centers.
- Cardiovascular System. Testosterone stimulates erythropoiesis, increasing blood volume and the hematocrit. In females whose uterine cycles have begun, the iron loss associated with menses increases the risk of developing iron-deficiency anemia. Late in each uterine cycle, estrogens and progesterone promote the movement of water from plasma into interstitial fluid, leading to an increase in tissue water content. Estrogens decrease plasma cholesterol levels and slow the formation of plaque. As a result, premenopausal women have a lower risk of atherosclerosis ("hardening of the arteries") than do adult men.
- *Respiratory System.* Testosterone stimulates growth of the larynx and a thickening and lengthening of the vocal cords. These changes cause a gradual deepening of the voice of males compared with those of females.

Figure 29–13 Growth and Changes in Body Form and Proportion. The views at 4, 8, and 16 weeks of gestation are presented at actual size. Notice the changes in body form and proportions as development proceeds. For example, the head, which contains the brain and sense organs, is proportionately large at birth.

1 month

1 year

18 years

• *Reproductive System.* In males, testosterone stimulates the functional development of the accessory reproductive glands, such as the prostate gland and seminal glands, and helps promote spermatogenesis. In females, estrogens target the uterus, promoting a thickening of the myometrium, increasing blood flow to the endometrium, and stimulating cervical mucus production. Estrogens also promote the functional development of accessory reproductive organs in females. The first few uterine cycles may or may not be accompanied by ovulation. After the initial stage, the woman will be fertile, even though her growth and physical maturation will continue for several years.

After puberty, the continued background secretion of estrogens or androgens maintains sex-specific differences. In both sexes, growth continues at a slower pace until age 18–21. By that time most of the epiphyseal cartilages have closed. The boundary between adolescence and maturity is hazy, because it has physical, emotional, and behavioral components. Adolescence is often said to be over when growth stops, in the late teens or early twenties. The individual is then considered physically mature.

Senescence

Physical growth may stop at maturity, but physiological changes continue. The sex-specific differences produced at puberty remain, but further changes take place when sex hormone levels decline at menopause or the male climacteric. \bigcirc p. 1088 All these changes are part of the process of **senescence** (*senesco*, to grow old), or aging, which reduces the functional capabilities of the person. Even without disease or injury, senescence-related changes at the molecular level ultimately lead to death.

Table 29–3 summarizes the age-related changes in physiological systems discussed in earlier chapters. Taken together, these changes both decrease the functional abilities of the individual and affect homeostatic mechanisms. As a result, elderly people are less able to make homeostatic adjustments in response to internal or environmental stresses. The risks of contracting a variety of infectious diseases are proportionately increased as immune function deteriorates. This deterioration leads to drastic physiological changes that affect all internal systems. Death ultimately occurs when the body's existing homeostatic mechanisms cannot counter some combination of stresses.

Physicians attempt to forestall death by adjusting homeostatic mechanisms or removing the sources of stress. **Geriatrics** (*geras*, old age) is the medical specialty that deals with the problems associated with aging. Physicians trained in geriatrics are known as **geriatricians**. Problems commonly encountered by geriatricians include infections, cancers, heart disease, strokes, arthritis, senile dementia, and anemia. These conditions are directly related to age-induced changes in vital systems.

Table 29–3 Effects of Aging on Organ Systems

The characteristic physical and functional changes that are part of the aging process affect all organ systems. Examples discussed in previous chapters include the following:

- A loss of elasticity in the skin that produces sagging and wrinkling.
 > pp. 172-173
- A decline in the rate of bone deposition, leading to weak bones, and degenerative changes in joints that make them less mobile.
 > pp. 199, 283
- Reductions in muscular strength and ability. 💙 p. 377
- Impairment of coordination, memory, and intellectual function.
 p. 557
- Reductions in the production of, and sensitivity to, circulating hormones. D p. 644
- Appearance of cardiovascular problems and a reduction in peripheral blood flow that can affect a variety of vital organs. **D p. 776**
- Reduced sensitivity and responsiveness of the immune system, leading to infection, cancer, or both. D p. 825
- Reduced elasticity in the lungs, leading to decreased respiratory function.
 D p. 873
- Decreased peristalsis and muscle tone along the digestive tract.
 D p. 928
- Decreased peristalsis and muscle tone in the urinary system, coupled with a reduction in the glomerular filtration rate. \bigcirc p. 1009
- Functional impairment of the reproductive system, which eventually becomes inactive when menopause or the male climacteric occurs.
 Dpp. 1088–1089

CHECKPOINT

- 18. Name the postnatal stages of development.
- **19**. Describe the time frame for each of the following stages: neonatal period, infancy, and adolescence.
- **20**. What is the difference between colostrum and breast milk?
- 21. Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of which stage of development?
- See the blue Answers tab at the back of the book.

29-8 Genes and chromosomes determine patterns of inheritance

Learning Outcome Relate basic principles of genetics to the inheritance of human traits.

Recall that chromosomes contain DNA and proteins, and genes are functional segments of DNA. Each gene carries the information needed to direct the synthesis of a specific polypeptide. We introduced chromosome structure and the functions of genes in Chapter 3. ^{\D} pp. 82–87 Every nucleated somatic cell in your body carries copies of the original 46 chromosomes present when you were a zygote. Those chromosomes and their genes make up your **genotype** (JĒN-ō-tīp; *geno-*, gene).

Through development and differentiation, the instructions contained in the genotype are expressed, or carried out, in many ways. No single cell or tissue uses all the information and instructions contained in the genotype. For example, in muscle fibers, the genes involved in the formation of excitable membranes and contractile proteins are active, but in cells of the pancreatic islets, a different set of genes is at work. Collectively, however, the instructions in your genotype determine the anatomical and physiological characteristics that make you a unique person. Those anatomical and physiological characteristics are your **phenotype** (FE-nō-tīp; *phaino*, to display). The phenotype results from the interaction between the person's genotype and the environment. In architectural terms, the genotype is a set of plans, and the phenotype is the finished building. Specific elements in your phenotype, such as hair and eve color, skin tone, and foot size, are called phenotypic traits, or characters.

Your genotype is derived from the genotypes of your parents. Yet you are not an exact copy of either parent. Nor are you an easily identifiable mixture of their characteristics. We begin our discussion of genetics with the basic patterns of inheritance and their implications. We then examine the mechanisms responsible for regulating the activities of the genotype during prenatal development.

Patterns of Inheritance

The 46 chromosomes carried by each human somatic cell occur in pairs. Every somatic cell contains 23 pairs of chromosomes. At amphimixis, the spermatozoon supplies one member of each pair, and the ovum supplies the other. The two members of each pair are known as **homologous** (huh-MOL-ō-gus) chromosomes. Twenty-two of those pairs are called autosomal (aw-to-SO-mul) chromosomes. Most of the genes of the autosomal chromosomes affect somatic, or body, characteristics, such as hair color and skin pigmentation. The chromosomes of the 23rd pair are known as the sex chromosomes. One of their functions is to determine whether the individual is genetically male or female. Figure 29-14 shows the karyotype (karyon, nucleus + typos, mark), or entire set of chromosomes, of a normal male. In the discussion that follows, we deal with the inheritance of traits carried on the autosomal chromosomes. We will examine the patterns of inheritance by the sex chromosomes in a later section.

The two chromosomes in a homologous autosomal pair have the same structure and carry genes that affect the same traits. For example, suppose that one member of the pair contains three genes in a row, with the first gene determining hair color, the second eye color, and the third skin pigmentation. The other chromosome, or *homolog*, carries genes that affect the same traits, and the genes are in the same sequence. The genes are also located at equivalent positions on their respective

Figure 29–14 A Human Male Karyotype.

chromosomes. A gene's position on a chromosome is called a **locus** (LŌ-kus; plural, *loci*).

The two chromosomes in a pair may not carry the same *form* of each gene, however. The various forms of a given gene are called **alleles** (uh-LĒLZ). These *alternative forms* determine the precise effect of the gene on your phenotype. If the two chromosomes of a homologous pair carry the same allele of a particular gene, you are **homozygous** (hō-mō-ZĪ-gus; *homos*, the same) for the trait affected by that gene. That allele will then indeed be expressed in your phenotype. For example, if you receive a gene for freckles from your father and a gene for freckles from you will have freckles. About 80 percent of an individual's genome consists of homozygous alleles. In **simple inheritance**, the phenotype is determined by interactions between a single pair of alleles.

Interactions between Alleles

Because the chromosomes of a homologous pair have different origins, one paternal and the other maternal, they do not necessarily carry the same alleles. If you have two different alleles for the same gene, you are **heterozygous** (het-er-ō-ZĪ-gus; *heteros*, other) for the trait determined by that gene. The phenotype that results from a heterozygous genotype depends on the nature of the interaction between the corresponding alleles. The potential interactions, which include examples of normal and abnormal phenotypic traits, are diagrammed in Figure 29–15. For example, if you received a gene for curly hair from your
Figure 29–15 Major Patterns of Inheritance.

father, but a gene for straight hair from your mother, whether *you* will have curly hair, straight hair, or even wavy hair depends on the relationship between the alleles for those traits. The relationship can be one of *strict dominance, incomplete dominance,* or *codominance,* as follows:

• In **strict dominance**, an allele that is **dominant** will be expressed in the phenotype, *regardless of any conflicting*

instructions carried by the other allele. For instance, an individual with only one allele for freckles will have freckles, because that allele is dominant over the "nonfreckle" allele. An allele that is **recessive** will be expressed in the phenotype only if that same allele is present on *both chromosomes* of a homologous pair. For example, in Chapter 5 you learned that people with albinism cannot synthesize

the yellow-brown pigment *melanin.* ⊃ **p. 156** The presence of one allele that directs melanin production will result in normal color. Two recessive alleles must be present to produce an individual with albinism. A single gene can have many different alleles *in a population*, some dominant and others recessive. An individual can have a maximum of only two alleles—one from the mother and the other one from the father. If both parents have the same alleles, then an individual has only one kind of allele, but two copies of it, and is thus, homozygous.

- In **incomplete dominance**, heterozygous alleles produce a phenotype that is intermediate (not completely dominant) to the phenotypes of individuals who are homozygous for one allele or the other. A good example is the sickling gene that affects the shape of red blood cells. Individuals with homozygous alleles that carry instructions for normal adult hemoglobin A have red blood cells of normal shape. Individuals with homozygous alleles for hemoglobin S, an abnormal form, have red blood cells that become sickle-shaped in peripheral capillaries when the P_{O_2} decreases. These individuals develop *sickle cell anemia*. \supset p. 660 Individuals who are heterozygous for this trait do not develop anemia but their red blood cells may sickle when tissue oxygen levels are extremely low. Incomplete dominance is relatively rare in humans.
- In codominance, an individual who is heterozygous (has different alleles) for a given trait exhibits both phenotypes for that trait. Blood type in humans is determined by co-dominance. The alleles for type A and type B blood are dominant over the allele for type O blood, but a person with one type A allele and one type B allele has type AB blood, not A or B. Type AB blood has *both* type A antigens and type B antigens. The distinction between incomplete dominance and codominance is not always clear-cut. For example, a person who has alleles for hemoglobin A and hemoglobin S shows incomplete dominance for RBC shape, but codominance for hemoglobin. Each red blood cell contains a mixture of hemoglobin A and hemoglobin S.

Penetrance and Expressivity

Differences in genotype lead to distinct variations in phenotype, but the relationships are not always predictable. The presence of a particular pair of alleles does not affect the phenotype in the same way in every individual. **Penetrance** is the percentage of individuals with a particular genotype that show the "expected" phenotype. In other individuals, the activity of other genes or environmental factors may override the effects of that genotype. For example, *emphysema*, a respiratory disorder discussed in Chapter 23, has been linked to a specific abnormal genotype. \bigcirc **p.** 875 However, about 20 percent of the individuals with this genotype do not develop emphysema, making the penetrance of this genotype approximately 80 percent. The effects of environmental factors are apparent: Most people who develop emphysema are cigarette smokers.

If a given genotype *does* affect the phenotype, it can do so to various degrees, again depending on the activity of other genes or environmental stimuli. For example, even though identical twins have the same genotype, they do not have exactly the same fingerprints. The extent to which a particular allele is expressed when it is present is termed its **expressivity**.

Environmental effects on genetic expression are particularly evident during embryonic and fetal development. Drugs, including certain antibiotics, alcohol, and nicotine in cigarette smoke, can disrupt fetal development. Factors that result in abnormal development are called **teratogens** (TER-uh-tō-jenz).

Predicting Inheritance

When an allele can be neatly characterized as dominant or recessive, you can predict the characteristics of individuals on the basis of their parents' alleles.

In such calculations, dominant alleles are traditionally indicated by capitalized abbreviations, and recessive alleles by lowercase abbreviations. For a given trait, the possibilities are indicated by AA (homozygous dominant), Aa (heterozygous), or aa (homozygous recessive). Each gamete involved in fertilization contributes a single allele for a given trait. That allele must be one of the two alleles contained by all cells in the parent's body. Consider, for example, the possible offspring of a mother with albinism (no skin pigmentation) and a father with normal skin pigmentation. The maternal alleles are abbreviated aa because albinism is a homozygous recessive trait. No matter which of her oocytes is fertilized, it will carry the recessive *a* allele. The father has normal pigmentation, a dominant trait. He is therefore either homozygous dominant or heterozygous for this trait, because both AA and Aa will produce the same phenotype: normal skin pigmentation. Every sperm produced by a homozygous dominant father will carry the A allele. In contrast, half the sperm produced by a heterozygous father will carry the dominant allele A, and the other half will carry the recessive allele a.

A simple box diagram known as a **Punnett square** helps us to predict the probabilities that children will have particular characteristics by showing the various combinations of parental alleles they can inherit. In the Punnett squares shown in **Figure 29–16**, the maternal alleles for skin pigmentation are listed along the horizontal axis, and the paternal ones along the vertical axis. The combinations of alleles appear in the small boxes. **Figure 29–16a** shows the possible offspring of an *aa* mother and an *AA* father. All the children will have the genotype *Aa*, so all will have normal skin pigmentation. Compare these results with those of **Figure 29–16b**, for a heterozygous father (*Aa*) and an *aa* mother. The heterozygous father produces two types of gametes, *A* and *a*. The mother's secondary oocyte,

carrying an *a* allele, may be fertilized by either one. As a result, the probability is 50 percent that a child of such a father will inherit the genotype *Aa* and so have normal skin pigmentation. The probability of inheriting the genotype *aa*, and thus having the albinism phenotype, is also 50 percent.

A Punnett square can also be used to draw conclusions about the identity and genotype of a parent. For example, in our scenario, a man with the genotype *AA* cannot be the father of an albino child (*aa*).

We can also predict the frequency of appearance of any inherited disorder that results from simple inheritance by using a Punnett square. Although they are rare in terms of overall numbers, more than 1200 inherited disorders have been identified that reflect the presence of one or two abnormal alleles for a single gene.

Some phenotypic traits are determined by interactions among several genes. Such interactions constitute **polygenic inheritance**. We cannot predict the presence or absence of these phenotypic traits using a simple Punnett square because the resulting phenotype depends not only on the nature of the alleles but also on how those alleles interact. In *suppression*, one gene suppresses the other. As a result, the second gene has no effect on the phenotype. In *complementary gene action*, dominant alleles on two genes interact to produce a phenotype different from that seen when one gene contains recessive alleles. The risks of developing several important adult disorders, including hypertension and coronary artery disease, are linked to polygenic inheritance. Many of the developmental disorders responsible for fetal deaths and congenital malformations result from polygenic inheritance. In these cases, an individual's genetic composition does not by itself determine the onset of the disease. Instead, the conditions regulated by these genes establish a susceptibility to particular environmental influences. As a result, not every individual with the genetic tendency for a certain condition will develop that condition. For this reason, it is difficult to track polygenic conditions through successive generations. However, steps can be taken to prevent a crisis because many inherited polygenic conditions are *likely* (but not *guaranteed*) to occur. For example, you can reduce hypertension by controlling your diet and fluid volume, and you can prevent coronary artery disease by lowering your serum cholesterol levels.

Sources of Individual Variation

Just as you are not a copy of either of your parents, you also are not a mixture of their characteristics. We noted one reason for this in Chapter 28: During meiosis, maternal and paternal chromosomes are randomly distributed, so each gamete has a unique combination of maternal and paternal chromosomes. For this reason, you may have an allele for freckles from your father and an allele for nonfreckles from your mother, even though your sister received an allele for nonfreckles from each of your parents.

Only in very rare cases does an individual receive both alleles from one parent. The few documented cases appear to have resulted when duplicate maternal chromatids failed to

Genetic Recombination

During meiosis, various changes can occur in chromosome structure, producing gametes with chromosomes that differ from those of each parent. **Genetic recombination** greatly increases the genetic variation among gametes, and thus among the genotypes formed when those gametes combine in fertilization.

In one normal form of recombination, parts of homologous chromosomes become rearranged during synapsis of meiosis (Figure 29–17). When tetrads form, adjacent chromatids may overlap, an event called **crossing over**. The chromatids may then break, and the overlapping segments trade places. In general, the genetic exchange between homologous chromosomes is called crossing over, and between nonhomologous chromosomes it is called **translocation**. During recombination, portions of chromosomes may break away and be lost, or *deleted*. This event is abnormal, and it can have severe or even lethal effects on the zygote, depending on the nature of the lost genes.

Recombination that produces abnormal chromosome shapes or numbers is lethal for the zygote in almost all cases. Roughly 10 percent of zygotes have **chromosomal abnormalities**—that is, damaged, broken, missing, or extra copies of chromosomes—but only about 0.5 percent of newborns have such abnormalities. Few individuals with chromosomal abnormalities survive to full term. *Down's syndrome (trisomy 21)*, which involves one of the smallest chromosomes in human beings, is an exception. In addition to contributing to prenatal mortality, chromosomal abnormalities produce a variety of serious clinical conditions. The high mortality rate and

Figure 29–17 Crossing Over and Recombination.

the severity of the problems reflect the fact that large numbers of genes have been added or deleted. Women who become pregnant later in life run a higher risk of birth defects and miscarriage due to chromosomal abnormalities in the oocyte. It seems that the longer the oocyte remains suspended in meiosis I, the more likely are recombination errors when meiosis is completed.

However, a lack of specific gene expression in a zygote is not necessarily due to chromosomal aberrations or deletions. Genes can be present, yet be prevented from being fully expressed. A genetic process called genomic imprinting is particularly important in the early embryo. Imprinting does not change the DNA itself. Instead, it results in specific (and usually reversible) chemical modifications, or markings, of DNA and its associated proteins. Because such chemical markings occur at a level above the DNA sequences, the study of such changes is called *epigenetics*. These changes then dictate whether the gene is expressed or not (silenced). As gametes mature, a proportion of their genes develop characteristic, maternal and paternal specific, imprinting markings. These markings persist after fertilization and can regulate whether or not the maternally or the paternally derived gene is transcribed during embryonic development. Many of the estimated 150 genes known to be affected by genomic imprinting regulate many aspects of early development, including rates of prenatal and postnatal growth, behavior, and language development. Imprinting is a normal process that acts as a "volume control" for parental genes since it results in one active copy of an imprinted gene.

Incorrectly imprinted genes can have the same effect as deletion of the same gene. This is exemplified by two human genetic disorders linked to genes in a specific portion of chromosome 15 and their differential imprinting during sperm or oocyte formation. *Angelman syndrome*, which results in hyperactivity, severe developmental disability, and seizures, occurs when the maternal genes are inactive. *Prader–Willi syndrome*, which results in short stature, reduced muscle tone and skin pigmentation, underdeveloped gonads, and some degree of developmental disability, occurs when paternal genes are inactive.

Mutations

Variations at the level of the individual gene can result from *mutations*—changes in the nucleotide sequence of an allele. **Spontaneous mutations** result from random errors in DNA replication. Such errors are relatively common, but in most cases the error is detected and repaired by enzymes in the nucleus. Those errors that go undetected and unrepaired have the potential to change the phenotype in some way.

Mutations occurring during meiosis can produce gametes that contain abnormal alleles. These alleles may be dominant or recessive, and they may occur on autosomal chromosomes or on sex chromosomes. The vast majority of mutations make the zygote incapable of completing normal development. Mutation, rather than chromosomal abnormalities, is probably the primary cause of the high mortality rate among pre-embryos and embryos. (Approximately 50 percent of all zygotes fail to complete cleavage, and another 10 percent fail to reach the fifth month of gestation.)

If the abnormal allele is dominant but does not affect gestational survival, the individual's phenotype will show the effects of the mutation. If the abnormal allele is recessive and is on an autosomal chromosome, it will not affect the individual's phenotype as long as the zygote contains a normal allele contributed by the other parent at fertilization. Over generations, a recessive autosomal allele can spread through the population, remaining undetected until a fertilization occurs in which the two gametes contribute identical recessive alleles. This individual, who will be homozygous for the abnormal allele, will be the first to show the phenotypic effects of the original mutation. Individuals who are heterozygous for an abnormal allele but do not show the effects of the mutation are called **carriers**. Available genetic tests can determine whether an individual is a carrier for any of several autosomal recessive disorders, including Tay-Sachs disease. The information obtained from these tests can be useful in counseling prospective parents. For example, if both parents are carriers of the same disorder, they have a 25 percent probability of producing a child with the disease. This information may affect their decision to conceive.

Sex-Linked Inheritance

Sex-linked inheritance involves genes on the sex chromosomes. Unlike the other 22 chromosomal pairs, the sex chromosomes are not identical in appearance and gene content. There are two types of sex chromosomes: an **X chromosome** and a **Y chromosome**. X chromosomes are considerably larger and have more genes than do Y chromosomes. The smaller Y chromosome carries the *SRY gene* not found on the X chromosome. It specifies that an individual with that chromosome will be male. The normal pair of sex chromosomes in males is XY. Females do not have a Y chromosome. Their sex chromosome pair is XX.

All oocytes carry an X chromosome, because the only sex chromosomes females have are X chromosomes. But each sperm carries either an X or a Y chromosome, because males have one of each and can pass along either one during meiosis. As a Punnett square shows, the ratio of males to females in offspring should be 1:1. The birth statistics differ slightly from that prediction, with 106 males born for every 100 females. It has been suggested that more males are born because a sperm that carries the Y chromosome can reach the oocyte first, because that sperm does not have to carry the extra weight of the larger X chromosome.

The X chromosome also carries genes that affect somatic structures. Genes that are found on the X chromosome but not on the Y chromosome are called **X-linked**. The inheritance of characteristics, or traits, regulated by these X-linked genes does not follow the pattern of alleles on autosomal chromosomes.

(The SRY gene that determines "maleness" is an example of a Y-linked gene.)

The inheritance of color blindness shows the differences between sex-linked inheritance and autosomal inheritance. The presence of a dominant allele, C, on the X chromosome (X^{C}) results in normal color vision. A recessive allele, c, on the X chromosome (X^c) results in red-green color blindness. A woman, with her two (C) chromosomes, can be either homozygous dominant $(X^{C}X^{C})$ or heterozygous $(X^{C}X^{C})$ and still have normal color vision. She will be unable to distinguish reds from greens only if she carries two recessive alleles, X^cX^c. But a male has only one X chromosome, so whichever allele that chromosome carries determines whether he has normal color vision or has redgreen color blindness. The Punnett square in Figure 29-18 reveals that the sons produced by a father with normal vision and a heterozygous (carrier) mother have a 50 percent chance of being red-green color blind. Any daughters have normal color vision. Recessive alleles on X chromosomes produce genetic disorders in males at a higher frequency than in females.

A number of other clinical disorders noted earlier in the text are X-linked traits, including certain forms of hemophilia, diabetes insipidus, and muscular dystrophy. In several instances, advances in molecular genetics techniques have enabled geneticists to locate the specific genes on the X chromosome. These techniques provide a reasonably direct method of screening for the presence of a particular condition before any signs or symptoms appear, and even before birth.

The Human Genome Project and Beyond

The **Human Genome Project (HGP)** was completed about a decade ago. Its goal was to describe the **human genome**—the full set of genetic material (DNA) in our chromosomes.

One of its highlights was the expanded description of roughly 10,000 different single gene disorders. Most are very rare, but collectively they may affect 1 in every 200 births. Many of these disorders have been mapped to individual chromosomes. Several examples are included in Figure 29–19. Genetic screening and diagnostic tests for abnormal genes are now performed for many of these disorders.

The HGP sequenced the human genome's 3.2 billion base pairs nucleotide by nucleotide, and estimated that it contained

20,000–25,000 protein-coding genes. These genes accounted for only about 2 percent of the entire genome, which led to the remaining 98 percent of the genome to be assumed nonfunctional, or "junk."

It now turns out that our genome is not full of useless DNA sequences. Results of the recently completed, decadelong **Encyclopedia of DNA Elements (ENCODE)** project have revealed that some 80 percent of the genome is active in one way or another in gene regulation. For example, protein-coding genes are regulated by not only nearby DNA, but also by more distant sequences and by "non-coding" RNA. Non-coding RNA consists of short and long RNA strands that are not translated into protein. Some 18,400 non-coding RNA "genes" have so far been identified. In addition, ENCODE has documented a total

Figure 29–19 A Map of Human Chromosomes. The banding patterns of typical chromosomes in a male, and the locations of the genes associated with specific inherited disorders. The chromosomes are not drawn to scale.

* One form of the disease

Clinical Note

Chromosomal Abnormalities and Genetic Analysis

Embryos that have abnormal autosomal chromosomes rarely survive. However, *translocation defects* and *trisomy* are two types of autosomal chromosome abnormalities that do not invariably result in prenatal death.

In a **translocation defect**, an exchange occurs between different (nonhomologous) chromosome pairs. For example, a piece of chromosome 8 may become attached to chromosome 14. The genes moved to their new position may function abnormally, becoming inactive or overactive. In a balanced translocation, where there is no net loss or gain of chromosomal material, embryos may survive.

In **trisomy**, a mistake occurs in meiosis. One of the gametes involved in fertilization carries an extra copy of one chromosome, so the zygote then has three copies of this chromosome rather than two. (The nature of the trisomy is indicated by the number of the chromosome involved. Thus, individuals with trisomy 13 have three copies of chromosome 13.) Zygotes with extra copies of chromosomes seldom survive. Individuals with trisomy 13 and trisomy 18 may survive until delivery but rarely live longer than a year. The notable exception is trisomy 21.

Trisomy 21, or **Down's syndrome**, is the most common viable chromosomal abnormality. Estimates of its incidence in the U.S. population range from 1.5 to 1.9 per 1000 births. Affected individuals exhibit delayed mental development and have characteristic physical malformations, including a facial appearance that gave rise to the term *mongolism*, once used to describe this condition. The degree of developmental disability ranges from moderate to severe. Anatomical problems affecting the cardiovascular system often prove fatal during childhood or early adulthood. Although some individuals survive to moderate old age, many develop Alzheimer's disease while still relatively young (before age 40).

For unknown reasons, there is a direct correlation between maternal age and the risk of having a child with trisomy 21. For a maternal age below 25, the incidence of Down's syndrome approaches 1 in 2000 births, or 0.05 percent. For maternal ages 30–34, the odds increase to 1 in 900, and over the next decade they go from 1 in 290 to 1 in 46, or more than 2 percent. These statistics are becoming increasingly significant because many women are delaying childbearing until their mid-thirties or later.

Abnormal numbers of sex chromosomes do not produce effects as severe as those induced by extra or missing autosomal chromosomes. In **Klinefelter's syndrome**, the individual carries the sex chromosome pattern XXY. The phenotype is male, but the extra X chromosome causes reduced androgen production.

of 20,687 protein-coding genes in the human genome, with perhaps another 50 or so to be determined.

Epigenetics is the study of inherited traits that are *not* due to changes in a person's genotype or DNA sequences. Similar

As a result, the testes fail to mature so the individuals are sterile, and the breasts are slightly enlarged. The incidence of this condition among newborn males averages 1 in 750 births.

Individuals with **Turner's syndrome** have only a single, female sex chromosome; their sex chromosome complement is abbreviated XO. This kind of chromosomal deletion is known as **monosomy**. The incidence of this condition at delivery has been estimated as 1 in 10,000 live births. The condition may not be recognized at birth, because the phenotype is normal female. But maturational changes do not appear at puberty. The ovaries are nonfunctional, and estrogen production occurs at negligible levels.

Fragile-X syndrome causes developmental disability, abnormal facial development, and enlarged testes in affected males. The cause is an abnormal X chromosome that contains a *genetic stutter*, an abnormal repetition of a single nucleotide triplet. The presence of the stutter in some way disrupts the normal functioning of adjacent genes and so produces the signs and symptoms of the disorder.

Many of these conditions can be detected before birth through the analysis of fetal cells. In **amniocentesis**, a sample of amniotic fluid is removed and the fetal cells it contains are analyzed. This procedure permits the identification of more than 20 congenital conditions, including Down's syndrome. The needle inserted to obtain a fluid sample is guided into position during an ultrasound procedure. \bigcirc p. 21 Unfortunately, amniocentesis has two major drawbacks:

- 1. Because the sampling procedure represents a potential threat to the health of fetus and mother alike, amniocentesis is performed only when known risk factors are present. Examples of risk factors are a family history of specific conditions, or in the case of Down's syndrome, maternal age over 35.
- 2. Sampling cannot safely be performed until the volume of amniotic fluid is large enough that the fetus will not be injured during the process. The usual time for amniocentesis is at 14–15 weeks of gestation. It may take several weeks to obtain results once samples have been collected, and by the time the results are received, an induced or therapeutic abortion may no longer be a viable option.

An alternative procedure known as **chorionic villus sampling (CVS)** analyzes cells collected from the chorionic villi late in the first trimester. CVS carries a slightly higher risk of miscarriage than amniocentesis, but may be preferable because it can be done earlier in gestation.

to genomic imprinting discussed on p. 1127, it acts at a level "above" the DNA by activating or inactivating specific genes. Such gene regulation occurs in a number of ways. One way is by chemically marking DNA and its histone proteins with methyl

or acetyl groups, which permit or restrict transcription, respectively. Non-coding RNAs are another way gene expression can be modified.

Understanding the role of epigenetics in human clinical disorders, disease, and early development is an area of active study. Researchers are piecing together the human **epigenome**, that is, all the chemicals that mark our genome and affect its activities. Although the epigenetic modifiers are not part of the DNA, they can be passed on and inherited when cells divide.

The HGP and ENCODE have identified the normal genetic composition of a "typical" human and begun to reveal how our genes are regulated. Yet we all are variations on a basic theme. How do we decide what set of genes to accept as "normal"? Moreover, as we improve our abilities to alter our own genetic foundations, we will face many additional troubling ethical and legal dilemmas. Few people, for example, object to the insertion of a "correct" gene into somatic cells to cure a specific disease. But what if we could insert that modified gene into a

gamete and change not only that individual, but all of his or her descendants as well? And what if the goal of manipulating the gene was not to correct or prevent any disorder, but instead to "improve" the individual by increasing his or her intelligence, height, or vision, or by altering some other phenotypic characteristic? Such difficult questions will not go away. In the years to come, we will have to find answers that are acceptable to us all.

CHECKPOINT

- **22**. Describe the relationship between genotype and phenotype.
- 23. Define heterozygous.
- 24. Tongue rolling is an autosomal dominant trait. What would be the phenotype of a person who is heterozygous for this trait?
- 25. Why are children not identical copies of their parents?

• See the blue Answers tab at the back of the book.

Related Clinical Terms

- **eclampsia:** A condition in which one or more convulsions occur in a pregnant woman suffering from high blood pressure, often followed by coma and posing a threat to the health of mother and baby.
- **gamete intrafallopian transfer (GIFT):** An assisted reproductive procedure in which a woman's eggs are removed, mixed with sperm, and replaced into the woman's uterine tube where the fertilization takes place, rather than in the laboratory.
- **infertility:** The inability to achieve pregnancy after engaging in one year of appropriately timed intercourse.
- **in vitro fertilization:** Fertilization outside the body, generally in a Petri dish.
- **neural tube defects (NTDs):** Major birth defects caused by an abnormal development of the neural tube—the structure present during the embryonic stage that later becomes the central nervous system. These are very common birth defects that cause infant mortality and disability and include anencephaly and spina bifida.

- **placenta previa:** Condition during pregnancy in which the placenta is abnormally placed so as to totally or partially cover the cervix.
- **placenta abruptio:** Condition in which there is separation of the placenta from the uterine site of implantation before delivery of the baby.
- **preeclampsia:** A condition in pregnancy characterized by sudden hypertension, albuminuria, and edema of the hands, feet, and face. It is the most common complication of pregnancy, affecting about 5 percent of pregnancies.
- **therapeutic cloning:** A procedure that usually takes skin cells from a patient, and inserts a skin cell nucleus into a fertilized egg whose nucleus has been removed to create a new cell. That new cell divides repeatedly to form a blastocyst from which stem cells can be extracted to grow new tissue that is genetically matched to the patient.

- **29-1** Development, marked by various stages, is a continuous process that occurs from fertilization to maturity p. 1096
 - 1. **Development** is the gradual modification of anatomical structures and physiological characteristics from **conception** to maturity. The formation of different types of cells is **differentiation**.
 - Prenatal development occurs before birth; postnatal development begins at birth and continues to maturity, when aging begins. Inheritance is the transfer of genetically determined characteristics from generation to generation. Genetics is the study of the mechanisms of inheritance.

29-2 Fertilization—the fusion of a secondary oocyte and a spermatozoon—forms a zygote p. 1097

- **3. Fertilization**, or *conception*, normally occurs in the uterine tube within a day after ovulation. Spermatozoa cannot fertilize a secondary oocyte until they have undergone *capacitation*. (*Figure 29–1*)
- 4. The acrosomes of the spermatozoa release **hyaluronidase** and **acrosin**, enzymes required to penetrate the corona radiata and zona pellucida of the oocyte. When a single spermatozoon contacts the oocyte membrane, fertilization begins and **oocyte activation** follows. (*Figure 29–1*)
- **5.** During activation, the oocyte completes meiosis II and thus becomes a functionally mature ovum. **Polyspermy** is prevented by membrane depolarization and the *cortical reaction*.
- 6. After activation, the **female pronucleus** and the **male pronucleus** fuse in a process called *amphimixis*. (*Figure 29–1*)

29-3 Gestation consists of three stages of prenatal development: the first, second, and third trimesters p. 1099

- 7. During prenatal development, differences in the cytoplasmic composition of individual cells trigger changes in genetic activity. The chemical interplay among developing cells is **induction**.
- 8. The nine-month **gestation** period can be divided into three **trimesters**.

29-4 Cleavage, implantation, placentation, and embryogenesis are critical events of the first trimester p. 1100

- 9. In the **first trimester**, **cleavage** subdivides the cytoplasm of the zygote in a series of mitotic divisions; the zygote becomes a **pre-embryo** and then a **blastocyst**. During **implantation**, the blastocyst becomes enclosed within the uterine endometrium. **Placentation** occurs as blood vessels form around the blastocyst and the **placenta** develops. **Embryogenesis** is the formation of a viable embryo.
- **10.** The blastocyst consists of an outer **trophoblast** and an **inner cell mass**. (*Figure 29–2*)
- 11. Implantation occurs about seven days after fertilization as the blastocyst adheres to the uterine lining. (*Figure 29–3*)
- **12.** As the trophoblast enlarges and spreads, maternal blood flows through open **lacunae**. After **gastrulation**, there is an **embryonic disc** composed of **endoderm**, **ectoderm**, and an intervening **mesoderm**. It is from these **germ layers** that the body systems differentiate. (*Figure 29–4; Table 29–1*)
- **13.** Germ layers are involved in forming four **extraembryonic membranes**: the yolk sac, amnion, allantois, and chorion. (*Spotlight Figure 29–5*)
- 14. The **yolk sac** is an important site of blood cell formation. The **amnion** encloses fluid that surrounds and cushions the developing embryo. The base of the **allantois** later gives rise to the urinary bladder. Circulation within the vessels of the **chorion** provides a rapid-transit system that links the embryo with the trophoblast. (*Spotlight Figure 29–5, Figure 29–6*)
- 15. Chorionic villi extend outward into the maternal tissues, forming an intricate, branching network through which maternal blood flows. As development proceeds, the umbilical cord connects the fetus to the placenta. The syncytial trophoblast synthesizes human chorionic gonadotropin (hCG), estrogens, progesterone, human placental lactogen (hPL), placental prolactin, and relaxin. (*Figure 29–6*)

- **16.** The first trimester is critical, because events in the first 12 weeks establish the basis for **organogenesis** (organ formation). (*Figure 29–7; Table 29–2*)
- **29-5** During the second and third trimesters, maternal organ systems support the developing fetus, and the uterus undergoes structural and functional changes p. 1112
- 17. In the **second trimester**, the organ systems increase in complexity. During the **third trimester**, many of the organ systems become fully functional. (*Figure 29–8; Table 29–2*)
- The fetus undergoes its largest weight gain in the third trimester. At the end of gestation, the fetus and the enlarged uterus displace many of the mother's abdominal organs. (*Figure 29–9*)
- **19.** The developing fetus is totally dependent on maternal organs for nourishment, respiration, and waste removal. Maternal adaptations include increases in respiratory rate, tidal volume, blood volume, nutrient and vitamin intake, and glomerular filtration rate, as well as changes in the size of the uterus and mammary glands.
- **20.** Progesterone produced by the placenta has an inhibitory effect on uterine muscles. Estrogens, oxytocin, and prostaglandins oppose its calming action. At some point, multiple factors interact to produce **labor contractions** in the uterine wall. (*Figure 29–10*)
- **29-6** Labor consists of the dilation, expulsion, and placental stages p. 1115
- **21.** The goal of **true labor** is **parturition**, the forcible expulsion of the fetus.
- 22. Labor can be divided into three stages: the **dilation stage**, the **expulsion stage**, and the **placental stage**. The Apgar score is used to assess the overall health of a newborn. (*Figure 29–11*)
- 23. Premature labor may result in premature delivery.
- 24. Difficult deliveries can include *forceps deliveries* and **breech births**—deliveries in which the legs or buttocks of the fetus, rather than the head, enter the vaginal canal first.
- 25. Twins are either **dizygotic** (fraternal) **twins** or **monozygotic** (identical) **twins**.
- **29-7** Postnatal stages are the neonatal period, infancy, childhood, adolescence, and maturity, followed by senescence p. 1118
- **26.** Postnatal development involves a series of five **life stages**: the neonatal period, infancy, childhood, adolescence, and maturity. *Senescence*, or aging, begins at maturity and ends in the death of the individual.
- 27. The **neonatal period** extends from birth to one month. In the transition from fetus to **neonate**, the respiratory, circulatory, digestive, and urinary systems of the infant begin functioning independently. The newborn must also begin thermoregulation.
- 28. Mammary gland cells produce protein-rich **colostrum** during the neonate's first few days of life and then convert to milk production. These secretions are released as a result of the **milk let-down (milk-ejection) reflex**. (*Figure 29–12*)
- **29.** Body proportions gradually change during **infancy** (from age 1 month to 2 years) and during **childhood** (from age 2 years to puberty). (*Figure 29–13*)
- **30. Adolescence** begins at **puberty**, when (1) the hypothalamus increases its production of GnRH, (2) circulating levels of FSH and LH rise rapidly, and (3) ovarian or testicular cells become more sensitive to FSH and LH. These changes

initiate gamete formation, the production of sex hormones, and a sudden increase in the growth rate. The hormonal changes at puberty, especially changes in sex hormone levels, produce sex-specific differences in the structure and function of many systems; these differences will be retained. Adolescence continues until growth is completed. Further changes occur when sex hormone levels decline at menopause or the male climacteric.

31. Senescence then begins, producing gradual reductions in the functional capabilities of all systems. (Table 29–3)

29-8 Genes and chromosomes determine patterns of inheritance p. 1122

- 32. Every somatic cell carries copies of the original 46 chromosomes in the zygote; these chromosomes and their component genes constitute the individual's genotype. The physical expression of the genotype is the individual's **phenotype**.
- 33. Every somatic human cell contains 23 pairs of chromosomes; each pair consists of homologous chromosomes. Twentytwo pairs are **autosomal chromosomes.** The chromosomes of the twenty-third pair are the **sex chromosomes**; they differ between the sexes. (Figure 29–14)
- 34. Chromosomes contain DNA, and genes are functional segments of DNA. The various forms of a given gene are called alleles. If both homologous chromosomes carry the same allele of a particular gene, the individual is **homozygous**; if they carry different alleles, the individual is **heterozygous**.

- 35. In **simple inheritance**, phenotypic traits are determined by interactions between a single pair of alleles. Polygenic inheritance involves interactions among alleles on several genes. (Figure 29–15)
- 36. Alleles are either **dominant** or **recessive**, depending on how their traits are expressed.
- 37. Combining maternal and paternal alleles in a **Punnett square** helps us predict the characteristics of offspring. (Figure 29–16)
- 38. Genetic recombination, the gene reshuffling in crossing over and translocation during meiosis, increases the genetic variation of male and female gametes. (Figure 29-17)
- 39. Spontaneous mutations are the result of random errors in DNA replication. Such mutations can cause the production of abnormal alleles.
- 40. The two types of sex chromosomes are an **X chromosome** and a Y chromosome. The normal sex chromosome complement of males is XY; that of females is XX. Sex-linked inheritance involves genes on the sex chromosomes. The X chromosome carries **X-linked genes**, which affect somatic structures but have no corresponding alleles on the Y chromosome. (Figure 29–18)
- 41. Together, the HGP and ENCODE project have revealed that the human genome contains protein-coding genes, DNA sequences for non-coding RNAs, and epigenetic markings affecting gene expression. Close to 22,000 protein-coding genes have been mapped, including some of those responsible for inherited disorders. (Figure 29-19)

Review Questions

LEVEL 1 Reviewing Facts and Terms

- 1. The chorionic villi (a) form the umbilical cord, (b) form the umbilical vein, (c) form the umbilical arteries, (d) increase the surface area available for exchange between the placenta and maternal blood, (e) form the portion of the placenta called the decidua capsularis.
- 2. Identify the two extraembryonic membranes and the three different regions of the endometrium at week 10 of development in the following diagram.

See the blue Answers tab at the back of the book.

- 3. The hormone that is the basis for a pregnancy test is (a) LH, (b) progesterone, (c) human chorionic gonadotropin (hCG), (d) human placental lactogen (hPL), (e) either c or d, depending on the type of test.
- 4. Recessive X-linked traits (a) are passed from fathers to their sons, (b) are more likely to be expressed in males, (c) always affect some aspect of the reproductive system, (d) are never expressed in females, (e) cannot be passed from mothers to daughters.
- 5. The stage of development that follows cleavage is the (a) blastocyst, (b) morula, (c) trophoblast, (d) blastocoele.
- 6. The pre-embryo develops into a multicellular complex known as a . (a) blastocyst, (b) trophoblast, (c) lacuna, (d) blastomere.
- 7. The structure(s) that allow(s) active and passive exchange between the fetal and maternal bloodstreams is/are the (a) yolk stalk, (b) chorionic villi, (c) umbilical veins, (d) umbilical arteries.
- 8. If an allele must be present on both the maternal and paternal chromosomes to affect the phenotype, the allele is said to be (a) dominant, (b) recessive, (c) complementary, (d) heterozygous.
- 9. Describe the changes that occur in the oocyte immediately after fertilization.
- 10. (a) What are the four extraembryonic membranes? (b) From which germ layers do these membranes form, and what are their functions?
- 11. Identify the three stages of labor, and describe the events that characterize each stage.
- 12. List the factors involved in initiating labor contractions.
- 13. Identify the three life stages that occur between birth and approximately age 10. Describe the timing and characteristics of each stage.
- 14. What hormonal events are responsible for puberty? Which life stage does puberty initiate?

LEVEL 2 Reviewing Concepts

- 15. A normally pigmented woman whose father was an albino marries a normally pigmented man whose mother was an albino. What is the probability that they would have an albino child? (a) 50 percent, (b) 25 percent, (c) 12.5 percent, (d) 6.25 percent, (e) 100 percent.
- 16. If a sperm cell lacked sufficient quantities of hyaluronidase, it would *not* be able to (a) move its flagellum, (b) penetrate the corona radiata, (c) become capacitated, (d) survive the environment of the female reproductive tract, (e) metabolize fructose.
- 17. Problems involving the formation of the chorion would affect (a) the embryo's ability to produce blood cells, (b) the formation of limbs, (c) the embryo's ability to derive nutrition from the mother, (d) lung formation, (e) the urinary system.
- **18.** After implantation, how does the developing embryo obtain nutrients? What structures and processes are involved?
- 19. Name the primary placental hormones and their functions.
- **20.** Discuss the changes that occur in maternal systems during pregnancy. Why are these changes functionally significant?
- **21.** During true labor, what physiological mechanisms ensure that uterine contractions continue until delivery has been completed?
- **22.** What physiological adjustments must an infant make during the neonatal period in order to survive?
- Distinguish between the following paired terms: (a) genotype and phenotype, (b) heterozygous and homozygous, (c) simple inheritance and polygenic inheritance.
- 24. Indicate the type of inheritance involved in each of the following situations. (a) Children who exhibit the trait have at least one parent who also exhibits it, (b) Children exhibit the trait even though neither parent does, (c) The trait is expressed more commonly in sons than in daughters, (d) The trait is expressed equally in daughters and sons.

LEVEL 3 Critical Thinking and Clinical Applications

- **25.** Hemophilia A, a condition in which blood does not clot properly, is a recessive trait located on the X chromosome (X^h). Suppose that a woman who is heterozygous for this trait (XX^h) has children with a normal male (XY). What is the probability that the couple will have hemophiliac daughters? What is the probability that the couple will have hemophiliac sons?
- **26.** Joe and Jane desperately want to have children, and although they have tried for two years, they have not been successful. Finally, each of them consults a physician, and it turns out that Joe suffers from oligospermia (a low sperm count). He confides to you that he doesn't understand why this would interfere with his ability to have children since he remembers from biology class that it only takes one sperm to fertilize an egg. What would you tell him?
- 27. Cathy has just given birth to a little girl. When the nurses take the infant back to the nursery, she becomes cyanotic, a condition characterized by bluish discoloration of the skin. The episode passes, but when the infant is bathed, she becomes cyanotic again. Blood gas levels indicate that arterial blood is only 60 percent saturated. Physical examination reveals no structural deformities involving the respiratory or digestive system. What might be causing the problem?
- **28.** Sally gives birth to a baby with a congenital deformity of the stomach. Sally believes that her baby's affliction is the result of a viral infection she suffered during her third trimester. Is this a possibility? Explain.

CLINICAL CASE

The Twins That Looked Nothing Alike

The winners of the "least-alike" twins prize are named Hans and Willem. These charming boys traveled all the way from the Netherlands to win this award in Twinsburg.

Hans and Willem's parents used the services of a prestigious fertility clinic in the Netherlands in the 1990s. Their mother's ovaries were hormonally stimulated, and the secondary oocytes that were released were harvested laparoscopically (by abdominal surgery through small holes). These oocytes were then fertilized with sperm in the laboratory. On the sixth post-fertilization day, coinciding with the time a normally fertilized blastocyst would be finishing its journey through the uterine tube into the uterus, two blastocysts were transferred to the mother's uterus. Both had a successful implantation, placentation, embryogenesis, fetal development, and birth. Why, then, do Hans and Willem look so different? As it turned out, the technician performing the in vitro fertilization mistakenly used a previously-used pipette to transfer the sperm. The couple that

Wrap-Up

visited the clinic just before Hans and Willem's parents were of African descent, and the African man's sperm was still present in the pipette. As a result, one oocyte was fertilized by sperm from a Caucasian man, and the other was fertilized by sperm from an African man.

- 1. Why were the fertilized blastocysts implanted in Hans and Willem's mother on her sixth day after ovulation?
- 2. Are Hans and Willem monozygotic twins or dizygotic twins?

See the blue Answers tab at the back of the book.

Appendix

Normal Physiological Values

Tables 1 and 2 present normal averages or ranges for the chemical composition of body fluids. These values are approximations rather than absolute values, because test results vary from laboratory to laboratory due to differences in procedures, equipment, normal solutions, and so forth. Blanks in the tabular data appear where data are not available. The following locations in the text contain additional information about body fluid analysis: Table 19–3 (p. 672) presents data on the formed elements of whole blood.

Table 26–2 (p. 984) compares the normal values for solutes in plasma and urine.

Table 26–5 (p. 1001) gives the general characteristics of normal urine, and Table 26–2 (p. 1004) shows the typical values of substances in a standard urinalysis.

Table 1The Composition of Minor Body Fluids

	Normal Averages or Ranges							
Test	Perilymph	Endolymph	Synovial Fluid	Sweat	Saliva	Semen		
рН			7.4	4–6.8	6.4*	7.19

*S = serum, P = plasma, WB = whole blood.

[†]Because urinary output averages just over 1 liter per day, these electrolyte values are comparable to mEq/L.

⁺Because urinary metabolite and protein data approximate mg/L or g/L, these data must be divided by 10 for comparison with CSF or blood concentrations. [§]Venous blood sample.

The periodic table presents the known elements in order of their atomic weights. Each horizontal row represents a single electron shell. The number of elements in that row is determined by the maximum number of electrons that can be stored at that energy level. The element at the left end of each row contains a single electron in its outermost electron shell; the element at the right end of the row has a filled outer electron shell. Organizing the elements in this fashion highlights similarities that reflect the composition of the outer electron shell. These similarities are evident when you examine the vertical columns. All the gases of the right-most column—helium, neon, argon, krypton, xenon, and radon—have full electron shells;

each is a gas at normal atmospheric temperature and pressure, and none reacts readily with other elements. These elements, highlighted in blue, are known as the noble, or inert, gases. In contrast, the elements of the leftmost column below hydrogen—lithium, sodium, potassium, rubidium, caesium, and francium—are silvery, soft metals that are so highly reactive that pure forms cannot be found in nature. The fourth and fifth electron levels can hold up to 18 electrons. Table inserts are used for the so-called lanthanoids and actinoids to save space, as higher levels can store up to 32 electrons. Elements of particular importance to our discussion of human anatomy and physiology are highlighted in pink.

Codon Chart

A codon is a sequence of three consecutive nucleotides in mRNA that codes for a particular amino acid or signals to stop protein synthesis. Because each mRNA codon consists of three nucleotides, the four nucleotides in mRNA (A, U, G, and C) can produce 64 different combinations. Of these, 61 codons correspond to amino acids and three act as stop signals of

protein synthesis. There are only 20 different amino acids used to synthesize proteins, so most amino acids are represented by more than one codon. One codon, AUG, has a dual role. It codes for the amino acid methionine and also as the start signal for protein synthesis. It is always the first codon in a strand of mRNA.

Answers to Checkpoints, Review Questions, and Clinical Case Wrap-Ups

Chapter 1

Answers to Checkpoints

PAGE 3 1. Anatomy is the oldest medical science. 2. Studying human anatomy and physiology is important because understanding normal physiology assists in recognizing when something abnormal occurs within the body. **PAGE 4** 3. Anatomy is the study of internal and external body structures. 4. Physiology is the study of how living organisms perform functions. 5. Medical terminology is the use of prefixes, suffixes, word roots, and combining forms to construct anatomical, physiological, or medical terms. 6. An eponym is a commemorative name for a structure or clinical condition that was originally named for a real or mythical person. 7. The book used as the international standard for anatomical vocabulary is International Anatomical Terminology (Terminologia Anatomica). PAGE 6 8. Anatomy and physiology are closely related because all specific functions are performed by specific structures. 9. Gross anatomy (often referred to as macroscopic anatomy) involves studying body structures that can be seen with the unaided eye. Microscopic anatomy is the study of body structures using a microscope to magnify the objects. 10. Several specialties of physiology are cell physiology, organ physiology, systemic physiology, and pathological physiology. **11.** It is difficult to separate anatomy from physiology because the structures of body parts are so closely related to their functions; put another way, function follows form. **PAGE 7** 12. The major levels of organization of the human body from the simplest to the most complex are the following: chemical level \rightarrow cellular level \rightarrow tissue level \rightarrow organ level \rightarrow organ system level \rightarrow organism level. **13.** Major organ systems (and some structures of each) are the integumentary system (skin, hair, sweat glands, and nails), skeletal system (bones, cartilages, associated ligaments, and bone marrow), muscular system (skeletal muscles and associated tendons), nervous system (brain, spinal cord, peripheral nerves, and sense organs), endocrine system (pituitary gland, thyroid gland, pancreas, adrenal glands, gonads, and other endocrine tissues), cardiovascular system (heart, blood, and blood vessels), lymphatic system (spleen, thymus, lymphatic vessels, lymph nodes, and tonsils), respiratory system (nasal cavities, sinuses, larynx, trachea, bronchi, lungs, and alveoli), digestive system (teeth, tongue, pharynx, esophagus, stomach, small intestine, large intestine, liver, gallbladder, and pancreas), urinary system (kidneys, ureters, urinary bladder, and urethra), male reproductive system (testes, epididymides, ductus deferentia, seminal glands, prostate gland, penis, and scrotum), and female reproductive system (ovaries, uterine tubes, uterus, vagina, labia, clitoris, and mammary glands). 14. A histologist investigates structures and properties at the tissue level of organization. **PAGE 10** 15. Homeostasis refers to the existence of a stable internal environment. **16.** Extrinsic regulation is a type of homeostatic regulation resulting from activities of the nervous system or endocrine system. 17. Physiological systems can function normally only under carefully controlled conditions. Homeostatic regulation prevents potentially disruptive changes in the body's internal environment. **PAGE 14** 18. Negative feedback systems provide long-term control

over the body's internal conditions—that is, they maintain homeostasis-by counteracting the effects of a stimulus. 19. When homeostasis fails, organ systems function less efficiently or even malfunction. The result is the state that we call disease. If the situation is not corrected, death can result. **20.** A positive feedback system amplifies or reinforces the effects of a stimulus. 21. Positive feedback is useful in processes that must be completed quickly, such as blood clotting. In contrast, it is harmful in situations in which a stable condition must be maintained, because it tends to increase any departure from the desired condition. Positive feedback in the regulation of body temperature, for example, would cause a slight fever to spiral out of control, with fatal results. For this reason, physiological systems are typically regulated by negative feedback, which tends to oppose any departure from the norm. **22.** Equilibrium is a dynamic (constantly changing) state in which two opposing forces or processes are in balance. 23. When the body continuously adapts, utilizing homeostatic systems, it is said to be in a state of dynamic equilibrium. **PAGE 18** 24. The purpose of anatomical terms is to provide a standardized frame of reference for describing the human body. 25. In the anatomical position, an anterior view is seen from the front and a posterior view is from the back. **PAGE 22** 26. Body cavities protect internal organs and cushion them from thumps and bumps that occur while walking, running, or jumping. Body cavities also permit the organs that they surround to change in size and shape without disrupting the activities of nearby organs. 27. The thoracic cavity includes the pleural and pericardial cavities, which enclose the lungs and heart respectively. The diaphragm forms the boundary between the superior thoracic cavity and the inferior abdominopelvic cavity. The abdominopelvic cavity contains the peritoneal cavity, which contains the superior abdominal cavity and the inferior pelvic cavity.

Answers to Review Questions

PAGE 24

Level 1 Reviewing Facts and Terms

1. (a) superior (b) inferior (c) posterior or dorsal (d) anterior or ventral (e) cranial (f) caudal (g) lateral (h) medial (i) proximal (j) distal 2. g 3. d 4. a 5. j 6. b 7. l 8. n 9. f 10. h 11. e 12. c 13. o 14. k 15. m 16. i 17. b 18. c 19. d 20. c 21. b 22. (a) pericardial cavity (b) peritoneal cavity (c) pleural cavity (d) abdominal (or abdominopelvic) cavity 23. b

Level 2 Reviewing Concepts

24. (a) Anatomy is the study of internal and external structures and the physical relationships among body parts. (b) Physiology is the study of how organisms perform their vital functions.
25. d 26. Autoregulation occurs when the activities of a cell, tissue, organ, or organ system change automatically (that is, without neural or endocrine input) when faced with some environmental change. Extrinsic regulation results from the activities of the nervous or endocrine systems. It causes more extensive and potentially more effective adjustments in activities. 27. The body is erect, and the hands are at the sides with the palms facing forward. 28. b 29. c

Level 3 Critical Thinking and Clinical Applications

30. Calcitonin is released when when blood calcium levels are elevated. This hormone should bring about a decrease in blood calcium levels, thus decreasing the stimulus for its own release. **31.** A lack of blood flow to the hypothalamus of the brain would cause brain cells there to die. Since this is where the body's thermoregulatory center lies, then control of body temperature would be affected.

Answers to Clinical Case Wrap-Up

PAGE 25 1. In addition to the liver and most of the large intestine, the abdominal cavity contains the stomach, spleen, and small intestine. **2.** A deep knife wound superior to the diaphragm would have entered the thoracic cavity, which contains the lungs and heart; associated organs of the respiratory, cardiovascular, and lymphatic systems; the inferior portions of the esophagus; and the thymus.

Chapter 2

Answers to Checkpoints

PAGE 31 1. An atom is the smallest stable unit of matter. **2.** Atoms of the same element that have the same atomic number but different numbers of neutrons are called isotopes. **3.** Hydrogen has three isotopes: hydrogen-1, with a mass number of 1; deuterium, with a mass number of 2; and tritium, with a mass number of 3. The heavier sample must contain a higher proportion of one or both of the heavier isotopes. **PAGE 36** 4. A chemical bond is an attractive force acting between two atoms that may be strong enough to hold them together in a molecule or compound. The strongest attractive forces result from the gain, loss, or sharing of electrons. Examples of such chemical bonds are ionic bonds and covalent bonds. In contrast, the weaker hydrogen bonds occur between molecules or compounds. 5. The atoms in a water molecule are held together by polar covalent bonds. Water molecules are attracted to one another by hydrogen bonds. 6. Atoms combine with each other to gain a complete set of electrons in their outer energy level. Oxygen atoms do not have a full outer energy level, so they readily react with many other elements to attain this stable arrangement. Neon already has a full outer energy level so it cannot combine with other elements. **PAGE 38** 7. Using chemical notation, an ion is represented by one (or more) superscript plus or minus signs following the symbol of an element. 8. The molecular formula for glucose, a compound composed of 6 carbon atoms, 12 hydrogen atoms, and 6 oxygen atoms, is $C_6H_{12}O_6$. 9. Three types of chemical reactions important to the study of human physiology include decomposition reactions, synthesis reactions, and exchange reactions. In a decomposition reaction, a chemical reaction breaks a molecule into smaller fragments. A synthesis reaction assembles smaller molecules into larger ones. In an exchange reaction, parts of the reacting molecules are shuffled around to produce new products. **10.** This reaction involves a large molecule being broken down into two smaller ones, so it is a decomposition reaction. **PAGE 39 11.** An enzyme is a protein that lowers the activation energy of a chemical reaction, which is the amount of energy required to start the reaction. 12. Without enzymes, chemical reactions would proceed only under conditions that the cells could not tolerate (e.g., high temperatures). By lowering the activation energy, enzymes make it possible

for chemical reactions to rapidly proceed under conditions compatible with life. **13.** Organic compounds always contain carbon and hydrogen. Inorganic compounds do not contain carbon and hydrogen atoms as structural ingredients. **PAGE 41** 14. Specific chemical properties of water that make life possible include its solubility (its strong polarity enables it to be used as an efficient solvent), its reactivity (it participates in many chemical reactions), its high heat capacity (it absorbs and releases heat slowly), and its ability to serve as a lubri-**PAGE 42** 15. The pH is a measure of the concentration cant. of hydrogen ions in fluids. Acid and base concentrations are measured in pH, which is the negative logarithm of hydrogen ion concentration, expressed in moles per liter. On the pH scale, 7 represents neutrality; values below 7 indicate acidic solutions. and values above 7 indicate basic (alkaline) solutions. 16. If the body is to maintain homeostasis and thus health, the pH of different body fluids must remain within a fairly narrow range. **PAGE 43** 17. An acid is a compound whose dissociation in solution releases a hydrogen ion and an anion; a base is a compound whose dissociation releases a hydroxide ion (OH⁻) or removes a hydrogen ion (H⁺) from the solution; a salt is an inorganic compound consisting of a cation other than H⁺ and an anion other than OH⁻. **18.** Stomach discomfort is commonly the result of excessive stomach acidity ("acid indigestion"). Antacids contain a weak base that neutralizes the excess acid. **PAGE 46** 19. A compound with a C:H:O ratio of 1:2:1 is a carbohydrate. The body uses carbohydrates mainly as an energy source. **PAGE 51** 20. Lipids are a diverse group of compounds that include fatty acids, eicosanoids, glycerides, steroids, phospholipids, and glycolipids. They are organic compounds that contain carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1. **21.** Human plasma membranes contain mainly phospholipids, plus small amounts of cholesterol and glycolipids. PAGE 56 22. Proteins are organic compounds formed from amino acids, which contain a central carbon atom, a hydrogen atom, an amino group $(-NH_2)$, a carboxyl group $(-COOH_2)$, and an R group or variable side chain. Proteins function in support, movement, transport, buffering, metabolic regulation, coordination and control, and defense. **23.** The heat of boiling breaks bonds that maintain the protein's tertiary structure, quaternary structure, or both. The resulting structural change, known as denaturation, affects the ability of the protein molecule to perform its normal biological functions. **PAGE 57** 24. A nucleic acid is a large organic molecule made of carbon, hydrogen, oxygen, nitrogen, and phosphorus. Nucleic acids regulate protein synthesis and make up the genetic material in cells. 25. Both DNA (deoxyribonucleic acid) and RNA (ribonucleic acid) contain nitrogenous bases and phosphate groups, but the nucleic acid described is RNA because it contains the sugar ribose. **PAGE 59** 26. Adenosine triphosphate (ATP) is a high-energy compound consisting of adenosine to which three phosphate groups are attached. The second and third phosphate groups are each attached by a high-energy bond. 27. Phosphorvlation of an ADP molecule yields a molecule of ATP. **PAGE 60** 28. The biochemical building blocks that are components of cells include lipids (forming the plasma membrane), proteins (acting as enzymes), nucleic acids (directing the synthesis of cellular proteins), and carbohydrates (providing energy for cellular activities). 29. Metabolic turnover is the continuous breakdown and replacement of organic materials within cells.

