Classical accounts of the development of the hippocampal formation (Hines, 1922; Gastaut and Lammers, 1961; Humphrey, 1967) describe the main steps in the development of the hippocampus. A recent study by Arnold and Trojanowski (1996a) summarizes earlier details: by 9 weeks of gestation, the hippocampal anlage is located at the medial aspect of the developing cerebral hemisphere, and still it has not reached the doubly folded appearance of the more mature hippocampus. The hippocampal fissure does not appear until 10 weeks (Humphrey, 1967). By the middle of the second trimester (15–19 weeks), the hippocampal fields become apparent, and the subiculum is particularly clear at this time. The dentate gyrus demonstrates three layers, although they have an immature appearance. By the end of the second third of gestation (25 weeks), the hippocampal fissure is deeper, and the hippocampal fields have expanded. Still the border between CA1 and the subiculum is not distinct, but the layers of CA1 and CA2–CA3 are more evident. The dentate gyrus increases in cell density with many neurons still presenting immature features. By the last trimester of pregnancy (34 weeks), the hippocampal fissure is fused, and the border between CA1 and subiculum is present. CA1, CA2, and CA3 are all recognizable, and the pyramidal cell layer is more evident. The dentate gyrus takes on an adult appearance. In addition, the angular bundle is well defined and contains some myelin as determined by immunoreactivity to myelin basic protein. The hippocampus shows a decrease in cell density in the postnatal period, probably as a result of apoptotic processes and growth of neuronal processes and fibers. No significant morphological changes take place into adulthood, although the myelination is progressively more complete.

The development of the human entorhinal cortex has been studied by several authors (Macchi, 1951; Delmas, 1955; Kostovic *et al.*, 1993; Hevner and Kinney, 1996, Graterón *et al.*, 2002). The entorhinal cortex can be recognized as early as the 10th gestational week (Delmas, 1955, Kostovic *et al.*, 1993; Hevner and Kinney, 1996), and by week 13, the lamina dissecans is recognizable (Kostovic *et al.*, 1993). Hevner and Kinney (1996), by placing small amounts of the lipophilic tracer DiI in the surface of the foetal entorhinal cortex, demonstrated that by 17 weeks of gestation the entorhinal cortex is laminated and develops reciprocal connections with the CA1, while by the 19th week connections are established with the subiculum.

The postnatal development of the human entorhinal cortex has been analyzed by Graterón *et al.* (2002), who reported that all six layers of the entorhinal cortex are present at the time of birth. There is a gradient of differentiation such that at birth the lateral and caudal portions look more differentiated than rostral and medial parts. Moreover, deep layers (V and VI) develop prior to the superficial layers (II and III). The upper layers of the entorhinal cortex (II–III) look more mature by the end of the first postnatal year but do not reach adultlike morphology until the end of the second postnatal year. In contrast, the deep layers (V–VI) show little modification from their newborn appearance.

CLINICAL ANATOMY

Various clinical conditions result in morphological alterations of the human hippocampal formation. While the causative factors are not yet known for most of these disease states, it is clear that each of the different hippocampal cytoarchitectonic fields is more or less vulnerable to damage. In ischemia and temporal lobe epilepsy, for example, field CA1 of the hippocampus (the so-called Sommer's sector) suffers the greatest neuronal cell loss. In other neuropathological conditions, such as Alzheimer's disease, the pathological insult may actually demonstrate laminar specificity within some hippocampal fields.