Answers to Review Questions

PAGE 62

Level 1 Reviewing Facts and Terms

b. Two more electrons can fit into the outermost energy level of an oxygen atom. 2. hydrolysis 3. a 4. b 5. d 6. d 7. b 8. c 9. d 10. d 11. b 12. d 13. a 14. d 15. b 16. protons, neutrons, and electrons 17. carbohydrates, lipids, proteins, and nucleic acids 18. Triglycerides (1) provide a significant energy reserve, (2) serve as insulation and thus act in heat conservation, and (3) protect organs by cushioning them. 19. (1) support (structural proteins); (2) movement (contractile proteins); (3) transport (transport proteins); (4) buffering; (5) metabolic regulation; (6) coordination and control (hormones and neurotransmitters); and (7) defense (antibodies) 20. (a) DNA: deoxyribose, phosphate, and nitrogenous bases (A, T, C, G); (b) RNA: ribose, phosphate, and nitrogenous bases (A, U, C, G) 21. (1) adenosine, (2) phosphate groups, and (3) appropriate enzymes

Level 2 Reviewing Concepts

22. c 23. d 24. Enzymes are specialized protein catalysts that lower the activation energy for chemical reactions. Enzymes speed up chemical reactions but are not used up or changed in the process.
25. A salt is an ionic compound consisting of any cations other than hydrogen ions and any anions other than hydroxide ions. Acids dissociate and release hydrogen ions, while bases remove hydrogen ions from solution (usually by releasing hydroxide ions).
26. Nonpolar covalent bonds have an equal sharing of electrons. Polar covalent bonds have an equal sharing of electrons. Ionic bonds result from the loss or gain of electrons.
27. e 28. c
29. The molecule is a nucleic acid. Carbohydrates and lipids do not contain nitrogen. Although both proteins and nucleic acids contain nitrogen, only nucleic acids normally contain phosphorus.

Level 3 Critical Thinking and Clinical Applications

30. (a) number of electrons = 20; (b) atomic number = 20; (c) atomic weight = 40; (d) 2 electrons in first shell, 8 in second shell, 8 in third shell, and 2 in outer shell. **31.** Decreasing the amount of enzyme at the second step would slow down the remaining steps of the pathway because less substrate would be available for the next two steps. The net result would be a decrease in the amount of product. **32.** If a person exhales large amounts of CO_2 , the level of H⁺ in the blood will decrease. A decrease in the amount of H⁺ will cause the pH to increase.

Answers to Clinical Case Wrap-Up

PAGE 63 1. Baby Sean's stools contained undigested lipids and carbohydrates, which gave them a fatty or greasy appearance.2. Digestive enzymes aid in the decomposition reactions that break down lipids and carbohydrates in food, so they can be absorbed from the digestive tract. If these large molecules cannot be broken down, they cannot be used as energy sources or chemical building blocks.

Chapter 3

Answers to Checkpoints

PAGE 70 1. The general functions of the plasma membrane include physical isolation, regulation of exchange with the environment,

sensitivity to the environment, and structural support. 2. The components of the plasma membrane that allow it to perform its characteristic functions are membrane lipids, membrane proteins, and membrane carbohydrates. **3.** The phospholipid bilayer of the plasma membrane forms a physical barrier between the cell's internal and external environments. 4. Channel proteins are integral proteins that allow water and small ions to pass through the plasma membrane. **PAGE 81** 5. Cytoplasm is the material between the plasma membrane and the nuclear membrane. Cytosol is the fluid portion of the cytoplasm; cytosol is also called intracellular fluid. 6. Cytosol has a higher concentration of potassium ions and suspended proteins, and a lower concentration of sodium ions, than the extracellular fluid. Cytosol also includes small quantities of carbohydrates, and larger reserves of amino acids and lipids. **7.** The nonmembranous organelles and their functions include: (1) centriole = essential for movement of chromosomes during cell division; organization of microtubules in cytoskeleton; (2) cilia = movement of materials over cell surface (motile cilia), environmental sensor (primary cilium); (3) cytoskeleton = strength and support; movement of cellular structures and materials; cell movement; (4) microvilli = increase surface area to facilitate absorption of extracellular materials; (5) proteasomes = breakdown and recycling of intracellular proteins; (6) ribosomes = protein synthesis. 8. The membranous organelles and their functions include: (1) endoplasmic reticulum = synthesis of secretory products; intracellular storage and transport; (2) rough ER = modification and packaging of newly synthesized proteins; (3) smooth ER = lipid and carbohydrate synthesis; (4) Golgi apparatus = storage, modification, and packaging of secretory products and lysosomal enzymes; (5) lysosomes = intracellular removal of damaged organelles or pathogens; (6) mitochondria = production of 95 percent of the ATP required by the cell; (7) peroxisomes = neutralization of toxic compounds. 9. The SER synthesizes lipids, such as steroids. Ovaries and testes produce large amounts of steroid hormones, which are lipids, and thus need large amounts of SER. 10. Mitochondria produce energy, in the form of ATP molecules, for the cell. A large number of mitochondria in a cell indicates a high demand for energy. **PAGE 84** 11. The nucleus is a cellular organelle that contains DNA, RNA, enzymes, and proteins. The nuclear envelope is a double membrane that surrounds the nucleus; the perinuclear space is the region between this double membrane. Nuclear pores enable chemical communication between the nucleus and the cytosol. 12. A gene is a portion of a DNA strand that functions as a hereditary unit. Each gene is located at a particular site on a specific chromosome and codes for a specific protein **PAGE 87** 13. Gene activation is the process of uncoiling the segment of DNA containing that gene, and temporarily removing histones, so that the gene can affect the cell. 14. Transcription is the synthesis of RNA from a DNA template. Translation uses the information from an mRNA strand to form a linear chain of amino acids, or protein. 15. A cell that lacked the enzyme RNA polymerase would not be able to transcribe RNA from DNA. **PAGE 93** 16. A selectively permeable membrane allows the passage of some substances and restricts the passage of others. It falls between two extremes: impermeable, which allows no substance to pass, and freely permeable, which permits the passage of any substance. **17.** Diffusion is the passive molecular movement of a substance from an area of higher concentration to an area of lower concentration. Diffusion proceeds until the concentration gradient is eliminated (equilibrium is reached). 18. Five factors that influence the diffusion of substances in the body are (1) diffusion distance, (2) molecule size,

(3) temperature, (4) concentration gradient, and (5) electrical forces.

19. Diffusion is driven by a concentration gradient. The larger the concentration gradient, the faster the rate of diffusion, and the smaller the concentration gradient, the slower the rate of diffusion. If the concentration of oxygen in the lungs were to decrease, the concentration gradient between oxygen in the lungs and oxygen in the blood would decrease (as long as the oxygen level of the blood remained constant). Thus, oxygen would diffuse more slowly into the blood. **20.** Osmosis is the diffusion of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. **21.** The 10 percent salt solution is hypertonic with respect to the cells lining the nasal cavity, because it contains a higher salt (solute) concentration than do the cells. The hypertonic solution would draw water out of the cells, causing the cells to shrink and adding water to the mucus, thereby diluting it and relieving congestion. **PAGE 100** 22. In carriermediated transport, integral proteins bind specific ions or organic substrates and carry them across the plasma membrane. All forms of carrier-mediated transport are specific, have saturation limits, and are regulated (usually by hormones). **23.** An active transport process must be involved because it takes energy expenditure to move the hydrogen ions against their concentration gradient-that is, from a region where they are less concentrated (the cells lining the stomach) to a region where they are more concentrated (the interior of the stomach). 24. Endocytosis is the movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface. Types of endocytosis are receptor-mediated endocytosis, the vesicle-mediated movement into the cytoplasm of specific target molecules (ligands); pinocytosis, the vesicle-mediated movement into the cytoplasm of extracellular fluid and its contents; and phagocytosis, the vesicle-mediated movement into the cytoplasm of extracellular solids, especially bacteria and debris. 25. Exocytosis is the ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. 26. The process by which certain white blood cells engulf bacteria is called phagocytosis. PAGE 101 **27.** The membrane potential is the difference in electrical potential that results from the uneven distribution of positive and negative charges across the plasma membrane. It is expressed in millivolts (mV). **28.** If the plasma membrane were freely permeable to sodium ions, more of these positively charged ions would move into the cell, and the membrane potential would become less negative (move closer to zero). **PAGE 103** 29. The biological term for cellular reproduction is *cell division*, and the term for cell death is *apop*tosis. 30. Important enzymes for DNA replication include helicases, DNA polymerase, and ligases. **31.** Interphase is a stage in a cell's life when it performs all its normal functions, and, if necessary, prepares for cell division. The stages of interphase include G_{11} , S_1 , G_{21} , and G_0 . A cell in G_0 is not preparing for cell division. **32.** This cell is likely in the G₁ phase of its life cycle. **33.** Mitosis is the essential step in cell division in which a single cell nucleus divides to produce two identical daughter cell nuclei. The four stages of mitosis are prophase, metaphase, anaphase, and telophase. 34. If spindle fibers failed to form during mitosis, the cell would not be able to separate the chromosomes into two sets. If cytokinesis occurred, the result would be one cell with two sets of chromosomes and one cell with **PAGE 106 35.** A growth factor is a natural substance, such none as a peptide or hormone that can stimulate the division of specific cell types. Representative growth factors include chalones, epidermal growth factor (EGF), erythropoietin, fibroblast growth factor (FGF), growth hormone, M-phase promoting factor (maturation-promoting factor), nerve growth factor (NGF), prolactin, and thymosins and related compounds. PAGE 107 36. An illness characterized by

mutations that disrupt normal controls and produce potentially malignant cells is termed cancer. **37.** Metastasis is the spread of cancer cells to distant tissues and organs, leading to the establishment of secondary tumors. **PAGE 108 38.** Differentiation is the development of specific cellular characteristics and functions that are different from the original cell. It results from genes in the cell being switched off, restricting the cell's potential functions.

Answers to Review Questions

PAGE 111

Level 1 Reviewing Facts and Terms

1. a. isotonic b. hypotonic c. hypertonic 2. b 3. c 4. d 5. a 6. c 7. a 8. c 9. a 10. b 11. (1) Cells are the building blocks of all plants and animals. (2) Cells are produced by the division of pre-existing cells. (3) Cells are the smallest units that perform all vital physiological functions. (4) Each cell maintains homeostasis at the cellular level. **12.** Four general functions of the plasma membrane are (1) physical isolation, (2) regulation of exchange with the environment, (3) sensitivity, and (4) structural support. 13. Membrane proteins function as receptors, channels, carriers, enzymes, anchors, and identifiers. **14.** The major transport mechanisms are (1) diffusion, (2) carrier-mediated transport, and (3) vesicular transport. **15.** Factors that affect diffusion rate are (1) distance, (2) steepness of the concentration gradient, (3) molecule size, (4) temperature, and (5) electrical forces. **16.** Major functions of the ER are (1) synthesis of proteins, carbohydrates, and lipids: (2) storage of absorbed or synthesized molecules; (3) transport of materials; and (4) detoxification of drugs or toxins.

Level 2 Reviewing Concepts

17. b **18.** d **19.** b **20.** c **21.** c **22.** d **23.** b **24.** G_0 : normal cell functions; G_1 : cell growth, duplication of organelles, and protein synthesis; S: DNA replication and synthesis of histones; G_2 : protein synthesis **25.** Prophase: chromatin condenses and chromosomes become visible; centrioles migrate to opposite poles of the cell and spindle fibers develop; and the nuclear membrane disintegrates. Metaphase: chromatids attach to spindle fibers and line up along the metaphase plate. Anaphase: chromatids separate and migrate toward opposite poles of the cell. Telophase: the nuclear membrane forms; chromosomes disappear as the chromatin relaxes; and nucleoli appear. **26.** (a) Cytokinesis is the cytoplasmic movement that separates two daughter cells. (b) It completes the process of cell division.

Level 3 Critical Thinking and Clinical Applications

27. This process is facilitated diffusion, which requires a carrier molecule but not cellular energy. The energy for this process is provided by the concentration gradient of the substance being transported. When all the carriers are actively involved in transport, the rate of transport reaches a saturation point. 28. Solution A must have initially had more solutes than solution B. As a result, water moved by osmosis across the selectively permeable membrane from side B to side A, increasing the fluid level on side A. 29. c
30. The isolation of the internal contents of membrane-bound organelles allows them to manufacture or store secretions, enzymes, or toxins that could adversely affect the cytoplasm in general. Another benefit is the increased efficiency of having specialized enzyme systems concentrated in one place. For example, the concentration of enzymes necessary for energy production in the mitochondrion increases the efficiency of cellular respiration.

Answers to Clinical Case Wrap-Up

PAGE 112 1. The other cell that might also be affected is the sperm cell, the only human cell with a tail-like flagellum, which has the same microtubule structure as motile cilia. **2.** Because

Jackson's sperm cells will be affected, he is likely to experience difficulties in fathering children. Also, normal ciliary action is necessary to move sperm from the testes into the male reproductive tract.

Chapter 4

Answers to Checkpoints

PAGE 114 1. Histology is the study of tissues. **2.** The four major types of tissues that form all body structures are epithelial, connective, muscle, and neural tissue. **PAGE 118** 3. Epithelial tissue is characterized by cellularity, polarity, attachment, avascularity, and regeneration. 4. Epithelial tissue provides physical protection, controls permeability, provides sensation, and produces specialized secretions. 5. An epithelium whose cells have many microvilli is probably involved in absorption or secretion. The microvilli greatly increase the surface area available for these processes. **6.** Epithelial cell junctions include tight junctions, gap junctions, spot desmosomes, and hemidesmosomes. 7. Gap junctions allow small molecules and ions to pass from cell to cell. When connecting epithelial cells, they help coordinate such functions as the beating of cilia. In cardiac and smooth muscle tissues, they are essential for coordinating muscle cell contractions. **PAGE 126** 8. The three cell shapes that are characteristic of epithelial cells are squamous (thin and flat), cuboidal (box-shaped), and columnar (tall and slender). 9. A single layer of cells is termed simple, whereas multiple layers of cells are known as stratified. 10. No, this is not a sample from the skin surface. A simple squamous epithelium does not provide enough protection against infection, abrasion, or dehydration. The skin surface has a stratified squamous epithelium. **11.** All these regions are subject to mechanical trauma and abrasion-by food (pharynx and esophagus), by feces (anus), and by intercourse or childbirth (vagina). 12. The two primary types of glandular epithelia are endocrine glands and exocrine glands. 13. Sebaceous glands exhibit holocrine secretion. 14. This gland is an endocrine gland. **PAGE 133** 15. Functions of connective tissues include: (1) defending the body from invading microorganisms; (2) establishing a structural framework for the body; (3) protecting delicate organs; (4) storing energy reserves; (5) supporting, surrounding, and interconnecting other types of tissue; and (6) transporting fluids and dissolved materials. 16. The three categories of connective tissues are connective tissue proper, fluid connective tissues, and supporting connective tissues. 17. Cells found in connective tissue proper are adipocytes, fibroblasts, fibrocytes, lymphocytes, macrophages, mast cells, melanocytes, mesenchymal cells, and microphages. 18. The reduced collagen production resulting from a lack of vitamin C in the diet would cause connective tissue to be weak and prone to damage. 19. Mast cells and basophils produce the molecule histamine, which antihistamines block. 20. The type of connective tissue that contains triglycerides is adipose (fat) tissue. 21. The two connective tissues that contain a fluid matrix are blood and lymph. **PAGE 137** 22. The two types of supporting connective tissue are cartilage and bone. 23. Unlike cartilage, bone has a direct blood supply, which is necessary for proper and rapid healing to occur. 24. The type of cartilage damaged in a herniated intervertebral disc is fibrocartilage. PAGE 139 25. The four types of membranes found in the body are the cutaneous membrane, mucous membranes, serous membranes, and synovial membranes. 26. The pleural, peritoneal, and pericardial cavities are all lined by serous membranes. **27.** The lining of the nasal cavity is a mucous membrane. **PAGE 140** 28. This tissue is deep fascia, a type of dense connective tissue that attaches muscles to skin and bones. **PAGE 142** 29. The three types of muscle

tissue in the body are skeletal muscle, cardiac muscle, and smooth muscle. **30.** Muscle tissue that lacks striations is smooth muscle. Both cardiac and skeletal muscles are striated. **31.** Skeletal muscle is repaired by the division of myosatellite cells, which are stem cells that persist in adult skeletal muscle tissue. **PAGE 143 32.** The cells are most likely neurons. **PAGE 144 33.** The two phases in the response to tissue injury are inflammation and regeneration. **34.** The four common signs of inflammation are swelling, redness, heat (warmth), and pain. **PAGE 146 35.** With advancing age, the speed and effectiveness of tissue repair decrease, the rate of energy consumption in general declines, hormonal activity is altered, and other factors contribute to changes in structure and chemical composition. **36.** Longer life is associated with a longer period of potential exposure to chemicals and other environmental factors

Answers to Review Questions

PAGE 148

Level 1 Reviewing Facts and Terms

1. (a) simple squamous epithelium, (b) simple cuboidal epithelium, (c) simple columnar epithelium, (d) stratified squamous epithelium, (e) stratified cuboidal epithelium, (f) stratified columnar epithelium. 2. b 3. b 4. d 5. c 6. c 7. b 8. d 9. d 10. b 11. c 12. a 13. b 14. e 15. a 16. b 17. Epithelial tissue (1) provides physical protection; (2) controls permeability; (3) provides sensations; and (4) produces specialized secretions. 18. Endocrine glands secrete hormones onto the surface of the gland or directly into the surrounding fluid; exocrine glands secrete through ducts. **19.** Glandular epithelial cells function by (1) merocrine secretion, (2) apocrine secretion, or (3) holocrine secretion. 20. Connective tissues contain (1) specialized cells, (2) extracellular protein fibers, and (3) a fluid ground substance. **21.** The four membranes in the body are (1) serous membranes, (2) mucous membranes, (3) the cutaneous membrane (skin), and (4) synovial membranes. 22. Neural tissue contains (1) neurons, which transmit electrical impulses in the form of reversible changes in the membrane potential, and (2) neuroglia, which include several kinds of supporting cells and play a role in providing nutrients to neurons.

Level 2 Reviewing Concepts

23. Exocrine secretions are secreted onto a surface or outward through a duct. Endocrine secretions are secreted by ductless glands into surrounding tissues. Endocrine secretions are called hormones, which usually diffuse into the bloodstream for distribution to other parts of the body. 24. Tight junctions block the passage of water or solutes between cells. In the digestive system, these junctions keep enzymes, acids, and wastes from damaging delicate underlying tissues. 25. Fluid connective tissues have a liquid, watery matrix. They differ from supporting connective tissues in that they have many soluble proteins in the matrix, and they do not include insoluble fibers. 26. The extensive connections between cells formed by cell junctions, proteoglycans, and physical interlocking hold skin cells together and can deny access to chemicals or pathogens that cover their free surfaces. If the skin is damaged and the connections are broken, infection can occur. 27. b 28. b 29. Similarities: actin and myosin interactions produce contractions, calcium ions trigger and sustain contractions. Differences: skeletal muscles are relatively large, multinucleate, striated, and contract only under neural stimulation; cardiac muscles have 1-5 nuclei, are interconnected in a branching network, and contract in response to pacemaker cell activity; smooth muscles are small, spindle shaped, nonstriated, with only one nucleus, and are not under voluntary control.

Level 3 Critical Thinking and Clinical Applications

30. Because apocrine secretions are released by pinching off a portion of the secreting cell, you could test for the presence of plasma membranes, specifically for the phospholipids in plasma membranes. Merocrine secretions do not contain a portion of the secreting cell, so they would lack plasma membrane components. **31.** Skeletal muscle tissue would be made up of densely packed fibers running in the same direction, but since muscle fibers are composed of cells, they would have many nuclei and mitochondria. Skeletal muscle also has an obvious banding pattern, or striations, due to the arrangement of the actin and myosin filaments within the cell. The student is probably looking at a slide of tendon (dense connective tissue). The small nuclei would be those of fibroblasts. **32.** You would expect the skin in the area of the injury to become red and warm. It would also swell, and Jim would experience a painful sensation. These changes occur as a result of inflammation, the body's first response to injury. Injury to the epithelium and underlying connective tissue would trigger the release of chemicals such as histamine and heparin from mast cells in the area. These chemicals in turn initiate the changes that we observe.

Answers to Clinical Case Wrap-Up

PAGE 149 1. The collagen fibers within the matrix of connective tissue are defective in Ehlers-Danlos syndrome. **2.** Connective tissues throughout Anne Marie's body are affected by Ehlers-Danlos syndrome. This includes structures and organs composed of dense regular connective tissue (tendons, ligaments, aponeuroses), dense irregular connective tissue (skin, organ capsules of liver, kidneys, and spleen), and reticular tissue (spleen, liver, lymph nodes) as well.

Chapter 5

Answers to Checkpoints

PAGE 155 1. The layers of the epidermis are the stratum basale, stratum spinosum, stratum granulosum, stratum lucidum, and stratum corneum. 2. Dandruff consists of cells from the stratum corneum. **3.** This splinter is lodged in the stratum granulosum. 4. Wrinkles in the tips of the fingers (and toes) are due to the constriction of blood vessels in the underlying skin, which causes the skin to shrink. This effect is controlled by the autonomic nervous system, a division of the nervous system that acts outside our awareness. 5. Sanding the tips of the fingers will not permanently remove fingerprints. The ridges of the fingerprints are formed in layers of the skin that are constantly regenerated, so these ridges will eventually reappear. The pattern of the ridges is determined by the arrangement of tissue in the dermis, which is not affected by sanding. **PAGE 157** 6. The two major pigments in the epidermis are carotene, an orange-yellow pigment, and melanin, which ranges in color from red-yellow (pheomelanin) to brown-black (eumelanin). 7. When exposed to the ultraviolet radiation in sunlight, melanocytes in the epidermis and dermis synthesize the pigment melanin, darkening the skin. 8. When skin gets warm, arriving oxygenated blood is diverted to the superficial dermis for the purpose of eliminating heat. The oxygenated blood gives a reddish coloration to the skin. **PAGE 159** 9. In the presence of ultraviolet radiation in sunlight, epidermal cells in the stratum spinosum and stratum basale convert a cholesterol-related steroid into cholecalciferol, or vitamin D_3 . **10.** Cholecalciferol (vitamin D_3) is needed to form strong bones and teeth. When the body surface is covered, UV light cannot penetrate to the stratum basale in the skin to begin vitamin D₃ production, resulting in fragile bones.

PAGE 160 11. Salivary glands and duodenal glands (glands of the duodenum) produce epidermal growth factor (EGF). 12. Epidermal growth factor (EGF) promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating keratinocytes, stimulates epidermal development and epidermal repair after injury, and stimulates synthetic activity and secretion by epithelial glands. **PAGE 162** 13. The dermis (a connective tissue layer) lies between the epidermis and the hypodermis. **14.** The capillaries and sensory neurons that supply the epidermis are located in the papillary layer of the dermis. 15. The presence of elastic fibers and the flexibility and resilience of skin turgor allow the dermis to undergo repeated cycles of stretching and recoiling (returning to its original shape). **PAGE 163 16.** The tissue that connects the dermis to underlying tissues is the hypodermis or subcutaneous layer. 17. The hypodermis is a layer of loose connective tissue (areolar tissue) and adipose tissue below (deep to) the dermis. It is also called the subcutaneous layer or superficial fascia. The hypodermis is not considered a part of the integument, but it is important in stabilizing the position of the skin in relation to underlying tissues. 18. Subcutaneous fat provides insulation to help reduce heat loss, serves as an energy reserve, and acts as a shock absorber for the body. **PAGE 166** 19. A typical hair is a keratinous strand produced by epithelial cells of the hair follicle. **20.** The contraction of the arrector pili muscle pulls the hair follicle erect. The result is known as "goose bumps." **21.** Even though hair is a derivative of the epidermis, the hair follicles are in the dermis. Where the epidermis and deep dermis are destroyed, new hair will not grow. **PAGE 168** 22. Two types of exocrine glands found in the skin are sebaceous (oil) glands and sweat glands. 23. Sebaceous secretions (called sebum) lubricate and protect the keratin of the hair shaft, lubricate and condition the surrounding skin, and inhibit the growth of bacteria. **24.** Deodorants are used to mask the odor of apocrine sweat gland secretions, which contain several kinds of organic compounds. Some of these compounds have an odor, and others produce an odor when metabolized by skin bacteria. **25.** Apocrine sweat glands enlarge and increase secretory activity in response to the increase in sex hormones that occurs at puberty. **PAGE 169** 26. Keratin is the substance that gives fingernails their strength. 27. The area of thickened stratum corneum under the free edge of a nail is called the hyponychium. 28. Nail growth occurs at the nail root, an epidermal fold that is not visible from the surface. **PAGE 172** 29. The combination of fibrin clots, fibroblasts, and the extensive network of capillaries in tissue that is healing is called granulation tissue. **30.** Skin can regenerate effectively even after considerable damage because stem cells persist in both the epithelial and connective tissue components of skin. When injury occurs, cells of the stratum basale replace epithelial cells, and mesenchymal cells replace cells lost from the dermis. **PAGE 173** 31. As a person ages, the blood supply to the dermis decreases and merocrine sweat glands become less active. These changes make it more difficult for older individuals to cool themselves in hot weather. **32.** With advancing age, melanocyte activity decreases, leading to gray or white hair.

Answers to Review Questions

PAGE 176

Level 1 Reviewing Facts and Terms

 (e) hypodermis (subcutaneous layer)
 2. a
 3. c
 4. d
 5. d
 6. c
 7. a
 8. d
 9. b
 10. b
 11. d
 12. d
 13. b
 14. a
 15. Epidermal cell division occurs in the stratum basale.
 16. These

smooth muscles cause hairs to stand erect when stimulated. **17.** Epidermal growth factor promotes the divisions of basal cells in the stratum basale and stratum spinosum, accelerates the production of keratin in differentiating epidermal cells, stimulates both epidermal development and epidermal repair after injury, and stimulates synthetic activity and secretion by epithelial glands. **18.** The dermis is made up of (1) the papillary layer, which consists of loose connective tissue and contains capillaries and sensory neurons, and (2) the reticular layer, which consists of dense irregular connective tissue and bundles of collagen fibers. Both layers contain networks of blood vessels, lymphatic vessels, and nerve fibers. **19.** Regeneration of injured skin involves (1) bleeding and inflammation (inflammatory phase), (2) scab and granulation tissue formation (migratory phase), (3) loss of granulation and undermining of the scab (proliferation phase), and (4) scarring (scarring phase).

Level 2 Reviewing Concepts

20. Insensible perspiration is water loss by evaporation through the stratum corneum. Sensible perspiration is produced by active sweat glands. 21. The integument is the first barrier to substances entering the body. This method of delivering drugs requires the substance to move across the epidermal plasma membranes. The lipid bilayer of the plasma membranes creates a barrier that prevents water from rapidly entering or leaving the cells. Fat-soluble (lipophilic) substances, such as oil containing a dissolved drug, can easily pass through this barrier to underlying connective tissue and enter the circulation. Water-soluble drugs are lipophobic and thus do not readily penetrate the integument. **22.** A tan develops when the skin is exposed to the sun. The tan is a result of the synthesis of melanin in the skin. Melanin, in turn, helps prevent excessive skin damage by absorbing UV radiation before it reaches the deep layers of the epidermis and dermis. Within the epidermal cells, melanin concentrates around the nucleus, so it absorbs the UV light before it can damage nuclear DNA. A benefit of minimal sun exposure is that sunlight causes epidermal cells to convert a cholesterol-related steroid into cholecalciferol (Vitamin D_3), which is important to bone maintenance and growth. 23. Incisions along the lines of cleavage—which represent the orientation of dermal collagen and elastin fibers-are more likely to remain closed, and thus will heal more quickly, than incisions that cut across lines of cleavage. 24. c 25. c 26. d

Level 3 Critical Thinking and Clinical Applications

27. a 28. The puncture wound by the nail has a greater chance of becoming infected. Whereas the knife cut will bleed freely, washing many of the bacteria from the wound site, the nail can carry bacteria beneath the surface of the skin, where oxygen is limited (anaerobic), and past the skin's protective barriers. 29. (a) Ultraviolet radiation in sunlight converts a cholesterol-related steroid into vitamin D_{3i} or cholecalciferol. This compound is then converted to the hormone calcitriol, which is essential for absorbing the calcium and phosphorus by the small intestine that is necessary for normal bone maintenance and growth. (b) The child can drink more milk. Milk is routinely fortified with cholecalciferol, normally identified as "vitamin D," which is easily absorbed by the intestines. **30.** Sweating from merocrine glands is precisely regulated, and one influencing factor is emotional state. Presumably, a person who is lying is nervous and sweats profusely; the lie detector machine detects a change in electrical skin conductance caused by this sweating. **31.** The chemicals in hair dyes break the protective covering of the cortex, allowing the dyes to stain the medulla of the shaft. Dying is not permanent because the cortex remains damaged, allowing shampoo and UV rays from the sun to enter the medulla and affect

the color. Also, the living portion of the hair remains unaffected, so that when the shaft is replaced the color will be lost.

Answers to Clinical Case Wrap-Up

PAGE 177 1. The epidermis is affected by psoriasis. **2.** The underlying problem in psoriasis is that cell division and maturation occur too rapidly. Instead of basal cells dividing at a rate to replace the keratinocytes that wear away at the surface of the skin, they divide so rapidly, and migrate through the epithelial layers so quickly, that keratinocytes pile up on the skin surface.

Chapter 6

Answers to Checkpoints

PAGE 179 1. The five primary functions of the skeletal system are support, storage of minerals and lipids, blood cell production, protection, and leverage. **PAGE 182** 2. The six broad categories for classifying bones according to shape are sutural bones, irregular bones, short bones, flat bones, long bones, and sesamoid bones. **3.** A bone marking (surface feature) is an area on the surface of a bone structured for a specific function, such as joint formation, muscle attachment, or the passage of nerves and blood vessels. PAGE 184 4. Mature bone cells are known as osteocytes, bone-building cells are called osteoblasts, and osteoclasts are bone-resorbing cells. 5. If the ratio of collagen to hydroxyapatite in a bone increased, the bone would become less strong (as well as more flexible). 6. Because osteoclasts break down or demineralize bone, the bone would have a decreased mineral content (less mass); as a result, it would also be weaker. **PAGE 187** 7. Compact bone consists of osteons (Haversian systems) with little space between them. Compact bone lies over spongy bone and makes up most of the diaphysis. It functions to protect, support, and resist stress. Spongy bone consists of trabeculae with numerous red marrow-filled spaces. Spongy bone makes up most of the structure of short, flat, and irregular bones and is also found at the epiphyses of long bones. Spongy bone functions in storing marrow and providing some support. 8. The presence of lamellae that are not arranged in osteons is indicative of spongy bone, which is located in an epiphysis. **PAGE 192** 9. In endochondral ossification, cells of the inner layer of the perichondrium differentiate into osteoblasts, and a cartilage model is gradually replaced by bone. 10. During intramembranous ossification, fibrous connective tissue is replaced by bone. **11.** Long bones of the body, such as the femur, have an epiphyseal cartilage, a plate of cartilage that separates the epiphysis from the diaphysis so long as the bone is still growing lengthwise. An x-ray would indicate whether the epiphyseal cartilage is still present. If it is, growth is still occurring. If it is not, the bone has reached its adult length and thus, the person has reached full height. **PAGE 194** 12. Bone remodeling refers to the process whereby old bone is continuously being destroyed by osteoclasts while new bone is being constructed by osteoblasts. 13. The biochemistry of some heavy-metal ions, such as strontium, cobalt, uranium, and plutonium, is very similar to that of calcium. Osteoblasts cannot differentiate these heavymetal ions from normal calcium ions, so the heavy-metal ions become incorporated into the bone matrix. Over time, these dangerous ions can be released into the bloodstream during normal bone remodeling. **PAGE 195** 14. The larger arm muscles of the weight lifter would apply more mechanical stress to the bones of the upper limbs. In response to that stress, the bones would grow thicker. **15.** Growth continues throughout childhood. At puberty,

a growth spurt takes place and is followed by the closure of the epiphyseal cartilages. The later puberty begins, the taller the child will be when the growth spurt begins, so the taller the person will be when growth is completed. **16.** Increased levels of growth hormone prior to puberty will result in excessive bone growth, making the person taller. PAGE 197 17. Parathyroid hormone (PTH) influences osteoclast activity, which causes a release of stored calcium ions from bone. Under the influence of calcitonin, osteoclast activity is inhibited, while osteoblasts continue to lock calcium ions in the bone matrix. In this way, PTH serves to increase blood calcium levels by causing its release from bone, and calcitonin decreases blood calcium levels by causing calcium to remain in bone. 18. The bones of children who have rickets are poorly mineralized and as a result are quite flexible. Under the weight of the body, the leg bones bend. The instability makes walking difficult and can lead to other problems of the legs and feet. 19. Parathyroid hormone (PTH) indirectly stimulates osteoclasts to release calcium ions from bone and enhances calcitriol's effect on the intestinal absorption of calcium. Increased PTH secretion would result in an increase in the level of calcium ions in the blood. **20.** Calcitonin lowers blood calcium levels by inhibiting osteoclast activity and increasing the rate of calcium excretion by the kidneys. **PAGE 198** 21. Immediately following a fracture, extensive bleeding occurs at the injury site. After several hours, a large blood clot called a fracture hematoma develops. Next, an internal callus forms as a network of spongy bone unites the inner edges, and an external callus of cartilage and bone stabilizes the outer edges. The cartilaginous external callus is eventually replaced by bone, and the struts of new spongy bone now unite the broken ends. With time, the swelling that initially marks the location of the fracture is remodeled, new compact bone is formed, and little evidence that a break occurred remains. 22. An external callus forms early in the healing process, when cells from the endosteum and periosteum migrate to the area of the fracture. These cells form an enlarged collar (external callus) that encircles the bone in the area of the fracture. **PAGE 202** 23. Osteopenia is inadequate ossification and is common during the aging process. It results from decreasing osteoblast activity accompanied by normal osteoclast activity. **24.** In women, the sex hormones known as estrogens play an important role in moving calcium into bones. After menopause, the level of these hormones decreases dramatically. As a result, older women have difficulty replacing the calcium in bones that is being lost due to normal aging. In men, the level of sex hormones (androgens) does not decrease until much later in life.

Answers to Review Questions

PAGE 204

Level 1 Reviewing Facts and Terms

1. b 2. a 3. a 4. c 5. b 6. b 7. (a) long bone (b) flat bone (c) sutural bone (d) irregular bone (e) short bones (f) sesamoid bone. 8. a 9. a 10. c 11. (1) support; (2) storage of minerals and lipids; (3) blood cell production; (4) protection; and (5) leverage 12. (1) osteocytes; (2) osteoblasts; (3) osteoclasts; and (4) osteogenic cells 13. (1) diaphysis (shaft); (2) epiphysis; (3) epiphyseal cartilage/line; (4) articular cartilage; (5) medullary canal; (6) periosteum; (7) endosteum 14. In endochondral ossification, bone replaces mesenchyme or fibrous connective tissue. 15. organic = collagen; inorganic = hydroxyapatite crystals 16. (a) calcium salts, phosphate salts, and vitamins A, C, and D₃; (b) calcitriol, growth hormone, thyroxine, estrogens (in females) or androgens (in males), calciuonin, and parathyroid hormone (PTH)

17. The three organs or tissues are the bones, the intestinal tract, and the kidneys. **18.** Parathyroid hormone stimulates osteoclast activity, increases the rate of intestinal absorption of calcium ions, and decreases the rate of excretion of calcium ions by the kidneys. These effects increase blood calcium levels.

Level 2 Reviewing Concepts

19. Nutrients reach the osteocytes in spongy bone by diffusing along canaliculi that open onto the surface of the trabeculae. **20.** The osteons are aligned parallel to the long axis of the shaft, which does not bend when forces are applied to either end. Stresses or impacts to the side of the shaft can lead to a fracture. **21.** The lack of physical stress during inactivity leads to the removal of calcium salts from bones. Up to one-third of the bone mass can be lost in this manner, causing the bones to become thin and brittle. 22. The digestive and urinary (kidneys) systems play important roles in providing the calcium and phosphate minerals needed for bone growth. In return, the skeleton provides protection and acts as a reserve of calcium, phosphate, and other minerals that can compensate for changes in the dietary supplies of these ions. 23. There are many long bones in the hand, each of which has an epiphyseal cartilage (plate). Measuring the width of these plates will provide clues to the hormonal control of growth in the child. 24. Once a bone fracture has been repaired, the bone at the fracture site tends to be stronger and thicker than normal. 25. b 26. Bone markings give clues as to the size, age, sex, and general appearance of an individual.

Level 3 Critical Thinking and Clinical Applications

27. The fracture might have damaged the epiphyseal cartilage in Sally's right leg. Even though the bone healed properly, the damaged leg did not produce as much cartilage as did the undamaged leg. The result would be a shorter bone on the side of the injury. 28. d
29. a 30. The matrix of bone will absorb traces of minerals from the diet. These minerals can be identified hundreds of years later. A diet rich in calcium and vitamin B will produce denser bones than will a diet lacking these. Cultural practices such as the binding of appendages or the wrapping of infant heads will manifest in misshapen bones. Heavy muscular activity will result in larger bone markings, indicating an athletic or physically-demanding lifestyle.

Answers to Clinical Case Wrap-Up

PAGE 205 1. Having multiple fractures in varying stages of healing, with no good explanation for how they occurred, is a hallmark sign of physical abuse in children. (Emergency personnel are obligated by law to report such signs.) 2. Alex should avoid contact sports. As this incident shows, Alex is at much higher risk for fractures than any other soccer player on the field. He should be encouraged to pursue swimming, music, writing, art, or other stimulating, yet less physical, activities.

Chapter 7

Answers to Checkpoints

PAGE 207 1. The axial skeleton includes the skull (8 cranial bones and 14 facial bones), the bones associated with the skull (6 auditory ossicles and the hyoid bone), the vertebral column (24 vertebrae, the sacrum, and the coccyx), and the thoracic cage (the sternum and 24 ribs).
2. The axial skeleton serves as a framework that supports and protects organs, provides an extensive surface area for muscle attachment, and it also stabilizes and positions parts of the appendicular skeleton that support the limbs.
PAGE 223 3. The foramen magnum is located in the base of the occipital bone.

fractured his right parietal bone. 5. The sphenoid bone contains the sella turcica, which in turn contains the pituitary gland. 6. The 14 facial bones include 2 inferior nasal conchae, 2 lacrimal bones, 1 mandible, 2 maxillae (maxillary bones), 2 nasal bones, 2 palatine bones, 1 vomer, and 2 zygomatic bones. **7.** The mental foramen is found in the mandible. Structures passing through this opening include the mental nerve, which carries sensory information to the brain, and mental vessels, which supply the chin and lips. 8. The optic canal is found in the sphenoid bone. The optic nerve and ophthalmic artery pass through this structure. 9. The foramina in the ethmoid bone are the olfactory foramina. PAGE 224 **10.** The bones forming the orbital complex are the frontal, sphenoid, zygomatic, palatine, maxilla, lacrimal, and ethmoid. **11.** The bones forming the nasal complex are the frontal, ethmoid, nasal, maxilla, palatine, and sphenoid. 12. The sphenoid, ethmoid, frontal, and paired palatine and maxillary bones contain the paranasal sinuses. PAGE 225 13. A fontanelle is a relatively soft, flexible, fibrous region between two flat bones in the developing skull. The major fontanelles are the anterior fontanelle, occipital fontanelle, sphenoidal fontanelle, and mastoid fontanelle. 14. Because they are not ossified at birth, fontanelles permit the skull to change shape during childbirth, and they allow for growth of the brain during infancy and early childhood. PAGE 227 15. The secondary curves of the spine allow us to balance our body weight on our lower limbs with minimal muscular effort. Without the secondary curves, we would not be able to stand upright for extended periods. 16. When you run your finger along a person's spine, you can feel the spinous processes of the vertebrae. **PAGE 235** 17. The adult vertebral column has fewer vertebrae than a newborn because the five sacral vertebrae fuse to form a single sacrum, and the four coccygeal vertebrae fuse to form a single coccyx. **18.** The dens is part of the axis, or second cervical vertebra, which is located in the neck (cervical region). **19.** The presence of transverse foramina indicates that this vertebra is from the cervical region of the vertebral column. These foramina are passageways for important blood vessels that supply the brain. **20.** The lumbar vertebrae must support a great deal more weight than do vertebrae that are more superior in the spinal column. The large vertebral bodies allow the weight to be distributed over a larger area. **PAGE 237** 21. True ribs (ribs 1–7) attach directly to the sternum by their own costal cartilage. False ribs (ribs 8-12) either attach by means of a common costal cartilage (as in the vertebrochondral ribs) or do not attach to the sternum (as in the floating ribs). 22. Improper compression of the chest during CPR can-and commonly does-result in a fracture of the xiphoid process of the sternum or the ribs. 23. Vertebrosternal ribs, or true ribs (ribs 1–7), attach directly to the sternum by separate costal cartilages; vertebrochondral ribs (ribs 8-10) have costal cartilages that merge with the cartilages of rib pair 7 before they reach the sternum. Answers to Review Questions

PAGE 239

Level 1 Reviewing Facts and Terms

bone; (7) zygomatic bone **13.** The vomer forms the anterior, inferior portion of the bony nasal septum that separates the right and left nasal cavities. **14.** The fibrocartilage discs between adjacent vertebrae make the vertebral column more flexible.

Level 2 Reviewing Concepts

15. The petrous part of the temporal bone encloses the structures of the internal ear. The middle ear is located in the tympanic cavity within the petrous part. The external acoustic meatus (auditory canal) ends at the tympanic membrane, which leads into the middle ear. Mastoid air cells within the mastoid process are connected to the tympanic cavity. **16.** The ethmoid bone forms the superior surface of the nasal cavity. The olfactory foramina within the cribriform plate of the ethmoid bone allow neurons associated with the sense of smell to extend into the nasal cavity. **17.** The ribs raise and lower to increase and decrease the volume of the thoracic cage. When they rise, the thoracic cage expands and we breathe in. When the ribs are lowered to their original position, the volume of the thoracic cage decreases and we breathe out. **18.** Keeping your back straight keeps the weight aligned along the axis of your vertebral column, where it can be transferred to your lower limbs. Bending your back would strain the muscles and ligaments of the back, increasing the risk of injury. **19.** d **20.** Fontanelles are fibrous connections between cranial bones. They help ease birth by permitting the skull to distort without damage during delivery. 21. a 22. c 23. e

Level 3 Critical Thinking and Clinical Applications

24. d **25.** The large bones of a child's cranium are not yet fused; they are connected by fontanelles, areas of fibrous tissue. By examining the bones, the archaeologist could readily see if sutures had formed. By knowing approximately how long it takes for the various fontanelles to close and by determining their sizes, she could estimate the age of the person at death. **26.** Women in later stages of pregnancy develop lower back pain because of changes in the lumbar curvature of the spine. The increased mass of the pregnant uterus shifts the woman's center of gravity. To compensate, the lumbar curvature is exaggerated, and the lumbar region supports more of her body weight than normal. This results in sore muscles that produce lower back pain.

Answers to Clinical Case Wrap-Up

PAGE 240 1. The seven bones that make up the orbital complex are the frontal bone (forming the roof), the zygomatic bone (forming the lateral wall), the maxilla (forming most of the floor), the lacrimal bone, the lateral mass of the ethmoid bone, the sphenoid bone, and the palatine bone (forming the thin medial wall and floor).2. The four paranasal sinuses surrounding the orbital complex are the frontal, maxillary, and sphenoidal sinuses, and ethmoid air cells.

Chapter 8

Answers to Checkpoints

PAGE 245 1. Each of the two pectoral girdles consists of a clavicle (collarbone) and a scapula (shoulder blade). Each arm articulates with the trunk at the pectoral girdle. **2.** The clavicle attaches the scapula to the sternum, and restricts the scapula's range of motion. When the clavicle is broken, the scapula has a greater than normal range of motion and is less stable. **3.** The head of the humerus articulates with the scapula at the glenoid cavity. **PAGE 250 4.** The bones of an upper limb are the humerus, ulna, radius, carpal bones (scaphoid, lunate, triquetrum, pisiform, trapezium, trapezoid, capitate, and hamate), 5 metacarpal bones, and 14 phalanges. **5.** The

two rounded projections on either side of the elbow are the lateral and medial epicondyles of the humerus. **6.** The radius is lateral to the ulna while in the anatomical position; or the ulna is medial to the radius while in the anatomical position. **7.** The first distal phalanx is located at the tip of the thumb, so Bill's pollex is broken. **PAGE 254** 8. The pelvic girdle is composed of the paired hip bones, also known as the coxal bones or pelvic bones. 9. The three bones that make up a hip bone are the ilium, ischium, and pubis. **10.** The pelvis of females is adapted for supporting the weight of the developing fetus and enabling the newborn to pass through the pelvic outlet during delivery. Compared to males, such adaptations of the female pelvis include an enlarged pelvic outlet, a sacrum and coccyx with less curvature, a pelvic inlet that is wider and more circular, a relatively broad shape, ilia that project farther laterally, and an inferior angle between the pubic bones that is greater than 100 degrees (as opposed to 90 degrees or less for males). 11. When you are seated, your body weight is supported by the ischial tuberosities. **PAGE 258** 12. The bones of the lower limb are the femur (thigh), patella (kneecap), tibia and fibula (leg), tarsal (ankle) bones (talus, calcaneus, cuboid, navicular, medial cuneiform, intermediate cuneiform, and lateral cuneiform), 5 metatarsal bones, and 14 phalanges. 13. The fibula is not part of the knee joint and does not bear weight, but it is an important point of attachment for many leg muscles. When the fibula is fractured, these muscles cannot function properly to move the leg, so walking is difficult and painful. The fibula also helps stabilize the ankle joint. 14. Joey has most likely fractured the calcaneus (heel bone). 15. The talus transmits the weight of the body from the tibia toward the toes. **PAGE 259** 16. In general, the bones of males tend to be heavier than those of females, and bone markings are more prominent in males than in females. **17.** Bones can reveal information about a person's sex, age, muscular development, nutritional state, handedness, and occupation, plus other information relative to the medical history.

Answers to Review Questions

PAGE 261

Level 1 Reviewing Facts and Terms

 (f) hip bone 4. a 5. b 6. d 7. b 8. interosseus membrane 9. ischium, ilium, and pubis 10. (1) talus; (2) calcaneus;
 (3) cuboid; (4) navicular; and (5-7) three cuneiform bones

Level 2 Reviewing Concepts

11. d **12.** a **13.** e **14.** d **15.** d **16.** d **17.** c **18.** The pelvic girdle consists of the two hip bones, or coxal bones. The pelvis is a composite structure; it consists of the two hip bones of the appendicular skeleton and the sacrum and coccyx of the axial skeleton. **19.** d **20.** The clavicles are small and fragile, so they are easy to break. Once this part of the pectoral girdle is broken, the assailant would no longer have efficient use of his arms. **21.** e **22.** The slender fibula parallels the tibia of the leg and provides an important site for muscle attachment. It does not help in transferring weight to the ankle and foot because it is excluded from the knee joint. **23.** e

Level 3 Critical Thinking and Clinical Applications

24. In osteoporosis, a decrease in the calcium content of the bones leads to bones that are weak and brittle. Hip fractures involve the

femur, not the hip bones. Because the hip joint must help support the body's weight, any weakening of the femoral bones may result in their breaking under the weight of the body. The shoulder, by contrast, is not a load-bearing joint and is not subject to the same great stresses or strong muscle contractions as the hip joint. As a result, it is less likely to become broken. 25. Fred probably dislocated his shoulder, which is quite a common injury due to the weak nature of the glenohumeral joint. 26. Several characteristics are important in determining an individual's sex from a pelvis: its general appearance, the shape of the pelvic inlet, the depth of the iliac fossa, the characteristics of the ilium, the angle inferior to the pubic symphysis, the position of the acetabulum, the shape of the obturator foramen, and the characteristics of the ischium. The individual's age can be estimated by the bone's size, degree of mineralization, and various markings. The individual's general appearance can be reconstructed from the markings where muscles attach to the bones, which can indicate the size and shape of the muscles and thus the individual's general body contours.

Answers to Clinical Case Wrap-Up

PAGE 262 1. The distal humeral fracture fragment is still attached to the radius and ulna at the elbow joint. The fracture site is above the medial and lateral humeral epicondyles, and above the joint itself.2. In a severe fracture of the appendicular skeleton, massive swelling is likely to occur. A circular cast will not give, or expand, as swelling continues. This might literally squeeze off the circulation to the forearm and hand. To prevent this from happening, a posterior splint is used instead.

Chapter 9

Answers to Checkpoints

PAGE 266 1. The three types of joints as classified by their range of motion are the following: (1) an immovable joint or synarthrosis, (2) a slightly movable joint or amphiarthrosis, and (3) a freely movable joint or diarthrosis. A synarthrosis can be fibrous or cartilaginous, depending on the nature of the connection, or it can be a bony fusion, which develops over time. An amphiarthrosis is either fibrous or cartilaginous, depending on the nature of the connection. A diarthrosis is a synovial joint, which permits the greatest range of motion. **2.** Both synarthrotic joints (except synostoses) and amphiarthrotic joints consist of bony regions separated by fibrocartilage or cartilaginous connective tissue. **3.** These are fibrous joints known as sutures. PAGE 268 4. Components of a synovial joint include a joint capsule (articular capsule), articular cartilages, synovial fluid, and various accessory structures (menisci, fat pads, ligaments, tendons, and bursae). Synovial joints are freely movable joints that have a joint (synovial) cavity, which is the space between articulating surfaces of two bones in a joint. Articular cartilages resembling hyaline cartilage cover the articulating bone surfaces. The fibrous joint capsule surrounds the joint, and a synovial membrane, which secretes synovial fluid, lines the walls of the joint cavity. Within the cavity, synovial fluid lubricates, distributes nutrients, and absorbs shocks. Menisci are articular discs made of fibrocartilage that allow for variation in the shapes of the articulating surfaces. Fat pads protect the cartilages. Ligaments are cords of fibrous tissue that support, strengthen, and reinforce the joint. Tendons passing across or around the joint limit the range of motion and provide mechanical support. Bursae are synovial fluid-filled pockets that reduce friction and absorb shocks. 5. Because articular cartilages are avascular (lack a blood supply), they rely on synovial fluid to supply nutrients and eliminate wastes. Impairing the circulation of synovial fluid would have the same effect as impairing a tissue's blood supply: Nutrients would not be delivered to meet the tissue's needs, and wastes would accumulate. Damage to, and ultimately the death of, the cells in the tissue would result. 6. A subluxation is a partial dislocation of a bone from its joint. **PAGE 274** 7. Based on the shapes of the articulating surfaces, synovial joints are classified as gliding, hinge, pivot, condvlar (ellipsoid), saddle, and ball-and-socket joints. 8. When doing jumping jacks, you move your lower limbs away from the body's midline; this movement is abduction. When you bring the lower limbs back together, the movement is adduction. 9. Flexion and extension are the movements associated with hinge joints. **PAGE 276** 10. Movements possible across the intervertebral joints of the vertebral column are flexion (bending anteriorly), extension (bending posteriorly), lateral flexion (bending laterally), and rotation. 11. Intervertebral discs are not found between the first and second cervical vertebrae, between sacral vertebrae in the sacrum, or between coccygeal vertebrae in the coccyx. An intervertebral disc between the first and second cervical vertebrae would prohibit rotation. The vertebrae in the sacrum and coccyx are fused to provide a firm attachment for muscles and ligaments. 12. The vertebral movement involved in (a) bending forward is flexion. The movement involved in (b) bending to the side is lateral flexion. The movement involved in (c) moving the head to signify "no" is rotation. **PAGE 279** 13. Ligaments and muscles provide most of the stability for the shoulder joint. **14.** The subscapular bursa is located in the shoulder joint, so the tennis player would be more likely to develop inflammation of this structure (bursitis). The condition is associated with repetitive motion that occurs at the shoulder, such as swinging a tennis racket. The jogger would be more at risk for injuries to the knee joint. 15. A shoulder separation is an injury involving partial or complete dislocation of the acromioclavicular joint. 16. Terry has most likely damaged his annular ligament. **PAGE 283** 17. The bones making up the shoulder joint are the humerus and scapula. The bones involved with the knee joint are the femur, tibia, and patella. The fibula is not part of the knee joint. 18. The iliofemoral, pubofemoral, and ischiofemoral ligaments are at the hip joint. 19. Damage to the menisci of the knee joint decreases the joint's stability, so the person would have a difficult time locking the knee in place while standing and would have to use muscle contractions to stabilize the joint. If the person had to stand for a long time, the muscles would fatigue and the knee would "give out." It is also likely that the person would feel pain. 20. Like members of the clergy, carpet layers and roofers kneel a lot (and they also slide along on their knees), causing inflammation of the bursae in the knee joint. **PAGE 284** 21. Rheumatism is a general term describing any painful condition of the bones, muscles, and joints (musculoskeletal system). One of several forms of rheumatism is arthritis. 22. Arthritis applies to all the rheumatic diseases that affect synovial joints. Of the many different types of arthritis, osteoarthritis is the most common. 23. Osteoblast activity must equal osteoclast activity or else the integrity of bone structure is compromised. For example, if osteoclast activity outpaces osteoblast activity, the result is thin, brittle bones. 24. The skeletal system provides structural support for all body systems and stores energy, calcium, and phosphate. The integumentary system synthesizes vitamin D₃, which is essential for calcium and phosphorus absorption. Calcium and phosphorus are needed for bone growth and maintenance.

Answers to Review Questions

PAGE 287

Level 1 Reviewing Facts and Terms

1. (a) joint (articular) capsule; **(b)** synovial membrane; **(c)** articular cartilage; **(d)** joint cavity (contains synovial fluid)

2. d 3. b 4. c 5. c 6. d 7. c 8. b 9. c 10. b 11. b 12. d 13. c 14. c 15. a 16. b 17. a 18. d 19. b

Level 2 Reviewing Concepts

20. b 21. d 22. A meniscus (artcular disc) subdivides a synovial cavity, channels the flow of synovial fluid, and allows variations in the shape of the articular surfaces. Menisci also act as cushions and shock absorbers. 23. Partial or complete dislocation of the acromioclavicular joint is called a shoulder separation. 24. Articular cartilages lack a perichondrium, and their matrix contains more water than does the matrix of other cartilages. 25. In a bulging disc, the nucleus pulposus does not extrude. In a herniated disc, the nucleus pulposus breaks through the anulus fibrosus. 26. Height decreases during adulthood in part as a result of osteoporosis in the vertebrae, and in part as a result of the decrease in water content of the nucleus pulposus region of intervertebral discs. 27. (1) gliding: clavicle and sternum; (2) hinge: elbow; (3) pivot: atlas and axis; (4) condylar: radius and carpal bones; (5) saddle: thumb; (6) ball and socket: shoulder

Level 3 Critical Thinking and Clinical Applications

28. The problem is probably a sprained ankle. The ligaments have been damaged but not ruptured, and the joint remains unaffected. 29. Cartilage does not contain blood vessels, so the chondrocytes rely on diffusion to gain nutrients and eliminate wastes. The synovial fluid is very important in supplying nutrients to the articular cartilages that it bathes and in removing wastes. If the circulation of the synovial fluid is impaired or stopped, the cells will not get enough nutrients or be able to get rid of their waste products. This combination of factors can lead to the death of the chondrocytes and the breakdown of the cartilage. 30. Shoulder dislocations would occur more frequently than hip dislocations because the shoulder is a more mobile joint. Because the shoulder joint is not bound tightly by ligaments or other structures, it is easier to dislocate when excessive forces are applied. By contrast, the hip joint, although mobile, is less easily dislocated because it is stabilized by four heavy ligaments, and the bones fit together snugly in the joint. Additionally, the synovial capsule of the hip joint is larger than that of the shoulder, and its range of motion is decreased.

Answers to Clinical Case Wrap-Up

PAGE 288 1. Only diarthroses, or synovial joints, are affected by juvenile rheumatoid arthritis. This is a disease of the synovial lining, so it does not affect joints that have no synovial membrane.2. Normal synovial membranes are thin, delicate, and smooth. The inflamed synovial membrane in a joint affected by rheumatoid arthritis would look thickened, red, excessively fluid-filled, swollen, and overgrown.

Chapter 10

Answers to Checkpoints

PAGE 291 1. The three types of muscle tissue are skeletal muscle, cardiac muscle, and smooth muscle.
2. Skeletal muscles produce skeletal movement, maintain posture and body position, support soft tissues, guard body entrances and exits, maintain body temperature, and store nutrient reserves.
PAGE 292 3. The epimysium

is a dense layer of collagen fibers that surrounds the entire muscle; the perimysium divides the skeletal muscle into a series of compartments, each containing a bundle of muscle fibers called a fascicle; and the endomysium surrounds individual skeletal muscle cells (muscle fibers). The collagen fibers of the epimysium, perimysium, and endomysium come together to form either bundles known as tendons, or broad sheets called aponeuroses. Tendons and aponeuroses generally attach skeletal muscles to bones. 4. Because tendons attach muscles to bones, severing the tendon would disconnect the muscle from the bone, and so the muscle could not move a body part. **PAGE 299** 5. Sarcomeres, the smallest contractile units of a striated muscle cell, are segments of myofibrils. Each sarcomere has dark A bands and light I bands. The A band contains the M line, the H band, and the zone of overlap. Each I band contains thin filaments, but not thick filaments. Z lines bisect the I bands and mark the boundaries between adjacent sarcomeres. 6. Skeletal muscle appears striated when viewed through a light microscope because the Z lines and thick filaments of the myofibrils within the muscle fibers are aligned. 7. You would expect the greatest concentration of calcium ions in resting skeletal muscle to be in the terminal cisternae of the sarcoplasmic reticu-**PAGE 308** 8. The neuromuscular junction, also known as lum. the myoneural junction, is the synapse between a motor neuron and a skeletal muscle cell (fiber). This connection enables communication between the nervous system and a skeletal muscle fiber. 9. Acetylcholine (ACh) release is necessary for skeletal muscle contraction, because it serves as the first step in the process that enables the formation of cross-bridges in the sarcomeres. A muscle's ability to contract depends on the formation of cross-bridges between the myosin heads and actin myofilaments. A drug that blocks ACh release would interfere with this cross-bridge formation and prevent muscle contraction. **10.** If the sarcolemma of a resting skeletal muscle suddenly became permeable to Ca^{2+} , the cytosolic concentration of Ca²⁺ would increase, and the muscle would contract. In addition, because the amount of calcium ions in the cytosol must decrease for relaxation to occur, the increased permeability of the sarcolemma to Ca^{2+} might prevent the muscle from relaxing completely. **11.** Without acetylcholinesterase (AChE), the motor end plate would be continuously stimulated by acetylcholine, locking the muscle in a state of contraction. **PAGE 316** 12. A muscle's ability to contract depends on the formation of cross-bridges between the myosin and actin myofilaments in the muscle. In a muscle that is overstretched, the myofilaments would overlap very little, so very few cross-bridges between myosin and actin could form, and thus the contraction would be weak. If the myofilaments did not overlap at all, then no crossbridges would form and the muscle could not contract. **13.** Yes,

bridges would form and the muscle could not contract. **13.** Yes, a skeletal muscle can contract without shortening. The muscle can shorten (isotonic, concentric contraction), elongate (isotonic, eccentric contraction), or remain the same length (isometric contraction), depending on the relationship between the load (resistance) and the tension produced by actin–myosin interactions.