Normal Aging Versus Alzheimer's Disease

A recurrent question in aging research is to what extent humans lose neurons as they grow older. Until a few years ago, the common assumption was that the hippocampus begins to lose neurons in midlife and the loss continues into old age. However, this view was not based on studies that used unbiased sampling strategies. Recent numerical counts by West and colleagues (West 1993; West *et al.*, 1994; Simic *et al.*, 1997) show that the hippocampal formation does not generally suffer any age-related loss of neurons. Only the subiculum (52% or 7.3% per decade) and the hilus of the dentate gyrus (31% or 4.2% per decade) demonstrate substantial cell loss in normal aging (West, 1993). In contrast, neuronal loss in the hippocampal formation of Alzheimer's disease patients is much higher, even in very mild cases (West *et al.*, 1994; Simic *et al.*, 1997; Price *et al.*, 2001). Studies on the entorhinal cortex (Price *et al.*, 2001) reveal a similar trend (0.7% of neuron loss per year, and, specifically 1.2% for layer II neurons). The analysis of the extent of atrophy in the human entorhinal cortex in normal aging (age range of the series, 12–110 years old) based on the areal measurement of two-dimensional reconstructions of the entorhinal cortex reveals a decrease up to 4% in size over the life range (Insausti *et al.*, 1998).

Among the many conditions that produce pathological changes in the hippocampal formation, Alzheimer's disease is probably the most devastating (Ball, 1977, 1978; Hyman *et al.*, 1984, 1986; Kemper, 1978; Van Hoesen and Damasio, 1987). Myriad studies have come to the clear conclusion that this disorder is distinctly different from an elaboration of normal aging. Alzheimer's disease is associated with four neuropathological correlates in the hippocampal formation: neuronal cell loss, neurofibrillary tangles, neuritic plaques, and granulovacuolar degeneration (for more information about each one of these lesions, see Tomlinson and Corsellis, 1984).

Corsellis (1970) first drew attention to the near complete cell loss in the CA1 field of the brains of Alzheimer's patients. Ball and colleagues have subsequently conducted systematic analyses of cell loss in the hippocampal formation, and they estimate that there is a decrease of some 56% in the number of hippocampal pyramidal cells (versus 12% in age-matched controls, Ball, 1977). These early studies have been confirmed by more recent studies using unbiased sampling procedures (West *et al.*, 1994; Simic *et al.*, 1997). They demonstrate that CA1 suffers a profound neuron loss (an average of 68%), in contrast to normal aging where neuron loss is negligible. Hyman *et al.* (1984, 1986) have emphasized that the cell loss is pronounced not only in CA1, but that the subiculum and layers II and V of the entorhinal cortex are also depleted. More recent studies (Price *et al.*, 2001) show that there is already profound neuron loss (35% in the entorhinal cortex as a whole, of which 50% is in layer II, and 46% in CA1, in mild clinical cases of Alzheimer's disease). Interestingly, despite the fact that neurons in layers II and V of the entorhinal cortex are nearly eliminated, layers III and VI have a relatively normal appearance.

Neurofibrillary tangles, while occasionally observed in the normal-aged brain, are more numerous in the Alzheimer's brain and are located in the same regions that undergo the greatest amount of cell loss (Ball, 1978; Kemper, 1983). Ball (1977) noted that a greater number of neurofibrillary tangles occur in the posterior part of the hippocampus. Neuritic plaques are spherical foci, 5–200 μm in diameter, that may have a central amyloid core surrounded by argyrophilic rods and granules. They are very numerous in the hippocampal formation of patients with Alzheimer's disease and show a preference for the molecular layer or the dentate gyrus (Burger, 1983; Hyman *et al.*, 1984). The fourth pathological correlate of Alzheimer's disease is granulovacuolar degeneration (Ball, 1983). Neurons demonstrating granulovacuolar degeneration contain one or more 3- to 5-μm vacuoles that hold a 0.5- to 1.5-μm agyrophilic granule. These profiles are numerous in the subiculum and CA1 of the Alzheimer's brain but are not frequently found in the entorhinal cortex.

As a result of the cell loss and other pathological sequelae of Alzheimer's disease, especially in the entorhinal cortex, it has been suggested that, as the disease develops, the hippocampal formation becomes, in essence, functionally disconnected from its major afferent and efferent interactions (Hyman *et al.*, 1984; see Braak and Braak, 1992 for a comprehensive review

of the human entorhinal cortex in various pathologies). Given the important role the hippocampal formation is known to play in certain forms of memory, it is likely that a major portion of the problems with memory function observed in Alzheimer's disease is attributable to damage of the hippocampal formation.