PAGE 320 14. Muscle cells synthesize ATP continuously by utilizing creatine phosphate (CP) and metabolizing glycogen and fatty acids. Most cells generate ATP only through aerobic metabolism in the mitochondria and through glycolysis in the cytoplasm.
15. Muscle fatigue is a muscle's reduced ability to contract due to low pH (lactic acid buildup and its dissociation to lactate and a hydrogen ion), low ATP levels, or other problems. 16. Oxygen debt is the amount of oxygen required to restore normal, pre-exertion conditions in muscle tissue. PAGE 324 17. The three types of

skeletal muscle fibers are (1) fast fibers (also called white muscle fibers, fast-twitch glycolytic fibers, Type II-B fibers, and fast fatigue fibers); (2) slow fibers (also called red muscle fibers, slow-twitch oxidative fibers, Type I fibers, and slow oxidative fibers); and (3) intermediate fibers (also called fast-twitch oxidative fibers, Type II-A fibers, and fast resistant fibers). **18.** A sprinter requires large amounts of energy for a short burst of activity. To supply this energy, the sprinter's muscles rely on anaerobic metabolism. Anaerobic metabolism is less efficient in producing energy than aerobic metabolism, and the process also produces acidic wastes; this combination contributes to muscle fatigue. Conversely, marathon runners derive most of their energy from aerobic metabolism, which is more efficient and produces fewer wastes than anaerobic metabolism does. 19. Activities that require short periods of strenuous activity produce a greater oxygen debt, because such activities rely heavily on energy production by anaerobic metabolism. Because lifting weights is more strenuous over the short term than swimming laps, which is an aerobic activity, weight lifting would likely produce a greater oxygen debt than would swimming laps. **20.** Individuals who excel at endurance activities have a higher than normal percentage of slow fibers. Slow fibers are physiologically better adapted to this type of activity than are fast fibers, which are less vascular and fatigue faster. **PAGE 325** 21. Compared to skeletal muscle, cardiac muscle (1) has relatively small cells; (2) has cells with a centrally located nucleus (some may contain two or more nuclei); (3) has T tubules that are short and broad and do not form triads; (4) has an SR that lacks terminal cisternae and has tubules that contact the plasma membrane as well as the T tubules; (5) has cells that are nearly totally dependent on aerobic metabolism as an energy source; and (6) contains intercalated discs that assist in stabilizing tissue structure and spreading action potentials. 22. Cardiac muscle cells are joined by gap junctions, which allow ions and small molecules to flow directly between cells. As a result, action potentials generated in one cell spread rapidly to adjacent cells. Thus, all the cells contract simultaneously, as if they were a single unit (a syncytium). **PAGE 328** 23. Smooth muscle cells lack sarcomeres, and thus smooth muscle tissue is nonstriated. Additionally, the thin filaments are anchored to dense bodies. 24. Skeletal muscle contractions are least affected by changes in extracellular Ca²⁺ concentrations. In skeletal muscle, most of the calcium ions come from the sarcoplasmic reticulum. Most of the calcium ions that trigger a contraction in cardiac and smooth muscles come from the extracellular fluid. **25.** The looser organization of actin and myosin filaments in smooth muscle allows smooth muscle to contract over a wider range of resting lengths.

Answers to Review Questions

PAGE 330

Level 1 Reviewing Facts and Terms

1. (a) sarcolemma (b) sarcoplasm (c) mitochondria (d) myofibril (e) thin filament (f) thick filament (g) sarcoplasmic reticulum (h) T tubules 2. d 3. c 4. c 5. a 6. d 7. d 8. d 9. (1) skeletal muscle; (2) cardiac muscle; and (3) smooth muscle 10. (1) epimysium: surrounds entire muscle; (2) perimysium: surrounds muscle bundles (fascicles); and (3) endomysium: surrounds skeletal muscle fibers 11. a 12. The transverse (T) tubules propagate action potentials into the interior of the cell. 13. (1) exposure of active sites; (2) attachment of cross-bridges; (3) pivoting of myosin heads (power stroke); (4) detachment of cross-bridges; and (5) activation of myosin heads (cocking) 14. Both the frequency of motor unit stimulation and the number of motor units involved affect the amount of tension produced when a skeletal muscle contracts. **15.** Resting skeletal muscle fibers contain ATP, creatine phosphate, and glycogen. **16.** Aerobic metabolism and glycolysis generate ATP from glucose in muscle cells. **17.** Calmodulin is the calcium-binding protein in smooth muscle tissue.

Level 2 Reviewing Concepts

18. d 19. b 20. a 21. e 22. In an initial latent period (after the stimulus arrives and before tension begins to increase), an action potential generated in the muscle triggers the release of calcium ions from the SR. In the contraction phase, calcium ions bind to troponin (cross-bridges form) and tension begins to increase. In the relaxation phase, tension decreases because cross-bridges have detached and because calcium ion levels have decreased; the active sites are once again covered by the troponin-tropomyosin complex. **23.** (1) O_2 for aerobic respiration is consumed by liver cells, which must make a great deal of ATP to convert lactate to pyruvate to glucose; (2) O_2 for aerobic respiration is consumed by skeletal muscle fibers as they restore ATP, creatine phosphate, and glycogen concentrations to their former levels; and (3) the normal O₂ concentration in blood and peripheral tissues is replenished. 24. The timing of cardiac muscle contractions is determined by specialized cardiac muscle fibers called pacemaker cells; this property of cardiac muscle tissue is termed automaticity. 25. If atracurium blocked the binding of ACh to ACh receptors at the motor end plates of neuromuscular junctions, the muscle's ability to contract would be inhibited. **26.** In rigor mortis, the membranes of the dead cells are no longer selectively permeable; the SR is no longer able to retain calcium ions. As calcium ions enter the cytosol, a sustained contraction develops, making the body extremely stiff. Contraction persists because the dead muscle cells can no longer make the ATP required for cross-bridge detachment from the active sites. Rigor mortis begins a few hours after death and ends after one to six days, or when decomposition begins. Decomposition begins when the lysosomal enzymes released by autolysis break down the myofilaments. 27. c

Level 3 Critical Thinking and Clinical Applications

28. Because organophosphates block the action of acetylcholinesterase (AChE), ACh released into the synaptic cleft would not be removed. It would continue to stimulate the motor end plate, causing a state of persistent contraction (spastic paralysis). If the muscles of respiration were affected (which is likely). Ivan would die of suffocation. Prior to death, the most obvious sign would be uncontrolled tetanic contractions of skeletal muscles. 29. CK is the enzyme creatine kinase. It functions in the anaerobic reaction that transfers phosphate from creatine phosphate to ADP in muscle cells. The presence of cardiac troponin, a form found only in cardiac muscle cells, provides direct evidence that cardiac muscle cells have been severely damaged. 30. A skeletal muscle not regularly stimulated by a motor neuron will lose muscle tone and mass and become weak (it will atrophy). While his leg was immobilized, it did not receive sufficient stimulation to maintain proper muscle tone. It will take a while for Bill's muscles to build up enough to support his weight.

Answers to Clinical Case Wrap-Up

PAGE 331 1. A drug that inhibits acetylcholinesterase (AChE) is inhibiting the enzyme that breaks down the neurotransmitter acetylcholine (ACh). As a result, ACh stays around longer in the neuromuscular junction (NMJ). Because a patient with myasthenia gravis does not have enough functioning ACh receptors, a greater amount of ACh is better for strength of muscular response. In short, by

inhibiting the breakdown of ACh, the drug strengthens the patient's muscular response. **2.** Myasthenia gravis affects voluntary, skeletal muscle at the neuromuscular junction (NMJ). Cardiac muscle tissue contracts without neural stimulation, a property known as automaticity. There is no neural stimulation, no neuromuscular junction, no ACh neurotransmitter or receptor required for cardiac muscle contraction. For these reasons, myasthenia gravis would not affect cardiac muscle.

Chapter 11

Answers to Checkpoints

PAGE 335 1. Based on the patterns of fascicle organization, skeletal muscles can be classified as parallel muscles, convergent muscles, pennate muscles, or circular muscles. 2. Contraction of a pennate muscle generates more tension than would contraction of a parallel muscle of the same size because a pennate muscle contains more muscle fibers, and thus more myofibrils and sarcomeres, than does a parallel muscle of the same size. **3.** The opening between the stomach and the small intestine would be guarded by a circular muscle, or sphincter. The concentric circles of muscle fibers found in sphincters are ideally suited for opening and closing passageways and for acting as valves in the body. 4. A lever is a rigid structure—such as a board, a pry bar, or a bone—that moves on a fixed joint called the fulcrum. There are three classes of levers: In a first-class lever, the fulcrum lies between the applied force and load: in a second-class lever, the load lies between the applied force and fulcrum; and in a third-class lever, the applied force or pull exerted is between the fulcrum and the load. Third-class levers are the most common type in the body. **5.** The joint between the occipital bone and the first cervical vertebra is part of a first-class lever system. The joint between the two bones (the fulcrum) lies between the skull (which provides the load) and the neck muscles (which provide the applied force). **PAGE 339** 6. The origin of a muscle is the end that remains stationary during an action. Because the gracilis muscle moves the tibia, the origin of this muscle must be on the pelvis (pubis and ischium). **7.** Muscles A and B are antagonists to each other, because they perform opposite actions. 8. A synergist is a muscle that helps a larger prime mover (or agonist—a muscle that is responsible for a specific movement) perform its actions more efficiently. PAGE 341 9. Names of skeletal muscles are based on several factors, including location in the body, origin and insertion, fascicle organization, relative position, structural characteristics, and action. Names may also reflect the muscle shape, number of origins, and size. **10.** The name *flexor carpi radialis longus* tells you that this muscle is a long muscle (longus) that lies next to the radius (radialis) and flexes (flexor) the wrist (carpi). **PAGE 358** 11. Axial muscles arise on the axial skeleton. They position the head, neck, and vertebral column, move the rib cage,

and form the perineum. **12.** Contraction of the masseter muscle elevates the mandible, and relaxation of this muscle depresses the mandible. You would probably be chewing something. **13.** You would expect the buccinator muscle, which positions the mouth for blowing, to be well developed in a trumpet player. **14.** Swallowing involves contractions of the palatal muscles, which elevate the soft palate as well as portions of the superior pharyngeal wall. Elevation of the superior portion of the pharynx enlarges the opening to the auditory tube, permitting airflow to the middle ear and the inside of the eardrum. Making this opening larger by swallowing facilitates airflow into or out of the middle ear cavity. **15.** Damage

to the intercostal muscles would interfere with breathing. **16.** A hit in the rectus abdominis muscle would cause that muscle to contract forcefully, resulting in flexion of the vertebral column. In other words, you would "double over." 17. The sore muscles are most likely the erector spinae muscles, especially the longissimus and the iliocostalis muscles of the lumbar region. These muscles would have to contract harder to counterbalance the increased anterior weight when carrying heavy boxes. **PAGE 375** 18. When vou shrug vour shoulders, vou are contracting vour levator scapulae muscles. **19.** The muscles involved in a rotator cuff injury are the supraspinatus, infraspinatus, teres minor, and subscapularis (SITS) muscles. 20. Injury to the flexor carpi ulnaris muscle would impair your ability to flex and adduct the wrist. **21.** Injury to the obturator muscle would impair your ability to laterally rotate the hip. 22. A "pulled hamstring" refers to a strain affecting one or more of the three muscles that collectively flex the knee: the biceps femoris, semimembranosus, and semitendinosus muscles. 23. A torn calcaneal tendon would make plantar flexion difficult because this tendon attaches the soleus and gastrocnemius muscles to the calcaneus (heel bone). PAGE 379 24. General age-related effects on skeletal muscles include decreased skeletal muscle fiber diameters, diminished muscle elasticity, decreased tolerance for exercise, and a decreased ability to recover from muscular injuries. 25. Fibrosis is the development of increasing amounts of fibrous connective tissue. Fibrosis causes muscles to be less flexible, and the collagen fibers can restrict movement and circulation.

PAGE 381 26. The muscular system generates heat that maintains normal body temperature. **27.** Exercise affects the cardiovascular system by increasing heart rate and dilating blood vessels. With exercise, the rate and depth of breathing increases, and sweat gland secretion increases. The physiological effects that result from exercise are directed and coordinated by the nervous and endocrine systems.

Answers to Review Questions

PAGE 383

Level 1 Reviewing Facts and Terms

1. (a) deltoid muscle (multipennate); (b) extensor digitorum muscle (unipennate); (c) rectus femoris muscle (bipennate) **2.** (a) supraspinatus muscle; (b) infraspinatus muscle;

(c) teres minor muscle 3. b 4. a 5. a 6. a 7. b 8. c 9. a 10. a 11. b 12. d 13. a 14. The four fascicle organizations are (1) parallel, (2) convergent, (3) pennate, and (4) circular. 15. An aponeurosis is a collagenous sheet connecting two muscles. The epicranial aponeurosis and the linea alba are examples. 16. The axial musculature includes (1) muscles of the head and neck, (2) muscles of the vertebral column, (3) obligue and rectus muscles, and (4) muscles of the pelvic floor. 17. The muscles of the pelvic floor (1) support the organs of the pelvic cavity, (2) flex joints of the sacrum and coccyx, and (3) control movement of materials through the urethra and anus. **18.** The supraspinatus, infraspinatus, and teres minor originate on the posterior body of the scapula, and the subscapularis originates on the anterior body of the scapula. All four muscles insert on the humerus. 19. The functional muscle groups in the lower limbs are (1) muscles that move the thigh, (2) muscles that move the leg, and (3) muscles that move the foot and toes.

Level 2 Reviewing Concepts

20. b **21.** a **22.** hernia **23.** synovial tendon sheaths **24.** The vertebral column does not have a massive series of flexors, because many of the large trunk muscles flex the vertebral column when

they contract. In addition, most of the body weight lies anterior to the vertebral column, and gravity tends to flex the intervertebral joints. **25.** In a convergent muscle, the direction of pull can be changed by stimulating only one group of muscle cells at any one time. When all the fibers contract at once, they do not pull as hard on the tendon as would a parallel muscle of the same size, because the muscle fibers on opposite sides of the tendon are pulling in different directions rather than working together. **26.** A pennate muscle contains more muscle fibers, and thus more myofibrils and sarcomeres, than does a parallel muscle of the same size, resulting in a contraction that generates more tension. 27. Lifting heavy objects becomes easier as the elbow approaches a 90° angle. As you increase the angle at or near full extension, tension production decreases, so movement becomes more difficult. **28.** When the hamstrings are injured, flexion at the knee and extension at the hip are affected.

Level 3 Critical Thinking and Clinical Applications

29. Mary is not happy to see Jill. Contraction of the frontalis muscle would wrinkle Mary's brow, contraction of the procerus muscle would flare her nostrils, and contraction of the levator labii muscle on the right side would raise the right side of her lip, as in sneering.
30. b 31. Although the pectoralis muscle is located across the chest, it inserts on the greater tubercle of the humerus, the bone of the arm. When this muscle contracts, it contributes to flexion, adduction, and medial rotation of the humerus at the shoulder joint. All of these arm movements would be impaired if the muscle were damaged.

Answers to Clinical Case Wrap-Up

PAGE 384 1. In addition to the hamstrings (biceps femoris laterally, semitendinosus and semimembranosus medially) the sartorius muscle assists in knee flexion. The sartorius muscle is, however, too weak to do the job by itself. **2.** With the knee extended, and the avulsed hamstrings shortened to 70 percent of their resting length, the proximal tendons would not reach the ischial tuberosity. Flexing the knee moves the insertion closer to the origin, helping the tendons to reach their original attachment site.

Chapter 12

Answers to Checkpoints

PAGE 388 1. The two anatomical divisions of the nervous system are the central nervous system (CNS), consisting of the brain and spinal cord, and the peripheral nervous system (PNS), consisting of all neural tissue outside the CNS. 2. The two functional divisions of the peripheral nervous system are the afferent division, which brings sensory information to the CNS from receptors in peripheral tissues and organs, and the efferent division, which carries motor commands from the CNS to muscles, glands, and adipose tissue. 3. The two components of the efferent division of the PNS are the somatic nervous system (SNS) and the autonomic nervous system (ANS). 4. Damage to the afferent division of the PNS, which is composed of nerves that carry sensory information to the brain and spinal cord, would interfere with a person's ability to experience a variety of sensory stimuli. **PAGE 392** 5. Structural components of a typical neuron include a cell body or soma (which contains the nucleus and perikaryon), dendrites, an axon, telodendria, Nissl bodies, neurofilaments, intermediate neurotubules, neurofibrils, axoplasm, axolemma, initial segment, axon hillock, and collaterals. 6. According to structure, neurons are classified as anaxonic, bipolar, unipolar, and multipolar. 7. According to

function, neurons are classified as sensory neurons, motor neurons, and interneurons. 8. Because most sensory neurons of the PNS are unipolar, these neurons most likely function as sensory neurons. **PAGE 398** 9. Central nervous system neuroglia include ependymal cells, astrocytes, oligodendrocytes, and microglia. 10. Peripheral nervous system neuroglia include satellite cells and Schwann cells (neurilemma cells). 11. The small phagocytic cells called microglia occur in increased numbers in infected (and damaged) areas of the CNS. **PAGE 406** 12. The resting membrane potential is the membrane potential of a normal, unstimulated cell. 13. If the voltage-gated sodium channels in the plasma membrane of a neuron could not open, sodium ions could not flood into the neuron and it would not be able to depolarize. **14.** If the extracellular concentration of potassium ions decreased, more potassium would leave the cell, and the membrane potential would become more negative. This condition is called hyperpolarization. **PAGE 412** 15. An action potential is a propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions. **16.** The four steps involved in the generation of action potentials are (1) depolarization to threshold; (2) activation of voltage-gated sodium channels and rapid depolarization; (3) inactivation of voltage-gated sodium channels and activation of voltage-gated potassium channels; and (4) return to normal permeability. **PAGE 413** 17. The presence of myelin greatly increases the propagation speed of action potentials. **18.** Action potentials travel along myelinated axons (by saltatory propagation) at much higher speeds than along unmyelinated axons. The axon with a propagation speed of 50 meters per second must be the myelinated axon. Typical propagation speeds for unmyelinated axons are about 1 m/sec. **PAGE 416** 19. The major structural components of a synapse, the site where a neuron communicates with another cell, are a presynaptic cell and a postsynaptic cell, whose plasma membranes are separated by a narrow synaptic cleft. 20. If a synapse involves direct physical contact between cells, it is termed electrical; if the synapse involves a neurotransmitter, it is termed chemical. **21.** If the voltage-gated calcium ion channels at a cholinergic synapse were blocked, Ca²⁻ could not enter the axon terminal and trigger the release of ACh into the synapse, so no communication would take place across the synapse. **22.** Because of synaptic delay, the pathway with fewer neurons (in this case, three) will transmit impulses more rap-**PAGE 421** 23. Both neurotransmitters and neuromodulaidly tors are substances that are released by one neuron and that affect another neuron. A neurotransmitter alters the membrane potential of the other neuron, whereas a neuromodulator alters the other neuron's response to specific neurotransmitters. 24. Neurotransmitters and neuromodulators are either (1) compounds that have a direct effect on membrane potential, (2) compounds that have an indirect effect on membrane potential, or (3) lipid-soluble gases that exert their effects inside the cell. **PAGE 425** 25. No action potential will be generated. 26. Yes, an action potential will be generated. 27. Spatial summation would occur if the two EPSPs happened simultaneously.

Answers to Review Questions

PAGE 427

Level 1 Reviewing Facts and Terms

1. (a) dendrite; (b) nucleolus; (c) nucleus; (d) axon hillock; (e) initial segment; (f) axolemma; (g) axon; (h) telodendria; (i) axon terminals **2.** c **3.** c **4.** d **5.** b **6.** a **7.** b **8.** a **9.** (a) the CNS: brain and spinal cord (b) the PNS: all other nerve fibers, divided

between the efferent division (which consists of the somatic nervous system and the autonomic nervous system) and the afferent division (which consists of receptors and sensory neurons) **10.** Neuroglia in the PNS are (1) satellite cells and (2) Schwann cells. **11.** (1) sensory neurons: transmit impulses from the PNS to the CNS; (2) motor neurons: transmit impulses from the CNS to peripheral effectors; and (3) interneurons: analyze sensory inputs and coordinate motor outputs

Level 2 Reviewing Concepts

12. b 13. Neurons lack centrioles and therefore cannot divide and replace themselves. 14. Anterograde flow is the movement of materials from the cell body to the axon terminals. Retrograde flow is the movement of materials toward the cell body.

15. Chemically gated (ligand gated) channels open or close when they bind specific extracellular chemicals (ligands). Voltage-gated channels open or close in response to changes in the membrane potential. Mechanically gated channels open or close in response to physical distortion of the membrane surface. 16. The allor-none principle of action potentials states that any depolarization event sufficient to reach threshold will cause an action potential of the same strength, regardless of the amount of stimulation above threshold. 17. The membrane depolarizes to threshold. Next, voltage-gated sodium channels are activated, and the membrane rapidly depolarizes. These sodium channels are then inactivated, and voltage-gated potassium channels are activated. Finally, normal permeability returns. The voltage-gated sodium channels become activated once the repolarization is complete; the voltage-gated potassium channels begin closing as the membrane potential reaches the normal resting membrane potential. **18.** In saltatory propagation, which occurs in myelinated axons, only the nodes along the axon can respond to a depolarizing stimulus. In continuous propagation, which occurs in unmyelinated axons, an action potential appears to move across the membrane surface in a series of tiny steps. **19.** Type A fibers are myelinated and carry action potentials very quickly (120 m/sec). Type B fibers are also myelinated, but carry action potentials more slowly due to their smaller diameter. Type C fibers are extremely slow due to their small diameter and lack of myelination. **20.** (1) The action potential arrives at the axon terminal, depolarizing it; (2) extracellular calcium enters the axon terminal, triggering the exocytosis of ACh; (3) ACh binds to the postsynaptic membrane and depolarizes the next neuron in the chain; (4) ACh is removed by AChE. 21. Temporal summation is the addition of stimuli that arrive at a single synapse in rapid succession. Spatial summation occurs when simultaneous stimuli at multiple synapses have a cumulative effect on the membrane potential.

Level 3 Critical Thinking and Clinical Applications

22. Harry's kidney condition is causing the retention of potassium ions. As a result, the K⁺ concentration of the extracellular fluid is higher than normal. Under these conditions, less potassium diffuses from heart muscle cells than normal, resulting in a resting membrane potential that is less negative (more positive). This change in the resting membrane potential moves the membrane potential closer to threshold, so it is easier to stimulate the muscle. The ease of stimulation accounts for the increased number of contractions evident in the rapid heart rate. **23.** To reach threshold, the postsynaptic membrane must receive enough neurotransmitter to produce an EPSP of +20 mV (+10 mV to reach threshold and +10 mV to cancel the IPSPs produced by the five inhibitory neurons). Each neuron releases enough neurotransmitter to produce a change of +2 mV, so at least 10 of the 15 excitatory neurons must

be stimulated to produce this effect by spatial summation. **24.** Action potentials travel faster along fibers that are myelinated than fibers that are nonmyelinated. Destruction of the myelin sheath increases the time it takes for motor neurons to communicate with their effector muscles. This delay in response results in varying degrees of uncoordinated muscle activity. The situation is very similar to that of a newborn, who cannot control its arms and legs very well because the myelin sheaths are still being laid down. Since not all motor neurons to the same muscle may be demyelinated to the same degree, there would be some fibers that are slow to respond while others are responding normally, producing contractions that are erratic and poorly controlled. **25.** The absolute refractory period limits the number of action potentials that can travel along an axon in a given unit of time. During the absolute refractory period, the membrane cannot conduct an action potential, so a new depolarization event cannot occur until after the absolute refractory period has passed. If the absolute refractory period for a particular axon is 0.001 sec, then the maximum frequency of action potentials conducted by this axon would be 1000/sec.

Answers to Clinical Case Wrap-Up

PAGE 428 1. The polio virus attacks the motor neurons of the spinal cord gray matter. **2.** Guillain-Barré syndrome is an autoimmune disorder that attacks the myelin covering of peripheral nerves in adults. This causes both sensory and motor symptoms, usually in a symmetrical, ascending pattern over a few weeks. Involvement of the face, urinary bladder, and bowel is common.

Chapter 13

Answers to Checkpoints

PAGE 431 1. The central nervous system (CNS) is made up of the brain and spinal cord, while cranial nerves and spinal nerves make up the peripheral nervous system (PNS). 2. A spinal reflex is a rapid, automatic response triggered by specific stimuli that is controlled in the spinal cord. **PAGE 435** 3. The three spinal meninges are the dura mater, arachnoid mater, and pia mater. 4. Damage to the ventral root of a spinal nerve, which contains both visceral and somatic motor fibers, would interfere with motor function. 5. The cerebrospinal fluid that surrounds the spinal cord is located in the subarachnoid space, which lies beneath the epithelium of the arachnoid mater and superficial to the pia mater. **PAGE 437** 6. Sensory nuclei receive and relay sensory information from peripheral receptors. Motor nuclei issue motor commands to peripheral effectors. 7. The polio virus-infected neurons would be in the anterior gray horns of the spinal cord, where the cell bodies of somatic motor neurons are located. 8. A disease that damages myelin sheaths would affect the columns in the white matter of the spinal cord, because the columns are composed of bundles of myelinated axons. PAGE 447 9. The major nerve plexuses are the cervical, brachial, lumbar, and sacral. **10.** An anesthetic that blocks the function of the dorsal rami of the cervical spinal nerves would affect the skin and muscles of the back of the neck and of the shoulders. **11.** Damage to the cervical plexus—or more specifically to the left and right phrenic nerves, which originate in this plexus and innervate the diaphragm—would greatly interfere with the ability to breathe and might even be fatal. 12. Compression of the sciatic nerve produces the sensation that your leg has "fallen asleep."

PAGE 449 13. A neuronal pool is a functional group of organized interneurons within the CNS. 14. The five neuronal pool circuit patterns are divergence, convergence, serial processing, parallel processing, and reverberation. **PAGE 453** 15. A reflex is a rapid, automatic response to a specific stimulus. It is an important mechanism for maintaining homeostasis. 16. The minimum number of neurons required for a reflex arc is two. One must be a sensory neuron that brings impulses to the CNS, and the other a motor neuron that transmits a response to the effector. **17.** The suckling reflex is an innate reflex. **PAGE 455** 18. All polysynaptic reflexes involve pools of interneurons; are intersegmental in distribution; and involve reciprocal inhibition, reverberating circuits, and the cooperation of several reflexes. **19.** When intrafusal fibers are stimulated by gamma motor neurons, the muscle spindles become more sensitive. As a result, little if any stretching stimulus would be needed to stimulate the contraction of the quadriceps muscles in the patellar reflex. For this reason, the reflex response would appear more quickly. **20.** This response is the tendon reflex. **21.** During a withdrawal reflex, the limb on the opposite side is extended. This response is called a crossed extensor reflex. **PAGE 456** 22. Reinforcement is an enhancement of spinal reflexes. It occurs when the postsynaptic neuron enters a state of generalized facilitation caused by chronically active excitatory synapses. 23. A positive Babinski reflex is abnormal in adults. It indicates possible damage to descending tracts in the spinal cord.

Answers to Review Questions

PAGE 459

Level 1 Reviewing Facts and Terms

1. (a) white matter; (b) ventral root; (c) dorsal root; (d) pia mater; (e) arachnoid mater; (f) gray matter; (g) spinal nerve; (h) dorsal root ganglion; (i) dura mater **2.** d **3.** a **4.** d **5.** c **6.** c **7.** c **8.** c **9.** a **10.** d **11.** a **12.** b **13.** c14. c **15.** (a) 1 (b) 7 (c) 3 (d) 5 (e) 4 (f) 6 (g) 2 (h) 8

Level 2 Reviewing Concepts

16. The vertebral column continues to grow, extending beyond the spinal cord. The end of the spinal cord is visible as the conus medullaris near L₁, and the cauda equina extends the remainder of the vertebral column. 17. (1) arrival of stimulus and activation of receptor; (2) activation of sensory neuron; (3) information processing; (4) activation of a motor neuron; and (5) response by an effector (muscle, gland, or adipose tissue) 18. d 19. The first cervical nerve exits superior to vertebra C₁ (between the skull and vertebra); the last cervical nerve exits inferior to vertebra C₇ (between the last cervical vertebra and the first thoracic vertebra). So, there are 8 cervical nerves but only 7 cervical vertebrae. 20. The cell bodies of spinal motor neurons are located in the anterior gray horns, so damage to these horns would result in a loss of motor control. **21.** Within the CNS, cerebrospinal fluid fills the central canal in the spinal cord, the ventricles of the brain, and the subarachnoid space between the arachnoid mater and the pia mater. CSF acts as a shock absorber and a diffusion medium for dissolved gases, nutrients, chemicals, and wastes. 22. (1) involvement of pools of interneurons; (2) intersegmental distribution; (3) involvement of reciprocal innervation; (4) motor response prolonged by reverberating circuits; and (5) cooperation of reflexes to produce a coordinated, controlled response **23.** Transection of the spinal cord at segment C₇ would most likely result in paralysis from the

neck down. Transection at segment T_{10} would produce paralysis and eliminate sensory input in the lower half of the body only. **24.** a **25.** b **26.** a **27.** Stimulation of the sensory neuron will increase muscle tone.

Level 3 Critical Thinking and Clinical Applications

28. The median nerve is involved. 29. The radial nerve is involved. **30.** The individual would still exhibit a defecation (bowel) and urination (urinary bladder) reflex because these spinal reflexes are processed at the level of the spinal cord. Efferent impulses from the organs would stimulate specific interneurons in the sacral region that synapse with the motor neurons controlling the sphincters, thus bringing about emptying when the organs began to fill. (This is the same situation that exists in a newborn infant who has not yet fully developed the descending tracts required for conscious control.) However, an individual with the spinal cord transection at L1 would lose voluntary control of the bowel and bladder because these functions rely on impulses carried by motor neurons in the brain that must travel down the cord and synapse with the interneurons and motor neurons involved in the reflex. 31. The anterior horn in the lumbar region of the spinal cord contains somatic motor neurons that direct the activity of skeletal muscles of the hip, lower limb, and foot. As a result of the injury, Karen would be expected to have poor control of most muscles of the lower limbs, causing difficulty walking (if she could walk at all) and problems maintaining balance (if she could stand).

Answers to Clinical Case Wrap-Up

PAGE 460 1. No recovery of motor activity or sensation is to be expected inferior to the level of Joe's complete injury at T_{11} . Central nervous tissue (brain and spinal cord) has very limited healing ability. **2.** Joe's Babinski reflexes would be positive, with toes going up, or dorsiflexed, which is abnormal in adults (but not in infants). The descending motor pathways to the feet have been completely disrupted at T_{11} .

Chapter 14

Answers to Checkpoints

PAGE 465 1. The six major regions of the brain are the cerebrum, cerebellum, diencephalon, midbrain, pons, and medulla oblongata. 2. The brain stem consists of the midbrain, pons, and medulla oblongata. 3. The rhombencephalon or hindbrain develops into the cerebellum, pons, and medulla oblongata. **PAGE 470 4.** The layers of the cranial meninges are the outer dura mater, the middle arachnoid mater, and the inner pia mater. **5.** If the normal circulation or resorption of cerebrospinal fluid (CSF) became blocked, CSF would continue to be produced at the choroid plexuses in each ventricle, but the fluid would remain there, causing the ventricles to swell-a condition known as hydrocephahus **6.** If diffusion across the arachnoid granulations decreased, less CSF would re-enter the bloodstream, and CSF would accumulate in the ventricles. The increased pressure within the ventricles due to accumulated CSF could damage the brain. 7. Many water-soluble molecules are rare or absent in the extracellular fluid (ECF) of the brain because the blood-brain barrier regulates the movement of such molecules from the blood to the ECF of the brain. **PAGE 472** 8. The nucleus gracilis and nucleus cuneatus are responsible for relaying somatic sensory information to the thalamus. 9. Damage to the medulla oblongata can be lethal because it contains many vital autonomic reflex centers, including

those that control breathing and regulate heart rate and force of contraction, which affect blood pressure. **PAGE 473** 10. The pons contains (1) sensory and motor nuclei of cranial nerves, (2) nuclei involved with the control of respiration, (3) nuclei and tracts that process and relay information heading to or from the cerebellum, and (4) ascending, descending, and transverse tracts. 11. Damage to the respiratory centers of the pons could result in loss of ability to modify the rhythmicity centers of the medulla oblongata, which set the basic pace for respiratory movements. **PAGE 475** 12. Components of the cerebellar gray matter include the cerebellar cortex and cerebellar nuclei. 13. The arbor vitae, which is part of the cerebellum, connects the cerebellar cortex and nuclei with cerebellar peduncles. **PAGE 477** 14. Two pairs of sensory nuclei make up the corpora quadrigemina: the superior colliculi and inferior colliculi. 15. The superior colliculi of the midbrain control reflexive movements of the eyes, head, and neck to visual stimuli, such as a bright light. **PAGE 480** 16. The main components of the diencephalon are the epithalamus, thalamus, and hypothalamus. 17. Damage to the lateral geniculate nuclei would interfere with the sense of sight. 18. Changes in body temperature stimulate the preoptic area of the hypothalamus, a component of the diencephalon. **PAGE 481** 19. The limbic system is responsible for processing memories and creating emotional states, drives, and associated behaviors. 20. Damage to the amygdaloid body would interfere with the sympathetic ("fight or flight") division of the autonomic nervous system (ANS). **PAGE 491 21.** Projection fibers link the cerebral cortex to the spinal cord, passing through the diencephalon, brain stem, and cerebellum. 22. Damage to the basal nuclei would result in decreased muscle tone and the loss of coordination of learned movement patterns. 23. The primary motor cortex is located in the precentral gyrus of the frontal lobe of the cerebrum. 24. Damage to the temporal lobes of the cerebrum would interfere with the processing of olfactory (smell) and auditory (sound) impulses. 25. The stroke has damaged the speech center, located in the frontal lobe. **26.** The temporal lobe of the cerebrum is probably involved, specifically the hippocampus and the amygdaloid body. His problems may also involve other parts of the limbic system that act as a gate for loading and retrieving long-term memories. **PAGE 503** 27. Cranial reflexes are automatic responses to stimuli that involve the sensory and motor fibers of cranial nerves. Both monosynaptic and polysynaptic reflex arcs occur. Cranial reflex testing is often used to assess damage to cranial nerves or to the associated processing centers in the brain. 27. Shining a light in a person's eye tests the direct light reflex and the consensual light reflex, which are visceral reflexes.

Answers to Review Questions

 (2) supporting the brain; and (3) transporting nutrients, chemical messengers, and waste products 15. (1) portions of the hypothalamus where the capillary endothelium is extremely permeable;

(2) capillaries in the pineal gland; and (3) capillaries at the choroid plexus **16.** N I: olfactory nerve; N II: optic nerve; N III: oculomotor nerve; N IV: trochlear nerve; N V: trigeminal nerve; N VI: abducens nerve; N VII: facial nerve; N VIII: vestibulocochlear nerve; N IX: glossopharyngeal nerve; N X: vagus nerve; N XI: accessory nerve; and N XII: hypoglossal nerve

Level 2 Reviewing Concepts

17. The brain can respond with greater versatility because it includes many more interneurons, pathways, and connections than the tracts of the spinal cord. 18. The cerebellum adjusts voluntary and involuntary motor activities based on sensory information and stored memories of previous experiences. 19. d 20. In Parkinson's disease, the substantia nigra is inhibited from secreting the neurotransmitter, dopamine, at the basal nuclei. This is generally due to the loss of dopamine-producing neurons in the substantia nigra. 21. Roles of the hypothalamus include (1) subconscious control of skeletal muscle contractions, (2) control of autonomic functions, (3) coordination of nervous and endocrine systems, (4) secretion of two hormones, (5) production of emotions and drives, (6) coordination of autonomic and voluntary functions, (7) regulation of body temperature, and (8) control of circadian rhythms. 22. Stimulation of the feeding and thirst centers of the hypothalamus would produce sensations of hunger and thirst. 23. This nucleus is the hippocampus, which is part of the limbic system. 24. The left cerebral hemisphere contains the general interpretive and speech centers and is responsible for analytical tasks, logical decision-making, and language-based skills (reading, writing, and speaking). The right hemisphere analyzes sensory information and relates the body to the sensory environment. Interpretive centers in this hemisphere permit the identification of familiar objects by touch, smell, sight, taste, or feel. The right cerebral hemisphere is also important in understanding three-dimensional relationships and in analyzing the emotional context of a conversation. 25. d 26. c 27. Lesions in the general interpretive area (Wernicke's area, sensory) cause defective visual and auditory comprehension of language, repetition of spoken sentences, and defective naming of objects. Lesions in the speech center (Broca's area, motor) result in hesitant and distorted speech.

Level 3 Critical Thinking and Clinical Applications

28. Sensory innervation of the nasal mucosa occurs by the maxillary branch of the trigeminal nerve (NV). Irritation of the nasal lining by ammonia increases the frequency of action potentials along the maxillary branch of the trigeminal nerve through the semilunar ganglion to reach centers in the midbrain, which in turn excite the neurons of the reticular activating system (RAS). Increased activity by the RAS can bring the cerebrum back to consciousness. **29.** The officer is testing the function of Bill's cerebellum. Many drugs, including alcohol, have pronounced effects on cerebellar function. A person who is under the influence of alcohol cannot properly anticipate the range and speed of limb movement, because processing and correction by the cerebellum are slow. Because of disturbance in muscular coordination (ataxia), Bill might have a difficult time walking a straight line or touching his finger to his nose. **30.** Increasing pressure in the cranium could compress important blood vessels, leading to further brain damage in areas not directly affected by the hematoma. Pressure on the brain stem could disrupt vital respiratory, cardiovascular, and vasomotor functions and possibly cause death. Pressure on the motor nuclei of the cranial nerves would lead to drooping eyelids and dilated pupils. Pressure on descending motor tracts would impair muscle function and decrease muscle tone in the affected areas of the body.

31. In any inflamed tissue, edema occurs in the area of inflammation. The accumulation of fluid in the subarachnoid space can cause damage by pressing against neurons. If the intracranial pressure is excessive, brain damage can occur, and if the pressure involves vital autonomic reflex areas, death could occur. **32.** Most of the functional problems observed in shaken baby syndrome are the result of trauma to the cerebral hemispheres due to contact between the brain and the inside of the skull. Damage to and distortion of the brain stem and medulla oblongata can cause death.

Answers to Clinical Case Wrap-Up

PAGE 507 1. The speech center, also called Broca's area or the motor speech area, is usually located in the left hemisphere.
Dr. Taylor was unable to speak or understand speech after her stroke. The primary motor cortex that directs voluntary movements of the right side of the body is located in the left hemisphere, in the precentral gyrus of the cerebral cortex. Dr. Taylor was unable to use her right arm after her stroke. For these reasons, you would be able to determine that the left side of her brain was affected by the stroke.
Neuroplasticity is the ability of the nerve cells in the brain to make new connections to other nerve cells. Following trauma to the brain, as in Dr. Taylor's stroke, brain cells that are still alive but dormant can make new connections with other nerve cells. We can think of these changes as healing after a stroke or other trauma to the brain.

Chapter 15

Answers to Checkpoints PAGE 509

1. The specialized cells that monitor specific conditions in the body or the external environment are sensory receptors. 2. Yes, it is possible for somatic motor commands to occur at the subconscious level. They also occur at the conscious level. PAGE 513 3. Receptor A provides more precise sensory information because it has a smaller receptive field on the skin surface. 4. Adaptation is a decrease in receptor sensitivity or a decrease in perception after constant stimulation. **PAGE 517** 5. The four types of general sensory receptors (and the stimuli that excite them) are nociceptors (pain), thermoreceptors (temperature), mechanoreceptors (physical distortion), and chemoreceptors (chemical concentration). **6.** The three classes of mechanoreceptors are tactile receptors, baroreceptors, and proprioceptors. **7.** If proprioceptors in your legs could not relay information about limb position and movement to the CNS (especially the cerebellum), your movements would be uncoordinated and you likely could not walk. **PAGE 523** 8. The tract being compressed is the fasciculus gracilis

in the posterior column of the spinal cord, which carries information about touch and pressure from the lower limbs to the brain.
9. The tracts that carry action potentials generated by nociceptors (pain receptors) are the lateral spinothalamic tracts.
10. The left cerebral hemisphere (specifically, the primary sensory cortex) receives impulses carried by the right fasciculus gracilis.
PAGE 528 11. The anatomical basis for opposite-side motor control is crossing-over (decussation) of axons, so the motor fibers of the corticospinal pathway innervate lower motor neurons on the opposite side of the body.
12. An injury involving the superior portion of the motor cortex would affect the ability to control the muscles in the upper limb and the proximal portion of the lower limb.
13. Increased stimulation of the skeletal muscles in the upper limbs, thereby increasing their muscle tone.

Answers to Review Questions

6. (1) free nerve endings: sensitive to touch and pressure; (2) root hair plexus: monitors distortions and movements across the body surface; (3) tactile discs: detect fine touch and pressure; (4) tactile corpuscles: detect fine touch and pressure; (5) lamellated corpuscles: sensitive to pulsing or vibrating stimuli (deep pressure); and (6) Ruffini corpuscles: sensitive to pressure and distortion of the skin 7. (1) tactile receptors; (2) baroreceptors; and (3) proprioceptors 8. (1) spinothalamic pathway: provides conscious sensations of poorly localized ("crude") touch, pressure, pain, and temperature; (2) posterior column pathway: provides conscious sensations of highly localized ("fine") touch, pressure, vibration, and proprioception; and (3) spinocerebellar pathway: carries proprioceptive information about the position of skeletal muscles, tendons, and joints to the cerebellum 9. (1) corticobulbar tracts; (2) lateral corticospinal tracts; and (3) anterior corticospinal tracts **10.** (1) vestibulospinal tract; (2) tectospinal tract; and (3) reticulospinal tract **11.** The cerebellum (1) integrates proprioceptive sensations with visual information from the eyes and equilibrium-related sensations from the internal ear, and (2) adjusts the activities of the voluntary and involuntary motor centers on the basis of sensory information and the stored memories of previous experiences. 12. a 13. (1) An arriving stimulus alters the membrane potential of the receptor cell. (2) The receptor potential directly or indirectly affects a sensory neuron. (3) Action potentials travel to the CNS along an afferent fiber.

Level 2 Reviewing Concepts

14. A tonic receptor is always active; a phasic receptor is normally inactive and becomes active only when a change occurs in the condition (modality) being monitored.
15. A motor homunculus, a mapped-out area of the primary motor cortex, provides an indication of the degree of fine motor control available. A sensory homunculus indicates the relative number of peripheral sensory receptors.
16. A sensory neuron that delivers sensations to the CNS is a first-order neuron. Within the CNS, the axon of the first-order neuron synapses on a second-order neuron, which is an interneuron located in the spinal cord or brain stem. The second-order neuron synapses on a third-order neuron in the thalamus. The axons of third-order neurons synapse on neurons of the primary sensory cortex of the cerebral hemispheres.
17. Damage to the posterior spinocerebellar tract on the left side of the spinal cord at the L₁ level would interfere with the coordinated movement of the left

leg. **18.** Injury to the primary motor cortex affects the ability to exert fine control over motor units. Gross movements are still possible, however, because they are controlled by the basal nuclei that use the reticulospinal or rubrospinal tracts. Thus, walking and other voluntary and involuntary movements can be performed with difficulty, and the movements are imprecise and awkward. **19.** Muscle tone is controlled by the basal nuclei, cerebellum, and red nuclei through commands distributed by the reticulospinal and rubrospinal tracts. **20.** Strong pain sensations arriving at a particular segment of the spinal cord can cause stimulation of the interneurons of the spinothalamic pathway. This stimulation is interpreted by the sensory cortex as originating in the region of the body surface associated with the origin of that same pathway.

Level 3 Critical Thinking and Clinical Applications

21. Kayla's tumor is most likely adjacent to the corticobulbar tracts. The axons of those tracts carry action potentials to motor nuclei of the cranial nerves, which control eye muscles and muscles of facial expression. 22. Injuries to the motor cortex eliminate the ability to produce fine control of motor units. However, as long as the cerebral nuclei are functional, gross movements would still be possible. Harry should still be able to walk, maintain his balance, and perform voluntary and involuntary movements using the rubrospinal and reticulospinal tracts in place of the corticospinal tracts. Although these movements may be awkward or difficult, they will still be possible. 23. Denzel is experiencing phantom pain. Since pain perception occurs in the sensory cortex of the brain, he can still feel pain in his fingers if the brain projects feeling to that area. When he bumps the arm at the elbow, sensory receptors are stimulated to send impulses to the sensory cortex. The brain perceives a sensation from a general area, and projects that feeling to a body part. Since more sensory information reaches the brain from the hands and fingers, it is not unusual for the brain to project to this area.

Answers to Clinical Case Wrap-Up

PAGE 530 1. All the principal descending motor pathways carry information that would have been affected by the brain damage causing Michael's cerebral palsy. They include the corticospinal pathway, the medial pathway, and the lateral pathway. **2.** Poor motor control of the muscles used in swallowing can contribute to an increased risk of choking and poor infant nutrition, which can affect development and even be life-threatening.

Chapter 16

Answers to Checkpoints

PAGE 536 1. The two major divisions of the autonomic nervous system are the sympathetic division and the parasympathetic division. 2. Two neurons are needed to carry an action potential from the spinal cord to smooth muscles in the intestine. The first neuron carries the action potential from the spinal cord to the autonomic ganglion, and a second neuron carries the action potential from the autonomic ganglion to the smooth muscle. 3. The sympathetic division of the ANS is responsible for the physiological changes that occur in response to stress (confronting an angry dog) and increased activity (running). 4. The sympathetic division of the autonomic nervous system includes preganglionic fibers from the lumbar and thoracic regions of the spinal cord, whereas the parasympathetic division includes preganglionic fibers from the cranial and sacral regions. **PAGE 540** 5. The nerves that synapse in collateral ganglia originate in the inferior thoracic and superior lumbar regions of the spinal cord. The preganglionic

ANSWERS

fibers they contain pass through the sympathetic chain ganglia to the collateral ganglia. **PAGE 542** 6. Because preganglionic fibers of the sympathetic nervous system release acetylcholine (ACh), a drug that stimulates ACh receptors would stimulate the postganglionic fibers of sympathetic nerves, resulting in increased sympathetic activity. **7.** Blocking the beta receptors on cells would decrease or prevent sympathetic stimulation of tissues containing those cells. Heart rate, force of contraction of cardiac muscle, and contraction of smooth muscle in the walls of blood vessels would decrease. lowering blood pressure. **PAGE 544** 8. The vagus nerve (N X) carries preganglionic parasympathetic fibers that innervate the lungs, heart, stomach, liver, pancreas, and parts of the small and large intestines (as well as several other visceral organs). 9. The parasympathetic division is sometimes referred to as the anabolic system because parasympathetic stimulation leads to a general increase in the nutrient content of the blood. Cells throughout the body respond to the increase by absorbing the nutrients and using them to support growth and other anabolic activities.

PAGE 545 10. Acetylcholine (ACh) is the neurotransmitter released by all parasympathetic neurons. **11.** The two types of cholinergic receptors on the postsynaptic membranes of parasympathetic neurons are nicotinic receptors and muscarinic receptors. 12. Stimulation of muscarinic receptors, a type of cholinergic receptor located in postganglionic synapses of the parasympathetic nervous system, would cause K⁺ channels to open, resulting in hyperpolarization of cardiac plasma membranes and a decreased heart rate. **PAGE 549 13.** Most blood vessels receive sympathetic stimulation, so a loss of sympathetic tone would relax the smooth muscles lining the vessels; the resulting vasodilation would increase blood flow to the tissue. 14. In anxious individuals, an increase in sympathetic stimulation would probably cause some or all of the following changes: a dry mouth; increased heart rate, blood pressure, and rate of breathing; cold sweats; an urge to urinate or defecate; a change in the motility of the digestive tract (that is, "butterflies in the stomach"); and dilated pupils. **PAGE 551** 15. A visceral reflex is an autonomic reflex initiated in the viscera. It is an automatic motor response that can be modified, facilitated, or inhibited by higher centers, especially those of the hypothalamus. **16.** A brain tumor that interferes with hypothalamic function would also interfere with autonomic function, because centers in the hypothalamus are involved with autonomic (visceral) function. PAGE 556 **17.** Higher-order functions require action by the cerebral cortex. involve both conscious and unconscious information processing, and are subject to modification and adjustment over time. 18. Testtaking involves short-term memory, although your instructor would like you to transfer this information to long-term memory. 19. The two general levels of sleep are deep sleep and rapid eye movement (REM) sleep. 20. If your RAS were suddenly stimulated, it would rouse the cerebrum to a state of consciousness and you would wake up. **21.** A drug that increases the amount of serotonin released in the brain would produce a heightened perception of certain sensory stimuli (e.g., auditory or visual stimuli) and hallucinations. 22. Serotonin and norepinephrine are thought to be involved with sleep-wake cycles. 23. Amphetamines stimulate the secretion of dopamine. PAGE 557 24. Some possible reasons for slower recall and for loss of memory in older people include a loss of neurons (possibly those involved in specific memories), changes in synaptic organization of the brain, changes in the neurons themselves, and decreased blood flow, which would affect the metabolic rate of neurons and perhaps slow the retrieval of information from memory. 25. Common age-related anatomical changes in the nervous system include a reduction in brain size and weight, a reduction

in the number of neurons, a decrease in blood flow to the brain, changes in the synaptic organization of the brain, and intracellular and extracellular changes in CNS neurons. **26.** Alzheimer's disease is the most common form of senile dementia. **27.** The nervous system controls the actions of the arrector pili muscles and sweat glands of the integumentary system. It also controls skeletal muscle contractions of the skeletal system. It also coordinates muscular activities associated with the respiratory and cardiovascular systems.

Answers to Review Questions

PAGE 561 Level 1 Reviewing Facts and Terms 1.

2. d **3.** a **4.** b **5.** d **6.** preganglionic neuron $T_5-L_2 \rightarrow$ collateral ganglia \rightarrow postganglionic fibers \rightarrow visceral effector in abdominopelvic cavity **7.** (1) ciliary ganglion; (2) pterygopalatine ganglion; (3) submandibular ganglion; and (4) otic ganglion 8. Visceral reflex arcs include a receptor, a sensory neuron, an interneuron (may or may not be present), and two visceral motor neurons. 9. Increased neurotransmitter release, facilitation of synapses, and the formation of additional synaptic connections are thought to be involved in memory formation and storage. 10. During non-REM sleep, the entire body relaxes, and activity at the cerebral cortex is at a minimum; heart rate, blood pressure, respiratory rate, and energy utilization decrease. During REM sleep, active dreaming occurs, accompanied by alterations in blood pressure and respiratory rates; muscle tone decreases markedly, and response to outside stimuli decreases. 11. Aging causes a reduction in brain volume and weight, a reduction in the number of neurons, a decrease in blood flow to the brain, changes in synaptic organization, and intracellular and extracellular changes in CNS neurons. 12. c 13. d 14. Sympathetic preganglionic fibers emerge from the thoracolumbar area $(T_1 \text{ through } L_2)$ of the spinal cord. Parasympathetic fibers emerge from the brain stem and the sacral region of the spinal cord
(craniosacral). **15.** (1) celiac ganglion; (2) superior mesenteric ganglion; and (3) inferior mesenteric ganglion 16. Stimulation of sympathetic ganglionic neurons causes (1) release of norepinephrine at specific locations and (2) secretion of epinephrine (and modest amounts of norepinephrine) into the bloodstream. 17. The four pairs of cranial nerves are N III, N VII, N IX, and N X. 18. (1) cardiac plexus: heart rate increases (sympathetic)/decreases (parasympathetic); force of heart contraction increases (sympathetic)/decreases (parasympathetic); blood pressure increases (sympathetic)/decreases (parasympathetic); (2) pulmonary plexus: respiratory passageways dilate (sympathetic)/constrict (parasympathetic); (3) esophageal plexus: respiratory rate increases (sympathetic)/decreases (parasympathetic); (4) celiac plexus: digestion inhibited (sympathetic)/stimulated (parasympathetic); (5) inferior mesenteric plexus: digestion inhibited (sympathetic)/ stimulated (parasympathetic); and (6) hypogastric plexus: defecation inhibited (sympathetic)/stimulated (parasympathetic); urination inhibited (sympathetic)/stimulated (parasympathetic); sexual organs: stimulation of secretion (sympathetic)/erection (parasympathetic) **19.** Higher-order functions (1) are performed by neurons of the cerebral cortex and involve complex interactions between areas of the cortex and between the cerebral cortex and other parts of the brain; (2) involve both conscious and unconscious information processing; and (3) are subject to modification and adjustment over time.

Level 2 Reviewing Concepts

20. a **21.** c **22.** The preganglionic fibers innervating the cervical ganglia originate in the ventral roots of the thoracic segments, which are undamaged. 23. c 24. b 25. d 26. Due to the stimulation of the sympathetic division, you would experience increased respiratory rate, increased peripheral vasoconstriction and elevation of blood pressure, increased heart rate and force of contraction, and an increased rate of glucose release into the bloodstream. 27. If autonomic motor neurons maintain a background level of activity at all times, they can either increase or decrease their activity, providing a greater range of control options. 28. Cholinergic receptors are found in all the ganglia of the ANS, so nicotine would stimulate both sympathetic and parasympathetic responses in cardiovascular tissues. Although increased sympathetic stimulation increases heart rate and force of contraction, increased parasympathetic stimulation simultaneously decreases blood flow to the heart muscle. In addition to elevating heart rate and force of contraction, sympathetic stimulation also constricts peripheral blood vessels, all of which contribute to increased blood pressure. 29. The upsetting situation would be processed by the higher centers of the CNS and relayed to the hypothalamus. The hypothalamus could suppress the vasomotor center of the medulla oblongata, resulting in fewer sympathetic impulses to peripheral blood vessels. This would cause a decrease in sympathetic tone in the smooth muscle of the blood vessels resulting in vasodilation. The vasodilation would cause blood to pool in the limbs decreasing the amount of blood returning to the heart and producing shock.

Level 3 Critical Thinking and Clinical Applications

30. Epinephrine would be more effective, because it would reduce inflammation and relax the smooth muscle of the airways, making it easier for Phil to breathe. **31.** The molecule is probably mimicking NE and binding to alpha-1 receptors.

Answers to Clinical Case Wrap-Up

PAGE 562 1. Tim is less likely to hurt himself by falling if he is already lying down. Also, if he keeps his head on the same level as, or lower than, his heart, his brain will get more blood. Under

parasympathetic stimulation the heart rate, force of contraction, and blood pressure decrease. The heart cannot push blood against gravity. If the head is level with or below the level of the heart, gravity need not be overcome. **2.** In addition to the reflex sympathetic activity at the heart and vascular system, the hypothalamus would call for sympathetic activation. This would stimulate the reticular activating system, increasing alertness. Stimulation of the respiratory centers of the pons and medulla oblongata would cause breathing rate and depth to increase. Stimulation of the medial and lateral pathways would contribute to a general increase in muscle tone.

Chapter 17

Answers to Checkpoints

PAGE 568 1. Olfaction is the sense of smell; it involves olfactory receptor cells in paired olfactory organs responding to chemical stimuli. 2. Axons from the olfactory epithelium collect into bundles that reach the olfactory bulb. In the olfactory pathway, axons leaving the olfactory bulb then travel along the olfactory tract to the olfactory cortex, hypothalamus, and portions of the limbic system. **3.** By the end of the lab period, central adaptation has occurred. Inhibition of synapses along the olfactory pathway reduces the amount of information reaching the olfactory cortex, even though the olfactory neurons remain active. **PAGE 570 4.** Gustation is the sense of taste, provided by taste receptors responding to chemical stimuli. **5.** Taste receptors (in taste buds) are sensitive only to molecules and ions that are in solution. If you dry the surface of your tongue, the salt ions or sugar molecules have no moisture in which to dissolve, so they will not stimulate the taste receptors. 6. Your grandfather is experiencing the effects of several age-related changes. The number of taste buds decreases dramatically after age 50, and those that remain are not as sensitive as they once were. In addition, the loss of olfactory receptors contributes to the perception of fewer flavors in foods. **PAGE 581** 7. The conjunctiva would be the first layer of the eye affected by inadequate tear production. Drying of the conjunctiva would produce an irritated, scratchy feeling. 8. When the lens becomes more rounded, you are looking at an object that is close to you. 9. Sue will likely be unable to see at all. The fovea (fovea centralis) contains only cones, which need high-intensity light to be stimulated. The dimly lit room contains light that is too weak to stimulate the cones. **10.** If the scleral venous sinus (canal of Schlemm) were blocked, the aqueous humor could not drain, producing an eye condition called glaucoma. Accumulation of this fluid increases the pressure within the eye, distorting soft tissues and interfering with vision. If untreated, the condition would ultimately cause blindness. **PAGE 590** 11. If you were born without cones, you would still be able to see-so long as you had functioning rods-but you would lack color vision and see in black and white only. 12. A vitamin A deficiency would reduce the quantity of retinal (retinene) the body could produce, thereby interfering with night vision (which operates at the body's threshold ability to respond to light). 13. Vision would be impaired. Decreased phosphodiesterase activity would increase intracellular cGMP levels, which, by keeping gated sodium channels open, would prevent both hyperpolarization of the photoreceptor cell and a decrease in its neurotransmitter release. There would be no signal to the bipolar cell that a photon had been absorbed. **PAGE 603** 14. If the round window could not move, the perilymph would not be moved by the vibration of the stapes at the oval window, reducing or eliminating the perception of sound. 15. The loss of stereocilia (as a result of constant exposure to loud noises,

for instance) would reduce hearing sensitivity and could lead to deafness. **16.** If the auditory tube were blocked, it would not be possible to equalize the pressure on both sides of the tympanic membrane. If external pressure then decreases, the pressure in the middle ear would be greater than that on the outside, forcing the tympanic membrane outward and producing pain.

Answers to Review Questions

Level 1 Reviewing Facts and Terms

1. (a) vascular layer; (b) iris; (c) ciliary body; (d) choroid; (e) inner layer (retina); (f) neural part; (g) pigmented part; (h) fibrous layer; (i) cornea; (j) sclera 2. d 3. c 4. e 5. c 6. c 7. b 8. d 9. b 10. (a) auricle; (b) external acoustic meatus; (c) tympanic membrane; (d) auditory ossicles; (e) semicircular canals; (f) vestibule; (g) auditory tube; (h) cochlea; (i) vestibulocochlear nerve (N VIII) 11. d 12. d 13. c 14. (1) filiform papillae; (2) fungiform papillae; (3) foliate papillae; and (3) vallate papillae 15. The fibrous layer (a) is composed of the sclera and the cornea and (b) provides mechanical support and some physical protection, serves as an attachment site for the extrinsic eye muscles, and contains structures that assist in the focusing process. 16. The vascular layer consists of the iris, ciliary body, and choroid. 17. The malleus, incus, and stapes transmit a mechanical vibration (amplified along the way) from the tympanic membrane to the oval window.