Epilepsy

Temporal lobe or complex partial epilepsy is another neurological disorder in which the hippocampal formation is severely affected (Meldrum and Corsellis, 1984). This most common form of epilepsy was first associated with damage to the hippocampal formation by Sommer (1880), who conducted the first postmortem microscopic examination of a brain from a long-term epileptic patient. Sommer noted a dramatic loss of neurons in the hippocampal formation that was relatively selective and involved a region that in modern terminology would encompass CA1 and part of the subiculum. During the first part of this century, it was generally believed that hippocampal pathology was a consequence of the epileptic seizures rather than their cause. Currently, however, increasing emphasis is being placed on the idea that disruption of normal hippocampal function may be an initiating factor in temporal lobe seizures (Babb *et al.*, 1984; Falconer, 1974), and a number of animal models have been established to study this possibility (Schwarcz and Ben-Ari, 1986).

In approximately two-thirds of the cases of temporal lobe epilepsy, the hippocampal formation is the only structure that shows pathological modifications (Cavanagh *et al.*, 1958; Meldrum and Corsellis, 1984). As Sommer initially described, cell loss is most consistently found in the CA1 field of the hippocampus, but in many cases cell loss is also observed in the dentate gyrus and CA3 and portion of the subiculum immediately adjacent to CA1 (Babb *et al.*, 1984; Mouritzen Dam, 1982). The CA2 field is usually preserved, and the remainder of the hippocampal formation (presubiculum, parasubiculum, and entorhinal cortex) is also reported to be much less susceptible to damage, altough neuronal loss in layer III of the entorhinal cortex has been reported (Du *et al.*, 1993). Other morphological changes are observed in the dentate gyrus of the epileptic brain such as dispersion of granule cells and a bilaminar organization of the granule cell layer (Houser *et al.*, 1992). Other changes include the absence of mossy cells and altered dendritic pattern in the polymorphic cell layer of the dentate gyrus (Blümcke *et al.*, 1999). In some cases of long-term epilepsy, cell loss is so striking that the gross appearance of the hippocampus is shrunken and the term "Ammon's horn sclerosis" is applied at this stage (for review see Sloviter, 1994) . Tissue characteristics are so modified at this point that the pathology can be detected by using magnetic resonance imaging (Kuzniecky *et al.*, 1987; Hogan *et al.*, 2000).

The sequence of events that leads to the initial establishment of a seizure-inducing focus in the hippocampal formation is not clear. Damage following infantile seizures is often invoked as a possibility (Meldrum and Corsellis, 1984; Delgado-Escueta and Walsh, 1985), but the exact metabolic alteration (ischemia, hypoxia, etc.) is not yet known. Using an animal model of epilepsy, Sloviter (1987) had advanced the interesting hypothesis that initial seizure episodes are particularly damaging to a class of hippocampal interneurons that are immunoreactive for somatostatin. The loss of this class of neuron could initiate a cascade of destabilizing events that ultimately leads to loss of the CA1 pyramidal cells. However, neurons containing the calcium-binding proteins parvalbumin and calbindin (see chemical neuroanatomy section) are among the surviving neurons in the hippocampal formation (Sloviter *et al.*, 1991). The process of cell loss in the hippocampal formation is accompanied by cell remodeling, as shown by Mikkonen *et al.* (1998) with respect to the cell adhesion molecule PSA-NCAM immunoreactivity increased not only in the dentate gyrus but in CA1 and the entorhinal cortex as well.

Ischemia, Schizophrenia, and Other Disorders

There are a number of other neurological or neuropsychiatric conditions in which the hippocampal formation may demonstrate pathology. Among these is the loss of neurons, primarily in CA1, consequent to the ischemia associated with cardiorespiratory arrest (Cummings *et al.*, 1984; Petito *et al.*, 1987; Zola-Morgan *et al.*, 1986). These patients demonstrate an anterograde memory impairment apparently resulting from the hippocampal damage (Zola-Morgan *et al.*, 1986). Much less clear-cut is the involvement of the hippocampal formation in major psychiatric disorders such as schizophrenia. It has been argued that developmental abnormalities in the hippocampal formation may be an important contributon to the symptoms of schizophrenia. Akbarian *et al.* (1993) reported a decrease of nicotinamide-adenine dinucleotide phosphate-diaphorase (NADPH-d) in the hippocampal formation of schizophrenic patients, although there was a tendency for an increase in NADPH-d positive cells in the white matter of the parahippocampal gyrus. The normal distribution of NADPH-d in the human hippocampal formation has been reported by Yan and Ribak (1997) in prenatal development and Sobreviela

and Mufson (1995) in the adult. Arnold *et al.* (1991) analyzed the expression of different neuronal cytoskeletal proteins and found that the rostral entorhinal cortex and subiculum had much lower expression of microtubule-associated proteins 2 and 5 (MAP2 and MAP5) in the schizophrenic brain.

A number of studies have highlighted the entorhinal cortex as one of the regions that present morphological changes in schizophrenic patients. Jakob and Beckmann (1986, 1994) and Arnold *et al.* (1997) proposed that the entorhinal cortex in schizophrenia presented disturbances in neuronal migration that could explain the disorganized appearance of layer II neurons and misplacement of these neurons into layer III. The role of a developmental problem in neuronal migration in the pathogenesis of schizophrenia awaits further confirmation.

There are some indications that the hippocampal formation has a significantly reduced volume in cases of schizophrenia (Bogerts *et al.*, 1985; Crow and Johnstone, 1987). No volumetric changes have been observed in the parahippocampal gyrus of schizophrenics compared to controls (Heckers *et al.*, 1990). While Falkai and Bogerts (1986) had found a significant loss of pyramidal cells in the CA fields of the hippocampus but not in the dentate gyrus or subicular cortices, more recent estimates of the number of neurons in the hippocampal formatioin (Heckers *et al.*, 1991) and in the entorhinal cortex (Krimer *et al.*, 1997) do not demonstrate differences between control and schizophrenic brains.

Pathological changes in the hippocampal formation have also been reported in several other dementing neurological diseases. Misuzawa *et al.* (1987), for example, found spongiform changes in the stratum lacunosum-moleculare of the hippocampus in three of five cases of Creutzfeldt-Jacob disease, a form of encephalopathy caused by a slow virus. The contribution of hippocampal impairment, however, to the overall behavioral deterioration in this disease is difficult to predict.

Neurodevelopmental Disorders

Autism and related disorders (for a recent review, see Lord *et al.*, 2000) is an increasingly common neurodevelopmental disorder for which abnormalities in the hippocampal formation have been described. Bauman and Kemper (1985) and Kemper and Baumann (1998) describe an increase in cell density in the CA3, CA2, and CA1 fields of the hippocampus, as well as in the entorhinal cortex, in addition to an "extra" lamina dissecans under layer II. Although these observations are interesting, they have not yet been independently confirmed. Moreover, structural imaging studies have produced highly conflictive findings on volume changes related to autism. This will clearly be an important area for future study.

FUNCTIONAL CONSIDERATION—THE EMERGENCE OF NEUROIMAGING

When this chapter first appeared in 1990, functional magnetic resonance imaging (fMRI) had not yet appeared as a tool for investigation of the human brain (Belliveau *et al.*, 1991). Since that time, hundreds of studies have been carried out using fMRI and PET to study the function of the hippocampal formation in awake behaving human subjects. Recent studies have even endeavored to fractionate component process of behavior to subfields of the hippocampal formation or to related cortical regions. In this final section, we will briefly provide an historical perspective on the function(s) of the hippocampal formation and then discuss some of the advances that the use of structural and functional imaging techniques has allowed. Given the intense activity in this area, this will necessarily provide only a sense of the issues that are being studied. However, we will refer to a number of recent review papers for further reading and references.