Level 2 Reviewing Concepts

18. Axons leaving the olfactory epithelium collect into 20 or more bundles that penetrate the cribriform plate of the ethmoid bone to reach the olfactory bulbs of the cerebrum. Axons leaving the olfactory bulb travel along the olfactory tract to reach the olfactory cortex, hypothalamus, and portions of the limbic system.
19. Olfactory sensations are long lasting and important to memories because the sensory information reaches the cerebral cortex by the hypothalamus and the limbic system without first being filtered through the thalamus.
20. An infected sebaceous gland of an eyelash or tarsal gland usually becomes a sty, a painful swelling.
21. a 22. c 23. a

Level 3 Critical Thinking and Clinical Applications

24. Your medial rectus muscles would contract, directing your gaze more medially. In addition, your pupils would constrict and the lenses would become more spherical. 25. Myopia is corrected by (a) concave lenses. 26. In removing the polyps, some of the olfactory epithelium was probably damaged or destroyed, decreasing the area available for the solution of odorants and reducing the intensity of the stimulus. As a result, after the surgery it would take a larger stimulus to provide the same level of smell. 27. The rapid descent in the elevator causes the otoliths of the saccular maculae to slide upward, producing the sensation of downward vertical motion. After the elevator abruptly stops, it takes a few seconds for the otoliths of the maculae to come to rest in the normal position. So long as the otoliths are displaced, you will perceive movement. 28. When Juan closes his eyes, visual cues are gone, and his brain must rely solely on proprioceptive information from the equilibrium centers of the internal ear to maintain normal posture. Because either the internal ear receptors or the sensory nerves are not functioning normally, he is unstable. The most likely reason for his drift to the left is that he is getting inappropriate sensations from equilibrium receptors, either at the maculae (affecting his ability to determine which way is "down") or one of the horizontal semicircular ducts (making him attempt to compensate for a perceived roll to the right).

PAGE 607 1. A visual acuity of 20/200 means Makena must be 20 feet away from an object to see it as clearly as someone with normal vision would see it at 200 feet. In the United States she would be considered legally blind.2. If Makena's vision is corrected to a state of emmetropia, her vision would be corrected to normal.

Chapter 18

Answers to Checkpoints

PAGE 611 1. A hormone is a chemical messenger that is secreted by one cell and travels through the bloodstream to affect the activities of cells in other parts of the body. 2. Paracrine communication is the use of chemical messengers to transfer information from cell to cell within a single tissue. 3. The four mechanisms of intercellular communication are direct, paracrine, endocrine, and synaptic. PAGE 619 4. Neural responses occur within fractions of a second and are of short duration. Endocrine responses are slow to appear but last for minutes to days. 5. A substance that inhibits adenvlate cyclase, the enzyme that converts ATP to cAMP, would block the action of any hormone that requires cAMP as a second messenger. 6. A cell's hormonal sensitivities are determined by the presence or absence of the receptor complex needed to bind a given hormone. **PAGE 625** 7. The two lobes of the pituitary gland are the anterior lobe and the posterior lobe. 8. In dehydration, blood osmotic concentration is increased, which would stimulate the posterior lobe of the pituitary gland to release more ADH. 9. Somatomedins mediate the action of growth hormone. Elevated levels of growth hormone typically accompany elevated levels of somatomedins. 10. Elevated circulating levels of cortisol inhibit the endocrine cells that control the release of ACTH from the pituitary gland, so ACTH levels would decrease. This is an example of a negative feedback mechanism. **PAGE 629** 11. Thyroxine (T_4) , triiodothyronine (T₃), and calcitonin (CT) are hormones associated with the thyroid gland. 12. An individual whose diet lacks iodine would be unable to form the thyroid hormones thyroxine (T_4) and triiodothyronine (T_3) . As a result, you would expect to see signs and symptoms associated with their deficiency: decreased metabolic rate, decreased body temperature, a poor response to physiological stress, and an increase in the size of the thyroid gland (goiter). **13.** Most of the body's reserves of the thyroid hormones, T_4 and T_{34} are bound to blood-borne proteins called thyroid-binding globulins. Because these compounds represent such a large reservoir of T_4 and $T_{3'}$ it takes several days after removal of the thyroid gland for blood levels of thyroxine and T_3 to decline. **PAGE 631** 14. The parathyroid glands are embedded in the posterior surface of the lateral lobes of the thyroid gland. 15. The hormone secreted by the parathyroid glands is parathyroid hormone (PTH). 16. The removal of the parathyroid glands would result in a decrease in the blood concentration of calcium ions. **PAGE 634** 17. The two regions of the adrenal gland are the cortex and medulla. The cortex secretes mineralocorticoids (mainly aldosterone), glucocorticoids (mainly cortisol, hydrocortisone, and corticosterone), and androgens; the medulla secretes epinephrine and norepinephrine. 18. The three zones of the adrenal cortex from superficial to deep are the zona glomerulosa, zona fasciculata, and zona reticularis. 19. One function of cortisol is to decrease the cellular use of glucose while increasing both the available glucose (by promoting the breakdown of glycogen) and the conversion of amino acids to carbohydrates. Therefore, the net result of elevated cortisol levels

would be an elevation of blood glucose. PAGE 635 20. Pinealocytes are the special secretory cells in the pineal gland. **21.** Increased amounts of light would inhibit the production (and release) of melatonin from the pineal gland, which receives neural input from the optic tracts. Melatonin secretion is influenced by day-night patterns. 22. Melatonin inhibits reproductive functions, protects against free radical damage, and influences circadian rhythms. **PAGE 639** 23. The cells of the pancreatic islets (and their hormones) are alpha cells (glucagon), beta cells (insulin), delta cells (GH-IH), and F cells (pancreatic polypeptide). 24. A person with Type 1 or Type 2 diabetes has such high blood glucose levels that the kidneys cannot reabsorb all the glucose; some glucose is lost in urine. Because the urine contains high concentrations of glucose, less water can be reclaimed by osmosis, so the volume of urine production increases. The water losses reduce blood volume and elevate blood osmotic pressure, promoting thirst and triggering the secretion of ADH. 25. Increased levels of glucagon stimulate the conversion of glycogen to glucose in the liver, which would in turn decrease the amount of glycogen in the liver. **PAGE 643** 26. Two hormones secreted by the kidneys are erythropoietin (EPO) and calcitriol. 27. Leptin is a hormone released by adipose tissue. 28. Once released into the bloodstream, renin functions as an enzyme, catalyzing the conversion of angiotensinogen to angiotensin I. **PAGE 646** 29. The type of hormonal interaction in which two hormones have opposite effects on their target tissues is called antagonism. **30.** A lack of GH, thyroid hormone, PTH, and the gonadal hormones would inhibit the formation and development of the skeletal system. **31.** During the resistance phase of the general adaptation syndrome, there is a high demand for glucose, especially by the nervous system. The hormones GH-RH and CRH increase the levels of GH and ACTH, respectively. Growth hormone (GH) mobilizes fat reserves and promotes the catabolism of protein; ACTH increases cortisol, which stimulates both the conversion of glycogen to glucose and the catabolism of fat and protein. Together, these metabolic processes conserve glucose for use by neural tissue. 32. The endocrine system adjusts metabolic rates and substrate utilization, and regulates growth and development, in all other body systems. 33. Hormones of the endocrine system adjust muscle metabolism, energy production, and growth; hormones also regulate calcium and phosphate levels, which are critical to normal muscle functioning. Skeletal muscles protect some endocrine organs.

Answers to Review Questions

PAGE 650

Level 1 Reviewing Facts and Terms

1. b 2. c 3. d 4. a 5. d 6. d 7. d 8. (a) hypothalamus; (b) pituitary gland; (c) thyroid gland; (d) thymus; (e) adrenal glands; (f) pineal gland; (g) parathyroid glands; (h) heart; (i) kidney; (j) adipose tissue; (k) digestive tract; (l) pancreatic islets (within pancreas); (m) gonads 9. (1) The hypothalamus produces regulatory hormones that control secretion by endocrine cells in the anterior lobe of the pituitary gland. (2) The hypothalamus contains autonomic centers that exert direct neural control over the endocrine cells of the adrenal medullae. (3) The hypothalamus releases ADH and oxytocin into the bloodstream at the posterior lobe of the pituitary gland. These mechanisms are adjusted through negative feedback loops involving hormones released by peripheral endocrine tissues and organs. **10.** The anterior lobe of the pituitary gland releases (1) thyroid-stimulating hormone (TSH); (2) adrenocorticotropic hormone (ACTH); (3) follicle-stimulating hormone

(6) growth hormone (GH); and (7) melanocyte-stimulating hormone (MSH). **11.** Growth is affected by (1) growth hormone, (2) thyroid hormones, (3) insulin, (4) parathyroid hormone, (5) calcitriol, and (6) the reproductive hormones. **12.** Effects of thyroid hormones are (1) increased rate of energy consumption and utilization in cells; (2) accelerated production of sodiumpotassium ATPase; (3) activation of genes coding for the synthesis of enzymes involved in glycolysis and energy production: (4) accelerated ATP production by mitochondria; and (5) in growing children, normal development of the skeletal, muscular, and nervous systems. 13. Calcitonin decreases the concentration of calcium ions in body fluids; parathyroid hormone causes an increase in the concentration of calcium ions in body fluids. 14. (1) zona glomerulosa: mineralocorticoids; (2) zona fasciculata: glucocorticoids; and (3) zona reticularis: androgens 15. The kidneys release (1) erythropoietin, which stimulates the production of RBCs by the red bone marrow, and (2) calcitriol, which stimulates calcium and phosphate absorption along the digestive tract. 16. Natriuretic peptides (1) promote the loss of sodium ions and water at the kidneys; (2) inhibit the secretion of water-conserving hormones, such as ADH and aldosterone; (3) suppress thirst; and (4) block the effects of angiotensin II and norepinephrine on arterioles. Angiotensin II opposes these actions by stimulating aldosterone secretion by the adrenal cortex and ADH by the posterior lobe of the pituitary gland, and further by retaining salt and water by the kidneys. Angiotensin II also stimulates thirst and elevates blood pressure. **17.** (1) alpha cells: glucagon; (2) beta cells: insulin; (3) delta cells: growth hormone-inhibiting hormone (GH-IH, or somatostatin); and (4) F cells: pancreatic polypeptide

(FSH); (4) luteinizing hormone (LH); (5) prolactin (PRL);

Level 2 Reviewing Concepts

18. The primary difference involves speed and duration. In the nervous system, the source and destination of communication are quite specific, and the effects are extremely quick and short lived. In endocrine communication, the effects are slow to appear and commonly persist for days. A single hormone can alter the metabolic activities of multiple tissues and organs simultaneously. 19. Hormones can (1) direct the synthesis of an enzyme (or other protein) not already present in the cytoplasm, (2) turn an existing enzyme "on" or "off," and (3) increase the rate of synthesis of a particular enzyme or other protein. **20.** In endocrine reflexesthe functional counterpart of neural reflexes-a stimulus triggers the production of a hormone. Both neural and endocrine reflexes are typically controlled by negative feedback mechanisms. 21. Inactivation of phosphodiesterase (PDE), which converts cAMP to AMP, would prolong the effect of the hormone. **22.** The adrenal medulla is controlled by the sympathetic nervous system, whereas the adrenal cortex is stimulated by the release of ACTH from the anterior lobe of the pituitary gland. 23. b 24. a 25. b

Level 3 Critical Thinking and Clinical Applications

26. Extreme thirst and frequent urination are characteristic of both diabetes insipidus and diabetes mellitus. To distinguish between the two, glucose levels in the blood and urine could be measured. A high glucose concentration would indicate diabetes mellitus. **27.** Julie's poor diet would not supply enough Ca^{2+} for her developing fetus, which would remove large amounts of Ca²⁺ from the maternal blood. A lowering of the mother's blood Ca²⁺ would lead to an increase in parathyroid hormone levels and increased release of stored Ca^{2+} from maternal bones. **28.** Sherry's signs and symptoms suggest hyperthyroidism. Blood tests could be performed to assay the levels of TSH, T_{34} and T_{4} . From these tests, the physician could make a positive diagnosis (hormone levels would be elevated in hyperthyroidism) and also determine whether the condition is primary (a problem with the thyroid gland) or secondary (a problem with hypothalamo-pituitary control of the thyroid gland). **29.** One benefit of a portal system is that it ensures that the controlling hormones will be delivered directly to the target cells. Secondly, because the hormones go directly to their target cells without first passing through the general circulation, they are not diluted. The hypothalamus can control the cells of the anterior lobe of the pituitary gland with much smaller amounts of releasing and inhibiting hormones than would be necessary if the hormones had to first go through the circulatory pathway before reaching the pituitary. **30.** The natural effects of testosterone are to increase muscle mass. increase endurance, and enhance the "competitive spirit." Side effects in women include hirsutism (abnormal hair growth on the face or body), enlargement of the laryngeal cartilages, premature closure of the epiphyseal cartilages, and liver dysfunction.

Answers to Clinical Case Wrap-Up

PAGE 651 1. In addition to mobilizing Ca^{2+} from bone, PTH enhances the reabsorption of Ca^{2+} by the kidneys, decreasing urinary losses and keeping blood concentrations high. PTH also stimulates the secretion of calcitriol by the kidneys, which enhances absorption of Ca^{2+} in the digestive tract, which also increases blood concentrations of Ca^{2+} . **2.** Calcitonin, produced by the thyroid, decreases blood Ca^{2+} levels. Calcitonin does this by encouraging Ca^{2+} deposition in bone and by causing an increased excretion of Ca^{2+} by the kidneys.

Chapter 19

Answers to Checkpoints

PAGE 656 1. The five major functions of blood are transporting dissolved gases, nutrients, hormones, and metabolic wastes; regulating the pH and ion composition of interstitial fluids; restricting fluid losses at injury sites; defending against toxins and pathogens; and stabilizing body temperature. 2. Red blood cells, white blood cells, and platelets are the formed elements of blood. 3. Whole blood is composed of plasma and formed elements. 4. Venipuncture is a common sampling technique because superficial veins are easy to locate, the walls of veins are thinner than those of arteries, and blood pressure in veins is relatively low, so the puncture wound seals quickly. **PAGE 657** 5. The three major types of plasma proteins are albumins, globulins, and fibrinogen. 6. A decrease in the amount of plasma proteins in the blood would lower plasma osmotic pressure, reduce the ability to fight infection, and decrease the transport and binding of some ions, hormones, and other molecules. 7. During a viral infection, you would expect the level of immunoglobulins (antibodies) in the blood to be elevated. **PAGE 664** 8. Hemoglobin is a protein composed of four globular subunits, each bound to a heme molecule, which gives red blood cells the ability to transport oxygen in the blood. 9. After a significant loss of blood, the hematocrit-the amount of formed elements (mostly red blood cells) as a percentage of the total blood-would be reduced. 10. Dave's hematocrit will increase, because reduced blood flow to the kidneys triggers the release of erythropoietin, which stimulates an increase in erythropoiesis (red blood cell formation). **11.** Bilirubin would accumulate in the blood, producing jaundice, because diseases that damage the liver, such as hepatitis or cirrhosis, impair the liver's ability to excrete bilirubin in

the bile. **PAGE 667** 12. Surface antigens on RBCs are glycoproteins or glycolipids in the plasma membrane; they determine blood type. 13. Only type O blood can be safely transfused into a person whose blood type is O. **14.** If a person with type A blood receives a transfusion of type B blood, which contains anti-A antibodies, the red blood cells will agglutinate (clump), potentially blocking blood flow to various organs and tissues. **PAGE 674** 15. The five types of white blood cells are neutrophils, eosinophils, basophils, monocytes, and lymphocytes. 16. An infected cut would contain a large number of neutrophils, because these phagocytic white blood cells are the first to arrive at the site of an injury. 17. The blood of a person fighting a viral infection would contain elevated numbers of lymphocytes, because B lymphocytes produce circulating antibodies. 18. Basophils respond to an injury by releasing a variety of chemicals, including histamine and heparin. Histamine dilates blood vessels and heparin prevents blood clotting. Basophils also release other chemicals that attract eosinophils and other basophils to the area. **PAGE 675** 19. Thrombocytopoiesis is the term for platelet production. **20.** Platelets are nonnucleated cell fragments in mammalian blood, whereas thrombocytes are nucleated platelets in nonmammalian vertebrate blood. 21. Platelets release chemicals important to the clotting process, form a temporary patch in the walls of damaged blood vessels, and reduce the size of a break in the vessel wall. PAGE 679 22. A decreased number of megakaryocytes would interfere with the blood's ability to clot properly, because fewer megakaryocytes would produce fewer platelets. **23.** Fruit juice and water do not contain fats, which are required for vitamin K absorption, leading to a vitamin K deficiency. This would lead to a decreased production of several clotting factors-most notably, prothrombin. As a result, clotting time would increase. 24. The activation of Factor XII initiates the intrinsic pathway.

Answers to Review Questions

PAGE 682

Level 1 Reviewing Facts and Terms

1. (a) neutrophil; (b) eosinophil; (c) basophil; (d) monocyte; (e) lymphocyte 2. c 3. c 4. a 5. d 6. d 7. b 8. d 9. a 10. Blood (1) transports dissolved gases, nutrients, hormones, and metabolic wastes; (2) regulates pH and electrolyte composition of interstitial fluids throughout the body; (3) restricts fluid losses through damaged vessels or at other injury sites; (4) defends against toxins and pathogens; and (5) stabilizes body temperature. **11.** Major types of plasma proteins are (1) albumins, which maintain the osmotic pressure of plasma and are important in the transport of fatty acids; (2) globulins, which (a) bind small ions, hormones, or compounds that might otherwise be filtered out of the blood at the kidneys or have very low solubility in water (transport globulins), or (b) attack foreign proteins and pathogens (immunoglobulins); and (3) fibrinogen, which functions in blood clotting. 12. (a) anti-B antibodies; (b) anti-A antibodies; (c) neither anti-A nor anti-B antibodies; (d) both anti-A and anti-B antibodies 13. WBCs exhibit (1) emigration (diapedesis), squeezing between adjacent endothelial cells in the capillary wall; (2) amoeboid movement, a gliding movement that transports the cell; (3) positive chemotaxis, the attraction to specific chemical stimuli, and (4) phagocytosis (engulfing particles for neutrophils, eosinophils, and monocytes). 14. Neutrophils, eosinophils, basophils, and monocytes function in nonspecific defenses. 15. The primary lymphocytes are (1) T cells, which are responsible for cellmediated immunity; (2) B cells, which are responsible for humoral immunity; and (3) NK cells, which are responsible for immune

surveillance. **16.** Prothrombin is an inactive precursor that is converted to thrombin during coagulation. Thrombin is an enzyme that causes the clotting of blood by converting fibrinogen to fibrin. **17.** Erythropoietin is released (1) during anemia, (2) when blood flow to the kidneys declines, (3) when oxygen content of the air in the lungs declines, and (4) when the respiratory surfaces of the lungs are damaged. **18.** Initiation of the common pathway requires the activation of Factor X by the extrinsic and/or intrinsic pathways.

Level 2 Reviewing Concepts

19. a 20. d 21. c 22. c 23. Red blood cells are biconcave discs that lack mitochondria, ribosomes, and nuclei, and they contain a large amount of hemoglobin. RBCs transport oxygen, while WBCs are involved in immunity. The five types of white blood cells vary in size from slightly larger to twice the diameter of an RBC, contain a prominent nucleus, and may contain granules with distinct staining properties. 24. White blood cells defend against toxins and pathogens. Neutrophils, eosinophils, and monocytes engulf and digest bacteria, protozoa, fungi, viruses, and cellular debris. Lymphocytes are specialized to attack and destroy specific foreign cells, proteins, and cancerous cells, directly or through the production of antibodies. 25. Blood stabilizes and maintains body temperature by absorbing and redistributing the heat produced by active skeletal muscles. 26. Each molecule of hemoglobin consists of four protein subunits, each of which contains a single molecule of heme, a nonprotein ring surrounding an iron ion. These central iron ions are what actually pick up and release oxygen molecules. 27. Aspirin helps prevent vascular problems by inhibiting clotting. It inhibits platelet enzymes involved in the production of thromboxane A₂ and prostaglandins, thereby inhibiting clotting. It also prolongs bleeding time.

Level 3 Critical Thinking and Clinical Applications

28. A prolonged prothrombin time and a normal partial thromboplastin time indicate a deficiency in the extrinsic system but not in the intrinsic system or common pathway. Factor VII would be deficient. **29.** As the spleen enlarges, so does its capacity to store additional red blood cells, leading to fewer red blood cells in circulation, producing anemia. The decreased number of RBCs in circulation decreases the body's ability to deliver oxygen to the tissues, slowing their metabolism and producing the tired feeling and lack of energy. Because there are fewer RBCs than normal, the blood circulating through the skin is not as red, producing a pale complexion. **30.** Taking a broad-spectrum antibiotic kills a wide range of bacteria, both pathogenic and nonpathogenic, including many of the normal flora of the intestine. Reducing the intestinal flora substantially decreases the amount of vitamin K they make available to the liver to produce prothrombin, a vital component of the common pathway. With decreased amounts of prothrombin in the blood, normal minor breaks in the vessels of the nasal passageways do not seal off as quickly, producing nosebleeds. 31. Removal of most of Randy's stomach eliminated the production of intrinsic factor, which is essential for the absorption of vitamin B_{12} by intestinal cells. Thus Randy was prescribed vitamin B₁₂ to prevent pernicious anemia, and he needed injections of vitamin B₁₂ because if taken orally, his intestines could no longer absorb it.

Answers to Clinical Case Wrap-Up

PAGE 683 1. Jasmine bleeds and bruises so easily because she has too few platelets to initiate the platelet phase of blood clotting. This also causes her prolonged menstrual periods. **2.** Jasmine is short of breath climbing stairs because she has too few red blood cells carrying oxygen to her skeletal muscles.

Chapter 20

Answers to Checkpoints PAGE 697 1. Damage to the semilunar valve of the right ventricle

would affect blood flow to the pulmonary trunk. 2. Contraction of the papillary muscles (just before the rest of the ventricular myocardium contracts) pulls on the chordae tendineae, which prevent the AV valves from opening back into the atria. **3.** The left ventricle is more muscular than the right ventricle because the left ventricle must generate enough force to propel blood throughout the body, except the lungs, whereas the right ventricle must generate only enough force to propel blood a few centimeters to the **PAGE 706 4.** Automaticity, or autorhythmicity, is the abillungs. ity of cardiac muscle tissue to contract without neural or hormonal stimulation. 5. The sinoatrial (SA) node is known as the cardiac pacemaker or the natural pacemaker. 6. If the cells of the SA node did not function, the heart would still continue to beat, but at a slower rate; and the AV node would act as the pacemaker. **7.** If the impulses from the atria were not delayed at the AV node, they would be conducted through the ventricles so quickly by the bundle branches and Purkinje cells that the ventricles would begin contracting immediately, before the atria had finished their contraction. As a result, the ventricles would not be as full of blood as they could be, and the pumping of the heart would not be as efficient, especially during physical activity. **PAGE 711** 8. The technical term for heart contraction is systole, and the term for heart relaxation is diastole. 9. The phases of the cardiac cycle are atrial systole, atrial diastole, ventricular systole, and ventricular diastole. 10. No. When pressure in the left ventricle first rises, the heart is contracting but no blood is leaving the heart. During this initial phase of contraction, both the AV valves and the semilunar valves are closed. The increase in pressure is the result of increased tension as the cardiac muscle contracts. When the pressure in the ventricle exceeds the pressure in the aorta, the aortic semilunar valves are forced open, and blood is rapidly ejected from the ventricle. **11.** One possible cause for an increase in the size of the QRS complex, which indicates a larger-than-normal amount of electrical activity during ventricular depolarization, is an enlarged heart. Because more cardiac muscle is depolarizing, the magnitude of the electrical event would be greater. **PAGE 718** 12. Cardiac output is the amount of blood pumped by the left ventricle in one minute. **13.** Caffeine acts directly on the conducting system and contractile cells of the heart, increasing the rate at which they depolarize. Drinking large amounts of caffeinated drinks would increase the heart rate. 14. Damage to the cardioinhibitory center of the medulla oblongata, which is part of the parasympathetic division of the autonomic nervous system, would reduce parasympathetic stimulation of the heart. The resulting sympathetic dominance would increase the heart rate. 15. A drug that increases the length of time required for the repolarization of pacemaker cells would decrease the heart rate, because the pacemaker cells would generate fewer action potentials per minute. 16. The heart pumps in proportion to the amount of blood that enters. A heart that beats too rapidly does not have sufficient time to fill completely between beats. Thus, when the heart beats too fast, very little blood leaves the ventricles and enters the circulation, so tissues suffer damage from inadequate blood supply. 17. Stimulating the acetylcholine receptors of the heart would slow the heart rate. Since cardiac output is the product of stroke volume and heart rate, a reduction in heart rate will lower the cardiac output (assuming that the stroke volume remains the same or doesn't increase). **18.** The venous return fills the heart with blood,

stretching the heart muscle. According to the Frank–Starling principle, the more the heart muscle is stretched, the more forcefully it will contract (to a point). The more forceful the contraction, the more blood the heart will eject with each beat (stroke volume). Therefore, increased venous return would increase the stroke volume (if all other factors are constant). **19.** An increase in sympathetic stimulation of the heart would increase heart rate and force of contraction. The end-systolic volume (ESV) is the amount of blood that remains in a ventricle after a contraction (systole). The more forcefully the heart contracts, the more blood it ejects and the lower the ESV is. Therefore, increased sympathetic stimulation should result in a lower ESV. **20.** SV = EDV – ESV, so SV = 125 mL - 40 mL = 85 mL

Answers to Review Questions

PAGE 721

Level 1 Reviewing Facts and Terms

1. (a) superior vena cava; (b) auricle of right atrium; (c) right ventricle; (d) left ventricle; (e) aortic arch; (f) left pulmonary artery; (g) pulmonary trunk; (h) auricle of left atrium

2. (a) ascending aorta; (b) opening of coronary sinus; (c) right atrium; (d) cusp of right AV (tricuspid) valve; (e) chordae tendineae; (f) right ventricle; (g) pulmonary valve; (h) left pulmonary veins; (i) left atrium; (j) aortic valve; (k) cusp of left AV (mitral) valve; (1) left ventricle; (m) interventricular septum 3. c 4. b 5. d 6. b 7. d 8. a and b 9. b 10. a 11. a 12. During ventricular contraction, tension in the papillary muscles pulls against the chordae tendineae, which keep the cusps of the AV valve from swinging into the atrium. This action prevents the backflow, or regurgitation, of blood into the atrium as the ventricle contracts. **13.** (1) The epicardium is the visceral pericardium, which covers the outer surface of the heart. (2) The myocardium is the muscular wall of the heart, which forms both atria and ventricles. It contains cardiac muscle tissue and associated connective tissues, blood vessels, and nerves. (3) The endocardium is a squamous epithelium that covers the inner surfaces of the heart, including the valves. 14. The right atrioventricular (AV) valve (the tricuspid valve) and the left AV valve (the bicuspid valve) prevent the backflow of blood from the ventricles into the atria. The pulmonary and aortic semilunar valves prevent the backflow of blood from the pulmonary trunk and aorta into the right and left ventricles. **15.** SA node \rightarrow AV node \rightarrow AV bundle \rightarrow right and left bundle branches \rightarrow Purkinje fibers (into the mass of ventricular muscle tissue) 16. The cardiac cycle comprises the events in a complete heartbeat, including a contraction/relaxation period for both atria and ventricles. The cycle begins with atrial systole as the atria contract and push blood into the relaxed ventricles. As the atria relax (atrial diastole), the ventricles contract (ventricular systole), forcing blood through the semilunar valves into the pulmonary trunk and aorta. The ventricles then relax (ventricular diastole). For the rest of the cardiac cycle, both the atria and ventricles are in diastole; passive filling occurs. **17.** The factors that regulate stroke volume are (1) preload, the stretch on the heart before it contracts; (2) contractility, the forcefulness of contraction of individual ventricular muscle fibers; and (3) afterload, the pressure that must be exceeded before blood can be ejected from the ventricles.

Level 2 Reviewing Concepts

18. c **19.** a **20.** d **21.** a **22.** The SA node, which is composed of cells that exhibit rapid prepotential, is the pacemaker of the heart. The AV node slows the impulse that signals contraction, because its cells are smaller than those of the conduction pathway. **23.** The first sound ("lubb"), which marks the start of

ventricular contraction, is produced as the AV valves close and the semilunar valves open. The second sound ("dupp") occurs when the semilunar valves close and the AV valves open, marking the start of ventricular diastole. The third heart sound is associated with blood flow into the ventricles, and the fourth sound is associated with atrial contraction. Listening to the heart sounds (auscultation) is a simple and effective diagnostic tool. **24.** Stroke volume (SV) is the volume of blood ejected by a ventricle in a single contraction. Cardiac output (CO) is the amount of blood pumped by the left ventricle in one minute: CO (in mL/min) = HR (in beats/min) \times SV (in mL/beat). 25. Stroke volume and heart rate influence cardiac output. 26. Sympathetic activation increases the heart rate and the force of contractions; parasympathetic stimulation decreases the heart rate and the force of contractions. **27.** All these hormones have positive inotropic effects, which means that they increase the strength of cardiac contraction.

Level 3 Critical Thinking and Clinical Applications

28. During tachycardia (an abnormally fast heart rate), there is less time between contractions for the heart to fill with blood again. Thus, over time the heart fills with less and less blood, and pumps less blood out. As the stroke volume decreases, the cardiac output decreases. When cardiac output decreases to the point where not enough blood reaches the brain, loss of consciousness occurs. 29. Harvey probably has a regurgitating left atrioventricular (AV) valve. This valve is also called the mitral valve or the bicuspid valve. When an AV valve fails to close properly, blood flowing back into the atrium produces a murmur. A murmur at the beginning of systole implicates the AV valve because this is the period when the valve has just closed and the blood in the ventricle is under increasing pressure; thus the likelihood of backflow is the greatest. A sound heard at the end of systole or the beginning of diastole would implicate a regurgitating semilunar valve—in this case, the aortic semilunar valve. **30.** Using $CO = HR \times SV$, person 1 has a cardiac output of 4500 mL, and person 2 has a cardiac output of 8550 mL. According to the Frank-Starling principle (Starling's law of the heart), in a normal heart the cardiac output is directly proportional to the venous return. Thus, person 2 has the greater venous return. Ventricular filling decreases with increased heart rate; person 1 has the lower heart rate and therefore the longer ventricular filling time. **31.** By blocking calcium channels, verapamil will decrease the force of cardiac contraction, which directly lowers Karen's stroke volume.

Answers to Clinical Case Wrap-Up

PAGE 722 1. The "lubb" heard when the AV valves close, and the "dupp" heard when the semilunar valves close, would be muffled and difficult to hear because the sounds were transmitted through a pericardial cavity filled with blood. This dampens the sounds when heard through a stethoscope. **2.** The right atrium and right ventricle sit anteriorly, just deep to the sternum, and would likely be injured in this collision. Delicate structures that could also be injured include the anterior interventricular artery and great cardiac vein, running in the anterior interventricular sulcus. With a hard enough impact, the papillary muscles and chordae tendineae could rupture, leading to failure of the AV valves.

Chapter 21

Answers to Checkpoints

PAGE 734 1. The five general classes of blood vessels are arteries, arterioles, capillaries, venules, and veins. **2.** The blood vessels are

veins. Arteries and arterioles have a large amount of smooth muscle tissue in a thick, well-developed tunica media. 3. In the arterial system, pressures are high enough to keep the blood moving forward. In the venous system, blood pressure is too low to keep the blood moving on toward the heart. Valves in veins prevent blood from flowing backward whenever the venous pressure drops. 4. Fenestrated capillaries are located where fluids and small solutes move freely into and out of the blood, including endocrine glands, the choroid plexus of the brain, absorptive areas of the intestine, and filtration areas of the kidneys. **PAGE 742** 5. The factors that contribute to total peripheral resistance are vascular resistance, vessel length, vessel diameter, blood viscosity, and turbulence. 6. In a healthy person, blood pressure is greater at the aorta than at the inferior vena cava. Blood, like other fluids, moves along a pressure gradient from areas of high pressure to areas of low pressure. If the pressure were higher in the inferior vena cava than in the aorta, the blood would flow backward. 7. While Sally was standing for a period of time, blood pooled in her lower limbs, which decreased venous return to her heart. In turn, cardiac output decreased, so less blood reached her brain, causing light-headedness and fainting. A hot day adds to this effect, because the loss of body water through sweating reduces blood volume. 8. Mike's mean arterial pressure is approximately 88.3 mm Hg; 70 + (125 - 70)/3 = 70+ 18.3 = 88.3. **PAGE 749 9.** Vasodilators promote the dilation of precapillary sphincters. Local vasodilators, such as decreased O₂ levels or increased CO₂ levels, act at the tissue level to accelerate blood flow through their tissue of origin. 10. Pressure on the common carotid artery would decrease blood pressure at the baroreceptors in the carotid sinus. This decrease would cause a decreased frequency of action potentials along the glossopharyngeal cranial nerve (IX) to the medulla oblongata, and more sympathetic impulses would be sent to the heart. The net result would be an increase in the heart rate. **11.** Vasoconstriction of the renal artery would decrease both blood flow and blood pressure at the kidney. In response, the kidney would increase the amount of renin it releases, which in turn would lead to an increase in the level of angiotensin II. The angiotensin II would bring about increased blood pressure and increased blood volume. PAGE 753 12. Blood pressure increases during exercise because (1) cardiac output increases and (2) resistance in visceral tissues increases. 13. The immediate problem during hemorrhaging is maintaining adequate blood pressure and peripheral blood flow; the long-term problem is restoring normal blood volume. 14. Both aldosterone and ADH promote fluid retention and reabsorption at the kidneys, preventing further reductions in blood volume. **PAGE 754** 15. The two circuits of the cardiovascular system are the pulmonary circuit and the systemic circuit. 16. The three major patterns are the following: (1) The peripheral distributions of arteries and veins on the body's left and right sides are generally identical, except near the heart, where the largest vessels connect to the atria or ventricles; (2) a single vessel may have several names as it crosses specific anatomical boundaries, making accurate anatomical descriptions possible; and (3) tissues and organs are usually serviced by several arteries and veins. PAGE 755 17. The pulmonary arteries enter the lungs carrying deoxygenated blood, and the pulmonary veins leave the lungs carrying oxygenated blood. **18.** Right ventricle \rightarrow pulmonary trunk \rightarrow left and right pulmonary arteries \rightarrow pulmonary arterioles \rightarrow alveoli \rightarrow pulmonary venules \rightarrow pulmonary veins \rightarrow left atrium **PAGE 772** 19. A blockage of the left subclavian artery would interfere with blood flow to the left arm. 20. Compression of the common carotid arteries would decrease blood pressure

at the carotid sinus and cause a rapid reduction in blood flow to the brain, resulting in a loss of consciousness. An immediate reflexive increase in heart rate and blood pressure would follow. **21.** Rupture of the celiac trunk would most directly affect the stomach, spleen, liver, and pancreas. 22. The vein that is bulging in Tim's neck is the external jugular vein. 23. A blockage of the popliteal vein would interfere with blood flow in the tibial and fibular veins (which form the popliteal vein) and the small saphenous vein (which joins the popliteal vein). **PAGE 773** 24. Two umbilical arteries supply blood to the placenta, and one umbilical vein returns blood from the placenta. The umbilical vein then drains into the ductus venosus within the fetal liver. (Remember, arteries carry blood away from the heart, and veins carry blood to the heart.) 25. This blood sample was taken from the umbilical vein, which carries oxygenated, nutrient-rich blood from the placenta to the fetus. 26. Structures specific to the fetal circulation include two umbilical arteries, an umbilical vein, the ductus venosus, the foramen ovale, and the ductus arteriosus. In the newborn, the foramen ovale closes and persists as the fossa ovalis, a shallow depression; the ductus arteriosus persists as the ligamentum arteriosum, a fibrous cord; and the umbilical vessels and ductus venosus persist throughout life as fibrous cords. **PAGE 775** 27. Components of the cardiovascular system affected by age include the blood, heart, and blood vessels. 28. A thrombus is a stationary blood clot within the lumen of a blood vessel. **29.** An aneurysm is the ballooning out of a weakened arterial wall resulting from sudden pressure increases. **30.** The cardiovascular system provides other body systems with oxygen, hormones, nutrients, and white blood cells in blood, while removing carbon dioxide and metabolic wastes; it also transfers heat to body tissues. **31.** The skeletal system provides calcium needed for normal cardiac muscle contraction, and it protects developing blood cells in the red bone marrow. The cardiovascular system provides calcium and phosphate for bone deposition, delivers erythropoietin to red bone marrow, and transports parathyroid hormone and calcitonin to osteoblasts and osteoclasts.

Answers to Review Questions

PAGE 779

Level 1 Reviewing Facts and Terms

1. (a) brachiocephalic trunk; (b) brachial; (c) radial; (d) external iliac; (e) anterior tibial; (f) right common carotid; (g) left subclavian; (h) common iliac; (i) femoral 2. b 3. e 4. c 5. b 6. b 7. b 8. d 9. (a) external jugular; (b) brachial; (c) median cubital; (d) radial; (e) great saphenous; (f) internal jugular; (g) superior vena cava; (h) left and right common iliac; (i) femoral 10. b 11. b 12. d 13. c 14. c 15. c 16. c 17. (a) Capillary hydrostatic pressure forces fluid out of the capillary at the arterial end. (b) Blood colloid osmotic pressure causes the movement of fluid back into the capillary at its venous end. **18.** When an infant takes its first breath, the lungs expand and pulmonary vessels dilate. The smooth muscles in the ductus arteriosus contract, due to increased venous return from the lungs, isolating the pulmonary and aortic trunks, and blood begins flowing through the pulmonary circuit. As pressure increases in the left atrium, the valvular flap closes the foramen ovale, completing the vascular remodeling.

Level 2 Reviewing Concepts

19. b **20.** b **21.** a **22.** Artery walls are generally thicker and contain more smooth muscle and elastic fibers, enabling them to resist and adjust to the pressure generated by the heart. Venous walls are thinner; the pressure in veins is less than that in arteries.

ANSWERS

Arteries constrict more than veins do when not expanded by blood pressure, due to a greater degree of elastic tissue. Finally, the endothelial lining of an artery has a pleated appearance because it cannot contract and so forms folds. The lining of a vein looks like a typical endothelial layer. 23. Capillary walls are thin, so distances for diffusion are short. Continuous capillaries have small gaps between adjacent endothelial cells that permit the diffusion of water and small solutes into the surrounding interstitial fluid but prevent the loss of blood cells and plasma proteins. Fenestrated capillaries contain pores that permit very rapid exchange of fluids and solutes between interstitial fluid and plasma. The walls of arteries and veins are several cell layers thick and are not specialized for diffusion. 24. Contraction of the surrounding skeletal muscles squeezes venous blood toward the heart. This mechanism, the muscular pump, is assisted by the presence of valves in the veins, which prevent backflow of the blood. The respiratory pump, which results from the increase in internal pressure of the thoracic cavity during exhalation, pushes venous blood into the right atrium. **25.** Cardiac output and peripheral blood flow are directly proportional to blood pressure. Blood pressure is closely regulated by a combination of neural and hormonal mechanisms. The resistance of the vascular system opposes the movement of blood, so blood flow is inversely proportional to the resistance. Sources of peripheral resistance include vascular resistance, blood viscosity, and turbulence. 26. The brain receives arterial blood from four arteries that form anastomoses within the cranium. An interruption of any one vessel will not compromise the blood flow to the brain. **27.** The cardioacceleratory and vasomotor centers are stimulated when general sympathetic activation occurs. The result is an increase in cardiac output and blood pressure. When the parasympathetic division is activated, the cardioinhibitory centers are stimulated, reducing cardiac output.

Level 3 Critical Thinking and Clinical Applications

28. Fluid loss lowers blood volume, leading to sympathetic stimulation, which elevates blood pressure. So, Bob's blood pressure is high instead of low. 29. Antihistamines and decongestants are sympathomimetic drugs; they have the same effects on the body as does stimulation of the sympathetic nervous system. In addition to the desired effects of counteracting the symptoms of the allergy, these medications can produce an increased heart rate, increased stroke volume, and increased peripheral resistance, all of which will contribute to elevating blood pressure. In a person with hypertension (high blood pressure), these drugs would aggravate this condition, with potentially hazardous consequences. **30.** When Jolene stood up rapidly, gravity caused her blood volume to move to the lower parts of her body away from the heart, decreasing venous return. The decreased venous return resulted in a decreased end-diastolic volume (EDV), leading to a decreased stroke volume and cardiac output. In turn, blood flow to the brain decreased, so the diminished oxygen supply caused her to be light-headed and feel faint. This reaction doesn't happen all the time because as soon as the pressure drops due to inferior movement of blood, baroreceptors in the aortic arch and carotid sinuses trigger the baroreceptor reflex. Action potentials are carried to the medulla oblongata, where appropriate responses are integrated. In this case, we would expect an increase in peripheral resistance to compensate for the decreased blood pressure. If this doesn't compensate enough for the drop, then an increase in heart rate and force of contraction would occur. Normally, these responses occur so quickly that changes in pressure following changes in body position go unnoticed.

Answers to Clinical Case Wrap-Up

PAGE 780 1. Calcification follows the degeneration of smooth muscle in the tunica media of arteries. Calcification in arteries is related to atherosclerotic injury of the vessels. Calcification does not occur in normal, young, healthy blood vessel walls. **2.** Atherosclerosis is never seen in the venous system because veins are never subjected to the pressures of the arterial system. (In the average person the systemic arterial pressure is over 100 mm Hg.) This causes wear and tear in the arterial walls, leading to gradual degeneration of the smooth muscle in the tunica media, followed by deposition of calcium salts, and then by deposition of atherosclerotic plaques. The pressure within the venous system is always quite low (usually around 16 mm Hg). Damage to the endothelial surfaces does not get started.

Chapter 22

Answers to Checkpoints

PAGE 783 1. A pathogen is any disease-causing organism, such as a virus, bacterium, fungus, or parasite, that can survive and even thrive inside the body. 2. Innate (nonspecific) defenses are anatomical barriers and defense mechanisms that either prevent or slow the entry of infectious organisms but do not distinguish one potential threat from another. Adaptive (specific) defenses involve an immune response against a specific type of threat. **PAGE 795** 3. The components of the lymphatic system are lymph, lymphatic vessels, primary lymphoid tissues and organs (red bone marrow and the thymus), and secondary lymphoid tissues and organs (lymph nodes, tonsils, MALT, appendix, and the spleen). 4. A blockage of the thoracic duct would impair the drainage of lymph from inferior to the diaphragm and from the left side of the head and thorax, retarding the return of lymph to the venous blood and promoting the accumulation of fluid in the limbs (lymphedema). 5. A lack of thymic hormones would drastically reduce the population of T lymphocytes by preventing their differentiation from lymphoid stem cells. 6. Lymph nodes enlarge during some infections because lymphocytes and phagocytes in the nodes multiply to defend against the infectious agent. **PAGE 802** 7. The body's innate (nonspecific) defenses include physical barriers, phagocytes, immune surveillance, interferons, complement, inflammation, and fever. 8. A decrease in the number of monocyte-forming cells in red bone marrow would result in fewer macrophages of all types, including Kupffer cells of the liver, dendritic (Langerhans) cells in the skin and digestive tract, and alveolar macrophages. 9. A rise in the level of interferon suggests a viral infection. Interferon does not help an infected cell, but "interferes" with the virus's ability to infect other cells. 10. Pyrogens increase body temperature (produce a fever) by stimulating the temperature control area of the preoptic nucleus of the hypo-**PAGE 805 11.** In cell-mediated (cellular) immunity, thalamus. T cells defend against abnormal cells and pathogens inside cells. In antibody-mediated (humoral) immunity, B cells secrete antibodies that defend against antigens and pathogens in body fluids. 12. The two forms of active immunity are naturally acquired active immunity and artificially induced active immunity; the two forms of passive immunity are naturally acquired passive immunity and artificially induced passive immunity. 13. The four general properties of adaptive immunity are specificity, versatility, memory, and tolerance. PAGE 809 14. The four major types of T cells are cytotoxic T (T_C) cells, memory T cells (both T_C and T_H), helper

T (T_H) cells, and suppressor T (T_S) cells. **15.** Abnormal peptides in the cytoplasm of a cell can become attached to MHC (major histocompatibility complex) proteins and then displayed on the surface of the cell's plasma membrane. The recognition of such displayed peptides by T cells can initiate an immune response. 16. A decrease in the number of cytotoxic T cells would affect cell-mediated immunity, reducing the effectiveness of T_C cells in killing foreign cells and virus-infected cells. 17. Without helper T cells-which promote B cell division, the maturation of plasma cells, and antibody production by plasma cells-the antibody-mediated immune response would probably not occur. PAGE 817 18. Sensitization is the process by which a B cell becomes able to react with a specific antigen. 19. Plasma cells produce and secrete antibodies, so observing an elevated number of plasma cells would lead us to expect increasing levels of antibodies in the blood. 20. An antibody molecule consists of two parallel pairs of polypeptide chains: one pair of heavy chains and one pair of light chains. Each chain contains both constant segments and variable segments. 21. Because production of a secondary response depends on the presence of memory B cells and memory T cells formed during a primary response, the secondary response would be more negatively affected by a lack of memory B cells for a particular antigen. PAGE 823 22. A developing fetus is protected primarily by natural passive immunity, through the maternal production of IgG antibodies that have crossed the placenta from the mother's bloodstream. 23. An autoimmune disorder is a condition that results when the immune system's sensitivity to normal cells and tissues causes the production of autoantibodies. 24. Stress can interfere with the immune response by depressing inflammation, reducing the number and activity of phagocytes, and inhibiting interleukin secretion. **PAGE 825** 25. Elderly people are more susceptible to viral and bacterial infections because the number of helper T cells declines with age and B cells are less responsive, so antibody levels rise more slowly after antigen exposure. 26. As one ages, immune surveillance declines, so cancerous cells are not eliminated as effectively. 27. Glucocorticoids released by the endocrine system have anti-inflammatory effects; thymic hormones stimulate the development and maturation of lymphocytes; and many hormones affect immune function. The thymus gland secretes thymic hormones, and cytokines affect cells throughout the body. **28.** The lymphatic system provides defenses against infection; performs immune surveillance to eliminate cancer cells; and returns tissue fluid to the circulation.

Answers to Review Questions

PAGE 828

Level 1 Reviewing Facts and Terms

1. (a) tonsil; (b) cervical lymph nodes; (c) right lymphatic duct;
(d) thymus; (e) cisterna chyli; (f) lumbar lymph nodes; (g) appendix; (h) lymphatics of lower limb; (i) lymphatics of upper limb;
(j) axillary lymph nodes; (k) thoracic duct; (l) lymphatics of mammary gland; (m) spleen; (n) mucosa-associated lymphoid tissue (MALT); (o) pelvic lymph nodes; (p) inguinal lymph nodes; (q) red bone marrow 2. b 3. d 4. c 5. c 6. c 7. a 8. c
9. d 10. d 11. c 12. (1) red bone marrow: maintain normal lymphocyte populations and other defense cells, such as monocytes and macrophages; (2) thymus: production of mature T cells and hormones that promote immune function; (3) spleen: filtration of blood, recycling of red blood cells, detection of blood-borne pathogens or toxins; (4) lymph nodes: filtration of lymph, detection of pathogens, initiation of immune response; (5) Lymphoid nodules, and MALT: defense of entrance and passageways of digestive tract

and protection of epithelia lining the respiratory, urinary, and reproductive tracts against pathogens and foreign proteins or toxins; (6) lymphatics: movement of lymph from interstitial spaces to the venous system 13. (a) lymphocytes responsible for cell-mediated immunity; (b) stimulate the activation and function of T cells and B cells; (c) inhibit the activation and function of both T cells and B cells; (d) produce and secrete antibodies; (e) recognize and destroy abnormal cells; (f) produce interleukin-7, which promotes the differentiation of B cells; (g) regulate T cell development and function.; (h) interfere with viral replication inside the cell and stimulate the activities of macrophages and NK cells; (i) reset the body's thermostat, causing a rise in body temperature (fever); (j) provide cell-mediated immunity, which defends against abnormal cells and pathogens inside cells; (k) provide humoral immunity, which defends against antigens and pathogens in the body (but not inside cells); (1) enhance innate (nonspecific) defenses and increase T cell sensitivity and stimulate B cell activity; (m) slow tumor growth and kill sensitive tumor cells; (n) stimulate the production of blood cells in the bone marrow and lymphocytes in lymphoid tissues and organs 14. (1) T cells, derived from the thymus; (2) B cells, derived from red bone marrow; and (3) NK cells, derived from red bone marrow 15. Innate (nonspecific) defenses: (1) physical barriers; (2) phagocytic cells; (3) immune surveillance; (4) interferons; (5) complement system; (6) inflammation; and (7) fever

Level 2 Reviewing Concepts

16. c **17.** c **18.** b **19.** b **20.** Complement can rupture the target cell's plasma membrane by releasing perforin, kill the target cell by secreting a cytotoxic lymphotoxin, or activate genes within the nucleus of the cell that stimulate programmed cell death (apoptosis). Interferon interferes with viral replication inside virus-infected cells by triggering the production of antiviral proteins. **21.** Cytotoxic T cells kill by rupturing the target cell's plasma membrane, by stimulating lymphotoxin secretion, or by activating genes in the nucleus that program cell death. 22. Formation of an antigen–antibody complex eliminates antigens by neutralization; by agglutination and precipitation: by activating complement: by attracting phagocytes: by opsonization; by stimulating inflammation; or by preventing bacterial and viral adhesion. 23. Innate immunity is genetically programmed; an example is immunity to fish diseases. Naturally acquired immunity develops after birth from contact with pathogens; an example is exposure to chickenpox in grade school. Artificially induced active immunity develops after intentional exposure to a pathogen; an example is administration of measles vaccine. Artificially induced passive immunity is temporary immunity provided by injection with antibodies produced in another organism, such as antibodies against rabies. Natural passive immunity is gained by acquiring antibodies from mother's milk or placental exchange. 24. The injections are timed to trigger the primary and secondary responses of the immune system. Upon first exposure to hepatitis antigens, B cells produce daughter cells that differentiate into plasma cells and memory B cells. The plasma cells begin producing antibodies, which represent the primary response to exposure. However, the primary response does not maintain elevated antibody levels for long periods, so the second and third injections are necessary to trigger secondary responses, when memory B cells differentiate into plasma cells and produce antibody concentrations that remain high much longer.

Level 3 Critical Thinking and Clinical Applications

25. Yes, the crime lab could determine whether the sample is blood plasma, which contains IgM, IgG, IgD, and IgE, or semen, which contains only IgA.26. Ted cannot yet know whether

he'll come down with the measles. Ted's elevated blood IgM level and titer indicates that he is in the early stages of a primary response to the measles virus. If his immune response proves unable to control and then eliminate the virus, Ted will develop the measles. **27.** In a radical mastectomy, lymph nodes in the nearby axilla and surrounding region are removed along with the cancerous breast to try to prevent the spread of cancer cells by the lymphatic system. Lymphatic vessels from the limb on the affected side are tied off, and because there is no place for the lymph to drain, over time lymphedema causes swelling of the limb. 28. A key characteristic of cancer cells is their ability to metastasize-to break free from a tumor and form new tumors in other tissues. The primary route of metastasis is the lymphatic system, including the lymph nodes. Examination of regional lymph nodes for the presence of cancer cells can help the physician determine if the cancer was caught in an early stage or whether it has started to spread to other tissues. 29. Allergies occur when allergens bind to specific IgE antibodies that are bound to the surface of mast cells and basophils. A person becomes allergic when they develop IgE antibodies for a specific allergen. Theoretically, at least, a molecule that would bind to the specific IgE for ragweed allergen and prevent the allergen from binding should help to relieve the signs and symptoms of the allergy.

Answers to Clinical Case Wrap-Up

PAGE 829 1. Innate immunity is genetically determined and present at birth. For example, skin and mucous membranes provide an innate physical and chemical barrier to infecting organisms. All humans are susceptible to chickenpox, an infectious disease. The immunity developed after a chickenpox vaccination is adaptive immunity, developed to a specific antigen, the varicella-zoster virus (VZV).
2. Baby Ruthie has developed life-long immunity to chickenpox as a result of having the disease. Her immune memory will provoke a secondary immune response if she is exposed to the varicella-zoster virus again. The recommended schedule (according to the Centers for Disease Control and Prevention, CDC) for varicella-zoster immunization is 12–15 months of age. However, there is no need for Ruthie to get a chickenpox vaccination after having had the disease.

Chapter 23

Answers to Checkpoints

PAGE 834 1. Functions of the respiratory system include providing an extensive surface area for gas exchange between blood and air, moving air to and from exchange surfaces, protecting exchange surfaces from environmental variations and pathogens, producing sounds, detecting olfactory stimuli, and indirectly assisting in blood volume regulation and blood pressure through the conversion of angiotensin I to angiotensin II. 2. The two anatomical divisions of the respiratory system are the upper respiratory system and the lower respiratory system. **3.** The respiratory mucosa lines the conducting portion of the respiratory tract. **PAGE 837** 4. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. 5. The rich vascularization to the nose delivers body heat to the nasal cavity, so inhaled air is warmed before it leaves the nasal cavity. The heat also evaporates moisture from the epithelium to humidify the incoming air. **6.** The lining of the nasopharynx, which receives air from only the nasal cavity, is the same as that of the nasal cavity: a pseudostratified ciliated columnar epithelium. Because the oropharynx and laryngopharynx receive air from the nasal cavity and potentially abrasive food from

the oral cavity, they have a more highly protective lining: a stratified squamous epithelium. **PAGE 839** 7. The paired cartilages are the arytenoid cartilages, corniculate cartilages, and cuneiform cartilages. The unpaired larvngeal cartilages include the thyroid cartilage, cricoid cartilage, and epiglottis. 8. The highly elastic vocal folds of the glottis are better known as the vocal cords. 9. When vocal fold tension increases, the pitch of the voice is raised. **PAGE 841** 10. The trachea conveys air between the larvnx and primary bronchi; cilia and the mucus produced by epithelial cells also protect the respiratory tree by trapping inhaled debris and sweeping it toward the pharynx, where it is removed through coughing or swallowing. **11.** The tracheal cartilages are C-shaped to allow space for expansion of the esophagus when food or liquid is swallowed. **12.** Objects are more likely to be lodged in the right bronchus because it is slightly larger and more vertical than the left bronchus. PAGE 847 13. Without surfactant, the alveoli would collapse as a result of surface tension in the thin layer of water that moistens the alveolar surfaces. **14.** Air passing through the glottis flows into the larvnx and through the trachea. From there, the air flows into a primary bronchus, which supplies the lungs. In the lungs, the air passes to bronchi, bronchioles, a terminal bronchiole, a respiratory bronchiole, an alveolar duct, an alveolar sac, an alveolus, and ultimately to the respiratory membrane. **15.** The pulmonary arteries supply the gas exchange surfaces; the external carotid arteries, the thyrocervical trunks, and the bronchial arteries supply the conducting portions of the respiratory system. **16.** The pleura is a serous membrane that secretes pleural fluid, which lubricates the opposing parietal and visceral surfaces to prevent friction during breathing.

PAGE 848 17. External respiration includes all the processes involved in the exchange of oxygen and carbon dioxide between the body's interstitial fluids and the external environment. Internal respiration is the absorption of oxygen and the release of carbon dioxide by the body's cells. **18.** The integrated steps involved in external respiration are pulmonary ventilation (breathing), gas diffusion, and the transport of oxygen and carbon dioxide.

PAGE 856 19. Compliance is the ease with which the lungs expand. Factors affecting compliance include (a) the connective tissue structure of the lungs, (b) the level of surfactant production, and (c) the mobility of the thoracic cage. **20.** The pulmonary volumes are tidal volume $(V_{\rm T})$, expiratory reserve volume (ERV), residual volume, and inspiratory reserve volume (IRV). **21.** When the rib penetrates Mark's chest wall, it also penetrates the pleural cavity, allowing atmospheric air to enter and increase the intrapleural pressure within the pleural cavity (a condition called pneumothorax). As a result, the natural elasticity of the lung may cause the lung to collapse, a condition called atelectasis. 22. Because the fluid produced in pneumonia takes up space that would normally be occupied by air, vital capacity would decrease. **PAGE 860** 23. Dalton's law states that each gas in a mixture exerts a pressure equal to its relative abundance. 24. Henry's law states that at a constant temperature, the quantity of a particular gas that will dissolve in a liquid is directly proportional to the partial pressure of that gas. PAGE 864 25. Carbon dioxide is transported in the bloodstream as carbonic acid, bound to hemoglobin, or dissolved in the plasma. **26.** During exercise, active skeletal muscles generate heat and acidic wastes. A combination of increased body temperature and decreased pH causes hemoglobin to release more oxygen when you are exercising than when you are resting. **27.** Blockage of the trachea would interfere with the body's ability to gain oxygen and eliminate carbon dioxide. Because most carbon dioxide is transported in blood as

bicarbonate ions formed from the dissociation of carbonic acid, an inability to eliminate carbon dioxide would result in an excess of hydrogen ions, which decreases blood pH. PAGE 873 **28.** Exciting the pneumotaxic centers would inhibit the inspiratory and apneustic centers, which would result in shorter and more rapid breaths. 29. Peripheral chemoreceptors are more sensitive to carbon dioxide levels than to oxygen levels. When carbon dioxide dissolves, it forms carbonic acid, which dissociates and releases hydrogen ions, thereby decreasing pH and altering cell or tissue activity. **30.** Johnny's mother shouldn't worry. When Johnny holds his breath, blood carbon dioxide levels increase, causing increased stimulation of the inspiratory center and forcing Johnny to breathe again. **31.** Aging results in deterioration of elastic tissue (reducing compliance), arthritic changes in rib articulations, decreased flexibility at costal cartilages, decreased vital capacity, and some degree of emphysema. PAGE 875 32. The respiratory system provides oxygen and eliminates carbon dioxide for all body systems. 33. The respiratory system provides alveolar phagocytes and respiratory defenses to trap pathogens and protect deeper tissues. Tonsils within the lymphatic system protect against respiratory infection, and lymph drainage from the lungs mobilizes defenses to ward off infection.

Answers to Review Questions

PAGE 878

Level 1 Reviewing Facts and Terms

1. d **2.** c **3.** a **4.** c **5.** c **6.** (a) nasal cavity; (b) pharynx; (c) right lung; (d) nose; (e) larynx; (f) trachea; (g) bronchus; (h) bronchioles; (i) left lung 7. Since the air Brad is breathing is dry, large amounts of moisture are leaving the mucus in his respiratory tract to humidify inhaled air. Drying makes the mucus tacky and makes it difficult for the cilia to move, so mucus builds up, producing nasal congestion by morning. When Brad showers and drinks fluids, body water is replaced, so the mucus loosens up and can be moved along as usual. 8. The upper respiratory system consists of the nose, nasal cavity, paranasal sinuses, and pharynx. The lower respiratory system consists of the larynx, trachea, bronchi, bronchioles, and alveoli of the lungs. 9. The regions of the pharynx are the superior nasopharynx, where the nasal cavity opens into the pharynx; the middle oropharynx, posterior to the oral cavity; and the inferior laryngopharynx, which is posterior to the hyoid bone and glottis. 10. The thyroid cartilage forms the anterior walls of the larynx; the cricoid cartilage protects the glottis and the entrance to the trachea; the epiglottis forms a lid over the glottis; the arytenoid cartilages and the corniculate cartilages are involved in the formation of sound; and the cuneiform cartilages are found in the folds of the larynx. 11. The steps of external respiration are (a) pulmonary ventilation (breathing); (b) gas diffusion across the respiratory membrane and between blood and interstitial fluids; and (c) the transport of oxygen and carbon dioxide between alveolar and peripheral capillaries. 12. Fetal hemoglobin has a higher affinity for oxygen than does adult hemoglobin. Thus, it binds more of the oxygen that is present, enabling it to "steal" oxygen from the maternal hemoglobin. **13.** Carbon dioxide is transported in the blood as carbonic acid, bound to hemoglobin, and dissolved in the plasma.