The hippocampal formation has historically been implicated in a variety of functions. Sommer (1880), for example, considered it to be a component of the motor system because he found that damage to the hippocampal formation highly correlated with the occurrence of temporal lobe epilepsy. For much of the first half of this century, the hippocampal formation was thought to be primarily related to olfactory function and was considered to be a prominent component of what was called the rhinencephalon or olfactory brain. This concept was put to rest by Brodal (1947), who indicated that the hippocampal formation was as prominent in anosmic species as in species that rely heavily on the sense of smell. Papez (1937) considered the hippocampal formation to be a central component in a system for marshaling emotional expression to sensory experiences. In his view, the hippocampus was something of a conduit by which perceptions could be channeled to the mammillary nuclei of the hypothalamus, where appropriate emotions could be effected. There has been very little substantiation of Papez's theory, and the role of modulator of emotional expression is now more closely linked to the amygdaloid complex than to the hippocampal formation.

Perhaps the most widely accepted and long-lived proposal of hippocampal function relates to its role in

memory (Milner, 1970; Squire, 1987). It has been known for nearly a century that damage to certain brain regions can result in an enduring, polysensory amnesic syndrome that is characterized by a complete, or near complete, anterograde amnesia with a variable degree of premorbid retrograde amnesia. Affected patients are incapable of recreating a record of day-to-day events though most past memories remain intact. Structures most commonly associated with this "global" or "general" form of amnesia are located either in the medial temporal lobe (the hippocampal formation and adjacent cortex) or in the diencephalon (the mammillary nuclei and mediodorsal nucleus of the thalamus) (Amaral, 1987; Ojemann, 1966; Squire, 1987). Until recently, there was no compelling evidence that damage isolated to any one of these structures leads to a clinically significant amnesia, though, in the last few years, the association between damage to the hippocampal formation and memory impairment has become substantially more established.

Bechterew (1900) was among the first to suggest that memory impairment could occur following damage to the temporal lobe. He based this conclusion on his studies of the brain of a 60-year-old man who had suffered from severe memory problems during the last 20 years of his life. Bechterew found that there was bilateral softening of the medial temporal lobe in this patient´s brain covering an area that included the amygdaloid complex and the hippocampal formation. Several decades later, Grunthal (1939) and Glees and Griffith (1952) published case reports of patients who had suffered vascular accidents that bilaterally damaged the hippocampal formation and parahippocampal gyrus. In both cases, memory function was compromised though formal testing was not carried out. In 1954, Scoville described a patient (H.M.) with severe anterograde amnesia resulting from bilateral surgical removal of the anterior medial temporal lobe that was intended to ameliorate intractable epilepsy. The resection involved the amygdaloid complex, the anterior two-thirds of the hippocampal formation, and portions of the adjacent parahippocampal gyrus. A recent and detailed MRI study has been reported (Corkin *et al.*, 1997). Interestingly, while the initial surgical report indicated that the entire hippocampal formation was removed, Corkin *et al.* (1997) found that only about half of the rostrocaudal extension of the hippocampus was removed. The entorhinal cortex, however, was totally removed so that the residual posterior hippocampus in H.M. is largely devoid of sensory input. From studies of H.M. and nine other patients with less extensive bilateral resection of the medial temporal lobe, Scoville and Milner (1957) concluded that damage to the hippocampal formation was necessary for the occurrence of the amnesic syndrome. They believed that damage confined to the amygdaloid complex did not produce amnesia.

This conclusion, however, has remained controversial. Horel (1978), for example, suggested that medial temporal lobe amnesia was not related to damage of the hippocampal formation or amygdaloid complex but rather to the interruption of efferent connections between the temporal neocortex and other cortical and subcortical regions. He suggested that the region just above the hippocampal formation in which these fibers travel, the so-called temporal stem, was damaged in the surgical approach followed by Scoville in patient H.M. At about the same time, Mishkin (1978) offered the alternative suggestion that amnesia results only when both the amygdala and hippocampal formation are damaged. He pointed out that in all human cases demonstrating medial temporal lobe amnesia, including case H.M., there was damage to both the amygdala and hippocampus. In experiments designed to test this hypothesis, Mishkin (1978) found that monkeys experimentally prepared with lesions of either the hippocampus or amygdala demonstrated only mild changes in memory performance whereas a conjoint lesion of both structures produced a profound memory impairment analogous to human global amnesia. While Zola-Morgan and Squire (1985, 1986) have confirmed that conjoint lesions produce a marked memory impairment, they found, in contrast to Mishkin (1978), that selective hippocampal lesions also result in a significant decrease in memory function. The question remained, therefore, whether damage to the human hippocampal formation alone would lead to a clinically significant amnesia.