Level 2 Reviewing Concepts

14. c 15. d 16. c 17. b 18. The nasal cavity cleanses, moistens, and warms inhaled air, whereas the mouth does not. Drier air entering through the mouth can irritate the trachea and cause throat soreness. 19. Smooth muscle tissue in the walls of

bronchioles allows changes in airway diameter (bronchodilation or bronchoconstriction), which provides control of the flow and distribution of air within the lungs, just as vasodilation and vasoconstriction of the arterioles control blood flow and blood distribution. 20. Type II pneumocytes (type II alveolar cells) produce surfactant, which reduces surface tension in the fluid coating the alveolar surface. Without surfactant, the surface tension would be so high that the delicate alveoli would collapse. **21.** Pulmonary ventilation, the physical movement of air into and out of the respiratory tract, maintains adequate alveolar ventilation. Alveolar ventilation, air movement into and out of the alveoli, prevents the buildup of carbon dioxide in the alveoli and ensures a continuous supply of oxygen that keeps pace with absorption by the bloodstream. 22. (a) Boyle's law describes the inverse relationship between gas pressure and volume: If volume decreases, pressure rises; if volume increases, pressure falls. It is the basis for the direction of air movement in pulmonary ventilation. (b) Dalton's law states that each of the gases that make up a mixture of gases contributes to the total pressure in proportion to its relative abundance; that is, all the partial pressures added together equal the total pressure exerted by the gas mixture. This relationship is the basis for the calculation of the partial pressures of oxygen and carbon dioxide, and their exchange between blood and alveolar air. (c) Henry's law states that, at a given temperature, the amount of a particular gas that dissolves in a liquid is directly proportional to the partial pressure of that gas. Henry's law underlies the diffusion of gases between capillaries, alveoli, and interstitial fluid. **23.** Both sneezing and coughing involve a temporary cessation of respiration, known as apnea. 24. Pulmonary volumes are determined experimentally and include tidal volume (averaging 500 mL), expiratory reserve volume (approximately 1200 mL), residual volume (averaging 1200 mL), minimal volume (30–120 mL), and inspiratory reserve volume (approximately 3600 mL). Respiratory capacities include inspiratory capacity, functional residual capacity, vital capacity, and total lung capacity. The difference between the two measures is that respiratory capacities are the sums of various pulmonary volumes. **25.** The DRG is the inspiratory center that contains neurons that control lower motor neurons innervating the external intercostal muscles and the diaphragm. The DRG functions in every respiratory cycle, whether quiet or forced. The VRG functions only during forced respiration-active exhalation and maximal inhalation. The neurons involved with active exhalation are sometimes said to form an expiratory center.

Level 3 Critical Thinking and Clinical Applications

26. AVR = respiratory rate \times (tidal volume – dead space). In this case, the dead air space is 200 mL (the anatomical dead air space plus the volume of the snorkel); therefore, AVR = respiratory rate \times (500 - 200). To maintain an AVR of 6.0 L/min, or 6000 mL/min, the respiratory rate must be 6000/(500 - 200), or 20 breaths per minute. 27. A person with chronic emphysema has constantly elevated blood levels of P_{CO2} due to an inability to eliminate CO₂ efficiently because of physical damage to the lungs. Over time, the brain ignores the stimulatory signals produced by the increased CO₂ and begins to rely on information from peripheral chemoreceptors to set the pace of breathing. (In other words, accommodation has occurred.) The peripheral chemoreceptors also accommodate to the elevated CO₂ and respond primarily to the level of O₂ in the blood, increasing breathing when O₂ levels are low and decreasing breathing when O₂ levels are high. When pure O₂ was administered, chemoreceptors responded with fewer

action potentials to the medulla oblongata, so Mr. B. stopped breathing. 28. Cary's hyperventilation resulted in abnormally low P_{CO2}. This reduced his urge to breathe, so he stayed underwater longer, unaware that his PO2 was dropping to the point of loss of consciousness. 29. In anemia, the blood's ability to carry oxygen is decreased due to the lack of functional hemoglobin, red blood cells, or both. Anemia does not interfere with the exchange of carbon dioxide within the alveoli, nor with the amount of oxygen that will dissolve in the plasma. Because chemoreceptors respond to dissolved gases and pH, as long as the pH and the concentrations of dissolved carbon dioxide and oxygen are normal, ventilation patterns should not change significantly. 30. The obstruction in Doris's right lung would prevent gas exchange. Thus, blood moving through the right lung would not be oxygenated and would retain carbon dioxide, which would lead to a lower blood pH than that of blood leaving the left lung. The lower pH for blood in the right lung would shift the oxygen-hemoglobin saturation curve to the left (the Bohr effect) as compared with the curve for the left lung.

Answers to Clinical Case Wrap-Up

PAGE 879 1. Andrea's cough is serving a good purpose. As she expels the irritating mucus, she is also expelling the virus. This is a good thing and should not be suppressed. She should, however, be very careful to use tissues to cover her cough and dispose of the infective mucus. **2.** Andrea's nose (runny), pharynx (sore throat), trachea, and bronchi (productive cough) seem to be infected by this virus. Her bronchioles are likely infected as well.

Chapter 24

Answers to Checkpoints

PAGE 889 1. Organs of the digestive system include the oral cavity, pharynx, esophagus, stomach, small intestine, large intestine, and accessory organs (teeth, tongue, gallbladder, salivary glands, liver, and pancreas). 2. The six primary functions of the digestive system include the following: (1) ingestion = consciously eating food; (2) mechanical processing = crushing and shearing foodstuffs to make them more susceptible to enzymatic attack; (3) digestion = the chemical breakdown of food into smaller products for absorption; (4) secretion = the release of water, acids, and other substances by (4)the epithelium of the digestive tract and by glandular organs; (5) absorption = movement of digested particles across the digestive epithelium and into the interstitial fluid of the digestive tract; and (6) excretion = the removal of waste products from the body. **3.** The mesenteries-sheets consisting of two layers of serous membrane connected by their loose connective tissue-support and stabilize the organs in the abdominopelvic cavity and provide a route for the associated blood vessels, nerves, and lymphatic vessels. 4. The layers of the gastrointestinal tract, beginning at the surface of the lumen are the mucosa (adjacent to the lumen), submucosa, muscularis externa, and serosa.

5. The waves of contractions responsible for peristalsis are more efficient in propelling intestinal contents than segmentation, which is basically a churning action that mixes intestinal contents with digestive fluids.
6. A drug that blocks parasympathetic stimulation, which increases muscle tone and activity in the digestive tract, would slow peristalsis.
PAGE 893 7. Structures associated with the oral cavity include the tongue, salivary glands, and teeth.
8. Stratified squamous epithelium lines the oral cavity. It protects

against friction or abrasion by food. 9. Damage to the parotid salivary glands, which secrete the carbohydrate-digesting enzyme salivary amylase, would interfere with the digestion of complex carbohydrates. 10. The incisors are the teeth most useful for chopping (or cutting or shearing) pieces of relatively rigid food, such as raw vegetables. **11.** The fauces are the dividing line between the oral cavity and the pharynx. **PAGE 895** 12. The pharynx is an anatomical space that receives a food bolus or liquids and passes them to the esophagus as part of the swallowing process. Air also passes through the pharynx. **13.** Muscles associated with the pharynx are pharyngeal constrictor muscles, the palatopharyngeus and stylopharyngeus muscles, and palatal muscles. **PAGE 897** 14. The structure connecting the pharynx to the stomach is the esophagus. 15. The muscularis externa of the esophagus is an unusual segment of the digestive tract because it (1) contains skeletal muscle cells along most of the length of the esophagus and (2) is surrounded by an adventitia rather than a serosa. 16. When the soft palate and larynx elevate and the glottis closes, swallowing (deglutition) is oc-**PAGE 901** 17. The four regions of the stomach are the curring. cardia, fundus, body, and pylorus. **18.** The low pH of the stomach creates an acidic environment that kills most microorganisms ingested with food, denatures proteins and inactivates most enzymes in food, helps break down plant cell walls and meat connective tissue, and activates pepsin. 19. Large meals, especially meals with a high protein content, stimulate increased stomach acid secretion. When gastric glands are secreting, bicarbonate ions enter the bloodstream and increase the blood pH. This phenomenon is referred to as the alkaline tide. **20.** The vagus nerves contain parasympathetic motor fibers that can stimulate gastric secretions, even if food is not present in the stomach (the cephalic phase of gastric digestion). Cutting the branches of the vagus nerves that supply the stomach would prevent this type of secretion from occurring and thereby reduce the likelihood of ulcer formation. **PAGE 915** 21. The three regions of the small intestine are the duodenum, jejunum, and ileum. 22. The small intestine has several adaptations that increase its surface area and thus its absorptive capacity for nutrients. The walls of the small intestine have folds called the circular folds (plicae circulares). The tissue that covers the circular folds forms fingerlike projections, the villi. The epithelial cells that cover the villi have an exposed surface covered by small fingerlike projections, the microvilli. In addition, the small intestine has a very rich supply of blood vessels and lymphatic vessels, which transport the nutrients that are absorbed. 23. A high-fat meal would raise the cholecystokinin level in the blood. 24. The hormone secretin, among other things, stimulates the pancreas to release fluid high in buffers to neutralize the chyme that enters the duodenum from the stomach. If the small intestine did not produce secretin, the pH of the intestinal contents would be lower than normal. **25.** Damage to the exocrine pancreas would most impair the digestion of fats (lipids), because it is the primary source of lipases. Even though such damage would also reduce carbohydrate and protein digestion, enzymes for digesting these nutrients are produced by other digestive system structures, including the salivary glands (carbohydrates), the small intestine (carbohydrates and proteins), and the stomach (proteins). **PAGE 922** 26. The four regions of the colon are the ascending colon, transverse colon, descending colon, and sigmoid colon. 27. The large intestine is larger in diameter than the small intestine. The thin walls of the large intestine lack villi and have an abundance of mucous cells and intestinal glands. **28.** In haustral churning, segmentation movements mix the contents of nearby haustra. In mass movements, which occur a few

times per day, strong peristaltic contractions move material from the transverse colon through the rest of the large intestine.

PAGE 928 29. The nutrients the body requires are carbohydrates, lipids, proteins, vitamins, minerals, and water. **30.** Because chylomicrons are formed from the fats digested in a meal, fats increase the number of chylomicrons in the lacteals. **31.** Removal of the stomach would interfere with the absorption of vitamin B₁₂. Parietal cells of the stomach are the source of intrinsic factor, which is required for the vitamin's absorption. **32.** When someone with diarrhea loses fluid and electrolytes faster than they can be replaced, the resulting dehydration can be fatal. Although constipation can be quite uncomfortable, it does not interfere with any life-supporting processes; the few toxic wastes normally eliminated by the digestive system can move into the blood and be eliminated by the kidneys. 33. General age-related digestive system changes include decreased secretory mechanisms, decreased gastric and intestinal motility, decreased mitotic activity of epithelial cells, and loss of muscle tone associated with tract sphincters; cumulative damage becomes more apparent, cancer rates increase, and dehydration occurs as a result of decreased osmoreceptor sensitivity. **34.** The digestive system absorbs the organic substrates, vitamins, ions, and water required by cells of all other body systems. 35. The skeletal, muscular, nervous, endocrine, and cardiovascular systems may all be affected by inadequate absorption of calcium.

Answers to Review Questions

PAGE 932

Level 1 Reviewing Facts and Terms

1. d **2.** a **3.** d **4.** c **5.** (a) oral cavity (mouth); (b) liver; (c) gallbladder; (d) pancreas; (e) large intestine; (f) salivary glands; (g) pharynx; (h) esophagus; (i) stomach; (j) small intestine; (k) anus 6. (a) mucosa; (b) submucosa; (c) muscularis externa; (d) serosa 7. e 8. a 9. a 10. (a) duodenum; (b) jejunum; (c) ileum 11. d 12. c 13. a 14. The six main functions of the digestive system are: (1) ingestion; (2) mechanical processing; (3) secretion; (4) digestion (conversion into a form usable by cells); (5) absorption; and (6) excretion. 15. Layers of the digestive tract from the innermost layer nearest the lumen to the outermost layer are (1) the mucosa: the epithelial layer that performs chemical digestion and absorption of nutrients; (2) the submucosa: the connective tissue layer containing lymphatic and blood vessels and the submucosal nerve plexus; (3) the muscularis externa: the smooth muscle layer containing the myenteric nerve plexus; and (4) the serosa: the outermost layer, epithelium and connective tissue that forms the visceral peritoneum (or connective tissue that forms the adventitia). 16. Activities of the digestive tract are regulated by local, hormonal, and neural mechanisms. 17. The three phases of swallowing-the buccal, pharyngeal, and esophageal phases-are controlled by the swallowing center of the medulla oblongata by the trigeminal and glossopharyngeal cranial nerves. The motor commands originating at the swallowing center are distributed by cranial nerves V, IX, X, and XII. Along the esophagus, primary peristaltic contractions are coordinated by afferent and efferent fibers within the glossopharyngeal and vagus cranial nerves, but secondary peristaltic contractions occur in the absence of CNS instructions. 18. The pancreas provides digestive enzymes, plus bicarbonate ions that elevate the pH of the chyme. The liver produces bile and is also the primary organ involved in regulating the composition of circulating blood. The gallbladder stores and releases bile, which contains additional buffers and bile salts that aid in the digestion and absorption of lipids. 19. The hormones include the

following: enterocrinin, which stimulates the submucosal glands of the duodenum; secretin, which stimulates the pancreas and liver to increase the secretion of water and bicarbonate ions; cholecystokinin (CCK), which causes an increase in the release of pancreatic secretions and bile into the duodenum, inhibits gastric activity, and appears to have CNS effects that reduce the sensation of hunger; gastric inhibitory peptide (GIP), which stimulates insulin release at pancreatic islets and the activity of the duodenal submucosal glands; vasoactive intestinal peptide (VIP), which stimulates the secretion of intestinal glands, dilates regional capillaries, and inhibits acid production in the stomach; gastrin, which is secreted by G cells in the duodenum when they are exposed to large quantities of incompletely digested proteins; and, in small quantities, motilin, which stimulates intestinal contractions, villikinin, which promotes the movement of villi and associated lymph flow, and somatostatin, which inhibits gastric secretion. 20. The large intestine reabsorbs water and compacts the intestinal contents into feces, absorbs important vitamins liberated by bacterial action, and stores fecal material prior to defecation. **21.** Positive feedback loops in the defecation reflex involve (1) stretch receptors in the rectal walls, which promote a series of peristaltic contractions in the colon and rectum, moving feces toward the anus; and (2) the sacral parasympathetic system, also activated by the stretch receptors, which stimulates peristalsis by motor commands distributed by the pelvic nerves.

Level 2 Reviewing Concepts

22. e 23. e 24. a 25. A root canal involves drilling through the enamel and the dentin. 26. The stomach is protected from digestion by mucous secretions of its epithelial lining and by neural and hormonal control over the times and rates of acid secretion. **27.** (1) The cephalic phase of gastric secretion begins with the sight or thought of food. Directed by the CNS, this phase prepares the stomach to receive food. (2) The gastric phase begins with the arrival of food in the stomach; this phase is initiated by distension of the stomach, an increase in the pH of the gastric contents, and the presence of undigested materials in the stomach. (3) The intestinal phase begins when chyme starts to enter the small intestine. This phase controls the rate of gastric emptying and ensures that the secretory, digestive, and absorptive functions of the small intestine can proceed reasonably efficiently. 28. After a heavy meal, bicarbonate ions pass from the parietal cells of the stomach into the interstitial fluid. The diffusion of bicarbonate ions from the interstitial fluid into the bloodstream increases blood pH. This sudden influx of bicarbonate ions into the bloodstream has been called the alkaline tide.

Level 3 Critical Thinking and Clinical Applications

29. If a gallstone is small enough, it can pass through the common bile duct and block the pancreatic duct. Enzymes from the pancreas then cannot reach the small intestine. As the enzymes accumulate, they irritate the duct and ultimately the exocrine pancreas, producing pancreatitis. **30.** The darker color of his urine is probably due to increased amounts of the pigment urobilin, which gives urine its normal yellow color. Urobilin is derived from urobilinogen, which is formed in the large intestine by the action of intestinal bacteria on bile pigments. In an intestinal obstruction, the bile pigments cannot be eliminated by their normal route, so a larger-thannormal amount diffuses into the bloodstream, where the kidneys eliminate it. **31.** If an individual cannot digest lactose, this sugar passes into the large intestine in an undigested form. The presence of extra sugar in the chyme increases its osmolarity, so less water is reabsorbed by the intestinal mucosa. The bacteria that inhabit the large intestine can metabolize the lactose, and in the process they

produce large amounts of carbon dioxide. This gas overstretches the intestine, which stimulates local reflexes that increase peristalsis. The combination of more-fluid contents and increased peristalsis causes diarrhea. The overexpansion of the intestine by gas, which is directly related to increased gas production by the bacteria, causes the severe pain and abdominal cramping. **32.** The primary effect of such surgeries would be a reduction in the volume of food (and thus in the amount of calories) consumed because the person feels full after eating a small amount. This can result in significant weight loss.

Answers to Clinical Case Wrap-Up

PAGE 934 1. If Mirasol's *Clostridium difficile* colitis is not successfully treated with a fecal transplant, she is likely to continue to experience bloody diarrhea. This may result in progressive dehydration that can eventually lead to her death. She may also continue to experience abdominal pain and blood loss. Eventually she may suffer from a lack of vitamin K (required for clotting factor production), biotin, and vitamin B_5 . **2.** If you could look at the lining of Mirasol's large intestine with a colonoscope, the surface would look inflamed, swollen, reddened. You would likely see areas of raw, bleeding mucosa. You might even see areas of white cells, accumulated in pockets of pus, as Mirasol's immune system tries to fight this *C. difficile* infection.

Chapter 25

Answers to Checkpoints

PAGE 938 1. Metabolism is the sum of all biochemical processes under way within the human body; it includes anabolism and catabolism. 2. Catabolism is the breakdown of organic molecules into simpler components, accompanied by the release of energy. 3. Anabolism is the synthesis of new organic molecules from simpler components, and it requires energy. PAGE 947 **4.** The primary role of the citric acid cycle in ATP production is to transfer electrons from substrates to coenzymes. These electrons provide energy for the production of ATP by the electron transport system. 5. The NADH produced by glycolysis cannot enter the mitochondria, where the enzymes of the electron transport chain are located. However, an intermediary in the mitochondrial membrane can transfer the electrons from the NADH to a coenzyme within the mitochondria. In skeletal muscle cells, the intermediary transfers the electrons to FAD, whereas cardiac muscle cells use a different intermediary, which transfers the electrons to another NAD. In mitochondria, each NADH yields 3 molecules of ATP, whereas each FADH₂ yields just 2 molecules of ATP. The different intermediaries account for the difference in ATP yield. **6.** A decrease in cytosolic NAD would reduce ATP production in mitochondria. Decreased NAD would reduce the amount of pyruvate produced by glycolysis; less pyruvate means that the citric acid cycle could produce less ATP in mitochondria. **PAGE 952** 7. Beta-oxidation is fatty acid catabolism that produces molecules of acetyl-CoA. 8. The five major groups of lipoproteins are chylomicrons, very low density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). 9. High-density lipoproteins (HDLs) are considered beneficial to health because they reduce the amount of fat (including cholesterol) in the bloodstream by transporting it to the liver for storage or excretion in the bile. **PAGE 956** 10. Transamination is the transfer of an amino group from one molecule to another, especially from an amino acid to a keto acid. 11. Deamination is

the removal of an amino group from an amino acid. **12.** A diet deficient in pyridoxine (vitamin B_6), an important coenzyme in deaminating and transaminating amino acids in cells, would interfere with the body's ability to metabolize proteins. **PAGE 957 13.** Glycogenesis (the formation of glycogen) in the liver increases after a high-carbohydrate meal. 14. Blood levels of urea increase during the postabsorptive state because the deamination of many amino acids at that time yields ammonium ions, which are then converted to urea by the liver. **15.** Accumulated acetyl-CoA is likely to be converted into ketone bodies. **PAGE 961** 16. The two classes of vitamins are fat-soluble and water-soluble. 17. An athlete who is adding muscle mass through extensive training would try to maintain a positive nitrogen balance. **18.** A decrease in the amount of bile salts, which are necessary for digesting and absorbing fats and fat-soluble vitamins (including vitamin A). would result in less vitamin A in the body, and perhaps a vitamin A deficiency. **PAGE 968** 19. The BMR of a pregnant woman would be higher than her own BMR when she is not pregnant, due to both the increased metabolism associated with supporting the fetus and the contribution of fetal metabolism **20**. The vasoconstriction of peripheral vessels would decrease blood flow to the skin and thus the amount of heat the body can lose. As a result, body temperature would increase. **21.** Infants have higher surface-to-volume ratios than do adults, and the body's temperature-regulating mechanisms are not fully functional at birth. As a result, infants must expend more energy to maintain body temperature, and they get cold more easily than do healthy adults.

Answers to Review Questions

PAGE 970

Level 1 Reviewing Facts and Terms

1. d 2. e 3. d 4. a 5. b 6. d 7. (a) fatty acids; (b) glucose; (c) amino acids; (d) two-carbon chains; (e) citric acid cycle; (f) CO_2 ; (g) ATP; (h) electron transport system; (i) H_2O **8.** a **9.** Lipoproteins are lipid–protein complexes that contain large insoluble glycerides and cholesterol, with a superficial coating of phospholipids and proteins. The major groups are chylomicrons, which consist of 95 percent triglyceride, are the largest lipoproteins, and carry absorbed lipids from the intestinal tract to the bloodstream; very low density lipoproteins (VLDLs), which consist of triglyceride, phospholipid, and cholesterol, and transport triglycerides to peripheral tissues; intermediate-density lipoproteins (IDLs), which are intermediate in size and composition between VLDLs and LDLs; low-density lipoproteins (LDLs, or "bad cholesterol"), which are mostly cholesterol and deliver cholesterol to peripheral tissues; and high-density lipoproteins (HDLs, or "good cholesterol"), which are equal parts protein and lipid (cholesterol and phospholipids) and transport excess cholesterol to the liver for storage or excretion in bile.

Level 2 Reviewing Concepts

10. Oxidative phosphorylation is the generation of ATP within mitochondria, through a process called chemiosmosis that requires coenzymes, ATP synthase, and consumes oxygen. The electron transport system consists of a sequence of metal ion–containing proteins (metalloproteins) called cytochromes, embedded in the inner mitochondrial membrane. Energy from the stepwise passage of electrons (from H atoms) along the cytochrome molecules is used to pump hydrogen ions from the matrix into the intermembrane space. This forms a proton gradient across the inner mitochondrial membrane. The hydrogen ions diffuse back through ATP synthase

ANSWERS

and generate ATP. The electrons, hydrogen ions, and oxygen combine to produce water as a byproduct. **11.** In lipid catabolism, a triglyceride is hydrolyzed, yielding glycerol and fatty acids. Glycerol is converted to pyruvate and enters the citric acid cycle. Fatty acids are broken into 2-carbon fragments by beta-oxidation inside mitochondria. The 2-carbon compounds then enter the citric acid cycle. 12. During the absorptive state, insulin prevents a large surge in blood glucose after a meal by causing the liver to remove glucose from the hepatic portal circulation. During the postabsorptive state, blood glucose begins to decline, triggering the liver to release glucose produced through glycogenolysis and gluconeogenesis. 13. Liver cells can break down or synthesize most carbohydrates, lipids, and amino acids. Because the liver has an extensive blood supply, it can easily monitor blood composition of these nutrients and regulate them accordingly. The liver also stores energy in the form of glycogen. 14. Vitamins and minerals are essential components of the diet because the body cannot synthesize most of the vitamins and minerals it requires. 15. These terms refer to lipoproteins in the blood that transport cholesterol. "Good cholesterol" (high-density lipoproteins, or HDLs) transports excess cholesterol to the liver for storage or breakdown, whereas "bad cholesterol" (lowdensity lipoproteins, or LDLs) transports cholesterol to peripheral tissues, which unfortunately may include the arteries. The buildup of cholesterol in the arteries is linked to cardiovascular disease.

Level 3 Critical Thinking and Clinical Applications

16. c **17.** Based just on the information given, Charlie would appear to be in good health, at least relative to his diet and probable exercise. Problems are associated with elevated levels of LDLs, which carry cholesterol to peripheral tissues and make it available for the formation of atherosclerotic plaques in blood vessels. High levels of HDLs indicate that a considerable amount of cholesterol is being removed from the peripheral tissues and carried to the liver for disposal. You would encourage Charlie not to change, and keep up the good work. **18.** It appears that Jill is suffering from ketoacidosis as a consequence of her anorexia. Because she is literally starving herself, her body is metabolizing large amounts of fatty acids and amino acids to provide energy, and in the process is producing large quantities of ketone bodies (normal metabolites from these catabolic processes). One of the ketones formed is acetone, which can be eliminated through the lungs. Acetone has a fruity aroma, so her breath would also smell fruity. The ketones are also converted into keto acids such as acetic acid. In large amounts, this lowers the body's pH. This is probably the cause of her arrhythmias.

Answers to Clinical Case Wrap-Up

PAGE 971 1. Diet and vitamin supplementation are the only known sources of vitamin A. Unlike some other vitamins that can be made by our skin (vitamin D_3) or by intestinal bacteria (vitamin K, Biotin $[B_7]$, Pantothenic acid $[B_5]$), vitamin A is a true *essential* vitamin that must be consumed orally. **2.** Justine's vitamin-deficient diet is likely to lead to deficiencies of all the fat-soluble and water-soluble vitamins, including D, E, K, all the B vitamins, and vitamin C.

Chapter 26

Answers to Checkpoints

PAGE 974 1. The major functions of the urinary system include (1) the excretion of organic wastes from body fluids, (2) the elimination of body wastes to the exterior, and (3) the regulation of homeostasis by maintaining the volume and solute concentration

of blood. 2. The urinary system consists of two kidneys, two ureters, a bladder, and a urethra. **3.** Micturition, or urination, is the elimination of urine from the body. **PAGE 983** 4. The renal corpuscle, proximal convoluted tubule, distal convoluted tubule, and the proximal portions of the nephron loop and collecting duct are all in the renal cortex. (In a cortical nephron, most of the nephron loop is in the cortex; in a juxtamedullary nephron, most of the nephron loop is in the medulla.) **5.** Plasma proteins are too large to pass through the pores of the glomerular capillaries: only the smallest plasma proteins can pass through the filtration slits of the podocytes. 6. Damage to the juxtaglomerular complex of a nephron would interfere with the hormonal control of blood pressure. **PAGE 987** 7. The three distinct processes that form urine in the kidney are filtration, reabsorption, and secretion. 8. When the plasma concentration of a substance exceeds its tubular maximum, the excess is not reabsorbed, so it is excreted in the **PAGE 992 9.** The primary nephron structures involved urine in filtration are the glomerular capillaries, the dense layer, and the filtration slits of the podocytes. **10.** The factors that influence net filtration pressure are net hydrostatic pressure and blood colloid osmotic pressure. **11.** The factors that influence the rate of filtrate formation are the filtration pressure across glomerular capillaries, plus interactions among autoregulation, hormonal regulation, and autonomic regulation. 12. A decrease in blood pressure would decrease the GFR by decreasing the blood hydrostatic pressure within the glomerulus. **PAGE 1004** 13. Increased amounts of aldosterone, which promotes Na⁺ retention and K⁺ secretion by the kidneys, would increase the K⁺ concentration of urine. **14.** If the concentration of Na⁺ in the filtrate decreased, fewer hydrogen ions could be secreted by the countertransport mechanism involving these two ions. As a result, the pH of the tubular fluid would increase. 15. Without juxtamedullary nephrons, a large osmotic gradient could not exist in the medulla, and the kidneys would be unable to form concentrated urine. 16. When the amount of Na⁺ in the tubular fluid passing through the distal convoluted tubule decreases, the cells of the macula densa are stimulated to release renin. The resulting activation of angiotensin II increases blood pressure. **PAGE 1009** 17. Digestion of a high-protein diet would lead to increased production of urea, a nitrogenous waste formed from the metabolism of amino acids during the breakdown of proteins. As a result, the urine would contain more urea, and urine volume might also increase as a result of the need to flush the excess urea. 18. An obstruction of a ureter would interfere with the passage of urine between the renal pelvis and the urinary bladder. 19. The ability to control the micturition reflex depends on the ability to control the external urethral sphincter, a ring of skeletal muscle formed by the urogenital diaphragm, which acts as a valve. **20.** Four general age-related changes in the urinary system are a decrease in the number of functional nephrons, a reduction in the GFR, a reduced sensitivity to ADH, and problems with the micturition reflex. 21. Nephrolithiasis is the formation of renal calculi, or kidney stones. 22. Incontinence may develop in elderly individuals as a result of either decreased muscle tone of sphincter muscles controlling micturition or disorders of the CNS affecting the ability to control urination. **PAGE 1011** 23. For all systems, the urinary system excretes wastes collected from blood and maintains normal body fluid pH and ion composition. 24. Body systems that make up the body's excretory system include the urinary, integumentary, respiratory, and digestive systems.

Answers to Review Questions

PAGE 1013

Level 1 Reviewing Facts and Terms

1. (a) renal sinus; (b) renal pelvis; (c) hilum; (d) renal papilla; (e) ureter; (f) renal cortex; (g) renal medulla; (h) renal pyramid; (i) minor calyx; (j) major calyx; (k) kidney lobe; (l) renal columns; (m) fibrous capsule 2. a 3. e 4. c 5. d 6. d 7. The urinary system performs vital excretory functions and eliminates the organic wastes generated by cells throughout the body. It also regulates the volume and solute concentration of body fluids. 8. The kidneys, ureters, urinary bladder, and urethra are the organs of the urinary system. 9. renal corpuscle (glomerulus/glomerular capsule) \rightarrow proximal convoluted tubule \rightarrow nephron loop \rightarrow distal convoluted tubule \rightarrow collecting duct \rightarrow papillary duct \rightarrow renal pelvis **10.** proximal convoluted tubule: reabsorbs all the useful organic substrates from the filtrate; nephron loop: reabsorbs over 90 percent of the water in the filtrate; and distal convoluted tubule: secretes wastes into the tubular fluid that were not filtered or reabsorbed **11.** The juxtaglomerular complex secretes the enzyme renin and the hormone erythropoietin. **12.** renal artery \rightarrow segmental arteries \rightarrow interlobar arteries \rightarrow arcuate arteries \rightarrow cortical radiate arteries \rightarrow afferent arterioles \rightarrow glomerulus \rightarrow venules \rightarrow cortical radiate veins \rightarrow arcuate veins \rightarrow interlobar veins \rightarrow renal vein 13. Processes in urine production are (1) filtration: the selective removal of large solutes and suspended materials from a solution on the basis of size; requires a filtration membrane and hydrostatic pressure, as provided by gravity or by blood pressure; (2) reabsorption: the removal of water and solute molecules from the filtrate after it enters the renal tubules; and (3) secretion: the transport of solutes from the peritubular fluid, across the tubular epithelium, and into the tubular fluid 14. In peripheral capillary beds, angiotensin II causes powerful vasoconstriction of precapillary sphincters, increasing pressures in the renal arteries and their branches. At the nephron, angiotensin II causes the efferent arteriole to constrict, increasing glomerular pressures and filtration rates. At the PCT, it stimulates the reabsorption of sodium ions and water. In the CNS, angiotensin II triggers the release of ADH, stimulating the reabsorption of water in the distal portion of the DCT and the collecting system, and it causes the sensation of thirst. At the adrenal gland, angiotensin II stimulates the secretion of aldosterone by the cortex. Aldosterone accelerates sodium reabsorption in the DCT and the cortical portion of the collection system. 15. Structures responsible for the transport, storage, and elimination of urine are the ureters, urinary bladder, and urethra.

Level 2 Reviewing Concepts

16. d **17.** d **18.** c **19.** a **20.** a **21.** Proteins are excluded from filtrate because they are too large to fit through the filtration slits between adjacent pedicels. Keeping proteins in the plasma ensures that blood colloid osmotic pressure will oppose filtration and return water to the plasma. **22.** Controls on GFR are autoregulation at the local level, hormonal regulation initiated by the kidneys, and autonomic regulation (by the sympathetic division of the ANS). **23.** As a result of facilitated diffusion and cotransport mechanisms in the PCT, 99 percent of the glucose, amino acids, and other nutrients are reabsorbed before the filtrate leaves the PCT. A reduction of the solute concentration of the tubular fluid occurs due to active ion reabsorption of sodium, potassium, calcium, magnesium, bicarbonate, phosphate, and sulfate ions. The passive diffusion of urea, chloride ions, and lipid-soluble materials further reduces the solute concentration of the tubular fluid and promotes

additional water reabsorption. **24.** Countercurrent multiplication (1) is an efficient way to reabsorb solutes and water before the tubular fluid reaches the DCT and collecting system, and (2) establishes a concentration gradient that permits the passive reabsorption of water from urine in the collecting system. **25.** The urge to urinate usually appears when the urinary bladder contains about 200 mL of urine. The micturition reflex begins to function when the stretch receptors have provided adequate stimulation to the parasympathetic motor neurons. The activity in the motor neurons generates action potentials that reach the smooth muscle in the wall of the urinary bladder. These efferent impulses travel over the pelvic nerves, producing a sustained contraction of the urinary bladder.

Level 3 Critical Thinking and Clinical Applications

26. d **27.** c **28.** Increasing the volume of urine produced decreases the total blood volume of the body, which in turn leads to a decreased blood hydrostatic pressure. Edema frequently results when the hydrostatic pressure of the blood exceeds the opposing forces at the capillaries in the affected area. Depending on the actual cause of the edema, decreasing the blood hydrostatic pressure would decrease edema formation and possibly cause some of the fluid to move from the interstitial spaces back to the blood. 29. Renal arteriosclerosis restricts blood flow to the kidneys and produces renal ischemia. Decreased blood flow and ischemia triggers the juxtaglomerular complex to produce more renin, which leads to elevated levels of angiotensin II and aldosterone. Angiotensin II causes vasoconstriction, increased peripheral resistance, and thus increased blood pressure. The aldosterone promotes sodium retention, which leads to more water retained by the body and an increase in blood volume. This too contributes to a higher blood pressure. Additionally, in response to tissue hypoxia, erythropoietin release is increased, stimulating the formation of red blood cells, which leads to increased blood viscosity and again contributes to hypertension. **30.** Because mannitol is filtered but not reabsorbed, drinking a mannitol solution would lead to an increase in the osmolarity of the filtrate. Less water would be reabsorbed, and an increased volume of urine would be produced. **31.** Carbonic anhydrase catalyzes the reaction that forms carbonic acid, a source of hydrogen ions that are excreted by the kidneys. Hydrogen ion excretion occurs by an antiport system in which sodium ions are exchanged for hydrogen ions. Fewer hydrogen ions would be available, so less sodium would be reabsorbed, causing an increased osmolarity of the filtrate. In turn, an increased volume of urine and more-frequent urination would result.

Answers to Clinical Case Wrap-Up

PAGE 1014 1. Mike's x-rays show fractures of the left 11th and 12th ribs, overlying the left kidney. They also show fractures of the transverse processes of the first three lumbar vertebrae on the left. The left renal hilum lies between the fractured ribs and the fractured lumbar vertebral transverse processes. These visible fractures are a strong indication that the soft tissues and organs in this area are also injured.
If Mike survives this trauma, the GFR of his solitary right kidney is likely to increase to compensate for the loss of his left kidney. This is to be expected if there has been no trauma to his right kidney.

Chapter 27

Answers to Checkpoints PAGE 1017

1. The three interrelated processes essential to stabilizing body fluid volumes are fluid balance, electrolyte balance, and acid–base

balance. 2. The components of extracellular fluid (ECF) are interstitial fluid, plasma, and other body fluids; the intracellular fluid (ICF) is the cytosol of a cell. **PAGE 1021** 3. Three hormones affecting fluid and electrolyte balance are antidiuretic hormone (ADH), aldosterone, and natriuretic peptides (ANP and BNP). 4. Drinking a half-gallon of distilled water would temporarily decrease your blood osmolarity (osmotic concentration). This decrease in osmolarity would lead to a decrease in the level of ADH in your blood, because ADH release is triggered by increases in osmolarity. **PAGE 1024** 5. Edema is the movement of abnormally large amounts of water from plasma into interstitial fluid. 6. A fluid shift is a rapid movement of water between the ECF and ICF in response to an osmotic gradient. **7.** Dehydration is a decrease in the water content of the body that develops when water losses outpace water gains, and this threatens homeostasis. 8. Being in the desert without water, you would lose fluid through perspiration, urine formation, and respiration. As a result, the osmotic concentration of your blood plasma (and other body fluids) would increase. **PAGE 1029** 9. Important cations are sodium, potassium, calcium, and magnesium; important anions are phosphate and chloride. **10.** Sweat is a hypotonic solution with lower sodium concentration than the ECF. Sweating causes a greater loss of water than of sodium, increasing plasma sodium ion levels. 11. Potassium ion imbalances are more dangerous than sodium ion imbalances because they can lead to extensive muscle weakness or even paralysis when blood concentrations are too low, and to cardiac arrhythmias when the levels are too high. Disturbances in sodium balance, by contrast, produce dehydration or tissue edema **PAGE 1038** 12. The body's three major buffer systems are the phosphate buffer system, the protein buffer systems, and the carbonic acid-bicarbonate buffer system. 13. A decrease in the pH of body fluids accompanies an increase in the partial pressure of carbon dioxide. Chemoreceptors sensitive to P_{CO2} would stimulate the respiratory centers of the medulla oblongata, resulting in an increase in the respiratory rate. 14. Tubular fluid in nephrons must be buffered so that it can contain more H⁺ without decreasing the pH below approximately 4.5, at which point H⁺ secretion cannot continue because the H⁺ concentration gradient becomes too steep. The hydrogen ions would leak out of the tubule as fast as they are pumped in. **PAGE 1045** 15. In a prolonged fast, fatty acids are catabolized, producing large numbers of ketone bodies, which are organic acids that decrease the blood pH. (The decreased pH would eventually lead to ketoacidosis.) 16. In vomiting, large amounts of stomach hydrochloric acid are lost from the body. More acid is then formed by the parietal cells of the stomach. The H⁺ that are released were produced by the dissociation of carbonic acid and exchange of bicarbonate ions with chloride ions from the blood. The alkaline tide of released bicarbonate ions increases the blood pH, leading to metabolic alkalosis. **PAGE 1046** 17. A decrease in the glomerular filtration rate and the number of functional nephrons reduces the body's ability to regulate pH through renal compensation. 18. Total body water content gradually decreases with age.

Answers to Review Questions

PAGE 1048

Level 1 Reviewing Facts and Terms

1. c **2.** a **3.** d **4.** (a) carbonic acid $(H_2CO_3^-)$; (b) bicarbonate ion (HCO_3^-) ; (c) sodium bicarbonate $(NaHCO_3)$ **5.** d **6.** d **7.** a **8.** b **9.** a **10.** Four major hormones involved in fluid and electrolyte balance are (1) antidiuretic hormone (ADH): stimulates water conservation by the kidneys and stimulates the thirst center; (2) aldosterone: determines the rate of sodium reabsorption and potassium secretion along the DCT and collecting system of the kidney; and the natriuretic peptides, (3) ANP and (4) BNP: reduce thirst, promote the loss of Na^+ and water by the kidneys, and block the release of ADH and aldosterone.

Level 2 Reviewing Concepts

11. d 12. a 13. d 14. c 15. Fluid balance is a state in which the amount of water gained each day is equal to the amount lost to the environment. It is vital that the water content of the body remain stable, because water is an essential ingredient of cytoplasm and accounts for about 99 percent of ECF volume. Electrolyte balance exists when there is neither a net gain nor a net loss of any ion in body fluids. It is important that the ionic concentrations in body water remain within normal limits; if levels of calcium or potassium become too high, for instance, cardiac arrhythmias can develop. Acid-base balance exists when the production of hydrogen ions precisely offsets their loss. The pH of body fluids must remain within a relatively narrow range; variations outside this range can be life threatening. 16. Fluid shifts are rapid water movements between the ECF and the ICF that occur in response to increases or decreases in the osmotic concentration of the ECF. Such water movements dampen extreme shifts in electrolyte balance. 17. A person with a fever should increase fluid intake because for each degree (Celsius) the body temperature increases above normal, daily water loss increases by 200 mL. 18. (a) Acids that can leave solution and enter the atmosphere, such as carbonic acid, are volatile acids. (b) Acids that do not leave solution, such as sulfuric acid, are fixed acids. (c) Acids produced during metabolism, such as lactic acid and ketones, are organic acids. Volatile acids are the greatest threat because of the large amounts generated by normal cellular processes. **19.** (1) phosphate buffer system: This buffer system consists of H₂PO₄⁻, a weak acid that, in solution, reversibly dissociates into a hydrogen ion and HPO₄²⁻. The phosphate buffer system plays a relatively small role in regulating the pH of the ECF, because the ECF contains far higher concentrations of bicarbonate ions than phosphate ions; however, it is important in buffering the pH of the ICF. (2) protein buffer systems: These depend on the ability of amino acids to respond to changes in pH by accepting or releasing hydrogen ions. If the pH rises, the carboxyl group of the amino acid dissociates to release a hydrogen ion; if the pH drops, the amino group accepts an additional hydrogen ion to form an amino ion (NH_3^+) and the carboxylate ion can accept a hydrogen ion to form a carboxyl group. Plasma proteins contribute to the buffering capabilities of the blood; inside cells, protein buffer systems stabilize the pH of the ECF by absorbing extracellular hydrogen ions or exchanging intracellular hydrogen ions for extracellular potassium. (3) carbonic acid-bicarbonate system: Most carbon dioxide generated in tissues is converted to carbonic acid, which dissociates into a hydrogen ion and a bicarbonate ion. Hydrogen ions released by dissociation of organic or fixed acids combine with bicarbonate ions, elevating the P_{CO_2} ; additional CO_2 is lost at the lungs. **20.** Respiratory and renal mechanisms support buffer systems by secreting or absorbing hydrogen ions, by controlling the excretion of acids and bases, and by generating additional buffers. **21.** Respiratory compensation is a change in the respiratory rate that helps stabilize the pH of the ECF. Increasing or decreasing the rate of respiration alters pH by decreasing or increasing the P_{CO}. When the P_{CO}, decreases, the pH increases; when the P_{CO₂} increases, the pH decreases. Renal compensation is a change in the rates of hydrogen and bicarbonate ion secretion or reabsorption in response to changes in plasma pH. Tubular hydrogen ion secretion results in the diffusion

of bicarbonate ions into the ECF. 22. Respiratory disorders result from abnormal CO₂ levels in the ECF. An imbalance exists between the rate of CO₂ removal by the lungs and its generation in other tissues. Metabolic disorders are caused by the generation of organic or fixed acids or by conditions affecting the concentration of bicarbonate ions in the ECF. 23. Respiratory acidosis, which results from an abnormally high level of carbon dioxide (hypercapnia), is usually caused by hypoventilation. Metabolic acidosis, which occurs when bicarbonate ion levels decrease, can result from overproduction of fixed or organic acids, impaired ability to secrete H⁺ ions by the kidney, or severe bicarbonate loss. 24. Excessive salt intake causes an increase in total blood volume and blood pressure due to an obligatory increase in water absorption across the intestinal lining and recall of fluid from the ICF. 25. Since sweat is usually hypotonic, the loss of a large volume of sweat causes hypertonicity in body fluids. The loss of fluid volume is primarily from the interstitial space, which leads to a decrease in plasma volume and an increase in the hematocrit. Severe dehydration can cause the blood viscosity to increase substantially, resulting in an increased workload on the heart, ultimately increasing the probability of heart failure.

Level 3 Critical Thinking and Clinical Applications

26. The young boy has metabolic and respiratory acidosis. The metabolic acidosis resulted primarily from the large amounts of lactic acid generated by the boy's muscles as he struggled in the water. (The dissociation of lactic acid releases hydrogen ions and lactate ions.) Sustained hypoventilation during drowning contributed to both tissue hypoxia and respiratory acidosis. Respiratory acidosis developed as the P_{CO₂} increased in the ECF, increasing the production of carbonic acid and its dissociation into H⁺ and HCO₃⁻. Prompt emergency treatment is essential. The usual procedure involves some form of artificial or mechanical respiratory assistance (to increase the respiratory rate and decrease P_{CO_2} in the ECF) coupled with the intravenous infusion of a buffered isotonic solution containing sodium lactate, sodium gluconate, or sodium bicarbonate that would absorb the H⁺ in the ECF and increase body fluid pH. 27. a 28. When tissues are burned, cells are destroyed and their cytoplasmic contents leak into the interstitial fluid and then move into the plasma. Since potassium ions are normally found within the cell, damage to a large number of cells releases relatively large amounts of potassium ions into the blood. The elevated potassium level stimulates cells of the adrenal cortex to produce aldosterone and cells of the juxtaglomerular complex to produce renin. The renin activates the angiotensin-aldosterone system. Ultimately, angiotensin II stimulates increased aldosterone secretion, which promotes sodium retention and potassium secretion by the kidneys, thereby accounting for the elevated potassium levels in the patient's urine. **29.** Digestive secretions contain high levels of bicarbonate, so individuals with diarrhea can lose significant amounts of this important ion, leading to acidosis. We would expect Milly's blood pH to be lower than 7.35, and that of her urine to be low (due to increased renal excretion of hydrogen ions). We would also expect an increase in the rate and depth of breathing as the respiratory system tries to compensate by eliminating carbon dioxide. **30.** The hypertonic solution will cause fluid to move from the ICF to the ECF, further aggravating Yuka's dehydration. The slight increase in pressure and osmolarity of the blood should lead to an increase in ADH, even though ADH levels are probably quite high already. Despite the high ADH levels, urine volume would probably increase, because the kidneys could not reabsorb much of the glucose. The remaining glucose would increase the osmolarity of the tubular filtrate, decreasing water reabsorption and increasing

urine volume. **31.** Patient 1 has compensated respiratory alkalosis. Patient 2 has acute metabolic acidosis due to the generation or retention of organic or fixed acids. Patient 3 has acute respiratory acidosis. Patient 4 has metabolic alkalosis.

Answers to Clinical Case Wrap-Up

PAGE 1049 1. Marquis should be treated with potassium replacement. He can take K^+ orally, or it can be given intravenously (IV) for faster replacement. His doctor should consider changing his blood pressure medication to one that does not cause a loss of K^+ . (These are often called potassium-sparing diuretics.) **2.** When Marquis complains of a "frog jumping around in his chest" with dizziness, he is likely describing a cardiac arrhythmia. This can be the most serious complication of hypokalemia and can lead to sudden cardiac death.

Chapter 28

Answers to Checkpoints

PAGE 1052 1. A gamete is a functional male or female reproductive cell. **2.** Basic structures of the reproductive system are gonads (reproductive organs), ducts (which receive and transport gametes), accessory glands (which secrete fluids), and external genitalia (perineal structures). 3. Gonads are reproductive organs that produce gametes and hormones. **PAGE 1068** 4. Male reproductive structures are the scrotum, testes, epididymides, ductus deferentia, ejaculatory duct, urethra, seminal glands, prostate gland, bulbourethral glands, and penis. 5. On a warm day, the cremaster muscle (as well as the dartos muscle) would be relaxed so that the scrotal sac could descend away from the warmth of the body, thereby cooling the testes. 6. When the arteries within the penis dilate, the increased blood flow causes the erectile tissues of the corpora cavernosa and corpus spongiosum to engorge with blood, producing an erection. 7. Low FSH levels would lead to low levels of testosterone in the seminiferous tubules, decreasing both the sperm production rate and sperm count. 8. The pathway of sperm is as follows: seminiferous tubule \rightarrow straight tubule \rightarrow rete testis \rightarrow efferent ductules \rightarrow epididymis \rightarrow ductus deferens \rightarrow ejaculatory duct \rightarrow urethra. **PAGE 1087** 9. Structures of the female reproductive system include the ovaries, uterine tubes, uterus, vagina, and mammary glands. 10. The blockage of both uterine tubes would cause sterility. 11. The acidic pH of the vagina helps prevent bacterial, fungal, and parasitic infections in this region. 12. The functional zone of the endometrium is sloughed off, or shed, during menstruation. 13. Blockage of a single lactiferous sinus would not interfere with the delivery of milk to the nipple, because the mammary gland of each breast generally has 15-20 lactiferous sinuses. 14. If the LH surge did not occur during an ovarian cycle, ovulation and corpus luteum formation would not occur. **15.** Blockage of progesterone receptors in the uterus would inhibit the development of the endometrium, making the uterus unprepared for pregnancy. 16. A decrease in the levels of estrogens and progesterone signals the beginning of menses, the end of the uterine cycle. PAGE 1088 17. The physiological events of sexual intercourse in both sexes are arousal, erection, lubrication, orgasm, and detumescence. Emission and ejaculation are additional phases that occur only in males. 18. An inability to contract the ischiocavernosus and bulbospongiosus muscles would interfere with a male's ability to ejaculate and to experience orgasm. 19. Parasympathetic stimulation in females during sexual arousal causes (a) engorgement of the erectile tissue of the clitoris and vestibular bulbs, (b) increased

secretion of cervical and vaginal glands, (c) increased blood flow to the wall of the vagina, and (d) engorgement of the blood ves-**PAGE 1089** 20. Menopause is the time sels in the nipples. when ovulation and menstruation cease, typically around ages 45-55. 21. At menopause, circulating estrogen levels begin to decrease. Estrogen has an inhibitory effect on FSH (and on GnRH). As the level of estrogen decreases, the levels of FSH increase and remain high. **22.** The male climacteric, or andropause, is a period of declining reproductive function in men, typically between the ages of 50 and 60. **PAGE 1091** 23. The cardiovascular system distributes reproductive hormones; provides nutrients, oxygen, and waste removal for the fetus; and produces local blood pressure changes responsible for the physical changes that occur during sexual intercourse. The reproductive system supplies estrogens that may help maintain healthy blood vessels and slow the development of atherosclerosis. 24. Pelvic bones protect reproductive organs in females and portions of the ductus deferens and accessory glands in males; sex hormones stimulate growth and maintenance of bones, and accelerate growth and closure of epiphyseal cartilages at puberty.

Answers to Review Questions

PAGE 1093

Level 1 Reviewing Facts and Terms

1. (c) 2. d 3. c 4. b 5. a 6. The accessory structures include the seminal glands (seminal vesicles), which provide the nutrients that sperm need for motility, prostaglandins that stimulate smooth muscle contractions along the male and female reproductive tracts thereby propelling sperm and fluids, fibrinogen that temporarily clots the ejaculate within the vagina, and buffers that counteract the acidity of the prostatic secretions and urethral and vaginal contents; the prostate gland, which aids the activation of the spermatozoa (with seminal gland secretions); and the bulbourethral glands, which buffer acids in the penile urethra and lubricate the glans penis. The fluids secreted by the accessory glands make up about 95 percent of the volume of semen. 7. Interstitial cells (cells of Levdig) produce male sex hormones (androgens), the most important of which is testosterone; nurse cells maintain the blood-testis barrier, support spermatogenesis and spermiogenesis, and secrete inhibin, androgen-binding protein, and Müllerian-inhibiting factor. **8.** The three regions of the male urethra are the prostatic urethra, membranous urethra, and spongy urethra. 9. In males, testosterone stimulates spermatogenesis and promotes the functional maturation of spermatozoa; maintains the male accessory reproductive organs; determines male secondary sex characteristics; stimulates metabolic pathways, especially those concerned with protein synthesis and muscle growth; and affects CNS function, by stimulating sexual drive and sexual behaviors. 10. Steps of the ovarian cycle are (1) the formation of primary follicles, (2) the formation of secondary follicles, (3) the formation of a tertiary follicle, (4) ovulation, and (5) the formation of the corpus luteum and its degeneration into the corpus albicans. 11. The myometrium is the middle, muscular layer; the endometrium is the inner, glandular layer; and the perimetrium is an incomplete outer serosal layer. **12.** The clitoris—a part of the external genitalia of females that is derived from the same embryonic structures as the peniscontains erectile tissue that becomes engorged with blood during sexual arousal and provides pleasurable sensations. 13. Path of milk flow: secretory lobules of glandular tissue (lobes) \rightarrow ducts \rightarrow lactiferous duct \rightarrow lactiferous sinus, which opens onto the surface of the nipple. 14. (a) prostatic urethra; (b) spongy urethra;

- (c) ductus deferens; (d) penis; (e) epididymis; (f) testis;
- (g) external urethral orifice; (h) scrotum; (i) seminal gland;
- (j) prostate gland; (k) ejaculatory duct; (l) bulbourethral gland.

Level 2 Reviewing Concepts

15. e **16.** The hypothalamic secretion of GnRH triggers the pituitary secretion of FSH and LH. FSH initiates follicular development, and activated follicles and ovarian interstitial cells produce estrogens. High estrogen levels stimulate LH secretion and increase anterior pituitary lobe sensitivity to GnRH, causing the release of LH. Progesterone is the main hormone of the luteal phase. Changes in estrogen and progesterone levels are responsible for maintaining the uterine cycle. 17. Males produce gametes from puberty until death; females produce gametes only from menarche to menopause. Males produce many gametes at a time; females typically produce one or two per 28-day cycle. Males release mature gametes that have completed meiosis; females release secondary oocytes held in metaphase of meiosis II. 18. The corpora cavernosa extend along the length of the penis as far as the neck of the penis, and the erectile tissue within each corpus cavernosum surrounds a central artery. The slender corpus spongiosum surrounds the urethra and extends from the superficial fascia of the urogenital diaphragm to the tip of the penis, where it expands to form the glans penis. The sheath surrounding the corpus spongiosum contains more elastic fibers than the corpora cavernosa, and the erectile tissue contains a pair of arteries. When parasympathetic neurons innervating the penile arteries release nitric oxide, smooth muscles in the arterial walls relax, dilating the vessels and increasing blood flow; the resulting engorgement of the vascular channels with blood causes erection of the penis. **19.** (1) Menses, the interval marked by the degeneration and loss of the functional zone of the endometrium, lasts 1-7 days, and 35-50 mL (1.2-1.7 oz) of blood is lost. (2) The proliferative phase features growth and vascularization resulting in the complete restoration of the functional zone; it lasts from the end of menses until the beginning of ovulation, around day 14. (3) During the secretory phase, the uterine glands enlarge, accelerating their rates of secretion, and the arteries elongate and spiral through the tissues of the functional zone; this phase begins at ovulation, occurs under the combined stimulatory effects of progesterone and estrogens from the corpus luteum, and persists as long as the corpus luteum remains intact. 20. As follicular development proceeds, the concentration of circulating estrogen rises. Secondary follicles contain increased numbers of granulosa cells, and the level of circulating inhibin rises. The rising estrogen and inhibin levels inhibit hypothalamic secretion of GnRH and pituitary production and release of FSH. (GnRH pulse frequency is increased by estrogens and decreased by progesterone.) As the follicles develop and estrogen levels rise, the pituitary output of LH gradually increases. Estrogens, FSH, and LH continue to support follicular development and maturation despite a gradual decline in FSH levels. In the second week of the ovarian cycle, estrogen levels sharply increase, and the tertiary follicle enlarges in preparation for ovulation. By day 14, estrogen levels peak, triggering a massive outpouring of LH from the anterior lobe of the pituitary gland. The rupture of the follicular wall results in ovulation. Next, LH stimulates the formation of the corpus luteum, which secretes moderate amounts of estrogens but large amounts of progesterone, the principal hormone of the postovulatory period. About 12 days after ovulation, declining progesterone and estrogen levels stimulate hypothalamic receptors and GnRH production increases, leading to increased FSH and LH production in the anterior lobe of the pituitary gland; the cycle begins

again. 21. The corpus luteum degenerates and progesterone and estrogen levels decrease, causing degeneration of the endometrium and the onset of menses. Next, rising levels of FSH, LH, and estrogen stimulate the repair and regeneration of the functional zone of the endometrium. During the postovulatory phase, the combination of estrogen and progesterone causes the enlargement of the uterine glands and an increase in their secretory activity. **22.** During sexual arousal, erotic thoughts or physical stimulation of sensory nerves in the genital region increases the parasympathetic outflow over the pelvic nerve, leading to erection of the clitoris or penis. Orgasm is the intensely pleasurable sensation associated with perineal muscle contraction and ejaculation in males, and with uterine and vaginal contractions and perineal muscle contraction in females. These processes are comparable in males and females, but only males undergo emission and ejaculation. 23. Women ages 45–55 experience menopause—the time that ovulation and menstruation cease, accompanied by a sharp and sustained rise in the production of GnRH, FSH, and LH and a drop in the concentrations of circulating estrogen and progesterone. The decline in estrogen levels leads to reductions in the size of the uterus and breasts, accompanied by a thinning of the urethral and vaginal walls. In addition to neural and cardiovascular effects, reduced estrogen concentrations have been linked to the development of osteoporosis, presumably because bone deposition proceeds at a slower rate. Men aged 50-60 experience the male climacteric, a time when circulating testosterone levels begin to decline and circulating levels of FSH and LH rise. Although sperm production continues, a gradual reduction in sexual activity occurs in older men.

Level 3 Critical Thinking and Clinical Applications

24. Women more frequently experience peritonitis stemming from a urinary tract infection because infectious organisms exiting the urethral orifice can readily enter the nearby vagina. From there, they can then proceed to the uterus, into the uterine tubes, and finally into the peritoneal cavity. No such direct path of entry into the abdominopelvic cavity exists in men. 25. Regardless of their location, endometrial cells have receptors that respond to estrogen and progesterone. Under the influence of estrogen at the beginning of the menstrual cycle, any endometrial cells in the peritoneal cavity proliferate and begin to develop glands and blood vessels, which then further develop under the control of progesterone. The dramatic increase in size of this tissue presses on neighboring abdominal tissues and organs, causing periodic painful sensations. 26. Slightly elevated levels of estrogen and progesterone inhibit both GnRH release at the hypothalamus and the release of FSH and LH from the anterior lobe of the pituitary gland. Without FSH, primordial follicles do not begin to develop, and levels of estrogen remain low. An LH surge, triggered by the peaking of estradiol, is necessary for ovulation to occur. If the level of estradiol is not allowed to rise above the critical level, the LH surge will not occur, and thus ovulation will not occur, even if a follicle managed to develop to a stage at which it could ovulate. Any mature follicles would ultimately degenerate, and no new follicles would mature to take their place. Although the ovarian cycle is interrupted, the level of hormones is still adequate to regulate a normal menstrual cycle. 27. These observations suggest that a certain amount of body fat is necessary for menstrual cycles to occur. The nervous system appears to respond to circulating levels of the adipose tissue hormone leptin; when leptin levels fall below a certain set point, menstruation ceases. Because a woman lacking adequate fat reserves might not be able to have a successful pregnancy, the body prevents pregnancy by shutting down the ovarian cycle, and thus the menstrual cycle. Once sufficient energy reserves become available, the cycles begin again.

Answers to Clinical Case Wrap-Up

PAGE 1094 1. In addition to the blood vessels and the genitofemoral nerve, the ductus deferens with its layers of fascia and muscle are twisted with testicular torsion.2. If Dan were suffering from epididymitis, a painful inflammation of his epididymis, his cremasteric reflex would still be intact. His genitofemoral nerve would still be functioning and able to propagate this spinal reflex.

Chapter 29

Answers to Checkpoints

PAGE 1097 1. Differentiation is the formation of different types of cells during development. 2. Development begins at fertilization (conception), the union of a sperm and an oocyte, collectively known as gametes. 3. Inheritance refers to the transfer of genetically determined characteristics from one generation to the next. PAGE 1099 4. Two sperm enzymes important to secondary oocvte penetration are hvaluronidase and acrosin. **5.** A normal human zygote contains 46 chromosomes. **PAGE 1100** 6. Gestation is the period of prenatal development. It consists of three trimesters. **7.** The first trimester is the time of embryonic and early fetal development. The second trimester is a time of organ and organ system development. By the end of this stage, the fetus appears distinctly human. The third trimester is characterized by rapid fetal growth and the deposition of adipose tissue. **PAGE 1109** 8. The inner cell mass of the blastocyst eventually develops into the embryo. 9. Improper development of the yolk sac-the mesoderm-derived structure that gives rise to blood vessels and is an important site of blood cell formation-would affect the development and function of the cardiovascular system. **10.** Yes, Sue is pregnant. After fertilization, the developing trophoblast (and later, the placenta) produce and release the hormone hCG. **11.** Placental functions include **(a)** supplying the developing fetus with a route for gas exchange, nutrient transfer, and waste elimination; and (b) producing hormones that affect maternal systems. **PAGE 1115** 12. Pregnant women experience breathing difficulty because the pregnant uterus is pressing on the diaphragm and thus the lungs. 13. Three factors opposing the calming action of progesterone on the uterus are increasing estrogen levels, increasing oxytocin levels, and prostaglandin production. 14. A mother's blood volume increases during pregnancy to compensate for the reduction in maternal blood volume resulting from blood flow through the placenta. **PAGE 1118** 15. The three stages of labor are the dilation stage, expulsion stage, and placental stage. 16. Immature delivery is the birth of a fetus weighing at least 500 g (17.6 oz), which is the normal weight near the end of the second trimester. Premature delivery usually refers to birth at 28-36 weeks at a weight over 1 kg (2.2 lb). 17. Fraternal twins are dizygotic twins, and identical twins are monozygotic twins. **PAGE 1122** 18. The postnatal stages of development are the neonatal period, infancy, childhood, adolescence, and maturity. These stages are followed by senescence, or aging. **19.** The neonatal period is the time from birth to one month. Infancy continues from the neonatal period to age 1. Adolescence is the period after childhood in which sexual and physical maturity occur. 20. Colostrum is produced by the mammary glands from the end of the sixth month of pregnancy until a few days after birth. After that, the glands begin producing

breast milk, which contains fewer proteins (including antibodies) and far more fat than colostrum. **21.** Increases in the blood levels of GnRH, FSH, LH, and sex hormones mark the onset of puberty. **PAGE 1131** 22. Genotype is a person's genetic makeup. Phenotype is a person's physical and physiological characteristics. It results from the interaction between the person's genotype and the environment. 23. Heterozygous refers to possessing two different alleles at corresponding sites of a chromosome pair. For a heterozvgous trait, one or both of the alleles determines the individual's phenotype. **24.** The phenotype of a person who is heterozygous for tongue rolling-who has one dominant allele and one recessive allele for that trait—would be "tongue roller." **25.** One reason children are not identical copies of their parents is that during meiosis, parental chromosomes are randomly distributed such that each gamete has a unique set of chromosomes. Additionally, crossing-over and mutations during meiosis introduce new variations in gametes. Besides gene interactions, environmental factors can also affect the expression of genes and the resulting phenotype through epigenetic mechanisms.

Answers to Review Questions

PAGE 1133

Level 1 Reviewing Facts and Terms

1. d **2.** (a) decidua parietalis; (b) decidua basalis; (c) amnion; (d) chorion; (e) decidua capsularis 3. c 4. b 5. b 6. a 7. b 8. b 9. When a sperm contacts the secondary oocyte, their plasma membranes fuse. The oocyte is then activated: Its metabolic rate rises; it completes meiosis II; and the cortical reaction prevents additional sperm from entering. (Vesicles beneath the oocyte surface fuse with the plasma membrane and discharge their contents.) The male and female pronuclei fuse (amphimixis). and the zygote begins preparing for the first cleavage division. 10. (a) The four extraembryonic membranes are the yolk sac, amnion, allantois, and chorion. (b) The volk sac forms from endoderm and mesoderm; it is an important site of blood cell formation. The amnion forms from ectoderm and mesoderm; it encloses the fluid that surrounds and cushions the developing embryo and fetus. The allantois forms from endoderm and mesoderm; its base gives rise to the urinary bladder. The chorion forms from mesoderm and trophoblast; circulation through chorionic vessels provides a "rapid transit system" for blood and nutrients. 11. The dilation stage begins with the onset of true labor, as the cervix dilates and the fetus begins to move toward the cervical canal; late in this stage, the amniochorionic membrane ruptures. The expulsion stage begins as the cervix dilates completely and continues until the fetus has completely emerged from the vagina (delivery). In the placental stage, the uterus gradually contracts, tearing the connections between the endometrium and the placenta and ejecting the placenta. 12. The fetal pituitary secretes oxytocin, which is released into the maternal bloodstream at the placenta. This release may be the trigger for the onset of true labor. 13. (1) Neonatal period (birth to 1 month): The newborn becomes relatively self-sufficient and begins performing respiration (breathing), digestion, and excretion on its own. Heart rates and fluid requirements are higher than those of adults. Neonates have little ability to thermoregulate. (2) Infancy (1 month to 1 year): Major organ systems (other than those related to reproduction) become fully operational. (3) Childhood (1 year to puberty): Growth continues; body proportions change significantly. **14.** Three events interact to promote increased hormone production and sexual maturation at puberty: (1) The hypothalamus increases its production of

GnRH; (2) the anterior lobe of the pituitary gland becomes more sensitive to the presence of GnRH, and circulating levels of FSH and LH rise rapidly; and (3) ovarian or testicular cells become more sensitive to FSH and LH. Puberty initiates adolescence, which includes gametogenesis (gamete production) and the production of sex hormones that stimulate the appearance of secondary sexual characteristics and behaviors.

Level 2 Reviewing Concepts

15. b **16.** b **17.** c **18.** The post-implantation embryo obtains nutrients through the chorionic villi and later the placenta. The placenta develops during placentation. 19. The placenta produces (1) human chorionic gonadotropin, which maintains the integrity of the corpus luteum and promotes the continued secretion of progesterone (keeping the endometrial lining functional); and (2) human placental lactogen and placental prolactin, which help prepare the mammary glands for milk production. Human placental lactogen also ensures adequate levels of glucose and protein for the developing fetus. (3) The placenta also produces relaxin, which increases the flexibility of the pubic symphysis, causes dilation of the cervix, and suppresses the release of oxytocin by the hypothalamus, delaying the onset of labor contractions. 20. Respiratory rate and tidal volume increase, allowing the lungs to obtain the extra oxygen the fetus needs, and to remove the excess carbon dioxide the fetus generates. Maternal blood volume increases, compensating for blood flowing into the placenta. Nutrient and vitamin requirements increase 10-30 percent, reflecting the fact that some of the mother's nutrients go to nourish the fetus. Glomerular filtration rate increases by about 50 percent, which corresponds to the increased blood volume, and this accelerates the excretion of metabolic wastes generated by the fetus. The uterus and mammary glands increase in size, and secretory activity begins in the mammary glands. 21. Positive feedback mechanisms between increasing levels of oxytocin and increased uterine distortion ensure that labor contractions continue until delivery has been completed. 22. A neonate must fill its lungs (which are collapsed and filled with fluid at birth) with air, which alters the pattern of cardiovascular circulation due to changes in blood pressure and flow rates. It must excrete the mixture of debris (meconium) that has collected in the fetal digestive system. The neonate must obtain nourishment from a new source-the mother's mammary glands. Neonatal fluid requirements are high, because the newborn cannot concentrate its urine significantly. The infant also has little ability to thermoregulate, although as it grows its insulating adipose tissue increases, and its metabolic rate also rises. 23. (a) Genotype refers to all of an individual's genes; phenotype refers to the individual's physical and physiological characteristics. (b) A heterozygous genotype carries different alleles for a given gene; a homozygous genotype carries identical alleles for that gene. (c) In simple inheritance, phenotypes are determined by interactions between a single pair of alleles; in polygenic inheritance, interactions occur among multiple genes. 24. (a) dominant; (b) recessive; (c) X-linked; (d) autosomal

Level 3 Critical Thinking and Clinical Applications

25. The probability that this couple's daughters will have hemophilia is 0, because each daughter will receive a normal allele from her father. There is a 50 percent chance that a son will have hemophilia, because each son has a 50 percent chance of receiving the mother's normal allele and a 50 percent chance of receiving the mother's recessive allele. **26.** Although technically it only takes one sperm to fertilize an egg, the probability of this occurring if too few sperm are deposited is very low. Most sperm that enter the

female reproductive tract are killed or disabled before they reach the uterus. Many of the sperm reaching the uterus are incapable of reaching the secondary oocyte, which is in a uterine tube. Once at the oocyte, the sperm must penetrate the corona radiata, which requires the combined acrosomal enzymes of dozens of sperm. If too few sperm are deposited in the vagina, the number reaching the uterine tube is too low to penetrate the corona radiata. **27.** The most obvious possibility is that the infant has a problem with the cardiovascular supply to the lungs. A good guess would be a patent ductus arteriosus (the ductus arteriosus has failed to close off completely). When the baby is not being stressed (bathing creates heat loss and thermal stress) or eating (less air is entering the lungs), the infant appears normal. Because some of the blood flow to the lungs is being shunted over to the aorta during stress and eating, too little blood is being oxygenated, so the infant becomes cyanotic. 28. It is very unlikely that the baby's condition results from a viral

infection contracted during the third trimester, because organ systems develop during the first trimester and are fully formed by the end of the second trimester.

Answers to Clinical Case Wrap-Up

PAGE 1134 1. Implanting the blastocysts on the sixth day after ovulation matches the fertility cycle in nature. This timing ensures the blastocysts are available for implantation in the uterine wall by days 7 through 10 after ovulation. **2.** Hans and Willem are not monozygotic twins because they did not result from the fertilization of a single oocyte with a single sperm, forming a single zygote that subsequently split. Neither are they technically dizygotic twins. They are the developmental result of two separate oocytes from the same mother, but unlike dizygotic twins, they have different *biological* fathers. In terms of biological inheritance, they are half brothers. Socially they are fraternal twins.

Glossary of Key Terms

Α

- **abdomen:** The region of the trunk between the inferior margin of the rib cage and the superior margin of the pelvis. (1)
- **abdominopelvic cavity:** The term used to refer to the general region bounded by the abdominal wall and the pelvis; it contains the peritoneal cavity and visceral organs. (1)
- **abducens:** Cranial nerve VI, which innervates the lateral rectus muscle of the eye. (14)
- **abduction:** Movement away from the midline of the body, as viewed in the anatomical position. (9)
- **abortion:** The premature loss or expulsion of an embryo or fetus. (29)
- **abscess:** A localized collection of pus within a damaged tissue. (4, 22)
- **absorption:** The active or passive uptake of gases, fluids, or solutes. (25)
- **accommodation:** An alteration in the curvature of the lens of the eye to focus an image on the retina. (17)
- **acetabulum:** The fossa on the lateral aspect of the pelvis that accommodates the head of the femur. (8)
- **acetylcholine (ACh):** A chemical neurotransmitter in the brain and peripheral nervous system, the dominant neurotransmitter in the peripheral nervous system, released at neuromuscular junctions and synapses of the parasympathetic division. (10, 12, 16)
- acetylcholinesterase (AChE): An enzyme found in the synaptic cleft, bound to the postsynaptic membrane, and in tissue fluids; breaks down and inactivates acetylcholine molecules; also called *cholinesterase.* (10, 12)
- **acetyl-CoA:** An acetyl group bound to coenzyme A, a participant in the anabolic and catabolic pathways for carbohydrates, lipids, and many amino acids. (25)
- **acetyl group:** —CH₃CO; an acetic acid molecule without the hydroxyl group. (25)
- **acid:** A compound whose dissociation in solution releases a hydrogen ion and an anion; an acidic solution has a pH below 7.0 and has an excess of hydrogen ions. (2, 27)
- **acidosis:** An abnormal physiological state characterized by blood pH below 7.35. (2, 25, 26, 27)
- **acinus/acini:** A histological term referring to a blind pocket, pouch, or sac.
- **acoustic:** Pertaining to sound or the sense of hearing. (17)
- **acquired immunodeficiency syndrome (AIDS):** A disease caused by the human immunodeficiency virus (HIV); characterized by the destruction of helper T cells and a resulting severe impairment of the immune response. (22)
- **acromegaly:** A condition caused by the overproduction of growth hormone in adults, characterized by a thickening of bones and an enlargement of cartilages and other soft tissues. (6, 18)
- **acromion:** A continuation of the scapular spine that projects superior to the capsule of the glenohumeral joint. (8)
- **acrosome:** A membranous sac at the tip of a spermatozoon that contains hyaluronidase; also called *acrosomal cap.* (28)

- **actin:** The protein component of microfilaments that forms thin filaments in skeletal muscles and produces contractions of all muscles through interaction with thick (myosin) filaments; *see also* **sliding filament theory**. (3, 10)
- **action potential:** A propagated change in the membrane potential of excitable cells, initiated by a change in the membrane permeability to sodium ions; *see also* **nerve impulse**. (10, 12)
- **active transport:** The ATP-dependent absorption or secretion of solutes across a plasma membrane. (3, 26)
- **acute:** Sudden in onset, typically severe in intensity, and brief in duration.

adaptation: A change in pupillary size in response to changes in light intensity (17); a decrease in receptor sensitivity or perception after chronic stimulation (15); physiological responses that produce acclimatization. (25)

Addison's disease: A condition resulting from the hyposecretion of glucocorticoids; characterized by lethargy, weakness, hypotension, and increased skin pigmentation. (5, 18)

adduction: Movement toward the axis or midline of the body, as viewed in the anatomical position. (9)

adenine: A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

adenohypophysis: The anterior lobe of the pituitary gland. (18)

- **adenoid:** The pharyngeal tonsil. (22, 23)
- **adenosine:** A compound consisting of adenine and ribose. (2)

adenosine diphosphate (ADP): A compound consisting of adenosine with two phosphate groups attached. (2, 25)

adenosine monophosphate (AMP): A nucleotide consisting of adenosine plus a phosphate group (PO₄³⁻); also called *adenosine phosphate*.

adenosine triphosphate (ATP): A high-energy compound consisting of adenosine with three phosphate groups attached; the third is attached by a high-energy bond. (2, 10, 25)

adenylate cyclase: An enzyme bound to the inner surfaces of plasma membranes that can convert ATP to cyclic AMP; formerly called *adenylyl cyclase*. (12)

adhesion: The fusion of two mesenterial layers after damage or irritation of their opposing surfaces; this process restricts relative movement of the organs involved (4); the binding of a phagocyte to its target (22).

- adipocyte: A fat cell. (4)
- **adipose tissue:** Loose connective tissue dominated by adipocytes. (4, 18)
- **adrenal cortex:** The superficial region of the adrenal gland that produces steroid hormones; also called the *suprarenal cortex*. (18)

adrenal gland: A small endocrine gland that secretes steroids and catecholamines and is located superior to each kidney; also called *suprarenal gland*. (18)

adrenal medulla: The core of the adrenal gland (18); a modified sympathetic ganglion that secretes catecholamines into the blood during sympathetic activation; also called *suprarenal medulla*. (16)

adrenergic: An axon terminal that, when stimulated, releases norepinephrine. (12)

adrenocortical hormone: Any steroid produced by the adrenal cortex. (18)

adrenocorticotropic hormone (ACTH): The

hormone that stimulates the production and secretion of glucocorticoids by the zona fasciculata of the adrenal cortex; released by the anterior lobe of the pituitary gland (adenohypophysis) in response to corticotropin-releasing hormone. (18)

adventitia: The superficial layer of connective tissue surrounding an internal organ; fibers are continuous with those of surrounding tissues, providing support and stabilization. (24)

- aerobic: Requiring oxygen.
- aerobic metabolism: The complete breakdown of organic substrates into carbon dioxide and water, by pyruvate; a process that yields large amounts of ATP but requires mitochondria and oxygen. (3, 10, 25)
 afferent: Conducting toward a center.
- **afferent arteriole:** An arteriole that carries blood to a glomerulus of the kidney. (26)
- afferent fiber: An axon that carries sensory information to the central nervous system. (12)
- **agglutination:** The aggregation of red blood cells due to interactions between surface antigens and plasma antibodies. (19, 22)
- **agglutinins:** Immunoglobulins (antibodies) in plasma that react with antigens on the surfaces of foreign red blood cells when donor and recipient differ in blood type. (19)
- **agglutinogens:** Genetically determined surface antigens on red blood cells that stimulate the formation of specific agglutinins. (19)
- aggregated lymphoid nodules: Lymphoid nodules beneath the epithelium of the small intestine; also called *Peyer's patches*. (22)agonist: A muscle responsible for a specific
- movement; also called a *prime mover*. (11)
- **agranular:** Without granules; *agranular leukocytes* are monocytes and lymphocytes. (19)

AIDS: See acquired immunodeficiency syndrome.

- **aldosterone:** A mineralocorticoid produced by the zona glomerulosa of the adrenal cortex; stimulates the kidneys to conserve sodium and water; secreted in response to the presence of angiotensin II. (18, 26, 27)
- **alkalosis:** The condition characterized by a blood pH greater than 7.45; associated with a relative deficiency of hydrogen ions or an excess of bicarbonate ions. (2, 27)
- **alpha receptors:** Membrane receptors sensitive to norepinephrine or epinephrine; stimulation normally results in target cell excitation. (16)
- **alveolar sac:** An air-filled chamber at the terminal end of the alveolar duct which gives rise to the alveoli in the lung. (23)
- **alveolus/alveoli:** Blind pockets at the end of the respiratory tree, lined by a simple squamous epithelium and surrounded by a capillary network; sites of gas exchange with the blood (23); a bony socket that holds the root of a tooth. (24)
- **Alzheimer's disease:** A disorder resulting from degenerative changes in populations of neurons in the cerebrum, causing dementia characterized by problems with attention, short-term memory, and emotions. (16)
- **amination:** The attachment of an amino group to a carbon chain; performed by a variety of cells and important in the synthesis of amino acids. (25)
- **amino acids:** Organic compounds made up of carbon, hydrogen, oxygen, and nitrogen; building

block of protein; chemical structure can be summarized as R-CHNH2-COOH. (2, 25)

amnion: One of the four extraembryonic membranes; surrounds the developing embryo or fetus (29)

amniotic fluid: Fluid that fills the amniotic cavity; cushions and supports the embryo or fetus. (4, 29)

amphiarthrosis: A joint (articulation) that permits a small degree of independent movement; see interosseous membrane (8) and pubic symphysis. (9)

ampulla/ampullae: A localized dilation in the lumen of a canal or passageway. (17, 24, 28)

amygdaloid body: A basal nucleus that is a component of the limbic system and acts as an interface between the limbic system, the cerebrum, and sensory systems; also called amygdala. (14)

amylase: An enzyme that breaks down polysaccharides; produced by the salivary glands and pancreas. (24)

anabolism: The synthesis of complex organic compounds from simpler precursors. (2, 25) anaerobic: Without oxygen.

analgesic: A substance that relieves pain. (15) anal triangle: The posterior subdivision of the perineum. (11)

anaphase: The mitotic stage in which the paired chromatids separate and move toward opposite ends of the spindle apparatus. (3)

anaphylaxis: A hypersensitivity reaction due to the binding of antigens to immunoglobulins (IgE) on the surfaces of mast cells; the release of histamine, serotonin, and prostaglandins by mast cells then causes widespread inflammation; a sudden decrease in blood pressure may occur, producing anaphylactic shock. (22)

anastomosis: The joining of two tubes, usually referring to a connection between two peripheral vessels without an intervening capillary bed. (21)

anatomical position: An anatomical reference position; the body viewed from the anterior surface with the palms facing forward. (1)

anatomy: The study of the structure of the body. (1) androgen: A steroid sex hormone mainly produced by the interstitial cells of the testis and

- manufactured in small quantities by the adrenal cortex in both sexes. (18, 28)
- anemia: The condition marked by a decrease in the hematocrit, the hemoglobin content of the blood, or both (19)

angiotensin I: The hormone produced by the activation of angiotensinogen by renin (18); angiotensin-converting enzyme (ACE) converts angiotensin I into angiotensin II in lung capillaries. (26)

angiotensin II: A hormone that causes an increase in systemic blood pressure, stimulates the secretion of aldosterone, promotes thirst, and causes the release of antidiuretic hormone (18); angiotensin-converting enzyme (ACE) in lung capillaries converts angiotensin I into angiotensin II. (21, 26)

angiotensinogen: The blood protein produced by the liver that is converted to angiotensin I by the enzyme renin. (18)

anion: An ion having a negative charge. (2, 27)

anoxia: Inadequate oxygen reaching body tissues. (23) antagonist: A muscle that opposes the movement of an agonist. (10)

antebrachium: The forearm. (8)

- anterior: On or near the front, or ventral surface, of the body
- antibiotic: A chemical agent that selectively kills pathogens, primarily bacteria. (20)

antibody: A globular protein produced by plasma cells that will bind to specific antigens and promote their destruction or removal from the body. (19, 22)

antibody-mediated immunity: The form of immunity resulting from the presence of circulating antibodies produced by plasma cells; also called humoral immunity. (22)

anticodon: Three nitrogenous bases on a tRNA molecule that interact with a complementary codon on a strand of mRNA. (3)

antidiuretic hormone (ADH): A hormone synthesized in the hypothalamus and secreted at the posterior lobe of the pituitary gland (neurohypophysis): causes the kidneys to retain water and an increase in blood pressure. (18, 21, 26, 27)

antigen: A substance capable of inducing the production of antibodies. (22)

antigen-antibody complex: The combination of an antigen and a specific antibody. (22)

antigenic determinant site: A region of an antigen that can interact with an antibody molecule. (22)

antigen-presenting cell (APC): A cell that processes antigens and displays them, bound to Class II MHC proteins; essential to the initiation of a normal immune response. (22)

antihistamine: A chemical that blocks the action of histamine on peripheral tissues. (22)

antrum: A chamber or pocket. (28) anulus: A cartilage or bone shaped like a ring; also spelled annulus. (9)

anus: The external opening of the anal canal. (24)

aorta: The large, elastic artery that carries blood away from the left ventricle and into the systemic circuit. (20)

apocrine secretion: A mode of secretion in which the glandular cell sheds portions of its cytoplasm. (4, 5)

aponeurosis/aponeuroses: Broad tendinous sheet(s) that may serve as the origin or insertion of a skeletal muscle. (4, 6, 10)

appendicular: Pertaining to the upper or lower limbs. (8)

appendix: A blind sac connected to the cecum of the large intestine. (24)

appositional growth: The enlargement of a cartilage or bone by the addition of cartilage or bony matrix at its surface. (4)

aqueous humor: A fluid similar to perilymph or cerebrospinal fluid that fills the anterior chamber of the eye. (17)

arachidonic acid: One of the essential fatty acids. (2, 18)

arachnoid granulations: Processes of the arachnoid mater that project into the superior sagittal sinus; sites where cerebrospinal fluid enters the venous circulation. (14)

arachnoid mater: The middle meninx (layer) that encloses cerebrospinal fluid and protects the central nervous system. (13, 14)

arbor vitae: The central, branching mass of white matter inside the cerebellum. (14)

arcuate: Curving.

areolar: Containing minute spaces, as in areolar tissue

areolar tissue: Loose connective tissue with an open framework. (4)

arrector pili: Smooth muscles whose contractions force hairs to stand erect. (5)

arrhythmias: Abnormal patterns of cardiac contractions. (20)

arteriole: A small arterial branch that delivers blood to a capillary network. (21)

artery: A blood vessel that carries blood away from the heart and toward a peripheral capillary. (4, 20, 21)

articular: Pertaining to a joint.

articular capsule: The dense collagen fiber sleeve that surrounds a joint and provides protection and stabilization; also called joint capsule. (6, 9)

articular cartilage: The cartilage pad that covers the surface of a bone inside a joint cavity. (6, 9) articulation: A joint. (9)

arytenoid cartilages: A pair of small cartilages in the larvnx. (23)

ascending tract: A tract carrying information from the spinal cord to the brain. (13, 14)

association areas: Cortical areas of the cerebrum that are responsible for the integration of sensory inputs and/or motor commands. (14)

association neuron: See interneuron. **astrocyte:** One of the four types of neuroglia in the central nervous system; responsible for

maintaining the blood-brain barrier by the stimulation of endothelial cells. (12)

atherosclerosis: The formation of fatty plaques in the walls of arteries, restricting blood flow. (21) atom: The smallest stable unit of matter. (2)

atomic number: The number of protons in the nucleus of an atom. (2)

atomic weight: The average of the different atomic masses and isotope proportions of a particular element. (2)

- atria: Thin-walled chambers of the heart that receive venous blood from the pulmonary or systemic circuit.
- atrial natriuretic peptide (ANP): See natriuretic peptides. (20)

atrial reflex: The reflexive increase in heart rate after an increase in venous return: due to mechanical and neural factors; also called Bainbridge reflex. (20, 21)

atrioventricular (AV) node: Specialized cardiocytes that relay the contractile stimulus to the atrioventricular bundle (bundle of His), the bundle branches, the Purkinje fibers, and the ventricular myocardium; located at the boundary between the atria and ventricles. (20)

atrioventricular (AV) valve: One of the valves that prevents backflow into the atria during ventricular systole (contraction). (20)

atrophy: The wasting away of tissues from a lack of use, ischemia, or nutritional abnormalities. (10)

auditory: Pertaining to the sense of hearing. (17) auditory ossicles: The bones of the middle ear:

malleus, incus, and stapes. (7, 17) auditory tube: A passageway that connects the nasopharynx with the middle ear cavity; also called Eustachian tube or pharyngotympanic tube. (17)

auricle: A broad, flattened process that resembles the external ear; in the ear, the expanded, projecting portion that surrounds the external auditory meatus, also called pinna (17); in the heart, the externally visible flap formed by the collapse of the outer wall of a relaxed atrium (20)

autoantibodies: Antibodies that react with antigens on the surfaces of a person's own cells and tissues. (22)

autoimmunity: The immune system's sensitivity to one's own tissues, resulting in the production of autoantibodies. (22)

autolysis: The destruction of a cell due to the rupture of lysosomal membranes in its cytoplasm. (3)

automaticity: The spontaneous depolarization to threshold, characteristic of cardiac pacemaker cells. (10, 20)

autonomic ganglion: A collection of visceral motor neurons outside the central nervous system. (16)

- **autonomic nerve:** A peripheral nerve consisting of preganglionic or postganglionic autonomic fibers. (16)
- **autonomic nervous system (ANS):** Centers, nuclei, tracts, ganglia, and nerves involved in the unconscious regulation of visceral functions; includes components of the central nervous system and the peripheral nervous system. (12, 16)
- **autoregulation:** Changes in activity that maintain homeostasis in direct response to changes in the local environment; does not require neural or endocrine control. (1, 21, 26)
- **autosome:** A chromosome other than the X or Y sex chromosome. (29)
- avascular: Without blood vessels. (4)
- axilla: The armpit. (1, 8)
- **axolemma:** The plasma membrane of an axon, continuous with the plasma membrane of the cell body and dendrites and distinct from any neuroglial coverings. (12)
- **axon:** The elongated extension of a neuron that conducts an action potential. (4, 12)
- axon hillock: In a multipolar neuron, the portion of the cell body adjacent to the initial segment. (12)axoplasm: The cytoplasm within an axon. (12)

B

- **bacteria:** Single-celled microorganisms, some pathogenic, that are common in the environment and in and on the body. (22)
- Bainbridge reflex: See atrial reflex.
- **baroreception:** The ability to detect changes in pressure. (15, 23)
- **baroreceptor reflex:** A reflexive change in cardiac activity in response to changes in blood pressure. (21)
- **baroreceptors:** The nerve endings that sense pressure changes. (15, 21)
- **basal nuclei:** Nuclei of the cerebrum that are important in the subconscious control of skeletal muscle activity. (14, 15)
- **base:** A compound whose dissociation releases a hydroxide ion (OH⁻) or removes a hydrogen ion (H⁺) from the solution. (2, 27)
- **basement membrane:** A layer of filaments and fibers that attach an epithelium to the underlying connective tissue; also called *basal lamina*. (4)
- **basophils:** Circulating granulocytes (white blood cells) similar in size and function to tissue mast cells. (19)
- **B cells:** Lymphocytes capable of differentiating into plasma cells, which produce antibodies. (19, 22) **benign:** Not malignant. (3)
- **beta cells:** Cells of the pancreatic islets that secrete insulin in response to increased blood sugar concentrations. (18)
- **beta oxidation:** Fatty acid catabolism that produces molecules of acetyl-CoA. (25)
- **beta receptors:** Membrane receptors sensitive to epinephrine; stimulation may result in the excitation or inhibition of the target cell. (16)
- **bicarbonate ion:** HCO₃⁻; anion component of the carbonic acid–bicarbonate buffer system. (26, 27)
- **bicuspid:** Having two cusps or points; refers to a premolar tooth, which has two roots, or to the left AV valve, which has two cusps. (24)
- **bicuspid valve:** The left atrioventricular (AV) valve, also called *mitral valve*. (20)
- bifurcate: To branch into two parts.
- **bile:** The exocrine secretion of the liver; stored in the gallbladder and ejected into the duodenum. (24)
- **bile salts:** Steroid derivatives in bile; responsible for the emulsification of ingested lipids. (2)

- **bilirubin:** A pigment that is the by-product of hemoglobin catabolism. (19)
- **biopsy:** The removal of a small sample of tissue for pathological analysis. (4, 13)
- **bladder:** A muscular sac that distends as fluid is stored and whose contraction ejects the fluid at an appropriate time; used alone, the term usually refers to the urinary bladder. (26)
- **blastocyst:** An early stage in the developing embryo, consisting of an outer trophoblast and an inner cell mass. (29)
- **blockers/blocking agents:** Drugs that block membrane pores or prevent binding to membrane receptors. (16)
- **blood-brain barrier:** The isolation of the central nervous system from the general circulation; primarily the result of astrocyte regulation of capillary permeabilities. (12, 14)
- blood clot: See clot.
- **blood–CSF barrier:** The isolation of the cerebrospinal fluid from the capillaries of the choroid plexus; primarily the result of specialized ependymal cells. (14)
- **blood pressure:** A force exerted against vessel walls by the blood in the vessels, due to the push exerted by cardiac contraction and the elasticity of the vessel walls; usually measured along one of the muscular arteries, with systolic pressure measured during ventricular systole (contraction) and diastolic pressure during ventricular diastole (relaxation). (21)
- **blood-testis barrier:** The isolation of the interior of the seminiferous tubules from the general circulation, due to the activities of the nurse (sustentacular) cells. (28)
- **Bohr effect:** The increased oxygen release by hemoglobin in the presence of increased carbon dioxide levels. (23)
- **bolus:** A compact mass; usually refers to compacted ingested material (food) on its way to the stomach. (23, 24)
- bone: See osseous tissue.
- **bowel:** The intestinal tract. (24)
- Bowman's capsule: See glomerular capsule. (26)
- brachial: Pertaining to the arm.
- **brachial plexus:** A network formed by branches of spinal nerves C_5-T_1 en route to innervating the upper limb. (13)
- brachium: The arm. (11)
- bradycardia: An abnormally slow heart rate, usually below 50 bpm. (20)
- brain natriuretic peptide (BNP): See natriuretic peptides.
- brain stem: The brain minus the cerebrum, diencephalon, and cerebellum; midbrain, pons, and medulla oblongata. (14)
- brevis: Short.
- **Broca's area:** The speech center of the brain, normally located on the neural cortex of the left cerebral hemisphere. (14)
- **bronchial tree:** The trachea, bronchi, and bronchioles. (23)
- **bronchodilation:** The dilation of the bronchial passages; can be caused by sympathetic stimulation. (23)
- **bronchus/bronchi:** Branch/branches of the bronchial tree between the trachea and bronchioles. (23)
- buccal: Pertaining to the cheeks. (24)
- **buffer:** A compound that stabilizes the pH of a solution by removing or releasing hydrogen ions. (2, 27)
- **buffer system:** Interacting compounds that prevent increases or decreases in the pH of body fluids; includes the carbonic acid–bicarbonate buffer

system, the phosphate buffer system, and the protein buffer systems. (27)

- **bulbar:** Pertaining to the brain stem. (14)
- **bulbourethral glands:** Mucous glands at the base of the penis that secrete into the penile urethra; the equivalent of the greater vestibular glands of females; also called *Cowper's glands*. (28)
- **bundle branches:** Specialized conducting cells in the ventricles that carry the contractile stimulus from the atrioventricular bundle (bundle of His) to the Purkinje fibers. (20)
- **bundle of His:** Specialized conducting cells in the interventricular septum that carry the contracting stimulus from the AV node to bundle branches and then to Purkinje fibers; also called the *atrioventricular bundle*. (20)
- **bursa:** A small sac filled with synovial fluid that cushions adjacent structures and reduces friction. (9)

С

- **calcaneal tendon:** The large tendon that inserts on the calcaneus; tension on this tendon produces extension (plantar flexion) of the foot; also called *Achilles tendon.* (8, 11)
- **calcaneus:** The heel bone, the largest of the tarsal bones. (8)
- **calcification:** The deposition of calcium salts within a tissue. (4, 6)
- **calcitonin:** The hormone secreted by C cells of the thyroid when calcium ion concentrations are abnormally high; restores homeostasis by increasing the rate of bone deposition and the rate of calcium loss by the kidneys. (6, 18)
- **calculus/calculi:** Solid mass/masses of insoluble materials that form within body fluids, especially the gallbladder, kidneys, or urinary bladder. (26)
- **callus:** A localized thickening of the epidermis due to chronic mechanical stresses (5); a thickened area that forms at the site of a bone break as part of the repair process. (6)
- **calorigenic effect:** The stimulation of energy production and heat loss by thyroid hormones. (18)
- **canaliculi:** Microscopic passageways between cells; bile canaliculi carry bile to bile ducts in the liver (24); in bone, canaliculi permit the diffusion of nutrients and wastes to and from osteocytes. (4, 6)
- **cancellous bone:** Spongy bone, composed of a network of bony struts. (6)
- **cancer:** An illness caused by mutations leading to the uncontrolled growth and replication of the affected cells. (3)
- **cannula:** A tube that can be inserted into the body; commonly placed in blood vessels prior to transfusion or dialysis. (19)
- **capacitation:** The activation process that must occur before a spermatozoon can successfully fertilize an oocyte; occurs in the vagina after ejaculation. (28, 29)
- **capillary:** A small blood vessel, located between an arteriole and a venule, whose thin wall permits the diffusion of gases, nutrients, and wastes between plasma and interstitial fluids. (4, 19, 20, 21)
- **capitulum:** A general term for a small, elevated articular process; refers to the rounded distal surface of the humerus that articulates with the head of the radius. (8)
- caput: The head. (7)
- **carbaminohemoglobin:** Hemoglobin bound to carbon dioxide molecules. (19, 23)
- **carbohydrase:** An enzyme that breaks down carbohydrate molecules. (24)
- **carbohydrate:** An organic compound containing carbon, hydrogen, and oxygen in a ratio that approximates 1:2:1. (2, 25)

- **carbon dioxide:** CO₂*;* a compound produced by the decarboxylation reactions of aerobic metabolism. (2, 23)
- **carbonic anhydrase:** An enzyme that catalyzes the reaction $H_2O + CO_2 \rightarrow H_2CO_3$, important in carbon dioxide transport (23), gastric acid secretion (24), and renal pH regulation (26). **carcinogenic:** Stimulating cancer formation in
- affected tissues. (3) **cardia:** The region of the stomach surrounding its

connection with the esophagus. (24) **cardiac:** Pertaining to the heart. (10, 20)

- **cardiac cycle:** One complete heartbeat, including atrial and ventricular systole and diastole. (20)
- **cardiac output:** The amount of blood ejected by the left ventricle each minute; normally about 5 liters. (20)
- **cardiac reserve:** The potential percentage increase in cardiac output above resting levels. (20)
- **cardiac tamponade:** A compression of the heart due to fluid accumulation in the pericardial cavity. (20)
- cardiocyte: A cardiac muscle cell. (4, 10, 20)cardiovascular: Pertaining to the heart, blood, and blood vessels. (19, 20, 21)
- **cardiovascular centers:** Poorly localized area in the reticular formation of the medulla oblongata of the brain; includes cardioacceleratory, cardioinhibitory, and vasomotor centers. (14, 21)
- **carotene:** A yellow-orange pigment, found in carrots, sweet potatoes, and other vegetables, that the body can convert to vitamin A. (5)
- **carotid artery:** The main artery of the neck, servicing cervical and cranial structures; one branch, the internal carotid, provides a major blood supply to the brain. (21)
- **carotid body:** A group of receptors, adjacent to the carotid sinus, that are sensitive to changes in the carbon dioxide levels, pH, and oxygen concentrations of arterial blood. (15, 21)
- **carotid sinus:** A dilated segment at the base of the internal carotid artery whose walls contain baroreceptors sensitive to changes in blood pressure. (21)
- **carotid sinus reflex:** Reflexive changes in blood pressure that maintain homeostatic pressures at the carotid sinus, stabilizing blood flow to the brain. (21)

carpus/carpal: The wrist. (8, 11)

- **cartilage:** A connective tissue with a gelatinous matrix that contains an abundance of fibers. (4)
- **catabolism:** The breakdown of complex organic molecules into simpler components, accompanied by the release of energy. (2, 25)
- **catalyst:** A substance that accelerates a specific chemical reaction but that is not altered by the reaction. (2)
- **catecholamines:** Epinephrine, norepinephrine, dopamine, and related compounds. (18)
- **catheter:** A tube surgically inserted into a body cavity or along a blood vessel or excretory passageway for the collection of body fluids, monitoring of blood pressure, or introduction of medications or radiographic dyes. (20)

cation: An ion having a positive charge. (2, 27)

- **cauda equina:** Bundle of spinal nerve roots arising from the lumbosacral enlargement and medullary cone of the adult spinal cord; they extend caudally inside the vertebral canal en route to lumbar and sacral segments. (13)
- **caudal/caudally:** Closest to or toward the tail (coccyx).
- **caudate nucleus:** One of the basal nuclei involved with the subconscious control of skeletal muscular activity. (14)

- **cell:** The smallest living structural unit in the human body. (3)
- **cell body:** The body of a neuron; also called *soma*. (4, 12)
- cell-mediated immunity: Resistance to disease by sensitized T cells that destroy antigen-bearing cells by direct contact or through the release of lymphotoxins; also called *cellular immunity*. (22) center of ossification: The site in a connective
- tissue where bone formation begins. (6) **central canal:** Longitudinal canal in the center of an osteon that contains blood vessels and nerves, also
- osteon that contains blood vessels and nerves, also called *Haversian canal* (6); a passageway along the longitudinal axis of the spinal cord that contains cerebrospinal fluid. (13, 14)
- **central nervous system (CNS):** The brain and spinal cord. (12)

centriole: A cylindrical intracellular organelle composed of nine groups of microtubules, three in each group (9 + 0 array); functions in mitosis or meiosis by organizing the microtubules of the spindle apparatus. (3)

centromere: The localized region where two chromatids remain connected after the chromosomes have replicated; site of spindle fiber attachment. (3)

- **centrosome:** A region of cytoplasm that contains a pair of centrioles oriented at right angles to one another. (3)
- **cerebellum:** The posterior portion of the metencephalon, containing the cerebellar hemispheres; includes the arbor vitae, cerebellar nuclei, and cerebellar cortex. (14, 15)

cerebral cortex: An extensive area of neural cortex covering the surfaces of the cerebral hemispheres. (14)

- **cerebral hemispheres:** A pair of expanded portions of the cerebrum covered in neural cortex. (14)
- **cerebrospinal fluid (CSF):** Fluid bathing the internal and external surfaces of the central nervous system; secreted by the choroid plexus. (12, 13, 14)
- **cerebrovascular accident (CVA):** The occlusion of a blood vessel that supplies a portion of the brain, resulting in damage to the dependent neurons; also called *stroke*. (14)
- **cerebrum:** The largest portion of the brain, composed of the cerebral hemispheres; includes the cerebral cortex, the basal nuclei, and the internal capsule. (14)
- **cerumen:** The waxy secretion of the ceruminous glands along the external acoustic meatus. (5, 17)

ceruminous glands: Integumentary glands that secrete cerumen. (5, 17)

- **cervix:** The inferior portion of the uterus. (28) **chemoreception:** The detection of changes in the concentrations of dissolved compounds or gases (mainly CO₂ and O₂). (15, 17, 21, 23, 25)
- **chemotaxis:** The attraction of phagocytic cells to the source of abnormal chemicals in tissue fluids. (22)
- **chemotherapy:** The treatment of illness through the administration of specific chemicals.

chloride shift: The movement of plasma chloride ions into red blood cells in exchange for bicarbonate ions generated by the intracellular dissociation of carbonic acid. (23, 27)

- **cholecystokinin (CCK):** A duodenal hormone that stimulates the contraction of the gallbladder and the secretion of enzymes by the exocrine pancreas. (24)
- **cholesterol:** A steroid component of plasma membranes and a substrate for the synthesis of steroid hormones and bile salts. (2, 25)
- **choline:** A breakdown product or precursor of acetylcholine. (12)

- **cholinergic synapse:** A synapse where the presynaptic membrane releases acetylcholine on stimulation. (12, 16)
- chondrocyte: A cartilage cell. (4)
 chondroitin sulfate: The predominant
 proteoglycan in cartilage, responsible for the
 gelatinous consistency of the matrix. (4)
- **chordae tendineae:** Fibrous cords that stabilize the position of the AV valves in the heart, preventing backflow during ventricular systole (contraction). (20)
- chorion/chorionic: An extraembryonic membrane, consisting of the trophoblast and underlying mesoderm, that forms the placenta. (29)
 choroid: The middle, vascular layer in the wall of the eve. (17)
- **choroid plexus:** The vascular complex in the roof of the third and fourth ventricles of the brain, responsible for the production of cerebrospinal fluid. (14)
- **chromatid:** One complete copy of a DNA strand and its associated nucleoproteins. (3, 28, 29)
- **chromatin:** A histological term referring to the grainy material visible in cell nuclei during interphase; the appearance of the DNA content of the nucleus when the chromosomes are uncoiled. (3)
- **chromosomes:** Dense structures, composed of tightly coiled DNA strands and associated histones, that become visible in the nucleus when a cell prepares to undergo mitosis or meiosis; normal human somatic cells each contain 46 chromosomes. (3, 28, 29)
- **chronic:** Habitual or long term. **chylomicrons:** Relatively large droplets that may contain triglycerides, phospholipids, and cholesterol in association with proteins; synthesized and released by intestinal cells and transported to the venous blood by the lymphatic system. (24, 25)
- **ciliary body:** A thickened region of the choroid that encircles the lens of the eye; includes the ciliary muscle and the ciliary processes that support the suspensory ligaments of the lens. (17)
- **cilium/cilia:** Slender organelle/organelles that extends above the free surface of an epithelial cell. Multiple *motile cilia* generally undergo cycles of movement and are composed of a basal body and microtubules in a 9 + 2 array; a nonmotile, solitary *primary cilium* acts as an environmental sensor, and has microtubules arranged in a 9 + 0 array. (3)
- **circulatory system:** The network of blood vessels and lymphatic vessels that facilitate the distribution and circulation of extracellular fluid. (21, 22)
- **circumduction:** A movement at a synovial joint in which the distal end of the bone moves in a circular direction, but the shaft does not rotate. (9)
- **cisterna:** An expanded or flattened chamber derived from and associated with the endoplasmic reticulum. (3, 10)
- citric acid cycle: The reaction sequence that occurs in the matrix of mitochondria; in the process, organic molecules are broken down, carbon dioxide molecules are released, and hydrogen molecules are transferred by coenzymes to the electron transport system. (3, 10, 25)
- **clot:** A network of fibrin fibers and trapped blood cells; also called a *thrombus* if it occurs within blood vessels. (19)
- clotting factors: Plasma proteins, synthesized by the liver, that are essential to the clotting response. (19)clotting response: The series of events that result in the formation of a clot. (19)

coccygeal ligament: The fibrous extension of the dura mater and filum terminale; provides longitudinal stabilization to the spinal cord. (13)

coccyx: The terminal portion of the spinal column, consisting of relatively tiny, fused vertebrae. (7)

cochlea: The spiral portion of the bony labyrinth of the internal ear that surrounds the organ of hearing. (17)

cochlear duct: See scala media. (17)

codon: A sequence of three nitrogenous bases along an mRNA strand that will specify the location of a single amino acid in a peptide chain. (3)

coelom: The body cavity lined by a serous membrane and subdivided during fetal development into the pleural, pericardial, and peritoneal cavities.

- **coenzymes:** Complex organic cofactors; most are structurally related to vitamins. (2, 25)
- **cofactor:** Ions or molecules that must be attached to the active site before an enzyme can function; examples include mineral ions and several vitamins. (2)
- **collagen:** A strong, insoluble protein fiber common in connective tissues. (4)

collateral ganglion: A sympathetic ganglion located anterior to the spinal column and separate from the sympathetic chain. (12, 16)

colliculus/colliculi: Little mound/mounds; in the brain, refers to one of the thickenings in the roof of the mesencephalon; the superior colliculi are associated with the visual system, and the inferior colliculi with the auditory system. (14, 15, 17)

colloid/colloidal suspension: A solution containing large organic molecules in suspension. (2, 26)

colon: The large intestine from the cecum to the rectum. (24)

coma: An unconscious state from which an individual cannot be aroused, even by strong stimuli. (16)

- comminuted: Broken or crushed into small pieces. commissure: A crossing over from one side to another.
- **common bile duct:** The duct formed by the union of the cystic duct from the gallbladder and the bile ducts from the liver; terminates at the duodenal ampulla, where it meets the pancreatic duct. (24)
- **compact bone:** Dense bone that contains parallel osteons. (6)

complement system: A group of distinct plasma proteins that interact in a chain reaction after exposure to activated antibodies or the surfaces of certain pathogens; complement proteins promote cell lysis, phagocytosis, and other defense mechanisms. (22)

compliance: Expandability; the ability of certain organs to tolerate changes in volume; indicates the presence of elastic fibers and smooth muscles. (23)

compound: A pure chemical substance made up of atoms of two or more different elements in a fixed proportion, regardless of the type of chemical bond joining them. (2)

concentration: The amount (in grams) or number of atoms, ions, or molecules (in moles) per unit volume. (2, 3, 25, 26)

concentration gradient: Regional differences in the concentration of a particular substance. (3, 25, 26)

conception: Fertilization. (29)

concha/conchae: Three pairs of thin, scroll-like bones that project into the nasal cavities; the superior and middle conchae are part of the ethmoid, and the inferior nasal conchae articulate with the ethmoid, lacrimal, maxilla, and palatine bones; also called *turbinate(s)*. (7)

- **condyle:** A rounded articular projection on the surface of a bone. (8)
- congenital: Present at birth.
- **congestive heart failure (CHF):** The failure to maintain adequate cardiac output due to cardiovascular problems or myocardial damage. (23)
- **conjunctiva:** A layer of stratified squamous epithelium that covers the inner surfaces of the eyelids and the anterior surface of the eye to the edges of the cornea. (17)
- **connective tissue:** One of the four primary tissue types; provides a structural framework that stabilizes the relative positions of the other tissue types; includes connective tissue proper, cartilage, bone, and blood; contains cell products, cells, and ground substance. (4)
- **continuous propagation:** The propagation of an action potential along an unmyelinated axon or a muscle plasma membrane, wherein the action potential affects every portion of the membrane surface. (12)

contractility: The ability to contract; possessed by skeletal, smooth, and cardiac muscle cells. (4, 20) contralateral reflex: A reflex that affects the

- opposite side of the body from the stimulus. (13) **conus medullaris:** The conical tip of the spinal cord that gives rise to the filum terminale. (13)
- **convergence:** In the nervous system, the innervation of a single neuron by axons from several neurons; most common along motor pathways. (13)

coracoid process: A hook-shaped process of the scapula that projects above the anterior surface of the capsule of the shoulder joint. (8)

Cori cycle: The metabolic exchange of lactate from skeletal muscle for glucose from the liver; occurs during the recovery period after muscular exertion. (10)

- **cornea:** The transparent portion of the fibrous layer of the anterior surface of the eye. (17)
- **corniculate cartilages:** A pair of small laryngeal cartilages. (23)
- cornu: Horn-shaped.
- coronoid: Hooked or curved. (8)
- **corpora quadrigemina:** The superior and inferior colliculi of the mesencephalic tectum (roof) in the brain. (14)
- corpus/corpora: Body/bodies.
- **corpus callosum:** A large bundle of axons that links centers in the left and right cerebral hemispheres. (14)

corpus luteum: The progesterone-secreting mass of follicle cells that develops in the ovary after ovulation. (18, 28)

- **cortex:** The outer layer or region of an organ (5) or bone. (6)
- **corticobulbar tracts:** Descending tracts that carry information or commands from the cerebral cortex to nuclei and centers in the brain stem. (15)
- **corticospinal tracts:** Descending tracts that carry motor commands from the cerebral cortex to the anterior gray horns of the spinal cord. (15)
- **corticosteroid:** A steroid hormone produced by the adrenal (suprarenal) cortex. (2, 18)

corticosterone: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)

corticotropin-releasing hormone (CRH): The releasing hormone, secreted by the hypothalamus, that stimulates secretion of adrenocorticotropic hormone (ACTH) by the anterior lobe of the pituitary gland (adenohypophysis). (18)

cortisol: A corticosteroid secreted by the zona fasciculata of the adrenal (suprarenal) cortex; a glucocorticoid. (18)

costa/costae: Rib/ribs. (7, 23)

- **cotransport:** The membrane transport of a nutrient, such as glucose, in company with the movement of an ion, normally sodium; transport requires a carrier protein but does not involve direct ATP expenditure and can occur regardless of the concentration gradient for the nutrient. (3, 24, 26)
- **countercurrent exchange:** The transfer of heat, water, or solutes between two fluids that travel in opposite directions. (25, 26)
- **countercurrent multiplication:** Active transport between two limbs of a loop that contains a fluid moving in one direction in which the effect of the transport increases; responsible for the concentration of urine in the kidney tubules. (26)
- covalent bond: A chemical bond between atoms that involves the sharing of electrons. (2)coxal bone: Hip bone. (7, 8)
- **cranial:** Pertaining to the head. (7)
- **cranial nerves:** Peripheral nerves originating at the brain. (12)

craniosacral division: The parasympathetic division of the autonomic nervous system. (16)

- **cranium:** The braincase; the skull bones that surround and protect the brain. (7)
- **creatine:** A nitrogenous compound, synthesized in the body, that can form a high-energy bond by connecting to a phosphate group and that serves as an energy reserve. (10)
- **creatine phosphate:** A high-energy compound in muscle cells; during muscle activity, the phosphate group is donated to ADP, regenerating ATP; also called *phosphorylcreatine*. (10)
- **creatinine:** A breakdown product of creatine metabolism. (26)
- **crenation:** Cellular shrinkage due to an osmotic movement of water out of the cytoplasm. (3)
- **cribriform plate:** A portion of the ethmoid that contains the foramina used by the axons of olfactory receptors en route to the olfactory bulbs of the cerebrum. (7)
- **cricoid cartilage:** A ring-shaped cartilage that forms the inferior margin of the larynx. (23)
- **crista/cristae:** A ridge-shaped collection of hair cells in the ampulla of a semicircular duct; the crista and cupula form a receptor complex sensitive to movement along the plane of the semicircular canal. (17)
- **cross-bridge:** The binding of a myosin head that projects from the surface of a thick filament at the active site of a thin filament in the presence of calcium ions. (10)
- **cuneiform cartilages:** A pair of small cartilages in the larynx. (23)
- **cupula:** A gelatinous mass that is located in the ampulla of a semicircular duct in the internal ear and whose movement stimulates the hair cells of the crista. (17)
- **Cushing's disease:** A condition caused by the oversecretion of adrenal steroids. (18)
- **cutaneous membrane:** The epidermis and papillary layer of the dermis. (4, 5)
- cuticle: The layer of dead, keratinized cells that surrounds the shaft of a hair; for nails, see eponychium. (5)
- **cyanosis:** An abnormal bluish coloration of the skin due to the presence of deoxygenated blood in vessels near the body surface. (5)
- **cystic duct:** A duct that carries bile between the gallbladder and the common bile duct. (24) **cytochrome:** A pigment component of the
- electron transport system; a structural relative of heme. (25)

- **cytokinesis:** The cytoplasmic movement that separates two daughter cells at the completion of mitosis. (3)
- **cytology:** The study of cells. (1, 3)
- **cytoplasm:** The material between the plasma membrane and the nuclear membrane; cell contents. (3)
- **cytosine:** A pyrimidine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)
- **cytoskeleton:** A network of microtubules and microfilaments in the cytoplasm. (3)
- **cytosol:** The fluid portion of the cytoplasm; also called *intracellular fluid*. (3, 27)
- cytotoxic: Poisonous to cells. (22)
- **cytotoxic T cells:** Lymphocytes involved in cellmediated immunity that kill target cells by direct contact or by the secretion of lymphotoxins; also called *killer T cells* and $T_{\rm C}$ cells. (22)

D

- **daughter cells:** Genetically identical cells produced by somatic cell division. (3, 28)
- **deamination:** The removal of an amino group from an amino acid. (25, 26)
- **decomposition reaction:** A chemical reaction that breaks a molecule into smaller fragments. (2)
- **decussate:** To cross over to the opposite side, usually referring to the crossover of the descending tracts of the corticospinal pathway on the ventral surface of the medulla oblongata. (15)
- defecation: The elimination of fecal wastes. (24)
- degradation: Breakdown, catabolism. (2, 25)
- **dehydration:** A reduction in the water content of the body that threatens homeostasis. (27)
- **dehydration synthesis:** The joining of two molecules associated with the removal of a water molecule. (2)
- **demyelination:** The loss of the myelin sheath of an axon, normally due to chemical or physical damage to Schwann cells or oligodendrocytes. (12)
- **denaturation:** A temporary or permanent change in the three-dimensional structure of a protein. (2)
- **dendrite:** A sensory process of a neuron. (4, 12) **deoxyribonucleic acid (DNA):** A nucleic acid consisting of a double chain of nucleotides that contains the sugar deoxyribose and the nitrogenous bases adenine, guanine, cytosine, and
- thymine. (2) **deoxyribose:** A five-carbon sugar resembling ribose but lacking an oxygen atom. (2)
- **depolarization:** A change in the membrane potential from a negative value toward 0 mV. (12, 20)
- **depression:** Inferior (downward) movement of a body part.
- **dermatitis:** An inflammation of the skin. (5) **dermatome:** A sensory region monitored by the
- dorsal rami of a single spinal segment. (13) **dermis:** The connective tissue layer beneath the
- epidermis of the skin. (5) **detrusor muscle:** Collectively, the three layers of smooth muscle in the wall of the urinary
- bladder. (26) **detumescence:** The loss of a penile erection. (28) **development:** Growth and the acquisition of
- increasing structural and functional complexity; includes the period from conception to maturity.
- **diabetes insipidus:** Disorder of the pituitary gland characterized by polyuria (excessive urination) and polydipsia (excessive thirst) that results from inadequate production of antidiuretic hormone (ADH). (18)
- **diabetes mellitus:** Disorder characterized by polyuria (excessive urination) and glycosuria (glucose in the urine), most commonly due to the

inadequate production or diminished sensitivity to insulin with a resulting increase of blood glucose levels. (18)

- **diapedesis:** The movement of white blood cells through the walls of blood vessels by migration between adjacent endothelial cells. (19, 22)
- **diaphragm:** Any muscular partition; the respiratory muscle that separates the thoracic cavity from the abdominopelvic cavity. (1, 11, 23)
- diaphysis: The shaft of a long bone. (6)
- diarthrosis: A synovial joint. (9)
- **diastolic pressure:** Pressure measured in the walls of a muscular artery when the left ventricle is in diastole (relaxation). (20)
- **diencephalon:** A division of the brain that includes the epithalamus, thalamus, and hypothalamus. (14)
- **differential count:** An estimate of the number of each type of white blood cell on the basis of a random sampling of 100 white blood cells. (19)
- **differentiation:** The gradual appearance of characteristic cellular specializations during development as the result of gene activation or repression. (3)
- **diffusion:** Passive molecular movement from an area of higher concentration to an area of lower concentration. (3, 21, 23, 26)
- **digestion:** The chemical breakdown of ingested food into simple molecules that can be absorbed by the cells of the digestive tract. (24)
- **digestive system:** The digestive tract and associated glands. (24)
- **digestive tract:** An internal passageway that begins at the mouth, ends at the anus, and is lined by a mucous membrane; also called *gastrointestinal tract.* (24)
- **dilate:** To increase in diameter; to enlarge or expand.
- disaccharide: A compound formed by the joining of two simple sugars by dehydration synthesis. (2)dissociation: See ionization.
- **distal:** A direction away from the point of attachment or origin; for a limb, away from its attachment to the trunk. (1, 8)
- **distal convoluted tubule (DCT):** The segment of the nephron closest to the connecting tubules and collecting duct; an important site of active secretion. (26)
- **diuresis:** Fluid loss by the kidneys; the production of unusually large volumes of urine. (26)
- **divergence:** In neural tissue, the spread of information from one neuron to many neurons; an organizational pattern common along sensory pathways of the central nervous system. (13)
- **diverticulum:** A sac or pouch in the wall of the colon or other organ. (24)
- **DNA molecule:** Two DNA strands wound in a double helix and held together by hydrogen bonds between complementary nitrogenous base pairs. (3)
- **dopamine:** An important neurotransmitter in the central nervous system. (12)
- dorsal: Toward the back, posterior.
- **dorsal root ganglion:** A peripheral nervous system ganglion containing the cell bodies of sensory neurons. (13)
- **dorsiflexion:** Upward movement of the foot through flexion at the ankle. (9)
- **Down's syndrome:** A genetic abnormality resulting from the presence of three copies of chromosome 21; people with this condition have characteristic physical and intellectual deficits; also called *trisomy 21.* (16)
- **duct:** A passageway that delivers exocrine secretions to an epithelial surface. (4)
- **ductus arteriosus:** A vascular connection between the pulmonary trunk and the aorta that functions

throughout fetal life; normally closes at birth or shortly thereafter and persists as the ligamentum arteriosum. (21, 23)

- **ductus deferens:** A passageway that carries spermatozoa from the epididymis to the ejaculatory duct; also called the *vas deferens.* (28)
- **duodenal ampulla:** A chamber that receives bile from the common bile duct and pancreatic secretions from the pancreatic duct. (24)
- **duodenal papilla:** A conical projection from the inner surface of the duodenum that contains the opening of the duodenal ampulla. (24)
- **duodenum:** The proximal 25 cm (9.8 in.) of the small intestine that contains short villi and submucosal glands. (24)
- **dura mater:** The outermost membrane (meninx) of the cranial and spinal meninges. (13, 14)

E

- **eccrine glands:** Sweat glands of the skin that produce a watery secretion. (5)
- ectoderm: One of the three primary germ layers; covers the surface of the embryo and gives rise to the nervous system, the epidermis and associated glands, and a variety of other structures. (29)
- ectopic: Outside the normal location.
- **effector:** A peripheral gland or muscle cell innervated by a motor neuron. (1, 12)
- **efferent:** Conducting a fluid or nerve impulse away from an organ or structure.
- **efferent arteriole:** An arteriole carrying blood away from a glomerulus of the kidney. (26)
- **efferent fiber:** An axon that carries impulses away from the central nervous system. (12)
- ejaculation: The ejection of semen from the penis as the result of muscular contractions of the bulbospongiosus and ischiocavernosus muscles. (28)
- **ejaculatory ducts:** Short ducts that pass within the walls of the prostate gland and connect the ductus deferens with the prostatic urethra. (28)
- elastase: A pancreatic enzyme that breaks down elastin fibers. (24)
- **elastin:** Connective tissue fibers that stretch and recoil, providing elasticity to connective tissues. (4, 5)
- electrical coupling: A connection between adjacent cells that permits the movement of ions and the transfer of graded or propagated changes in the membrane potential from cell to cell. (12)
- electrocardiogram (ECG, EKG): A graphic record of the electrical activities of the heart, as monitored at specific locations on the body surface. (20)
- electroencephalogram (EEG): A graphic record of the electrical activities of the brain. (14)
- electrolytes: Soluble inorganic compounds whose ions will conduct an electrical current in solution. (2, 27)
- **electron:** One of the three fundamental subatomic particles; has a negative charge and normally orbits the protons of the nucleus. (2, 25)
- electron transport system (ETS): The cytochrome system responsible for aerobic energy production in cells; a complex bound to the inner mitochondrial membrane. (25)
- **element:** All the atoms with the same atomic number. (2)
- **elevation:** Movement in a superior, or upward, direction.
- **elimination:** The ejection of wastes from the body through urination or defecation. (24, 26)
- **embolism:** The obstruction of a vessel, typically by a blood clot. (19)

- **embolus:** An air bubble, fat globule, or blood clot drifting in the bloodstream. (19)
- **embryo:** The developmental stage beginning at fertilization and ending at the start of the third developmental month. (29)
- **embryology:** The study of embryonic development, focusing on the first two months after fertilization. (1, 28)
- **endocardium:** The simple squamous epithelium that lines the heart and is continuous with the endothelium of the great vessels. (20)
- **endochondral ossification:** The replacement of a cartilaginous model with bone; the characteristic mode of formation for skeletal elements other than the bones of the cranium, the clavicles, and sesamoid bones. (6)
- **endocrine gland:** A gland that secretes hormones into the blood. (4, 18)
- **endocrine system:** The endocrine (ductless) glands and organs of the body. (18)
- **endocytosis:** The movement of relatively large volumes of extracellular material into the cytoplasm by the formation of a membranous vesicle at the cell surface; includes pinocytosis and phagocytosis. (3)
- **endoderm:** One of the three primary germ layers; the layer on the undersurface of the embryonic disc; gives rise to the epithelia and glands of the digestive system, the respiratory system, and portions of the urinary system. (29)
- endogenous: Produced within the body.
- **endolymph:** The fluid contents of the membranous labyrinth (the saccule, utricle, semicircular ducts, and cochlear duct) of the internal ear. (17)
- **endometrium:** The mucous membrane lining the uterus. (28)
- **endomysium:** A delicate network of connective tissue fibers that surrounds individual muscle cells. (10)
- **endoneurium:** A delicate network of connective tissue fibers that surrounds individual nerve fibers. (13)
- **endoplasmic reticulum:** A network of membranous channels in the cytoplasm of a cell that function in intracellular transport, synthesis, storage, packaging, and secretion. (3)
- **endorphins:** Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)
- **endosteum:** An incomplete cellular lining on the inner (medullary) surfaces of bones. (6)
- **endothelium:** The simple squamous epithelial cells that line blood and lymphatic vessels. (4, 19, 21)
- **enkephalins:** Neuromodulators, produced in the central nervous system, that inhibit activity along pain pathways. (12)
- **enterocrinin:** A hormone secreted by the lining of the duodenum after exposure to chyme; stimulates the secretion of the submucosal glands. (24)
- **enteroendocrine cells:** Endocrine cells scattered among the epithelial cells that line the digestive tract. (24)
- **enterogastric reflex:** The reflexive inhibition of gastric secretion; initiated by the arrival of chyme in the small intestine. (24)
- **enterohepatic circulation:** The excretion of bile salts by the liver, followed by the absorption of bile salts by intestinal cells for return to the liver by the hepatic portal vein. (24)
- **enteropeptidase:** An enzyme in the lumen of the small intestine that activates the proenzymes secreted by the pancreas; formerly called enterokinase. (24)
- **enzyme:** A protein that catalyzes a specific biochemical reaction. (2)

- **eosinophil:** A type of white blood cell with a lobed nucleus and red-staining granules; participates in the immune response and is especially important during allergic reactions. (19)
- **ependyma:** The layer of cells lining the ventricles and central canal of the central nervous system. (12)
- **epicardium:** A serous membrane covering the outer surface of the heart; also called *visceral pericardium*. (20)
- **epidermis:** The epithelium covering the surface of the skin. (5)
- **epididymis:** A coiled duct that connects the rete testis to the ductus deferens; site of functional maturation of spermatozoa. (28)
- **epidural space:** The space between the spinal dura mater and the walls of the vertebral foramen; contains blood vessels and adipose tissue; a common site of injection for regional anesthesia. (13)
- **epiglottis:** A blade-shaped flap of tissue, reinforced by cartilage, that is attached to the posterior and superior surface of the thyroid cartilage; folds over the entrance to the larynx during swallowing. (23)
- **epimysium:** A dense layer of collagen fibers that surrounds a skeletal muscle and is continuous with the tendons/aponeuroses of the muscle and with the perimysium. (10)
- **epineurium:** A dense layer of collagen fibers that surrounds a peripheral nerve. (13)
- **epiphyseal cartilage:** The cartilaginous region between the epiphysis and diaphysis of a growing bone; also called *epiphyseal plate*. (6)
- **epiphysis:** The head of a long bone. (6)
- **epithelium:** One of the four primary tissue types; a layer of cells that forms a superficial covering or an internal lining of a body cavity or vessel. (4, 24) **eponychium:** A narrow zone of stratum corneum
- that extends across the surface of a nail at its exposed base; also called the *cuticle*. (5) **equilibrium:** A dynamic state in which two opposing
- forces or processes are in balance. (1, 15, 17)
- **erection:** The stiffening of the penis due to the erectile tissues of the corpora cavernosa and corpus spongiosum filling with blood. (28)
- **erythema:** Redness and inflammation at the surface of the skin. (5, 22)
- erythrocyte: A red blood cell (RBC); has no nucleus and contains large quantities of hemoglobin. (4, 19)
- **erythropoietin:** A hormone released by most tissues, and especially by the kidneys, when oxygen levels decrease; stimulates erythropoiesis (red blood cell formation) in red bone marrow. (18, 19, 21)
- *Escherichia coli:* A normal bacterial resident of the large intestine. (24)
- **esophagus:** A muscular tube that connects the pharynx to the stomach. (24)
- **essential amino acids:** Amino acids that cannot be synthesized in the body in adequate amounts and must be obtained from the diet. (25)
- **essential fatty acids:** Fatty acids that cannot be synthesized in the body and must be obtained from the diet. (25)
- **estrogens:** A class of steroid sex hormones that includes estradiol. (2, 18)
- **evaporation:** A movement of molecules from the liquid state to the gaseous state.
- eversion: A turning outward. (9)
- **excitable membranes:** Membranes that propagate action potentials, a characteristic of muscle cells and nerve cells. (10, 12)
- **excitatory postsynaptic potential (EPSP):** The depolarization of a postsynaptic membrane by a chemical neurotransmitter released by the presynaptic cell. (12)

- **excretion:** The removal of wastes from the blood, tissues, or organs.
- exocrine gland: A gland that secretes onto the body surface or into a passageway connected to the exterior. (4)
- **exocytosis:** The ejection of cytoplasmic materials by the fusion of a membranous vesicle with the plasma membrane. (3)
- expiration: Exhalation; breathing out.
- **extension:** An increase in the angle between two articulating bones; the opposite of flexion. (8, 9)
- **external acoustic meatus:** A passageway in the temporal bone that leads to the tympanic membrane of the middle ear. (17)
- **external ear:** The auricle, external acoustic meatus, and tympanic membrane. (17)
- **external nares:** The nostrils; the external openings into the nasal cavity. (23)
- **external respiration:** The diffusion of gases between the alveolar air and the alveolar capillaries and between the systemic capillaries and peripheral tissues. (23)
- **exteroceptors:** General sensory receptors in the skin, mucous membranes, and special sense organs that provide information about the external environment and about our position within it. (12)
- **extracellular fluid:** All body fluids other than that contained within cells; includes plasma and interstitial fluid. (3, 27)
- **extraembryonic membranes:** The yolk sac, amnion, chorion, and allantois. (29)
- **extrafusal fibers:** Contractile muscle fibers (as opposed to the sensory intrafusal fibers, or muscle spindles). (13)
- **extrinsic pathway:** A clotting pathway that begins with damage to blood vessels or surrounding tissues and ends with the formation of tissue factor complex. (19)

F

- **fabella:** A sesamoid bone commonly located in the gastrocnemius muscle. (11)
- **facilitated:** Brought closer to threshold, as in the depolarization of a nerve plasma membrane toward threshold; making the cell more sensitive to depolarizing stimuli. (12)
- **facilitated diffusion:** The passive movement of a substance across a plasma membrane by means of a protein carrier. (3, 24, 26)
- falciform ligament: A sheet of mesentery that contains the ligamentum teres, the fibrous remains of the umbilical vein of the fetus. (29) falx: Sickle-shaped.
- **falx cerebri:** The curving sheet of dura mater that extends between the two cerebral hemispheres; encloses the superior sagittal sinus. (7, 14)
- **fasciae:** Connective tissue fibers, primarily collagen, that form sheets or bands beneath the skin to attach, stabilize, enclose, and separate muscles and other internal organs. (4)
- **fasciculus:** A small bundle; usually refers to a collection of nerve axons or muscle fibers. (10, 15)
- **fatty acids:** Hydrocarbon chains that end in a carboxyl group. (2)
- **fauces:** The passage from the mouth to the pharynx, bounded by the palatal arches, the soft palate, and the uvula. (24)
- **febrile:** Characterized by or pertaining to a fever. (22, 25)
- feces: Waste products eliminated by the digestive tract at the anus; contains indigestible residue, bacteria, mucus, and epithelial cells. (24) fenestra/fenestrae: Opening(s).
 - G-7

- **fertilization:** The fusion of a secondary oocyte and a spermatozoon to form a zygote. (28)
- **fetus:** The developmental stage lasting from the start of the third developmental month to delivery. (28, 29)
- **fibrin:** Insoluble protein fiber that forms the basic framework of a blood clot. (19)
- **fibrinogen:** A plasma protein that is the soluble precursor of the insoluble protein fibrin. (19)
- **fibroblasts:** Cells of connective tissue proper that produce extracellular fibers and secrete the organic substances of the extracellular matrix. (4)
- **fibrocartilage:** Cartilage containing an abundance of collagen fibers; located around the edges of joints, in the intervertebral discs, and the menisci of the knee; also referred to as *fibrous cartilage*. (4)
- **fibrocytes:** Mature fibroblasts; maintain connective tissue fibers of connective tissue proper. (4)
- **fibrous layer:** The outermost layer of the eye, composed of the sclera and cornea; also called *fibrous tunic.* (17)

fibula: The lateral, slender bone of the leg. (8)

- **filariasis:** A condition resulting from infection by mosquito-borne parasites; can cause elephantiasis. (21, 22)
- **filiform papillae:** Slender conical projections from the dorsal surface of the anterior two-thirds of the tongue. (17)
- **filtrate:** The fluid produced by filtration at a glomerulus in the kidney. (26)
- **filtration:** The movement of a fluid across a membrane whose pores restrict the passage of solutes on the basis of size. (21, 26)
- **filtration pressure:** The hydrostatic pressure responsible for filtration. (21, 26)
- **filum terminale:** A fibrous extension of the spinal cord, from the conus medullaris to the coccygeal ligament. (13)

fimbriae: Fringes; the fingerlike processes that surround the entrance to the uterine tube. (28)fissure: An elongated groove or opening. (7, 14)

- **fistula:** An abnormal passageway between two organs or from an internal organ or space to the body surface.
- **flaccid:** Limp, soft, flabby; a muscle without muscle tone.
- flagellum/flagella: An organelle that is structurally similar to a motile cilium but is used to propel a cell through a fluid; found on spermatozoa. (28) flatus: Intestinal gas. (24)
- **flexion:** A movement that decreases the angle between two articulating bones; the opposite of extension. (8, 9)

flexor: A muscle that produces flexion. (11)

- **flexor reflex:** A reflex contraction of the flexor muscles of a limb in response to a painful stimulus. (13)
- flexure: A bending.
- **folia:** Leaflike folds; the slender folds in the surface of the cerebellar cortex. (14)

follicle: A small secretory sac or gland.

- **follicle-stimulating hormone (FSH):** A hormone secreted by the adenohypophysis (anterior lobe of the pituitary gland); stimulates oogenesis (female) and spermatogenesis (male). (18, 28)
- **fontanelle:** A relatively soft, flexible, fibrous region between two flat bones in the developing skull; also spelled *fontanel*. (7)
- **foramen/foramina:** Opening/openings or passage/passages through a bone. (7, 20)
- **forearm:** The distal portion of the upper limb between the elbow and wrist. (8)
- forebrain: The cerebrum. (14)

- **fornix:** An arch or the space bounded by an arch; in the brain, an arching tract that connects the hippocampus with the mammillary bodies (14); in the eye, a slender pocket located where the epithelium of the ocular conjunctiva folds back on itself as the palpebral conjunctiva (17); in the vagina, the shallow recess surrounding the protrusion of the cervix. (28)
- **fossa:** A shallow depression or furrow in the surface of a bone. (8, 20)
- **fourth ventricle:** An elongated ventricle of the metencephalon (pons and cerebellum) and the myelencephalon (medulla oblongata) of the brain; the roof contains a region of choroid plexus. (14)
- **fovea:** The portion of the retina within the macula that provides the sharpest vision because it has the highest concentration of cones; also called *fovea centralis*. (17)
- fracture: A break or crack in a bone. (6)
- **frenulum:** A bridle; usually referring to a band of tissue that restricts movement, e.g., *lingual frenulum*. (24)

frontal plane: A sectional plane that divides the body into an anterior portion and a posterior portion; also called *coronal plane*. (1)

fructose: A hexose (six-carbon simple sugar) in foods and in semen. (2, 28)

fundus: The base of an organ such as the stomach, uterus, or gallbladder.

G

- **gallbladder:** The pear-shaped reservoir for bile after it is secreted by the liver. (24)
- **gametes:** Reproductive cells (spermatozoa or oocytes) that contain half the normal chromosome complement. (28, 29)
- gametogenesis: The formation of gametes. (28) gamma aminobutyric acid (GABA): A
- neurotransmitter of the central nervous system whose effects are generally inhibitory. (12) gamma motor neurons: Motor neurons that adjust
- the sensitivities of muscle spindles (intrafusal fibers). (13)
- **ganglion/ganglia:** A collection of neuron cell bodies in the peripheral nervous system. (12, 16)

gangliosides: Glycolipids that are important components of plasma membranes in the central nervous system. (12)

gap junctions: Connections between cells that permit electrical coupling. (4)

gaster: The stomach (24); the body, or belly, of a skeletal muscle. (11)

- gastric: Pertaining to the stomach. (24)
- **gastric glands:** The tubular glands of the stomach whose cells produce acid, enzymes, intrinsic factor, and hormones. (24)
- gastrointestinal (GI) tract: See digestive tract.
- **gene:** A portion of a DNA strand that functions as a hereditary unit, is located at a particular site on a specific chromosome, and codes for a specific protein or polypeptide. (3, 29)

genetic engineering: Research and experiments involving the manipulation of the genetic makeup of an organism. (29)

genetics: The study of heredity and genetic variations. (29)

- **geniculates:** The medial geniculate nuclei and the lateral geniculate nuclei are in the thalamus of the brain. (14)
- genitalia: The reproductive organs. (28)
- **germinal centers:** Pale regions in the interior of lymphoid tissues or lymphoid nodules, where

cell divisions occur that produce additional lymphocytes. (22)

- **gestation:** The period of intrauterine development; pregnancy. (29)
- **gland:** Cells that produce exocrine or endocrine secretions. (4)
- **glenoid cavity:** A rounded depression that forms the articular surface of the scapula at the shoulder joint. (8)
- glial cells: See neuroglia.
- **globular proteins:** Proteins whose tertiary structure makes them rounded and compact. (2)
- **glomerular capsule:** The expanded initial portion of the nephron that surrounds the glomerulus. (26)
- **glomerular filtration rate (GFR):** The rate of filtrate formation at the glomerulus. (26)
- **glomerulus:** A knot of capillaries that projects into the enlarged, proximal end of a nephron; the site of filtration, the first step in the production of urine. (26)
- glossopharyngeal nerve: Cranial nerve IX. (14)
- **glucagon:** A hormone secreted by the alpha cells of the pancreatic islets; increases blood glucose concentrations. (18)
- **glucocorticoids:** Hormones secreted by the zona fasciculata of the adrenal (suprarenal) cortex to modify glucose metabolism; cortisol and corticosterone are important examples. (18)
- **gluconeogenesis:** The synthesis of glucose from noncarbohydrate precursors (e.g., lactate, glycerol, or amino acids). (25)
- glucose: A six-carbon sugar, C₆H₁₂O₆; the preferred energy source for most cells and normally the only energy source for neurons. (2, 10, 18, 25) glycerides: Lipids composed of glycerol bound to
- fatty acids. (2) **glycogen:** A polysaccharide that is an important
- energy reserve; a polymer consisting of a long chain of glucose molecules. (2, 10)
- **glycogenesis:** The synthesis of glycogen from glucose molecules. (25)
- **glycogenolysis:** Glycogen breakdown and the liberation of glucose molecules. (25)
- glycolipids: Compounds created by the combination of carbohydrate and lipid components. (2)glycolysis: The anaerobic cytosolic breakdown of
- glucose into two 3-carbon molecules of pyruvate, with a net gain of two ATP molecules. (3, 10, 25)
- **glycoprotein:** A compound containing a relatively small carbohydrate group attached to a large protein. (2, 18)
- **glycosuria:** The presence of glucose in urine; also called *glucosuria*. (18, 26)
- **Golgi apparatus:** A cellular organelle consisting of a series of membranous plates that give rise to lysosomes and secretory vesicles. (3)
- **gomphosis:** A fibrous synarthrosis that binds a tooth to the bone of the jaw; *see* **periodontal ligament**. (24)
- **gonadotropin-releasing hormone (GnRH):** A hypothalamic releasing hormone that causes the secretion of both follicle-stimulating hormone and luteinizing hormone by the anterior lobe of the pituitary gland (adenohypophysis). (18, 28)
- **gonadotropins:** Follicle-stimulating hormone and luteinizing hormone, hormones that stimulate gamete development and sex hormone secretion. (18, 28)
- **gonads:** Reproductive organs that produce gametes and sex hormones. (28)
- **granulocytes:** White blood cells containing granules that are visible with the light microscope; includes eosinophils, basophils, and neutrophils; also called *granular leukocytes*. (19)

- **gray matter:** Areas in the central nervous system that are dominated by neuron cell bodies, neuroglia, and unmyelinated axons. (12, 13, 14)
- **gray ramus:** A bundle of postganglionic sympathetic nerve fibers distributed to effectors in the body wall, skin, and limbs by way of a spinal nerve. (13)
- **greater omentum:** A large fold of the dorsal mesentery of the stomach; hangs anterior to the intestines. (24)
- **groin:** The inguinal region. (11)
- **gross anatomy:** The study of the structural features of the body without the aid of a microscope.
- **growth hormone (GH):** An adenohypophysis (anterior lobe of the pituitary gland) hormone that stimulates tissue growth and anabolism when nutrients are abundant and restricts tissue glucose dependence when nutrients are in short supply. (18)
- growth hormone-inhibiting hormone (GH-IH): A hypothalamic regulatory hormone that inhibits growth hormone secretion by the anterior lobe of the pituitary gland (adenohypophysis); also called *somatostatin*. (18)
- **guanine:** A purine; one of the nitrogenous bases in the nucleic acids RNA and DNA. (2)

gustation: Sense of taste. (15, 17)

gyrus: A prominent fold or ridge of neural cortex on the surfaces of the cerebral hemispheres. (14)

Η

- **hair:** A keratinous strand produced by epithelial cells of the hair follicle. (5)
- **hair cells:** Sensory cells of the internal ear. (17) **hair follicle:** An accessory structure of the

integument; a tube lined by a stratified squamous epithelium that begins at the surface of the skin and ends at the hair papilla. (5)

- hallux: The big toe; also called the *great toe*. (8)haploid: Possessing half the normal number of chromosomes; a characteristic of gametes. (28, 29)
- **hard palate:** The bony roof of the oral cavity, formed by the maxillae and palatine bones. (23, 24)
- helper T cells: Lymphocytes whose secretions and other activities coordinate cell-mediated and antibodymediated immunities; also called T_H cells. (22)
- **hematocrit:** The percentage of formed elements in a sample of blood; also called *volume of packed red cells (VPRC)* or *packed cell volume (PCV)*. (19)
- hematoma: A tumor or swelling filled with blood.
 hematopoietic stem cells: Stem cells whose divisions produce each of the various populations
- of blood cells; also called *hemocytoblasts*. (19) **hematuria:** The abnormal presence of red blood

cells in urine. (19, 26) **heme:** A porphyrin ring containing a central iron atom that can reversibly bind oxygen molecules; a component of the hemoglobin molecule. (19)

- **hemoglobin:** A protein composed of four globular subunits, each bound to a heme molecule; gives red blood cells the ability to transport oxygen in the blood. (5, 19, 23, 27)
- **homozygous:** Having identical alleles at corresponding sites on a chromosome pair. (29)
- **hemolysis:** The breakdown of red blood cells. (3) **hemopoiesis:** Blood cell formation and
- differentiation. (19)
- hemorrhage: Blood loss; to bleed. (21)
- **hemostasis:** The stoppage of bleeding. (19) **heparin:** An anticoagulant released by activated
- basophils and mast cells. (4, 19)
- **hepatic duct:** The duct that carries bile away from the liver lobes and toward the union with the cystic duct. (24)

- **hepatic portal vein:** The vessel that carries blood from the intestinal capillaries to the sinusoids of the liver. (21)
- hepatocyte: A liver cell. (24)
- **heterozygous:** Possessing two different alleles at corresponding sites on a chromosome pair; a person's phenotype is determined by one or both of the alleles. (29)
- **hexose:** A six-carbon simple sugar. (2) **hiatus:** A gap, cleft, or opening.
- **hiatus:** A gap, cleft, or opening.
- **high density lipoprotein (HDL):** A lipoprotein with a relatively small lipid content; responsible for the movement of cholesterol from peripheral tissues to the liver. (25)
- **hilum:** A localized region where blood vessels, lymphatic vessels, nerves, and/or other anatomical structures are attached to an organ. (22, 23, 26)
- **hippocampus:** A region, deep to the floor of a lateral ventricle, involved with emotional states and the conversion of short-term to long-term memories. (12, 14)
- **histamine:** The chemical released by stimulated mast cells or basophils to initiate or enhance inflammation. (4, 12)
- histology: The study of tissues. (1, 4)
- **histones:** Proteins associated with the DNA of the nucleus; the DNA strands are wound around them. (3)
- **holocrine:** A form of exocrine secretion in which the secretory cell becomes swollen with vesicles and then ruptures. (4)
- **homeostasis:** The maintenance of a relatively constant internal environment. (1)
- **hormone:** A chemical that is secreted by one cell and travels through the bloodstream to affect the activities of cells in another part of the body. (2, 4, 6, 18, 21, 24, 28, 29)
- **human chorionic gonadotropin (hCG):** The placental hormone that maintains the corpus luteum for the first three months of pregnancy. (29)
- human immunodeficiency virus (HIV): The infectious agent that causes acquired immunodeficiency syndrome (AIDS). (22)human leukocyte antigen (HLA): See MHC protein.
- human placental lactogen (hPL): The placental hormone that stimulates the functional development of the mammary glands. (29)
 humoral immunity: See antibody-mediated immunity.
- **hyaluronan:** A carbohydrate component of proteoglycans in the matrix of many connective tissues. (4)
- **hyaluronidase:** An enzyme that breaks down the bonds between adjacent follicle cells; produced by some bacteria and found in the acrosome of a spermatozoon. (29)
- **hydrogen bond:** A weak interaction between the hydrogen atom on one molecule and a negatively charged portion of another molecule. (2)
- **hydrolysis:** The breakage of a chemical bond through the addition of a water molecule; the reverse of dehydration synthesis. (2)
- **hydrophilic:** Freely associating with water; readily entering into solution; water-loving. (2)
- **hydrophobic:** Incapable of freely associating with water molecules; insoluble; water-fearing. (2)
- **hydrostatic pressure:** Fluid pressure. (21, 26) **hydroxide ion:** OH⁻. (2)
- hypercapnia: High blood carbon dioxide concentrations, commonly as a result of hypoventilation or inadequate tissue perfusion. (23, 27)

- **hyperplasia:** An abnormal increase in the number of cells in a tissue or organ. (3)
- **hyperpolarization:** The movement of the membrane potential away from the normal resting potential and farther from 0 mV. (12)
- **hypersecretion:** The overactivity of glands that produce exocrine or endocrine secretions. (18)
- **hypertension:** Abnormally high blood pressure. (21) **hypertonic:** In comparing two solutions, the
- solution with the higher osmolarity. (3) **hypertrophy:** An increase in tissue size without cell division. (10)
- **hyperventilation:** A rate of respiration sufficient to decrease blood P_{CO2} to levels below normal. (23, 27)
- **hypocapnia:** An abnormally low blood P_{CO2}, commonly results from hyperventilation. (27)
- **hypodermic needle:** A needle inserted through the skin to introduce drugs into the subcutaneous layer. (5)
- **hypodermis:** The layer of loose connective tissue below the dermis; also called *subcutaneous layer* or *superficial fascia*. (4, 5)
- **hypophyseal portal system:** The network of vessels that carries blood from capillaries in the hypothalamus to capillaries in the anterior lobe of the pituitary gland (adenohypophysis). (18)
- hypophysis: See pituitary gland. (18)
- **hyposecretion:** Abnormally low exocrine or endocrine secretion. (18)
- **hypothalamus:** The floor of the diencephalon; the region of the brain containing centers involved with the subconscious regulation of visceral functions, emotions, drives, and the coordination of neural and endocrine functions. (14)
- **hypothermia:** An abnormally low body temperature. (25)
- **hypothesis:** A prediction that can be subjected to scientific analysis and review.
- **hypotonic:** In comparing two solutions, the solution with the lower osmolarity. (3)
- **hypoventilation:** A respiratory rate that is insufficient to keep blood P_{CO2} within normal levels. (23, 27)
- **hypoxia:** A low tissue oxygen concentration. (19, 23)

- **ileum:** The distal 2.5 m of the small intestine. (24) **ilium:** The largest of the three bones whose fusion creates a coxal bone. (8)
- **immunity:** Resistance to infection and disease caused by foreign substances, toxins, or pathogens. (22)
- **immunization:** The production of immunity by the deliberate exposure to antigens under conditions that prevent the development of illness but stimulate the production of memory B cells. (22)
- **immunoglobulin (Ig):** A circulating antibody. (19, 22)
- **implantation:** The attachment of a blastocyst into the endometrium of the uterine wall. (29)
- **inclusions:** Aggregations of insoluble pigments, nutrients, or other materials in cytoplasm. (3)
- **incus:** The central auditory ossicle, located between the malleus and the stapes in the middle ear cavity. (17)
- **inducer:** A stimulus that promotes the activity of a specific gene. (29)
- **inexcitable:** Incapable of propagating an action potential. (12)

- **infarct:** An area of dead cells that results from an interruption of blood flow. (19, 20)
- **infection:** The invasion and colonization of body tissues by pathogens. (4)
- **inferior:** Below, in reference to a particular structure, with the body in the anatomical position.
- **inferior vena cava:** The vein that carries blood from the parts of the body inferior to the heart to the right atrium. (20, 21)
- **infertility:** The inability to conceive; also called *sterility*. (28, 29)
- **inflammation:** A nonspecific defense mechanism that operates at the tissue level; characterized by swelling, redness, heat (warmth), pain, and sometimes loss of function. (4, 22)
- **infundibulum:** A tapering, funnel-shaped structure, in the brain, the connection between the pituitary gland and the hypothalamus (14, 18); in the uterine tube, the entrance bounded by fimbriae that receives the oocyte at ovulation. (28)
- **ingestion:** The introduction of food into the digestive tract by way of the mouth; eating. (24)
- **inguinal canal:** A passage through the abdominal wall that marks the path of testicular descent and that contains the testicular arteries, veins, and ductus deferens. (11, 28)
- **inguinal region:** The area of the abdominal wall near the junction of the trunk and the thighs that contains the external genitalia; the groin. (28)
- **inhibin:** A hormone, produced by nurse (sustentacular) cells of the testes and follicular cells of the ovaries, that inhibits the secretion of follicle-stimulating hormone by the adenohypophysis (anterior lobe of the pituitary gland). (18, 28)
- **inhibitory postsynaptic potential (IPSP):** A hyperpolarization of the postsynaptic membrane after the arrival of a neurotransmitter. (12)
- **initial segment:** The proximal portion of the axon where an action potential first appears. (12)
- **injection:** The forcing of fluid into a body part or organ.
- **inner cell mass:** Cells of the blastocyst that will form the body of the embryo. (29)

inner ear: See internal ear.

- **innervation:** The distribution of sensory and motor nerves to a specific region or organ. (11, 16)
- **insensible perspiration:** Evaporative water loss by diffusion across the epithelium of the skin or evaporation across the alveolar surfaces of the lungs. (5, 27)
- **insertion:** A point of attachment of a muscle; the end that is easily movable. (11)
- **insoluble:** Incapable of dissolving in solution. (2) **inspiration:** Inhalation; the movement of air into the respiratory system. (23)
- **insulin:** A hormone secreted by beta cells of the pancreatic islets; causes a decrease in blood glucose concentrations. (18)
- integument: The skin. (5)
- **intercalated discs:** Regions where adjacent cardiocytes interlock and where gap junctions permit electrical coupling between the cells. (4, 10, 20)

intercellular fluid: See interstitial fluid.

- **interferons:** Peptides released by virus-infected cells, especially lymphocytes, that slow viral replication and make other cells more resistant to viral infection. (22)
- **interleukins:** Peptides, released by activated monocytes and lymphocytes, that assist in the coordination of cell-mediated and antibody-mediated immunities. (22)
- **internal capsule:** The collection of afferent and efferent fibers of the white matter of the cerebral

hemispheres, visible on gross dissection of the brain. (14)

- **internal ear:** The membranous labyrinth that contains the organs of hearing and equilibrium. (17)
- **internal nares:** The entrance to the nasopharynx from the nasal cavity. (23)
- **internal respiration:** The diffusion of gases between interstitial fluid and cytoplasm. (23)
- **interneuron:** An association neuron; central nervous system neurons that are between sensory and motor neurons. (12)
- **interoceptors:** Sensory receptors monitoring the functions and status of internal organs and systems. (12)
- **interosseous membrane:** The fibrous connective tissue membrane between the shafts of the tibia and fibula and between the radius and ulna; an example of a fibrous amphiarthrosis. (8)
- **interphase:** The stage in the life cycle of a cell during which the chromosomes are uncoiled and all normal cellular functions except mitosis are under way. (29)
- **intersegmental reflex:** A reflex that involves several segments of the spinal cord. (13)
- **interstitial fluid:** The fluid in the tissues that fills the spaces between cells. (3)
- **interstitial growth:** A form of cartilage growth in which the cartilage expands from within through the growth, mitosis, and secretion of chondrocytes in the matrix. (4)
- **interventricular foramen:** The opening that permits fluid movement between the lateral and third ventricles of the brain. (14)
- **intervertebral disc:** A fibrocartilage pad between the bodies of successive vertebrae that absorbs shocks. (7, 9)
- **intestinal crypt:** A tubular epithelial pocket that is lined by secretory cells and opens into the lumen of the digestive tract; also called *intestinal gland*. (24)
- **intestine:** The tubular organ of the digestive tract. (18, 24)
- intracellular fluid: The cytosol. (27)
- **intrafusal fibers:** Muscle spindle fibers. (13) **intramembranous ossification:** The formation of bone within a connective tissue without the prior development of a cartilaginous model. (6)
- **intrinsic factor:** A glycoprotein, secreted by the parietal cells of the stomach, that facilitates the intestinal absorption of vitamin B₁₂. (19, 24, 25)
- **intrinsic pathway:** A pathway of the clotting system that begins with the activation of platelets and ends with the formation of factor X activator complex. (19)
- **inversion:** A turning inward. (9)
- **in vitro:** Outside the body, in an artificial environment.
- **in vivo:** In the living body.
- involuntary: Not under conscious control.
- **ion:** An atom or molecule having a positive or negative charge due to the loss or gain, respectively, of one or more electrons. (2, 26, 27)
- **ionic bond:** A molecular bond created by the attraction between ions with opposite charges. (2)

ionization: Dissociation; the breakdown of a molecule in solution to form ions. (2)

- **ipsilateral:** A reflex response that affects the same side as the stimulus. (13)
- **iris:** A contractile structure, made up of smooth muscle, that forms the colored portion of the eye. (17)
- **ischemia:** An inadequate blood supply to a region of the body. (11)
- **ischium:** One of the three bones whose fusion creates a coxal bone. (8)
- islets of Langerhans: See pancreatic islets.

- **isotonic:** A solution with an osmolarity that does not result in water movement across plasma membranes. (10)
- **isotopes:** Forms of an element whose atoms contain the same number of protons but different numbers of neutrons (and thus differ in atomic mass). (2)
- **isthmus:** A narrow band of tissue connecting two larger masses.

J

- **jejunum:** The middle part of the small intestine. (24) **joint:** An area where adjacent bones interact; also called *articulation*. (9)
- **juxtaglomerular cells:** Modified smooth muscle cells between the walls of the distal convoluted tubule and the afferent and efferent arterioles adjacent to the glomerulus and the macula densa. (26)
- **juxtaglomerular complex:** The macula densa and the juxtaglomerular cells; a complex responsible for the release of renin and erythropoietin. (26)

Κ

- **keratin:** The tough, fibrous protein component of nails, hair, calluses, and the general integumentary surface. (5)
- **keto acid:** The carbon chain that remains after the deamination or transamination of an amino acid. (25)
- ketoacidosis: A condition characterized by a decrease in blood pH due to the presence of large numbers of ketone bodies. (25, 26, 27)
- **ketone bodies:** Keto acids produced during the catabolism of lipids and ketogenic amino acids; specifically, acetone, acetoacetate, and beta-hydroxybutyrate. (25)
- **kidney:** A component of the urinary system; an organ functioning in the regulation of blood composition, including the excretion of wastes and the maintenance of normal fluid and electrolyte balances. (18, 26)
- killer T cells: See cytotoxic T cells.
- Krebs cycle: See citric acid cycle.
- **Kupffer cells:** Phagocytic cells of the liver sinusoids; also called *stellate reticuloendothelial cells*. (22, 24)

L

labium/labia: Lip/lips; the labia majora and labia minora are structures of the female external genitalia. (28)

labrum: A lip or rim.

- **labyrinth:** A maze of passageways; the structures of the internal ear. (17)
- **lacrimal gland:** A tear gland on the dorsolateral surface of the eye. (17)
- **lactase:** An enzyme that breaks down the milk sugar, lactose. (24)
- **lactate:** An anion released by the dissociation of lactic acid, produced from pyruvate under anaerobic conditions. (10)
- **lactation:** The production of milk by the mammary glands. (28)
- **lacteal:** A terminal lymphatic within an intestinal villus. (24)
- lacuna: A small pit or cavity. (4, 6)
- **lambdoid suture:** The synarthrosis between the parietal and occipital bones of the cranium. (7)
- **lamellae:** Concentric layers; the concentric layers of bone within an osteon. (6)
- **lamellated corpuscle:** A receptor sensitive to vibration. (15)

lamina: A thin sheet or layer.

- lamina propria: The reticular tissue that underlies a mucous epithelium and forms part of a mucous membrane. (4, 23, 24)
- Langerhans cells: Cells in the epithelium of the skin (15) and digestive tract (24) that participate in the immune response by presenting antigens to T cells: also called *dendritic cells*.
- large intestine: The terminal portions of the intestinal tract, consisting of the colon, the rectum, and the anal canal. (24)
- **laryngopharynx:** The division of the pharynx that is inferior to the epiglottis and superior to the esophagus. (23)
- **larynx:** A complex cartilaginous structure that surrounds and protects the glottis and vocal cords; the superior margin is bound to the hyoid bone, and the inferior margin is bound to the trachea. (23)
- latent period: The time between the stimulation of a muscle and the start of the contraction phase, (10)
- lateral: Pertaining to the side.
- lateral apertures: Openings in the roof of the fourth ventricle that permit the circulation of cerebrospinal fluid into the subarachnoid space. (14)
- lateral ventricle: A fluid-filled chamber within a cerebral hemisphere. (14)
- lens: The transparent refractive structure of the eye that is between the iris and the vitreous humor. (17)
- lesion: A localized abnormality in tissue organization. (4)
- lesser omentum: A double-layered peritoneal fold formed by the mesentery that connects the lesser curvature of the stomach to the liver. (24)

leukocyte: A white blood cell. (4, 19)

ligament: A dense band of connective tissue fibers that attaches one bone to another. (4, 9)

- ligamentum arteriosum: The fibrous strand in adults that is the remnant of the ductus arteriosus of the fetal stage. (21)
- ligamentum nuchae: An elastic ligament between the vertebra prominens and the occipital bone. (7)
- ligamentum teres: The fibrous strand in the falciform ligament of adults that is the remnant of the umbilical vein; also called the round ligament of the liver. (24)

ligate: To tie off.

limbic system: The group of nuclei and centers in the cerebrum and diencephalon that are involved with emotional states, memories, and behavioral drives. (14)

lingual: Pertaining to the tongue. (17, 24)

- lipid: An organic compound containing carbon, hydrogen, and oxygen in a ratio that does not approximate 1:2:1; includes fats, oils, and waxes. (2, 24, 25)
- lipogenesis: The synthesis of lipids from nonlipid precursors. (25)
- lipolysis: The catabolism of lipids as a source of energy. (25)
- lipoprotein: A compound containing a relatively small lipid bound to a protein. (25)
- liver: An organ of the digestive system that has varied and vital functions, including the production of plasma proteins, the excretion of bile, the storage of energy reserves, the detoxification of poisons, and the interconversion of nutrients. (24)
- lobule: Histologically, the basic organizational unit of the liver. (24)

local hormone: See prostaglandin.

loop of Henle: See nephron loop. (26)

loose connective tissue: A loosely organized, easily distorted connective tissue that contains

several fiber types, a varied population of cells, and a viscous ground substance. (4)

- lumbar: Pertaining to the lower back. (7, 13)
- lumen: The central space within a duct or other internal passageway. (4)
- lungs: The paired organs of breathing enclosed by the pleural cavities. (23)
- luteinizing hormone (LH): A hormone produced by the adenohypophysis (anterior lobe of the pituitary gland). In females, it assists FSH in follicle stimulation, triggers ovulation, and promotes the maintenance and secretion of endometrial glands. In males, it was formerly called interstitial cell-stimulating hormone because it stimulates testosterone secretion by the interstitial cells of the testes; also called lutropin. (18, 28)
- **lymph:** The fluid contents of lymphatic vessels, similar in composition to interstitial fluid. (4, 22)
- lymphatic vessels: The vessels of the lymphatic system; also called lymphatics. (4, 22)
- lymph nodes: Lymphoid organs that monitor the composition of lymph. (22)
- lymphocyte: A cell of the lymphatic system that plays a role in the immune response. (4, 19, 22)
- lymphokines: Chemicals secreted by activated lymphocytes. (22)
- **lymphopoiesis:** The production of lymphocytes from lymphoid stem cells. (19, 22)
- lymphotoxin: A secretion of lymphocytes that kills the target cells. (22)
- lysis: The destruction of a cell through the rupture of its plasma membrane. (3)
- lysosome: An intracellular vesicle containing digestive enzymes. (3)
- lysozyme: An enzyme, present in some exocrine secretions, that has antibiotic properties. (17)

Μ

- macrophage: A phagocytic cell of the monocytemacrophage system. (4, 22)
- macula: A receptor complex, located in the saccule or utricle of the internal ear, that responds to linear acceleration or gravity. (17)

macula (of retina): The oval area in the retina whose center (the fovea) is the region of sharpest vision; also called macula lutea. (17)

macula densa: A group of specialized secretory cells that is located in a portion of the distal convoluted tubule, adjacent to the glomerulus and the juxtaglomerular cells; a component of the juxtaglomerular complex. (26)

major histocompatibility complex: See MHC protein.

malignant tumor: A form of cancer characterized by rapid cell growth and the spread of cancer cells throughout the body. (3)

- malleus: An auditory ossicle, bound to the tympanic membrane and the incus. (17)
- malnutrition: An unhealthy state produced by inadequate dietary intake or absorption of nutrients (25)

mammillary bodies: Nuclei in the hypothalamus that affect eating reflexes and behaviors; a component of the limbic system. (14)

mammary glands: Milk-producing glands of the female breasts. (5, 28)

manus: The hand; manual. (8, 11)

- marrow: A tissue that fills the internal cavities in bone; dominated by hemopoietic cells (red bone marrow) or by adipose tissue (yellow bone marrow). (6, 19)
- mast cell: A connective tissue cell that, when stimulated, releases histamine, serotonin, and heparin, initiating the inflammatory response. (4)

mastication: Chewing. (11, 24)

- mastoid sinus: Air-filled spaces in the mastoid process of the temporal bone. (7)
- matrix: The extracellular fibers and ground substance of a connective tissue. (4)
- **maxillary sinus:** One of the paranasal sinuses; an air-filled chamber lined by a respiratory epithelium that is located in a maxilla and opens into the nasal cavity. (7)
- meatus: An opening or entrance into a passageway. (23, 26)
- mechanoreception: The detection of mechanical stimuli, such as touch, pressure, or vibration. (15) medial: Toward the midline of the body.
- mediastinum: The central tissue mass that divides the thoracic cavity into two pleural cavities. (1, 20) medulla: The inner layer or core of an organ.
- medulla oblongata: The most caudal of the brain regions, also called the *myelencephalon*. (14)
- medullary cavity: The space within a bone that contains the marrow. (6)
- medullary rhythmicity center: The center in the medulla oblongata that sets the background pace of respiration; includes inspiratory and expiratory centers. (14)
- megakaryocytes: Bone marrow cells responsible for the formation of platelets. (19)
- meiosis: Cell division that produces gametes with half the normal somatic chromosome complement. (3, 28)
- melanin: The yellow-brown pigment produced by the melanocytes of the skin. (5)
- melanocyte: A specialized cell in the deeper layers of the stratified squamous epithelium of the skin; responsible for the production of melanin. (4, 5, 18)
- melanocyte-stimulating hormone (MSH): A hormone, produced by the pars intermedia of the anterior lobe of the pituitary gland (adenohypophysis), that stimulates melanin production. (18)
- melatonin: A hormone secreted by the pineal gland; inhibits secretion of MSH and GnRH. (14, 18)
- membrane: Any sheet or partition; a layer consisting of an epithelium and the underlying connective tissue. (2)
- membrane flow: The continuous movement and exchange of membrane segments. (3)
- membrane potential: The potential difference, measured across a plasma membrane and expressed in millivolts, that results from the uneven distribution of positive and negative ions across the plasma membrane; also called transmembrane potential. (3, 10, 12)
- membranous labyrinth: Endolymph-filled tubes that enclose the receptors of the internal ear. (17)
- memory: The ability to recall information or sensations; can be divided into short-term and long-term memories. (16, 22)
- meninges: Three membranes that surround the surfaces of the central nervous system; the dura mater, the pia mater, and the arachnoid. (13)
- meniscus: A fibrocartilage pad between opposing surfaces in a joint. (9)
- menses: The first part of the uterine cycle in which the endometrial lining sloughs away; menstrual period. (28)
- merocrine: A method of secretion in which the cell ejects materials from secretory vesicles through exocytosis. (4, 5)
- mesencephalon: The midbrain; the region between the diencephalon and pons. (14)
- mesenchyme: Embryonic or fetal connective tissue. (4)
- mesentery: A double layer of serous membrane that supports and stabilizes the position of an organ

in the abdominopelvic cavity and provides a route for the associated blood vessels, nerves, and lymphatic vessels. (24)

mesoderm: The middle germ layer, between the ectoderm and endoderm of the embryo. (29)

mesothelium: A simple squamous epithelium that lines the body cavities enclosing the lungs, heart, and abdominal organs. (4)

messenger RNA (mRNA): RNA formed at transcription to direct protein synthesis in the cytoplasm. (2, 3)

metabolic turnover: The continuous breakdown and replacement of organic materials within cells. (2, 25)

metabolism: The sum of all biochemical processes under way within the human body at any moment: includes anabolism and catabolism. (25)

metabolites: Compounds produced in the body as a result of metabolic reactions. (2)

metacarpal bones: The five bones of the palm of the hand. (8)

metalloproteins: Proteins containing a metal ion cofactor; examples include plasma transport proteins, storage proteins, and enzymes. (19, 25)

metaphase: The stage of mitosis in which the chromosomes line up along the equatorial plane of the cell. (3)

metaphysis: The region of a long bone between the epiphysis and diaphysis, corresponding to the location of the epiphyseal cartilage of the developing bone. (6)

metarteriole: A vessel that connects an arteriole to a venule and that provides blood to a capillary plexus. (21)

metastasis: The spread of cancer cells from one organ to another, leading to the establishment of secondary tumors. (3)

metatarsal bone: One of the five bones of the foot that articulate with the tarsal bones (proximally) and the phalanges (distally). (8)

metencephalon: The pons and cerebellum of the brain. (14)

- **MHC protein:** A surface antigen that is important to the recognition of foreign antigens and that plays a role in the coordination and activation of the immune response; also called *major histocompatibility complex (MHC) protein* or *human leukocyte antigen (HLA).* (22)
- **micelle:** A droplet with hydrophilic portions on the outside; a spherical aggregation of bile salts, monoglycerides, and fatty acids in the lumen of the intestinal tract. (2, 24)
- **microfilaments:** Fine protein filaments visible with the electron microscope; components of the cytoskeleton. (3)
- **microglia:** Phagocytic neuroglia in the central nervous system. (12, 22)
- **microphages:** Neutrophils and eosinophils. (4, 19, 22)

microtubules: Microscopic tubules that are part of the cytoskeleton and are a component in cilia, flagella, the centrioles, and spindle fibers. (3)

microvilli: Small, fingerlike extensions of the exposed plasma membrane of an epithelial cell. (3)micturition: Urination. (26)

midbrain: The mesencephalon. (14)

middle ear: The space between the external and

internal ears that contains auditory ossicles. (17) **midsagittal plane:** A plane passing through the midline of the body that divides it into left and right halves. (1)

mineralocorticoids: Corticosteroids produced by the zona glomerulosa of the adrenal cortex; steroids such as aldosterone that affect mineral metabolism. (18) **mitochondrion:** An intracellular organelle responsible for generating most of the ATP required for cellular operations. (3, 25)

mitosis: The division of a single cell nucleus that produces two identical daughter cell nuclei; an essential step in cell division. (3, 28)

mitral valve: See bicuspid valve.

mixed gland: A gland that contains exocrine and endocrine cells, or an exocrine gland that produces serous and mucous secretions. (4)

mixed nerve: A peripheral nerve that contains sensory and motor fibers. (13)

mole: A quantity of an element or compound having a mass in grams equal to the element's atomic weight or to the compound's molecular weight. (2)

molecular weight: The sum of the atomic weights of all the atoms in a molecule or compound. (3)

molecule: A chemical structure containing two or more atoms that are bonded together by shared electrons. (3)

monoclonal antibodies: Antibodies produced by genetically identical cells under laboratory conditions. (22)

monocytes: Phagocytic agranulocytes (white blood cells) in the circulating blood. (19)

monoglyceride: A lipid consisting of a single fatty acid bound to a molecule of glycerol. (2)

 monokines: Secretions released by activated cells of the monocyte-macrophage system to coordinate various aspects of the immune response. (22)
 monosaccharide: A simple sugar, such as glucose or

ribose. (2, 24)

monosynaptic reflex: A reflex in which the sensory afferent neuron synapses directly on the motor efferent neuron. (13)

motor unit: All the muscle cells controlled by a single motor neuron. (10)

- **mucins:** Proteoglycans responsible for the lubricating properties of mucus. (2, 24)
- **mucosa:** A mucous membrane; the epithelium plus the lamina propria. (4, 24)
- **mucosa-associated lymphoid tissue (MALT):** The extensive collection of lymphoid tissues linked with the epithelia of the digestive, respiratory, urinary, and reproductive tracts. (22)

mucous (adjective): Indicating the presence or production of mucus.

 mucous cell: A goblet-shaped, mucus-producing, unicellular gland in certain epithelia of the digestive and respiratory tracts; also called *goblet cells*. (4)
 mucous membrane: See mucosa.

mucus (noun): A lubricating fluid that is composed of water and mucins and is produced by unicellular and multicellular glands along the digestive, respiratory, urinary, and reproductive tracts. (2, 4)

multipolar neuron: A neuron with many dendrites and a single axon; the typical form of a motor neuron. (12)

multiunit smooth muscle: A smooth muscle tissue whose muscle cells are innervated in motor units. (10)

muscarinic receptors: Membrane receptors sensitive to acetylcholine and to muscarine, a toxin produced by certain mushrooms; located at all parasympathetic neuromuscular and neuroglandular junctions and at a few sympathetic neuromuscular and neuroglandular junctions. (16)

muscle: A contractile organ composed of muscle tissue, blood vessels, nerves, connective tissues, and lymphatic vessels. (10, 11)

muscle tissue: A tissue characterized by the presence of cells capable of contraction; includes skeletal, cardiac, and smooth muscle tissues. (4, 10)

muscularis externa: Concentric layers of smooth muscle responsible for peristalsis. (24)

- **muscularis mucosae:** The layer of smooth muscle deep to the lamina propria; responsible for moving the mucosal surface. (24)
- **mutagens:** Chemical agents that induce mutations and may be carcinogenic. (3)

mutation: A change in the nucleotide sequence of the DNA in a cell. (3)

myelencephalon: See medulla oblongata.

myelin: An insulating sheath around an axon; consists of multiple layers of neuroglial membrane; significantly increases the nerve impulse propagation rate along the axon. (12)

myelination: The formation of myelin. (12) **myenteric plexus:** Parasympathetic motor neurons and sympathetic postganglionic fibers located between the circular and longitudinal layers of the muscularis externa. (24)

- **myocardial infarction:** A heart attack; damage to the heart muscle due to an interruption of regional coronary circulation. (20)
- **myocardium:** The cardiac muscle tissue of the heart. (20)
- **myofibril:** Organized collections of myofilaments in skeletal and cardiac muscle cells. (10)
- **myofilaments:** Fine protein filaments composed primarily of the proteins actin (thin filaments) and myosin (thick filaments). (10)
- **myoglobin:** An oxygen-binding pigment that is especially common in slow skeletal muscle fibers and cardiac muscle cells. (2, 10)
- **myogram:** A recording of the tension produced by muscle fibers on stimulation. (10)
- **myometrium:** The thick layer of smooth muscle in the wall of the uterus. (28)
- **myosin:** The protein component of thick filaments. (3, 10)

Ν

- **nail:** A keratinous structure produced by epithelial cells of the nail root. (5)
- **nares, external:** The entrance from the exterior to the nasal cavity. (23)
- **nares, internal:** The entrance from the nasal cavity to the nasopharynx. (23)
- **nasal cavity:** A chamber in the skull that is bounded by the internal and external nares. (7)

nasolacrimal duct: The passageway that transports tears from the nasolacrimal sac to the nasal cavity. (7, 17)

- **nasolacrimal sac:** A chamber that receives tears from the lacrimal ducts. (17)
- **nasopharynx:** A region that is posterior to the internal nares and superior to the soft palate and ends at the oropharynx. (23)
- natriuretic peptides (NP): Hormones released by specialized cardiocytes when they are stretched by an abnormally large venous return; promotes fluid loss and reductions in blood pressure and in venous return. Includes atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP). (18, 21, 26, 27)
- N compound: An organic compound containing nitrogen atoms. (25)
- **necrosis:** The death of cells or tissues from disease or injury. (4, 22)
- **negative feedback:** A corrective mechanism that opposes or negates a variation from normal limits. (18)
- neonate: A newborn infant, or baby. (29)

neoplasm: A tumor, or mass of abnormal tissue. (3) nephron: The basic functional unit of the kidney. (26)

- **nephron loop:** The segment of the nephron that creates the concentration gradient in the renal medulla; also called *loop of Henle*. (26)
- **nerve impulse:** An action potential in a neuron plasma membrane. (12)
- **neural cortex:** An area of gray matter at the surface of the central nervous system. (13) **neurilemma:** The outer surface of a Schwann cell
- that encircles an axon in the peripheral nervous system. (12)
- **neurofibrils:** Microfibrils in the cytoplasm of a neuron. (12)
- **neurofilaments:** Microfilaments in the cytoplasm of a neuron. (12)
- **neuroglandular junction:** A cell junction at which a neuron controls or regulates the activity of a secretory (gland) cell. (12)
- **neuroglia:** Cells of the central nervous system and peripheral nervous system that support and protect neurons; also called *glial cells*. (4, 12)
- **neurohypophysis:** The posterior lobe of the pituitary gland, or pars nervosa; contains the axons of hypothalamic neurons, which release OXT and ADH. (18)
- **neuromodulator:** A compound, released by a neuron, that adjusts the sensitivities of another neuron to specific neurotransmitters. (12)
- **neuromuscular junction:** A synapse between a neuron and a muscle cell. (10, 12)
- **neuron:** A cell in neural tissue that is specialized for intercellular communication through (1) changes in membrane potential and (2) synaptic connections. (4, 12, 15, 16)
- **neuroplasticity:** The ability of nerve cells to make new connections. (14)
- **neurotransmitter:** A chemical compound released by one neuron to affect the membrane potential of another. (12, 16)
- **neurotubules:** Microtubules in the cytoplasm of a neuron. (12)
- **neutron:** A fundamental particle that does not have a positive or a negative charge. (2)
- **neutrophil:** A white blood cell that is very numerous and normally the first of the mobile phagocytic cells to arrive at an area of injury or infection. (19)
- **nicotinic receptors:** Acetylcholine receptors on the surfaces of sympathetic and parasympathetic ganglion cells; respond to the compound nicotine. (16)
- **nipple:** An elevated epithelial projection on the surface of the breast; contains the openings of the lactiferous sinuses. (28)
- **Nissl bodies:** The ribosomes, Golgi apparatus, rough endoplasmic reticulum, and mitochondria of the perikaryon of a typical neuron. (12)
- **nitrogenous wastes:** Organic waste products of metabolism that contain nitrogen, such as urea, uric acid, and creatinine. (25)
- nociception: Pain perception. (15)
- **nodes:** The areas between adjacent neuroglia where the myelin covering of an axon is incomplete; also called *nodes of Ranvier*. (12)
- nodose ganglion: A sensory ganglion of cranial nerve X; also called *inferior ganglion*. (14) noradrenaline: See norepinephrine.
- **norepinephrine** (NE): A catecholamine neurotransmitter in the peripheral nervous system and central nervous system, released at most sympathetic neuromuscular and neuroglandular junctions, and a hormone secreted by the adrenal (suprarenal) medulla; also called *noradrenaline*.
- (12, 18) **nucleic acid:** A polymer of nucleotides that contains
- a pentose sugar, a phosphate group, and one of four nitrogenous bases that regulate the synthesis

of proteins and make up the genetic material in cells. (2)

- **nucleolus:** The dense region in the nucleus that is the site of RNA synthesis. (3)
- nucleoplasm: The fluid content of the nucleus. (3)nucleoproteins: Proteins of the nucleus that are generally associated with DNA. (3)
- **nucleotide:** A compound consisting of a nitrogenous base, a simple sugar, and a phosphate group. (2)
- **nucleus:** A cellular organelle that contains DNA, RNA, and proteins; in the central nervous system, a mass of gray matter. (3)
- **nucleus pulposus:** The gelatinous central region of an intervertebral disc. (9)
- **nurse cells:** Supporting cells of the seminiferous tubules of the testis; responsible for the differentiation of spermatids, the maintenance of the blood-testis barrier, and the secretion of inhibin, androgen-binding protein, and Müllerian-inhibiting factor; also called *sustentacular cells.* (18, 28)
- **nutrient:** An inorganic or organic substance that can be used by the body as a cofactor or to produce energy. (2, 25)
- **nystagmus:** An unconscious, continuous movement of the eyes as if to adjust to constant motion. (17)

0

- **obesity:** Body weight more than 20 percent above the ideal weight for a given individual. (25)
- **occlusal surface:** The opposing surfaces of the teeth that come into contact when chewing food. (24) **ocular:** Pertaining to the eye. (17)
- **oculomotor nerve:** Cranial nerve III, which controls the extraocular muscles other than the superior oblique and the lateral rectus muscles. (14)
- **olecranon:** The proximal end of the ulna that forms the prominent point of the elbow. (8)
- **olfaction:** The sense of smell. (15, 17, 23)
- **olfactory bulb:** The expanded ends of the olfactory tracts (17); the sites where the axons of the first cranial nerves (I) synapse on central nervous system interneurons that lie inferior to the frontal lobes of the cerebrum. (14)

oligodendrocytes: Central nervous system neuroglia that maintain cellular organization within gray matter and provide a myelin sheath in areas of white matter. (12)

- **oligopeptide:** A short chain of amino acids. (2) **oocyte:** A cell whose meiotic divisions will produce a
- single ovum and three polar bodies. (3, 28) **oogenesis:** Formation and development of an oocyte. (28)
- **opsonization:** An effect of coating an object with antibodies; the attraction and enhancement of phagocytosis. (22)
- **optic chiasm:** The crossing point of the optic nerves. (14)
- **optic nerve:** The second cranial nerve (II), which carries signals from the retina of the eye to the optic chiasm. (14)
- **optic tract:** The tract over which nerve impulses from the retina are transmitted between the optic chiasm and the thalamus. (14)
- **orbit:** The bony recess of the skull that contains the eyeball. (7)
- **organelle:** An intracellular structure with a specific function or group of functions. (3)
- **organic compound:** A compound containing carbon, hydrogen, and in most cases oxygen. (2)
- **organogenesis:** The formation of organs during embryonic and fetal development. (29)
- **organs:** Combinations of tissues that perform complex functions. (1)

- **origin:** In a skeletal muscle, the point of attachment that does not change position when the muscle contracts; usually defined in terms of movements from the anatomical position. (11)
- **oropharynx:** The middle portion of the pharynx, bounded superiorly by the nasopharynx, anteriorly by the oral cavity, and inferiorly by the laryngopharynx. (23)
- **osmolarity:** The total concentration of dissolved materials in a solution, regardless of their specific identities, expressed in moles; also called *osmotic concentration*. (3, 26, 27)
- **osmoreceptor:** A receptor sensitive to changes in the osmolarity of plasma. (27)
- **osmosis:** The movement of water across a selectively permeable membrane from one solution to another solution that contains a higher solute concentration. (3, 21, 26, 27)
- **osmotic pressure:** The force of osmotic water movement; the pressure that must be applied to prevent osmosis across a membrane. (3, 21, 26, 27)
- **osseous tissue:** A strong connective tissue containing specialized cells and a mineralized matrix of crystalline calcium phosphate and calcium carbonate; also called *bone.* (4, 6)
- ossicles: Small bones; middle ear bones. (17)
- **ossification:** The formation of bone; osteogenesis. (6) **osteoblast:** A cell that produces the fibers and matrix of bone. (6)
- **osteoclast:** A cell that dissolves the fibers and matrix of bone. (6)
- **osteocyte:** A bone cell responsible for the maintenance and turnover of the mineral content of the surrounding bone. (4, 6)
- **osteogenic layer:** The inner, cellular layer of the periosteum that aids in bone growth and repair. (6)
- **osteolysis:** The breakdown of the mineral matrix of bone. (6)
- **osteon:** The basic histological unit of compact bone, consisting of osteocytes organized around a central canal and separated by concentric lamellae. (6) **otic:** Pertaining to the ear. (17)
- **otoliths:** Calcium carbonate crystals embedded in a
- gelatinous matrix; located on each macula of the vestibule. (17)
- **oval window:** An opening in the bony labyrinth where the stapes attaches to the membranous wall of the scala vestibuli (vestibular duct). (17) **ovarian cycle:** The monthly chain of events that
- leads to ovulation. (28)
- **ovary:** The female reproductive organ that produces oocytes (gametes). (18, 28)
- **ovulation:** The release of a secondary oocyte, surrounded by cells of the corona radiata, after the rupture of the wall of a tertiary follicle (29); in females, the periodic release of an oocyte from an ovary (28).
- **ovum/ova:** The functional product of meiosis II, produced after the fertilization of a secondary oocyte. (28, 29)
- **oxytocin (OXT):** A hormone produced by hypothalamic cells and secreted into capillaries at the posterior lobe of the pituitary gland (neurohypophysis); stimulates smooth muscle contractions of the uterus or mammary glands in females and the prostate gland in males. (18)

Ρ

- **pacemaker cells:** Cells of the sinoatrial node that set the pace of cardiac contraction. (4, 10, 20)**palate:** The horizontal partition separating the oral cavity from the nasal cavity and nasopharynx;
 - G-13

divided into an anterior bony (hard) palate and a posterior fleshy (soft) palate. (7, 24)

- palatine: Pertaining to the palate. (24)
- palpate: To examine by touch.

palpebrae: Eyelids. (17)

- pancreas: A digestive organ containing exocrine and endocrine tissues; the exocrine portion secretes pancreatic juice, and the endocrine portion secretes hormones, including insulin and glucagon. (18, 24)
- pancreatic duct: A tubular duct that carries pancreatic juice from the pancreas to the duodenum. (18, 24)
- pancreatic islets: Aggregations of endocrine cells in the pancreas; also called islets of Langerhans. (18, 24)
- pancreatic juice: A mixture of buffers and digestive enzymes that is discharged into the duodenum under the stimulation of the enzymes secretin and cholecystokinin. (18, 24)
- Papanicolaou (Pap) test: A test for the detection of malignancies based on the cytological appearance of epithelial cells, especially those of the cervix and uterus. (28)

papilla: A small, conical projection.

- paralysis: The loss of voluntary motor control over a portion of the body. (13)
- paranasal sinuses: Bony chambers, lined by respiratory epithelium, that open into the nasal cavity; the frontal, ethmoidal, sphenoidal, and maxillary sinuses. (7)
- parasagittal: A section or plane that parallels the midsagittal plane but that does not pass along the midline. (1)
- parasympathetic division: One of the two divisions of the autonomic nervous system; generally responsible for activities that conserve energy and lower the metabolic rate; the "rest and digest" division; also called craniosacral division. (16)
- parathyroid glands: Four small glands embedded in the posterior surface of the thyroid gland that secrete parathyroid hormone. (6, 18)
- parathyroid hormone (PTH): A hormone secreted by the parathyroid glands when blood calcium levels decrease below the normal range; causes increased osteoclast activity, increased intestinal calcium uptake, and decreased calcium ion loss by the kidneys. (6, 18)
- parenchyma: The cells of a tissue or organ that are responsible for fulfilling its functional role; distinguished from the stroma of that tissue or organ. (4)
- paresthesia: A sensory abnormality that produces a tingling sensation.
- **parietal:** Relating to the parietal bone (7); referring to the wall of a cavity. (23)
- parietal cells: Cells of the gastric glands that secrete hydrochloric acid and intrinsic factor. (24)
- parotid salivary glands: Large salivary glands that secrete a saliva containing high concentrations of salivary (alpha) amylase. (24)
- pars distalis: The large, anterior portion of the anterior lobe of the pituitary gland (adenohypophysis). (18)
- pars intermedia: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that is immediately adjacent to the posterior lobe of the pituitary gland (neurohypophysis) and the infundibulum. (18)
- pars nervosa: The posterior lobe of the pituitary gland (neurohypophysis). (18)
- pars tuberalis: The portion of the anterior lobe of the pituitary gland (adenohypophysis) that wraps around the infundibulum superior to the posterior lobe (neurohypophysis). (18)

- patella: The sesamoid bone of the knee; also called the kneecat. (8)
- **pathogen:** A disease-causing organism. (1, 22)
- pathologist: A physician specializing in the identification of diseases on the basis of characteristic structural and functional changes in tissues and organs
- **pelvic cavity:** The inferior subdivision of the abdominopelvic cavity; encloses the urinary bladder, the sigmoid colon and rectum, and male or female reproductive organs. (1, 8)
- pelvis: A bony complex created by the articulations among the coxal bones, the sacrum, and the coccyx. (8, 11)
- penis: A component of the male external genitalia; a copulatory organ that surrounds the urethra and introduces semen into the female vagina; the developmental equivalent of the female clitoris. (28)
- peptide: A chain of amino acids linked by peptide bonds. (2, 18)
- peptide bond: A covalent bond between the amino group of one amino acid and the carboxyl group of another. (2)
- pericardial cavity: The space between the parietal pericardium and the epicardium (visceral pericardium) that encloses the outer surface of the heart. (20)
- pericardium: The fibrous sac that surrounds the heart; its inner, serous lining is continuous with the epicardium. (4, 20)
- perichondrium: The layer that surrounds a cartilage, consisting of an outer fibrous region and an inner cellular region. (4)
- perikaryon: The cytoplasm that surrounds the nucleus in the cell body of a neuron. (12)
- perilymph: A fluid similar in composition to cerebrospinal fluid: located in the spaces between the bony labyrinth and the membranous labyrinth of the internal ear. (17)
- perimysium: A connective tissue partition that separates adjacent fasciculi in a skeletal muscle. (10)
- perineum: The pelvic floor and its associated structures. (11)
- perineurium: A connective tissue partition that separates adjacent bundles of nerve fibers in a peripheral nerve. (13)

periodontal ligament: Collagen fibers that bind the cementum of a tooth to the periosteum of the surrounding alveolus. (24)

- periosteum: The layer that surrounds a bone, consisting of an outer fibrous region and inner cellular region. (4, 6)
- peripheral nervous system (PNS): All neural tissue outside the central nervous system. (12)
- peripheral resistance: The resistance to blood flow; primarily caused by friction with the vessel walls. (21)
- peristalsis: A wave of smooth muscle contractions that propels materials along the lumen of a tube such as the digestive tract (24), the ureters (26), or the ductus deferens. (28)
- peritoneal cavity: The potential space within the abdominopelvic cavity lined by the peritoneum.
- peritoneum: The serous membrane that lines the peritoneal cavity. (4, 28)
- peritubular capillaries: A network of capillaries that surrounds the proximal and distal convoluted tubules of the kidneys. (26)
- permeability: The ease with which dissolved materials can cross a membrane; if the membrane is freely permeable, any molecule can cross it; if impermeable, nothing can cross; most biological membranes are selectively permeable (allow some and restrict others). (3)

- peroxisome: A membranous vesicle containing enzymes that break down hydrogen peroxide $(H_2O_2).(3)$ pes: The foot. (8, 11)
- petrosal ganglion: A sensory ganglion of the glossopharyngeal nerve (N IX). (14, 15) petrous: Stony; usually refers to the thickened
- portion of the temporal bone that encloses the internal ear. (17)
- pH: The negative exponent (negative logarithm) of the hydrogen ion concentration, expressed in moles per liter. (2, 27)
- phagocyte: A cell that performs phagocytosis. (22)
- phagocytosis: The engulfing of extracellular materials or pathogens; the movement of extracellular materials into the cytoplasm by enclosure in a membranous vesicle. (3, 19, 22)
- phalanx/phalanges: Bone(s) of the finger(s) or toe(s). (8)
- pharmacology: The study of drugs, their physiological effects, and their clinical uses. pharynx: The throat; a muscular passageway shared
- by the digestive and respiratory tracts. (11, 23, 24) phasic response: A pattern of response to
- stimulation by sensory neurons that are normally inactive: stimulation causes a burst of neural activity that ends when the stimulus either stops or stops changing in intensity. (15)
- phenotype: Physical characteristics that are genetically determined. (29)
- **phosphate group:** PO₄³⁻; a functional group that can be attached to an organic molecule; required for the formation of high-energy bonds. (2, 25, 27)
- phospholipid: An important membrane lipid whose structure includes both hydrophilic and hydrophobic regions. (2, 3)
- phosphorylation: The addition of a high-energy phosphate group to a molecule. (2, 25)
- photoreception: Sensitivity to light. (17) physiology: The study of function; deals with the ways organisms perform vital activities. (1)
- pia mater: The innermost layer of the meninges bound to the underlying neural tissue. (13, 14)
- pineal gland: Neural tissue in the posterior portion of the roof of the diencephalon; secretes melatonin. (14, 18)
- pinna: See auricle.
- pinocytosis: The introduction of fluids into the cytoplasm by enclosing them in membranous vesicles at the cell surface. (3)
- pituitary gland: An endocrine organ that is located in the sella turcica of the sphenoid bone and is connected to the hypothalamus by the infundibulum; includes the posterior lobe (neurohypophysis) and the anterior lobe (adenohypophysis); also called the hypophysis. (14, 18)
- **placenta:** A temporary structure in the uterine wall that permits diffusion between the fetal and maternal circulatory systems. (29)
- plantar: Referring to the sole of the foot (1); muscles (11); plantar reflex. (13)
- plantar flexion: Ankle extension; toe pointing. (8, 11) plasma: The fluid ground substance of whole blood; what remains after the cells have been removed from a sample of whole blood. (4, 19)
- plasma cell: An activated B cell that secretes antibodies. (4, 19, 22)
- plasma membrane: A cell membrane; also called a plasmalemma. (3)
- platelets: Small packets of cytoplasm that contain enzymes important in the clotting response; manufactured in bone marrow by megakaryocytes. (4, 19)
- **pleura:** The serous membrane that lines the pleural (lung) cavities. (4, 23)
- **pleural cavities:** Body cavities of the thoracic region that surround the lungs. (1, 23)
- plexus: A network or braid.
- **polar body:** A nonfunctional packet of cytoplasm that contains chromosomes eliminated from an oocyte during meiosis. (28, 29)
- **polar bond:** A covalent bond in which electrons are shared unequally. (2)
- **polarized:** Referring to cells that have regional differences in organelle distribution or cytoplasmic composition along a specific axis, such as between the basement membrane and free surface of an epithelial cell. (4)
- pollex: The thumb. (8)
- **polymer:** A large molecule consisting of a long chain of monomer subunits. (2)
- **polypeptide:** A chain of amino acids strung together by peptide bonds; those containing more than 100 peptides are called *proteins*. (2)
- **polyribosome:** Several ribosomes linked by their translation of a single mRNA strand. (3)
- polysaccharide: A complex sugar, such as glycogen
 or a starch. (2)
 polysynaptic reflex: A reflex in which interneurons
- are interposed between the sensory fiber and the motor neuron(s). (13)
- **polyunsaturated fats:** Fatty acids containing carbon atoms that are linked by double bonds. (1, 2)
- **pons:** The portion of the metencephalon that is anterior to the cerebellum. (14)
- **popliteal:** Pertaining to the back of the knee. (9, 11, 21)
- **porphyrins:** Ring-shaped molecules that form the basis of important respiratory and metabolic pigments, including heme and the cytochromes. (23)
- **positive feedback:** A mechanism that increases a deviation from normal limits after an initial stimulus. (1)
- **postcentral gyrus:** The primary sensory cortex, where touch, vibration, pain, temperature, and taste sensations arrive and are consciously perceived. (14)
- **posterior:** Toward the back; dorsal.
- **postganglionic neuron:** An autonomic neuron in a peripheral ganglion, whose activities control peripheral effectors. (16)
- **postsynaptic membrane:** The portion of the plasma membrane of a postsynaptic cell that is part of a synapse. (12)
- **potential difference:** The separation of opposite charges; requires a barrier that prevents ion migration. (3, 12)
- **precentral gyrus:** The primary motor cortex of a cerebral hemisphere, located anterior to the central sulcus. (14)
- **prefrontal cortex:** The anterior portion of each cerebral hemisphere; thought to be involved with higher intellectual functions, predictions, and calculations. (14)
- **preganglionic neuron:** A visceral motor neuron in the central nervous system whose output controls one or more ganglionic motor neurons in the peripheral nervous system. (16)
- **premotor cortex:** The motor association area between the precentral gyrus and the prefrontal area. (14)
- **preoptic nucleus:** The hypothalamic nucleus that coordinates thermoregulatory activities. (14)
- **presynaptic membrane:** The synaptic surface where neurotransmitter release occurs. (12)
- prevertebral ganglion: See collateral ganglion. prime mover: A muscle that performs a specific
 - action. (11)

- **proenzyme:** An inactive enzyme secreted by an epithelial cell. (19)
- **progesterone:** The most important hormone secreted by the corpus luteum after ovulation. (18, 28)
- **prognosis:** A prediction about the possible course or outcome from a specific disease.
- **projection fibers:** Axons carrying information from the thalamus to the cerebral cortex. (14)
- **prolactin (PRL):** The hormone that stimulates functional development of the mammary glands in females; a secretion of the anterior lobe of the pituitary gland (adenohypophysis). (18)
- **pronation:** The rotation of the forearm that makes the palm face posteriorly. (9)
- **prone:** Lying face down with the palms facing the floor. (1)
- **pronucleus:** An enlarged ovum or spermatozoon nucleus that forms after fertilization but before amphimixis. (29)
- **prophase:** The initial phase of mitosis; characterized by the appearance of chromosomes, the breakdown of the nuclear membrane, and the formation of the spindle apparatus. (3)
- **proprioception:** The awareness of the positions of bones, joints, and muscles. (15)
- prostaglandin: A fatty acid secreted by one cell that alters the metabolic activities or sensitivities of adjacent cells; also called *local hormone*. (2, 18)
- **prostate gland:** An accessory gland of the male reproductive tract, contributing about one-third of the volume of semen. (28)
- **prosthesis:** An artificial substitute for a body part. **protease:** *See* **proteinase**.
- **protein:** A large polypeptide with a complex structure. (2, 25)
- **proteinase:** An enzyme that breaks down proteins into peptides and amino acids. (2, 3)
- **proteoglycan:** A substance containing a large polysaccharide complex attached to a relatively small protein; examples include hyaluronan and chondroitin sulfate. (2)
- **proton:** A fundamental subatomic particle having a positive charge. (2)
- **protraction:** Movement anteriorly in the horizontal plane.
- **proximal:** A direction toward the point of attachment or origin; for a limb, toward its attachment to the trunk. (1, 8)
- **proximal convoluted tubule (PCT):** The segment of the nephron between the glomerular capsule (Bowman's capsule) and the nephron loop; the major site of active reabsorption from filtrate. (26)
- **pseudopodia:** Temporary cytoplasmic extensions typical of mobile or phagocytic cells. (3)
- **pseudostratified epithelium:** An epithelium that contains several layers of nuclei but whose cells are all in contact with the underlying basement membrane. (4)
- **puberty:** A period of rapid growth, sexual maturation, and the appearance of secondary sexual characteristics; normally occurs at ages 10–15 years. (18, 28)
- **pubic symphysis:** The fibrocartilaginous amphiarthrosis between the pubic bones of the hip. (8, 9)
- **pubis:** The anterior, inferior component of the hip bone. (8)
- pudendum: The external genitalia. (28)
- **pulmonary circuit:** Blood vessels between the pulmonary semilunar valve of the right ventricle and the entrance to the left atrium; the blood flow through the lungs. (20)
- **pulmonary ventilation:** The movement of air into and out of the lungs. (23)

- **pulvinar nucleus:** The thalamic nucleus involved in the integration of sensory information prior to projection to the cerebral hemispheres. (14)
- **pupil:** The opening in the center of the iris through which light enters the eye. (17)
- **purine:** A nitrogen compound with a double ringshaped structure; examples include adenine and guanine, two nitrogenous bases that are common in nucleic acids. (2, 12)
- **Purkinje cell:** A large, branching neuron of the cerebellar cortex. (14)
- **Purkinje fibers:** Specialized conducting cardiocytes in the ventricles of the heart. (20)
- **pus:** An accumulation of debris, fluid, dead and dying cells, and necrotic tissue. (4, 20, 22)
- **pyloric sphincter:** A ring of smooth muscle that regulates the passage of chyme from the stomach to the duodenum. (24)
- **pylorus:** The gastric region between the body of the stomach and the duodenum; includes the pyloric sphincter. (24)
- **pyrimidine:** A nitrogen compound with a single ring-shaped structure; examples include cytosine, thymine, and uracil, nitrogenous bases that are common in nucleic acids. (2)
- **pyruvate:** The anion formed by the dissociation of pyruvic acid, a three-carbon compound produced by glycolysis. (25)

Q

quaternary structure: The three-dimensional protein structure produced by interactions between protein subunits. (2)

R

- **radiodensity:** The relative resistance to the passage of x-rays. (1)
- **radiographic techniques:** Methods of visualizing internal structures by using various forms of radiational energy. (1)
- **radiopaque:** Having a high radiodensity. (1)
- **rami communicantes:** Axon bundles that link the spinal nerves with the ganglia of the sympathetic chain. (8)
- ramus/rami: Branch/branches.
- raphe: A seam. (11, 28)
- **receptive field:** The area monitored by a single sensory receptor. (15)
- **rectum:** The inferior 15 cm (6 in.) of the digestive tract. (24)
- rectus: Straight.
- red blood cell (RBC): See erythrocyte.
- **reduction:** The gain of hydrogen atoms or electrons or the loss of an oxygen molecule. (25)
- **reductional division:** The first meiotic division, which reduces the chromosome number from 46 to 23. (28)
- **reflex:** A rapid, automatic response to a stimulus. (12, 13, 16, 18, 21)
- **reflex arc:** The receptor, sensory neuron, motor neuron, and effector involved in a particular reflex; interneurons may be present, depending on the reflex considered. (13)
- **refractory period:** The time between the initiation of an action potential and the restoration of the normal resting membrane potential; during this period, the membrane will not respond normally to stimulation. (12)
- **relaxation phase:** The period after a contraction when the tension in the muscle fiber returns to resting levels. (10)
- **relaxin:** A hormone that loosens the pubic symphysis; secreted by the placenta. (29)

GLOSSARY

renal: Pertaining to the kidneys. (26)

- **renal corpuscle:** The initial segment of the nephron, consisting of an expanded chamber that encloses the glomerulus. (26)
- **renin:** The enzyme released by cells of the juxtaglomerular complex when renal blood flow decreases; converts angiotensinogen to angiotensin I. (18, 26)
- **rennin:** A gastric enzyme that breaks down milk proteins. (24)

replication: Duplication. (29)

- **repolarization:** The movement of the membrane potential away from a positive value and toward the resting potential. (12, 20)
- **respiration:** The exchange of gases between cells and the environment; includes pulmonary ventilation, external respiration, and internal respiration. (23, 27)
- **respiratory minute volume** (\dot{V}_E) : The amount of air moved into and out of the respiratory system each minute. (23)

respiratory pump: A mechanism by which changes in the intrapleural pressures during the respiratory cycle assist the venous return to the heart; also called *thoracoabdominal pump*. (21, 23)

- **resting membrane potential:** The membrane potential of a normal cell under homeostatic conditions. (3, 12)
- **rete:** An interwoven network of blood vessels or passageways. (28)
- **reticular activating system (RAS):** The mesencephalic (midbrain) portion of the reticular formation; responsible for arousal and the maintenance of consciousness. (16)
- **reticular formation:** A diffuse network of gray matter that extends the entire length of the brain stem. (14)
- **reticulospinal tracts:** Descending tracts of the medial pathway that carry involuntary motor commands issued by neurons of the reticular formation. (15)
- **retina:** The innermost layer of the eye, lining the vitreous chamber; also called *inner layer*. (17)
- **retinal:** A visual pigment derived from vitamin A. (17) **retraction:** Movement posteriorly in the horizontal plane.
- **retroperitoneal:** Behind or outside the peritoneal cavity. (1)
- **reverberation:** A positive feedback along a chain of neurons such that they remain active once stimulated. (13)
- **rheumatism:** A general term used to describe pain in muscles, tendons, bones, or joints. (9)
- **Rh factor:** A surface antigen that may be present (Rh-positive) or absent (Rh-negative) from the surfaces of red blood cells. (19)
- **rhodopsin:** The visual pigment in the membrane discs of the distal segments of rods. (17)
- **rhythmicity center:** A medullary center responsible for the pace of respiration; includes inspiratory and expiratory centers. (23)
- **ribonucleic acid:** A nucleic acid consisting of a chain of nucleotides that contain the sugar ribose and the nitrogenous bases adenine, guanine, cytosine, and uracil. (2, 3)
- **ribose:** A five-carbon sugar that is a structural component of RNA. (2, 3)
- **ribosome:** An organelle that contains rRNA and proteins and is essential to mRNA translation and protein synthesis. (2, 3)
- **rod:** A photoreceptor responsible for vision in dim lighting. (17)

rough endoplasmic reticulum (RER): A

membranous organelle that is a site of protein synthesis and storage. (3)

- **round window:** An opening in the bony labyrinth of the internal ear that exposes the membranous wall of the tympanic duct to the air of the middle ear cavity. (17)
- **rubrospinal tracts:** Descending tracts of the lateral pathway that carry involuntary motor commands issued by the red nucleus of the mesencephalon. (15)
- **rugae:** Mucosal folds in the lining of the empty stomach that disappear as gastric distension occurs (24); folds in the urinary bladder (26).

S

- **saccule:** A portion of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a vertical dimension. (17)
- **sagittal plane:** A sectional plane that divides the body into left and right portions. (1)
- **salt:** An inorganic compound consisting of a cation other than H⁺ and an anion other than OH⁻. (2)
- **saltatory propagation:** The relatively rapid propagation of an action potential between successive nodes of a myelinated axon. (12)
- **sarcolemma:** The plasma membrane of a muscle cell. (10)
- **sarcomere:** The smallest contractile unit of a striated muscle cell. (10)
- sarcoplasm: The cytoplasm of a muscle cell. (10)scala media: The central membranous tube within the cochlea that is filled with endolymph and contains the spiral organ (*organ of Corti*); also called *cochlear duct*. (17)
- **scala tympani:** The perilymph-filled chamber of the internal ear, adjacent to the basilar membrane; pressure changes there distort the round window; also called *tympanic duct*. (17)
- **scala vestibuli:** The perilymph-filled chamber of the internal ear, adjacent to the vestibular membrane; pressure waves are induced by movement of the stapes at the oval window; also called *vestibular duct.* (17)
- **scar tissue:** The thick, collagenous tissue that forms at an injury site. (5)
- **Schwann cells:** Neuroglia responsible for the neurilemma that surrounds axons in the peripheral nervous system; also called *neurilemma cells*. (12)
- **sciatic nerve:** A nerve innervating the posteromedial portions of the thigh and leg. (13)
- **sclera:** The fibrous, outer layer of the eye that forms the white area of the anterior surface; a portion of the fibrous layer of the eye. (17)
- **sclerosis:** A hardening and thickening that commonly occurs secondary to tissue inflammation. (4)
- **scrotum:** The loose-fitting, fleshy pouch that encloses the testes of the male. (28)
- **sebaceous glands:** Glands that secrete sebum; normally associated with hair follicles. (5)
- **sebum:** A waxy secretion that coats the surfaces of hairs. (5)
- **secondary sex characteristics:** Physical characteristics that appear at puberty in response to sex hormones but are not involved in the production of gametes. (28)
- **secretin:** A hormone, secreted by the duodenum, that stimulates the production of buffers by the pancreas and inhibits gastric activity. (24)

- **semen:** The fluid ejaculate that contains spermatozoa and the secretions of accessory glands of the male reproductive tract. (28)
- **semicircular ducts:** The tubular components of the membranous labyrinth of the internal ear; respond to rotational movements of the head. (17)
- **semilunar valve:** A three-cusped valve guarding the exit from one of the cardiac ventricles; the pulmonary and aortic valves. (20)
- **seminal glands:** Glands of the male reproductive tract that produce roughly 60 percent of the volume of semen; also called *seminal vesicles*. (28)
- seminiferous tubules: Coiled tubules where spermatozoon production occurs in the testes. (28) senescence: Aging.
- sensible perspiration: Water loss due to secretion
- by sweat glands. (5, 27) **septa:** Partitions that subdivide an organ. (20, 22) **serosa:** *See* **serous membrane**.
- **serotonin:** A neurotransmitter in the central nervous system; a substance that enhances inflammation and is released by activated mast cells and basophils. (12, 19)
- **serous cell:** A cell that produces a serous secretion. (4) **serous membrane:** A squamous epithelium and
- the underlying loose connective tissue; the lining of the pericardial, pleural, and peritoneal cavities; also called a *serosa*. (4, 24)
- **serous secretion:** A watery secretion that contains high concentrations of enzymes; produced by serous cells. (4)
- serum: The ground substance of blood plasma from which clotting agents have been removed. (19)
 sesamoid bone: A bone that forms within a
- tendon. (6) sigmoid colon: The S-shaped region of the
- colon between the descending colon and the rectum. (24)
- **sign:** The visible, objective evidence of the presence of a disease.
- **simple epithelium:** An epithelium containing a single layer of cells superficial to the basement membrane. (4)
- **sinoatrial (SA) node:** The natural pacemaker of the heart; located in the wall of the right atrium. (20)
- **sinus:** A chamber or hollow in a tissue; a large, dilated vein. (6, 7, 20)
- sinusoid: An exchange vessel that is similar in general structure to a fenestrated capillary. The two differ in size (sinusoids are larger and more irregular in cross section), continuity (sinusoids have gaps between endothelial cells), and support (sinusoids have thin basement membranes, if present at all). (20)
- **skeletal muscle:** A contractile organ of the muscular system. (10)
- **skeletal muscle tissue:** A contractile tissue dominated by skeletal muscle fibers; characterized as striated, voluntary muscle. (4, 10)
- **sliding filament theory:** The concept that a sarcomere shortens as the thick and thin filaments slide past one another. (10)
- **small intestine:** The duodenum, jejunum, and ileum; the digestive tract between the stomach and the large intestine. (24)
- smooth endoplasmic reticulum (SER): A membranous organelle in which lipid and carbohydrate synthesis and storage occur. (3)
- smooth muscle tissue: Muscle tissue in the walls of many visceral organs; characterized as nonstriated, involuntary muscle. (4, 10, 24, 26)

- **soft palate:** The fleshy posterior extension of the hard palate, separating the nasopharynx from the oral cavity. (24)
- **solute:** Any materials dissolved in a solution. (2, 21, 26)
- **solution:** A fluid containing dissolved materials. (2, 21)
- **solvent:** The fluid component of a solution. (2, 21) **somatic:** Pertaining to the body.
- **somatic nervous system (SNS):** The efferent division of the nervous system that innervates skeletal muscles. (12, 15, 16)
- **somatomedins:** Substances stimulating tissue growth; released by the liver after the secretion of growth hormone; also called *insulin-like growth factors*. (18)
- somatotropin: Growth hormone (GH); produced by the anterior lobe of the pituitary gland (adenohypophysis) in response to growth hormone-releasing hormone (GH-RH). (18) sperm: See spermatozoon.
- **spermatic cord:** Collectively, the spermatic vessels, nerves, lymphatic vessels, and the ductus deferens, extending between the testes and the proximal end of the inguinal canal. (28)
- **spermatocyte:** A cell of the seminiferous tubules that is engaged in meiosis. (28)
- spermatogenesis: Spermatozoon production. (28)
 spermatozoon/spermatozoa: Male gamete(s);
 also called sperm. (3, 28)
- **sphincter:** A muscular ring that contracts to close the entrance or exit of an internal passageway. (10, 11, 26)
- spinal nerve: One of 31 pairs of nerves that originate on the spinal cord from anterior and posterior roots. (12, 13)
- **spindle apparatus:** Microtubule-based structure that distributes duplicated chromosomes to opposite ends of a dividing cell during mitosis. (3)
- spinocerebellar tracts: Ascending tracts that carry sensory information to the cerebellum. (15)spinothalamic tracts: Ascending tracts that carry
- poorly localized touch, pressure, pain, vibration, and temperature sensations to the thalamus. (15) **spinous process:** The prominent posterior
- projection of a vertebra; formed by the fusion of two laminae. (7)
- **spiral organ:** A receptor complex in the scala media of the cochlea that includes the inner and outer hair cells, supporting cells and structures, and the tectorial membrane; provides the sensation of hearing; also called the *organ of Corti.* (17)
- **spleen:** A lymphoid organ important for the phagocytosis of red blood cells, the immune response, and lymphocyte production. (22)**squama:** A broad, flat surface.
- squamous: Flattened.
- squamous epithelium: An epithelium whose superficial cells are flattened and platelike. (4)
- **stapes:** The auditory ossicle attached to the tympanic membrane. (17)
- **stenosis:** A constriction or narrowing of a passageway.
- **stereocilia:** Elongated microvilli characteristic of the epithelium of the epididymis, sections of the ductus deferens (28), and the internal ear. (17)
- **steroid:** A ring-shaped lipid structurally related to cholesterol. (2, 18)
- **stimulus:** An environmental change that produces a change in cellular activities; often used to refer to events that alter the membrane potentials of excitable cells. (15)
- stratified: Containing several layers. (4)

stratum: A layer; plural *strata*.

- **stretch receptors:** Sensory receptors that respond to stretching of the surrounding tissues. (13)
- **stroma:** The connective tissue framework of an organ; distinguished from the functional cells (parenchyma) of that organ.
- **subarachnoid space:** A meningeal space containing cerebrospinal fluid; the area between the arachnoid membrane and the pia mater. (13)
- **subclavian:** Pertaining to the region immediately posterior and inferior to the clavicle.
- subcutaneous layer: See hypodermis.
- **submucosa:** The region between the muscularis mucosae and the muscularis externa. (23, 24)
- **subserous fascia:** The loose connective tissue layer deep to the serous membrane that lines body cavities. (4)
- **substrate:** A participant (product or reactant) in an enzyme-catalyzed reaction. (2)
- sulcus: A groove or furrow. (14)
- summation: The temporal or spatial addition of contractile force or neural stimuli. (10, 12)superficial fascia: *See* hypodermis.
- **superior:** Above, in reference to a portion of the body in the anatomical position.
- **superior vena cava (SVC):** The vein that carries blood to the right atrium from parts of the body that are superior to the heart. (20, 21)
- **supination:** The rotation of the forearm such that the palm faces anteriorly. (9)
- **supine:** Lying face up, with palms facing anteriorly. (1)
- **suppressor T cells:** Lymphocytes that inhibit B cell activation and the secretion of antibodies by plasma cells. (22)
- suprarenal cortex: See adrenal cortex. (18)
- suprarenal gland: See adrenal gland. (18)
- suprarenal medulla: See adrenal medulla. (16)
- **surfactant:** A lipid secretion that coats the alveolar surfaces of the lungs and prevents their collapse. (23)
- sustentacular cells: See nurse cells.
- **sutural bones:** Irregular bones that form in fibrous tissue between the flat bones of the developing cranium; also called *Wormian bones*. (6)
- **suture:** A fibrous joint between flat bones of the skull. (7, 9)
- **sympathetic division:** The division of the autonomic nervous system that is responsible for "fight or flight" reactions; primarily concerned with the elevation of metabolic rate and increased alertness; also called the *thoracolumbar division*. (12, 16)
- **symphysis:** A fibrous amphiarthrosis, such as that between adjacent vertebrae or between the pubic bones of the coxal bones. (9)
- **symptom:** An abnormality of function as a result of disease; subjective experience of patient.
- **synapse:** The site of communication between a nerve cell and some other cell; if the other cell is not a neuron, the term *neuromuscular junction* or *neuroglandular junction* is often used. (12, 16, 18)
- **synaptic delay:** The period between the arrival of an impulse at the presynaptic membrane and the initiation of an action potential in the postsynaptic membrane. (12)
- **syncytium:** A multinucleate mass of cytoplasm, produced by the fusion of cells or repeated mitoses without cytokinesis. (29)
- **syndrome:** A discrete set of signs and symptoms that occur together.
- **synergist:** A muscle that assists a prime mover in performing its primary action. (11)

- **synovial cavity:** A fluid-filled chamber in a synovial joint. (4, 9)
- **synovial fluid:** The substance secreted by synovial membranes that lubricates joints. (4, 9)
- **synovial joint:** A freely movable joint where the opposing bone surfaces are separated by synovial fluid; a diarthrosis. (4, 9)
- **synovial membrane:** An incomplete layer of fibroblasts confronting the synovial cavity, plus the underlying loose connective tissue. (4)
- synthesis: Manufacture; anabolism. (23)
 system: An interacting group of organs that performs
- one or more specific functions. **systemic circuit:** The vessels between the aortic valve and the entrance to the right atrium; the system other than the vessels of the pulmonary circuit. (20)
- **systole:** A period of contraction in a chamber of the heart, as part of the cardiac cycle. (20)
- **systolic pressure:** The peak arterial pressure measured during ventricular systole. (20)

Т

- tactile: Pertaining to the sense of touch. (15)
- tarsal bones: The bones of the ankle (the talus,
- calcaneus, navicular, and cuneiform bones). (8) **tarsus:** The ankle. (8)
- TCA (tricarboxylic acid) cycle: see citric acid cycle. (3, 10, 25)
- **T cells:** Lymphocytes responsible for cell-mediated immunity and for the coordination and regulation of the immune response; includes regulatory T cells (helpers and suppressors) and cytotoxic (killer) T cells. (19, 22)
- **tectospinal tracts:** Descending tracts of the medial pathway that carry involuntary motor commands issued by the colliculi. (15)
- **telodendria:** Terminal axonal branches that end in axon terminals. (12)
- **telophase:** The final stage of mitosis, characterized by the disappearance of the spindle apparatus, the reappearance of the nuclear membrane, the disappearance of the chromosomes, and the completion of cytokinesis. (3)
- **temporal:** Pertaining to time (temporal summation) or to the temples (temporal bone). (7)
- **tendon:** A collagenous band that connects a skeletal muscle to an element of the skeleton. (4, 10) **teres:** Round.
- eres: Kound.
- **terminal:** Toward the end. **tertiary structure:** The protein structure that results from interactions among distant portions of the
- same molecule; complex coiling and folding. (2) **testes:** The male gonads, sites of gamete production
 - and hormone secretion; also called *testicles*. (18, 28)
- **testosterone:** The main androgen produced by the interstitial cells of the testes. (2, 18, 28)
- **tetraiodothyronine:** T₄, or thyroxine, a thyroid hormone. (18)
- **thalamus:** The walls of the diencephalon. (14)
- **therapy:** The treatment of disease. **thermoreception:** Sensitivity to temperature
- changes. (15)
- **thermoregulation:** Homeostatic maintenance of body temperature. (1, 25)
- **thick filament:** A cytoskeletal filament in a skeletal or cardiac muscle cell; composed of myosin, with a core of titin. (3, 10)
- thin filament: A cytoskeletal filament in a skeletal or cardiac muscle cell; consists of actin, troponin, nebulin, and tropomyosin. (3, 10)

- **thoracolumbar division:** The sympathetic division of the autonomic nervous system. (16)
- thorax: The chest. (7)
- **threshold:** The membrane potential at which an action potential begins. (12)
- **thrombin:** The enzyme that converts soluble fibrinogen to insoluble fibrin. (19)
- **thymine:** A pyrimidine; one of the nitrogenous bases in the nucleic acid DNA. (2)
- **thymosins:** Thymic hormones essential to the development and differentiation of T cells. (18, 22)
- **thymus:** A lymphoid organ, the site of T cell development and maturation. (18, 22)
- **thyroglobulin:** A circulating transport globulin that binds thyroid hormones. (18)
- **thyroid gland:** An endocrine gland whose lobes are lateral to the thyroid cartilage of the larynx. (18)
- **thyroid hormones:** Thyroxine (T_4) and triiodothyronine (T_3) , hormones of the thyroid gland; stimulate tissue metabolism, energy utilization, and growth. (18)
- **thyroid-stimulating hormone (TSH):** The hormone, produced by the adenohypophysis (anterior lobe of the pituitary gland), that triggers the secretion of thyroid hormones by the thyroid gland. (18)
- **thyroxine:** A thyroid hormone; also called *T*₄ or *tetraiodothyronine*. (18)
- **tidal volume:** The volume of air moved into and out of the lungs during a normal quiet respiratory cycle. (23)
- **tissue:** A collection of specialized cells and cell products that performs a specific function. (1, 4)
- **tonic response:** An increase or decrease in the frequency of action potentials by sensory receptors that are chronically active. (15)
- **tonsil:** A lymphoid nodule in the wall of the pharynx; the palatine, pharyngeal, and lingual tonsils. (22)

topical: Applied to the body surface.

- toxic: Poisonous.
- **trabecula:** A connective tissue partition that subdivides an organ. (22)
- **trachea:** The windpipe; an airway extending from the larynx to the primary bronchi. (23)
- **tract:** A bundle of axons in the central nervous system. (13, 14)
- **transcription:** The encoding of genetic instructions on a strand of mRNA. (3)
- **transection:** The severing or cutting of an object in the transverse plane.
- **translation:** The process of peptide formation from the instructions carried by an mRNA strand. (3)
- transmembrane potential: See membrane potential.
- **transudate:** A fluid that diffuses across a serous membrane and lubricates opposing surfaces. (4)
- **transverse tubules:** The transverse, tubular extensions of the sarcolemma that extend deep into the sarcoplasm, contacting cisternae of the sarcoplasmic reticulum; also called *T tubules*. (10)
- **tricuspid valve:** The right atrioventricular valve, which prevents the backflow of blood into the right atrium during ventricular systole. (20)
- **trigeminal nerve:** Cranial nerve V, which provides sensory information from the lower portions of the face (including the upper and lower jaws) and delivers motor commands to the muscles of mastication. (14)
- **triglyceride:** A lipid that is composed of a molecule of glycerol attached to three fatty acids. (2, 25) **triiodothyronine:** T₃, a thyroid hormone. (18)

- **trisomy:** The abnormal possession of three copies of a chromosome; trisomy 21 is responsible for Down's syndrome. (29)
- trochanter: Large process near the head of the
 femur. (8)
- **trochlea:** A pulley; the spool-shaped medial portion of the condyle of the humerus. (8)
- **trochlear nerve:** Cranial nerve IV, controlling the superior oblique muscle of the eye. (14)
- **trunk:** The thoracic and abdominopelvic regions (1); a major arterial branch (21).
- T tubules: See transverse tubules.
- tuberculum: A small, localized elevation on a bony surface. (7)tuberosity: A large, roughened elevation on a bony
- surface. (6)
- **tumor:** A tissue mass formed by the abnormal growth and replication of cells. (3)
- tunica: A layer or covering.
- **twitch:** A single stimulus-contraction-relaxation cycle in a skeletal muscle. (10)
- tympanic duct: See scala tympani.
- **tympanic membrane:** The membrane that separates the external acoustic meatus from the middle ear; the membrane whose vibrations are transferred to the auditory ossicles and ultimately to the oval window; also called *eardrum* or *tympanum*. (17)
- **type A axons:** Large myelinated axons. (12)
- type B axons: Small myelinated axons. (12)
- type C axons: Small unmyelinated axons. (12)

U

- umbilical cord: The connecting stalk between the fetus and the placenta; contains the allantois, the umbilical arteries, and the umbilical vein. (21, 29) umbilicus: The navel. (29)
- umbilicus: The navel. (29)
- unicellular gland: Mucous cells. (4)
- **unipolar neuron:** A sensory neuron whose cell body is in a dorsal root ganglion or a sensory ganglion of a cranial nerve. (12)
- **unmyelinated axon:** An axon whose neurilemma does not contain myelin and across which continuous propagation occurs. (12)
- **uracil:** A pyrimidine; one of the nitrogenous bases in the nucleic acid RNA. (2)
- **ureters:** Muscular tubes, lined by transitional epithelium, that carry urine from the renal pelvis to the urinary bladder. (26)
- **urethra:** A muscular tube that carries urine from the urinary bladder to the exterior. (26)
- **urinary bladder:** The muscular, distensible sac that stores urine prior to micturition. (26)
- **urination:** The voiding of urine; also called *micturition*. (26)
- **uterus:** The muscular organ of the female reproductive tract in which implantation, placenta formation, and fetal development occur. (28)
- **utricle:** The largest chamber of the vestibular apparatus of the internal ear; contains a macula important for providing sensations of gravity and linear acceleration in a horizontal dimension. (17)

V

- **vagina:** A muscular tube extending between the uterus and the vestibule. (28)
- **vallate papilla:** One of the large, dome-shaped papillae on the superior surface of the tongue that forms a V, separating the body of the tongue from the root. (17)
- vas deferens: See ductus deferens. (28)

vascular: Pertaining to blood vessels. (19)

- **vasoconstriction:** A reduction in the diameter of arterioles due to the contraction of smooth muscles in the tunica media; increases peripheral resistance; may occur in response to local factors, through the action of hormones, or from the stimulation of the vasomotor center. (21)
- **vasodilation:** An increase in the diameter of arterioles due to the relaxation of smooth muscles in the tunica media; decreases peripheral resistance; may occur in response to local factors, through the action of hormones, or after decreased stimulation of the vasomotor center. (21)
- **vasomotion:** Rhythmic changes in the pattern of blood flow through a capillary bed due to the alternate contraction and relaxation of precapillary sphincters. (21)
- **vasomotor center:** The center in the medulla oblongata whose stimulation produces vasoconstriction and an increase of peripheral resistance. (14)
- **vein:** A blood vessel carrying blood from a capillary bed toward the heart. (20, 21)
- **vena cava:** One of the major veins delivering systemic blood to the right atrium; superior and inferior venae cavae. (20, 21)
- **ventilation:** Air movement into and out of the lungs. (23)
- ventral: Pertaining to the anterior surface.
 ventricle: A fluid-filled chamber; in the heart, one of the large chambers discharging blood into the pulmonary or systemic circuits (20); in the brain, one of four fluid-filled interior chambers. (14)
- venule: Thin-walled veins that receive blood from capillaries. (21)vermiform appendix: See appendix.
- vertebral canal: The passageway that encloses the spinal cord; a tunnel bounded by the neural arches of adjacent vertebrae. (7)
- vertebral column: The cervical, thoracic, and lumbar vertebrae, the sacrum, and the coccyx. (7, 11)
- **vesicle:** A membranous sac in the cytoplasm of a cell. (3)
- vestibular duct: See scala vestibuli.
- **vestibular nucleus:** The processing center for sensations that arrive from the vestibular apparatus of the internal ear, located near the border between the pons and the medulla oblongata. (17)
- **vestibulospinal tracts:** Descending tracts of the medial pathway that carry involuntary motor commands issued by the vestibular nucleus to stabilize the position of the head. (15)
- villus/villi: Slender, finger-shaped projection(s) of a mucous membrane. (24)
- virus: A noncellular pathogen. (22) viscera: Internal organs of the thoracic and
- abdominopelvic cavities. (1) **visceral:** Pertaining to viscera (internal organs) or
- their outer coverings. (1) visceral smooth muscle: A smooth muscle tissue that forms sheets or layers in the walls of visceral organs; the cells may not be innervated, and the layers often show automaticity (rhythmic contractions). (10, 24)
- **viscosity:** The resistance to flow that a fluid exhibits as a result of molecular interactions within the fluid. (21)
- viscous: Thick, syrupy.
- vitamin: An essential organic nutrient that functions as a coenzyme in vital enzymatic reactions. (25)

vitreous humor: The fluid component of the vitreous body, the gelatinous mass in the posterior cavity (vitreous chamber) of the eye. (17)voluntary: Controlled by conscious thought processes.

W

white blood cells (WBCs): The granulocytes and agranulocytes of whole blood. (4, 19)
white matter: Regions in the central nervous system that are dominated by myelinated axons. (12, 13, 14)
white ramus: A nerve bundle containing the myelinated preganglionic axons of sympathetic

motor neurons en route to the sympathetic chain or to a collateral ganglion. (13) **Wormian bones**: See sutural bones.

X

xiphoid process: The slender, inferior extension of the sternum. (7)

Y

Y chromosome: The sex chromosome whose presence indicates that the individual is a genetic male. (29)

Ζ

zona fasciculata: The region of the adrenal cortex that secretes glucocorticoids. (18)
zona glomerulosa: The region of the adrenal cortex that secretes mineralocorticoids. (18)
zona reticularis: The region of the adrenal cortex that secretes androgens. (18)
zygote: The fertilized ovum, prior to the start of cleavage. (28)

COMMON ABBREVIATIONS USED IN SCIENCE

	acetylcholine	FRC	functional residual capacity
AChE	acetylcholinesterase	FSH	follicle-stimulating hormone
ACTH	adrenocorticotropic hormone	GABA	gamma aminobutyric acid
ADH	antidiuretic hormone	GAS	general adaptation syndrome
ADP	adenosine diphosphate	GC	glucocorticoid
AIDS	acquired immunodeficiency syndrome	GFR	glomerular filtration rate
ALS	amyotrophic lateral sclerosis	GH	growth hormone
AMP	adenosine monophosphate	GH–IH	growth hormone-inhibiting hormone
ANP	atrial natriuretic peptide	GHP	glomerular hydrostatic pressure
ANS	autonomic nervous system	GH-RH	growth hormone-releasing hormone
AP	arterial pressure	GIP	gastric inhibitory peptide
ARDS	adult respiratory distress syndrome	GnRH	gonadotropin-releasing hormone
atm	atmospheric pressure	GTP	guanosine triphosphate
ATP	adenosine triphosphate	Hb	hemoglobin
ATPase	adenosine triphosphatase	hCG	human chorionic gonadotropin
AV	atrioventricular	HCI	hydrochloric acid
AVP	arginine vasopressin	HDL	high-density lipoprotein
BCOP	blood colloid osmotic pressure	HDN	hemolytic disease of the newborn
BMR	basal metabolic rate	hGH	human growth hormone
BPG	bisphosphoglycerate	HIV	human immunodeficiency virus
bpm	beats per minute	HLA	human leukocyte antigen
BUN	blood urea nitrogen	HMD	hyaline membrane disease
с	large calorie; Celsius	HP	hydrostatic pressure
CABG	coronary artery bypass graft	hPL	human placental lactogen
CAD	coronary artery disease	HR	heart rate
cAMP	cyclic-AMP	Hz	Hertz
CAPD	continuous ambulatory peritoneal dialysis	ICF	intracellular fluid
ССК	cholecystokinin	ICOP	interstitial fluid colloid osmotic pressure
CD	cluster of differentiation	IGF	insulin-like growth factor
CF	cystic fibrosis	IH	inhibiting hormone
CHF	congestive heart failure	IM	intramuscular
СНР	capillary hydrostatic pressure	IP 3	inositol triphosphate
CsHP	capsular hydrostatic pressure	IPSP	inhibitory postsynaptic potential
CNS	central nervous system	IRV	inspiratory reserve volume
со	cardiac output; carbon monoxide	ISF	interstitial fluid
СоА	coenzyme A	IUD	intrauterine device
COMT	catechol-O-methyltransferase	IVC	inferior vena cava
COPD	chronic obstructive pulmonary disease	IVF	in vitro fertilization
СР	creatine phosphate	kcal	kilocalorie
СРК, СК	creatine phosphokinase	LDH	lactate dehydrogenase
СРМ	continuous passive motion	LDL	low density lipoprotein
CPR	cardiopulmonary resuscitation	L-DOPA	levodopa
CDE			
CRF	chronic renal failure	LH	luteinizing hormone
CRH	chronic renal failure corticotropin-releasing hormone	LH LLQ	luteinizing hormone left lower quadrant
CRH CSF	chronic renal failure corticotropin-releasing hormone cerebrospinal fluid; colony-stimulating	LH LLQ LM	luteinizing hormone left lower quadrant light micrograph
CRH CSF	chronic renal failure corticotropin-releasing hormone cerebrospinal fluid; colony-stimulating factors	LH LLQ LM LSD	luteinizing hormone left lower quadrant light micrograph lysergic acid diethylamide
CRH CSF CT	chronic renal failure corticotropin-releasing hormone cerebrospinal fluid; colony-stimulating factors computerized tomography; calcitonin	LH LLQ LM LSD LUQ	luteinizing hormone left lower quadrant light micrograph lysergic acid diethylamide left upper quadrant
CRH CSF CT CVA	chronic renal failure corticotropin-releasing hormone cerebrospinal fluid; colony-stimulating factors computerized tomography; calcitonin cerebrovascular accident	LH LLQ LM LSD LUQ MAO	luteinizing hormone left lower quadrant light micrograph lysergic acid diethylamide left upper quadrant monoamine oxidase
CRF CRH CSF CT CVA CVS	chronic renal failure corticotropin-releasing hormone cerebrospinal fluid; colony-stimulating factors computerized tomography; calcitonin cerebrovascular accident cardiovascular system	LH LLQ LM LSD LUQ MAO MAP	luteinizing hormone left lower quadrant light micrograph lysergic acid diethylamide left upper quadrant monoamine oxidase mean arterial pressure

FUNDAMENTALS OF Anatomy Physiology

Tenth Edition

Spotlight Figures

Spotlight Figures

are one- or two-page presentations that integrate text and art to communicate physiological, organizational, or clinical information in a visually effective format. SPOTLIGHT

Figure 6–11 Endochondral Ossification

Endochondral ossification begins with the formation of a hyaline cartilage model. This model serves as the pattern for almost all bone development. Limb bone development is a good example of this process. By the time an embryo is six weeks old, the proximal bones of the limbs, the humerus (upper limb) and femur (lower limb), have formed, but they are composed entirely of cartilage. These cartilage models continue to grow by expansion of the cartilage matrix (interstitial growth) and the production of more cartilage at the outer surface (appositional growth).

Initiation of Ossification in the Developing Bone (Steps 1–4)

Clear steps use text and art to guide students through complex processes.

NEW The Tenth Edition has 18 new Spotlight Figures for a total of 50, including at least one in every chapter.

DNA Replication Chapter 3, page 102

Joint Movement Chapter 9, pages 270-271

Watch the MasteringA&P° > A&PFlix on Endochondral Ossification.

Increasing the Length of a Developing Long Bone (Steps 5-7)

During the initial stages of ossification, osteoblasts move away from the primary ossification center toward the epiphyses. But they do not complete the ossification of the model immediately, because the cartilages of the epiphyses continue to grow. The region where the cartilage is being replaced by bone lies at the metaphysis, the junction between the diaphysis and an epiphysis. On the diaphyseal (shaft) side of the metaphysis osteoblasts continually invade the cartilage and replace it with bone, while on the epiphyseal side, new cartilage is produced at the same rate. The situation is like a pair of joggers, one in front of the other. As long as they are running at the same speed, they can run for miles without colliding. In this case, the osteoblasts and the epiphysis are both "running away" from the primary ossification center. As a result, the osteoblasts never catch up with the epiphysis, and the bone continues to grow longer and longer

5

Epiphysis

NEW There is one coordinating Spotlight Figure for every A&P Flix available in MasteringA&P.

The explanation is built directly into the illustration for efficient and effective learning.

The all-in-one-place presentation means no flipping back and forth between narrative and illustration to get the full story.

MasteringA&P[®] **NEW Spotlight Figure Coaching Activities**

One Spotlight Figure in each chapter now has an assignable Coaching Activity in MasteringA&P.

The Epidermis Chapter 5, page 154

Overview of the Autonomic Nervous System Chapter 16, pages 536-537

Clinical Content

Clinical Notes appear within every chapter, expand upon topics just discussed, and present diseases and pathologies along with their relationship to normal function.

Clinical Note

Carpal Tunnel Syndrome The carpal bones articulate with one another at joints that permit limited sliding and twisting. Ligaments interconnect the carpal bones and help stabilize the wrist joint. The tendons of muscles that flex the fingers pass across the anterior surface of the wrist. These tendons are sandwiched between the intercarpal ligaments and a broad, superficial transverse ligament called the *flexor retinaculum*. Inflammation of the connective tissues between the flexor retinaculum and the carpal bones can compress the tendons and the adjacent *median nerve*. The result is pain, weakness, and reduced wrist mobility. This condition is called *carpal tunnel syndrome*.

Related Clinical Terms end every chapter with a list of relevant clinical terms and definitions.

Related Clinical Terms

- **ankylosing spondylitis:** A chronic, progressive inflammatory disease of the intervertebral spaces that causes abnormal fusion of the vertebrae.
- **arthroplasty:** The surgical reconstruction or creation of an artificial joint.
- **arthroscopy:** Insertion of a narrow tube containing optical fibers and a tiny camera (arthroscope) directly into the joint for visual examination.
- **joint mice:** Small fibrous, cartilaginous, or bony loose bodies in the synovial cavity of a joint.
- **Lyme disease:** An infectious disease transmitted to humans from the bite of a tick infected with *Borrelia burgdorferi*, causing flulike symptoms and joint pain.
- **pannus:** Granulation tissue (combination of fibrous connective tissue and capillaries) forming within a synovial membrane, which releases cartilage-destroying enzymes.

Examples of Clinical Notes:

Congenital Talipes Equinovarus Chapter 8, page 258

Abnormal Bone Development Chapter 6, page 196

AIDs Chapter 22, page 819

NEW I Clinical Cases get students motivated for their future careers. Each chapter opens with a story-based Clinical Case related to the chapter content.

CLINICAL CASE

When Your Heart Is in the Wrong Place

Five-year-old Jackson came home from kindergarten with yet another ear infection. He is a happy child with a great appetite, but he can't seem to stay healthy. His nose is constantly plugged, and he always has a nasty cough. Sometimes he coughs so hard he vomits.

Jackson has been checked for cystic fibrosis, a genetic disease that causes thick, sticky, mucus secretions, to be sure this was not the cause of his earaches and chronic cough. There are no pets or smokers in the home. Because this cough has gone on so long, Jackson is now getting a chest x-ray. The radiology technologist asked if she could take another film and carefully checked to be sure she had the "right" marker on Jackson's right side.

"Now that's funny," the tech said. "It looks like this x-ray is backward, but I know I took it correctly. Jackson's heart

must be on the wrong side." Could Jackson's heart really be on the wrong side? To find out, turn to the Clinical Case Wrap-Up on p. 112.

Each chapter ends with a Clinical Case Wrap-Up that incorporates the deeper content knowledge students will have gained from the chapter.

Examples of Clinical Cases:

A Case of Child Abuse? Chapter 6, page 179

A Chance to See Chapter 17, page 565

A Real Eye Opener Chapter 10, page 290

MasteringA&P[®]

NEW Book-specific Clinical Case Activities

Every Clinical Case has a related assignable Activity in MasteringA&P.

MasteringA&P[®] Assignable Content

NEW I Interactive and Adaptive Capabilities

- Adaptive Follow-Up Assignments allow instructors to easily assign personalized content for each individual student based on strengths and weaknesses identified by his or her performance on MasteringA&P parent assignments.
- Dynamic Study Modules help students acquire, retain, and recall information faster and more
 efficiently than ever before. The flashcard-style modules are available as a self-study tool or can
 be assigned by the instructor. They can be easily accessed with smartphones.
- Learning Catalytics is a "bring your own device" (laptop, smartphone, or tablet) student engagement, assessment, and classroom intelligence system. With Learning Catalytics, instructors can assess students in real time using open-ended tasks to probe student understanding.

NEW ■ A&P Flix[™] Coaching Activities

bring interactivity to these popular 3D movie-quality animations by asking students to manipulate the visuals.

Video Tutor Coaching Activities

instruct and coach students on key A&P concepts from the book and are accompanied by questions with video hints and feedback specific to their misconceptions.

NEW Spotlight Figure Coaching Activities

bring interactivity to the Spotlight Figures from the book by asking students to manipulate the visuals.

Interactive Physiology Coaching Activities

help students dive deeper into complex physiological processes using the Interactive Physiology tutorial program.

Item Type: Cacching Activities Difficulty: Item: Learning Outcomes * Manage this tem: Standard View Interactive Physiology: Intrinsic Conduction System Ick on the link or the image below to explore the intrinsic Conduction System in Interactive Physiology, then complete the activities and questions below. Also Assignable in MasteringA&P[®]:

- Art-labeling Activities are drag and drop activities that allow students to assess their knowledge of terms and structures.
- Art-based Questions are conceptual questions related to art and instruct students with wrong-answer feedback.
- NEW Book-specific Clinical Case Activities stem from the story-based Clinical Cases in the book.

Interactive Physiology: Intrinsic Conduction System

- NEW Clinical Note Activities prepare students for future careers in allied health fields.
- Chemistry Review Activities reinforce chemistry concepts necessary for an understanding of A&P.

- PAL 3.0 and assessments
- PhysioEx 9.1 and assessments

Resources

•

- Reading Quiz Questions
- Chapter Test Questions
- Test Bank Questions

MasteringA&P[®] Study Area

MasteringA&P[°] includes a Study Area that will help students get ready for tests with its simple three-step approach. Students can:

- 1. Take a pre-test and obtain a personalized study plan.
- 2. Learn and practice with animations, labeling activities, and interactive tutorials.
- 3. Self-test with quizzes and a chapter practice test.

I Practice Anatomy Lab[™] (PAL[™]) 3.0

is a virtual anatomy study and practice tool that gives students 24/7 access to the most widely used lab specimens, including the human cadaver, anatomical models, histology, cat, and fetal pig. PAL 3.0 is easy to use and includes built-in audio pronunciations, rotatable bones, and simulated fill-in-the-blank lab practical exams.

NEW The PAL 3.0 App lets you access PAL 3.0 on **your iPad or Android tablet**. With the pinch-to-zoom feature, images can be instantly enlarged.

I A&P Flix[™]

are 3-D movie-quality animations with self-paced tutorials and gradable quizzes that help students master the toughest topics in A&P:

- NEW Protein Synthesis
- Membrane Transport
- DNA Replication
- Mitosis
- NEW Endochondral Ossification
- Events at the Neuromuscular Junction
- The Cross Bridge Cycle
- Excitation-Contraction Coupling
- Resting Membrane Potential
- Generation of an Action Potential
- Propagation of an Action Potential
- NEW The Stretch Reflex
- NEW The Mechanism of Hormone Action: Second Messenger cAMP
- Origins, Insertions, Actions, and Innervations Over Over 60 animations on this topic
- Group Muscle Actions and Joints Over 50 animations on this topic

Interactive Physiology[®] (IP)

helps students understand the hardest part of A&P: physiology. Fun, interactive tutorials, games, and quizzes give students additional explanations to help them grasp difficult concepts.

Modules:

- Muscular System
- Nervous System I
- Nervous System II
- Cardiovascular System
- Respiratory System
- Urinary System
- Fluids & Electrolytes
- Endocrine System
- Digestive System
- Immune System

Support for Instructors

MyReadinessTest[™]

NEW | MyReadinessTest

by Lori K. Garrett

MyReadinessTest for A&P is a powerful online system that gets students prepared before their course starts. It assesses students' proficiency in study skills and foundational science and math concepts and provides coaching in core areas where students need additional practice and review.

Instructor's Manual

by Jeff Schinske and Mary L. Puglia 978-0-321-96253-9 / 0-321-96253-2

Printed Test Bank

by Jackie Reynolds, Theresia Whelan , Michael G. Wood, and Judi L. Nath 978-0-321-92857-3 / 0-321-92857-1

Instructor Resource DVD (IRDVD)

with Lecture Outlines by Lee Ann Frederick and Clicker Questions by Rene Salazar 978-0-321-92859-7 / 0-321-92859-8

The IRDVD organizes all instructor media resources by chapter into one convenient and easy-to-use package. Highlights include:

- Customizable PowerPoint Lecture Presentations that combine lecture notes, figures, tables, and links to animations
- All figures from the book in JPEG format and PowerPoint slides (with editable labels and without) plus figures from *Martini's Atlas of the Human Body* and *A&P Applications Manual*
- Another set of JPEGs from the book featuring unlabeled figures with leader lines for quick and easy quizzing
- A&P Flix 3-D movie-quality animations on tough topics
- Interactive Physiology 10-System Suite (IP-10) Exercise Sheets and Answer Key
- Test Bank in TestGen and Microsoft Word formats
- Instructor's Manual in Microsoft Word format
- Transparency Acetate masters for all figures and tables
- The IRDVD for Practice Anatomy Lab (PAL) 3.0

I eText with Whiteboard Mode

The Fundamentals of Anatomy & Physiology eText comes with Whiteboard Mode, allowing instructors to use the eText for dynamic classroom presentations. Instructors can show one-page or two-page views from the book, zoom in or out to focus on select topics, and use the Whiteboard Mode to point to structures, circle parts of a process, trace pathways, and customize their presentations.

Instructors can also add notes to guide students, upload documents, and share their custom-enhanced eText with the whole class.

Instructors can find the eText with Whiteboard Mode on MasteringA&P.

Support for Students

Get Ready for A&P

by Lori K. Garrett 978-0-32181336-7 / 0-321-81336-7

This book and online component were created to help students be better prepared for their A&P course. Features include pre-tests, guided explanations followed by interactive quizzes and exercises, and endof-chapter cumulative tests. Also available in the Study Area of MasteringA&P.

10-SYSTEM SUITE

Interactive Physiology® 10-System Suite (IP-10) CD-ROM

978-0-13-136275-8 / 0-13-136275-5

IP helps students understand the hardest part of A&P: physiology. Fun, interactive tutorials, games, and quizzes give students additional explanations to help them grasp difficult physiological concepts.

Martini's Atlas of the Human Body

by Frederic H. Martini

978-0-321-94072-8 / 0-321-94072-5 The Atlas offers an abundant col-

lection of anatomy photographs, radiology scans, and embryology summaries, helping students visualize structures and become familiar with the types of images seen in a clinical setting.

Practice Anatomy Lab[™] (PAL[™]) 3.0 DVD

by Ruth Heisler, Nora Hebert, Jett Chinn, Karen Krabbenhoft, and Olga Malakhova

978-0-321-68211-6 / 0-321-68211-4

PAL 3.0 is an indispensable virtual anatomy study and practice tool that gives students 24/7 access to the most widely used lab specimens, including the human cadaver, anatomical models, histology, cat, and fetal pig.

Also Available: PAL 3.0 Lab Guide 978-0-321-84025-7 / 0-321-84025-9

A&P Applications Manual

by Frederic H. Martini and Kathleen Welch

978-0-321-94973-8 / 0-321-94973-0 This manual contains extensive

discussions on clinical topics and disorders to help students apply the concepts of anatomy and physiology to daily life and their future health professions.

PhysioEx[™] 9.1 Laboratory Simulations in Physiology

by Peter Zao, Timothy Stabler, Lori A. Smith, Andrew Lokuta, and Edwin Griff

978-0-321-92964-8 / 0-321-92964-0

This easy-to-use laboratory simulation software and lab manual consists of 12 exercises containing 63 physiology lab activities that can be used to supplement or substitute wet labs safely and cost-effectively. Now with input data variability.