A clinicopathological human case study (R.B.) of a patient with a selective hippocampal lesion indicates that this damage is sufficient to produce a clinically significant anterograde amnesia (Zola-Morgan *et al.*, 1986). R.B. was a retired, 52-year-old male postal worker who suffered a prolonged ischemic period following coronary bypass surgery. During his 5-year survival period, R.B. underwent extensive neuropsychological assessment. He exhibited marked anterograde amnesia, with little if any retrograde amnesia, and showed no signs of cognitive impairment other than memory. A postmortem histological analysis of the entire brain revealed a complete and bilateral loss of pyramidal cells in the CA1 field of the hippocampus; all other fields of the hippocampal formation had a normal appearance. While minor pathology was found elsewhere in the brain (patchy Purkinje cell loss in the cerebellum, gliosis in the left globus pallidus and internal capsule, infarct of the right postcentral gyrus), the only damage that could be reasonably

associated with the memory defect was the damage to the hippocampal formation. And, in this case, the amygdaloid complex, the mammillary nuclei, and the mediodorsal nucleus of the thalamus had an apparently normal appearance. Moreover, there was no widespread pathology in the temporal neocortex or in the region of the "temporal stem." Thus, this case provides strong evidence of amnesia following a lesion limited exclusively to the hippocampus.

While there is now fairly convincing evidence that the hippocampal formation plays a prominent role in the formation of enduring memories, the mechanism by which it exerts its influence is far from clear. Because damage to the hippocampal formation does not cause a loss of distant or well-established memories, it appears that the hippocampal formation cannot be the final repository for stored information. Rather, it appears that the hippocampal formation must interact with storage sites in other, presumably cortical, regions to consolidate ephemeral sensory experiences into long-term memory. The anatomical, physiological, and pharmacological bases for this interaction are among the most highly studied phenomena in current neuroscience. Yet, interestingly, the careful neuropsychological and histological analyses in studies of human cases have provided some or the most convincing evidence for the role of the hippocampal formation.

Spiers *et al.* (2001) have provided a comprehensive review of case studies of patients with medial temporal lobe lesions and resultant amnesia. They emphasized in this review that the human lesion studies are consistent in their conclusion that hippocampal damage leads to anterograde amnesia. They are less consistent in providing support for the role of the relationship between hippocampal damage and retrograde amnesia, deficits in semantic memory, or familiarity-based recognition. They also reiterated that there are suggestions that memory function is lateralized in human subjects. The left hippocampal formation is generally found to play a more prominent role in episodic or biographical memory, whereas the right hippocampal formation is more related to spatial memory processing.

One continuing controversial issue is whether the hippocampal formation is essential for semantic memory processing. Semantic memory is memory for factual knowledge devoid of the source of the information. Squire (1992) argued that the hippocampal formation is essential for encoding both semantic and autobiographical information. However, Vargha-Khadem and colleagues (Vargha-Khadem *et al.*, 1997; Gadian *et al.*, 2000) questioned this view. They studied children who had early ischemic/anoxic damage of the hippocampal formation. The surprising finding from this series of studies was that despite apparently near-normal learning of general information, these children had little or no autobiographical memory. This raised the prospect that regions outside and independent of the hippocampus might be able to support semantic memory processing. Interestingly, Maguire *et al.* (2001) demonstrated that the portion of the hippocampus that is not damaged in at least one of these children (Jon) can be activated in tasks of autobiographical memory. Therefore, it is not clear that these studies provide definitive evidence for nonhippocampal processing of semantic memory. This study, by Maguire and colleagues, provides an excellent example of how fMRI can provide information from patients with focal brain damage on which regions are supporting residual behavioral function (reviewed in Maguire, 2001).

Functional imaging studies have also dealt with the issue of retrograde amnesia. Retrograde amnesia is the loss of memories for events or information that was gained prior to the lesion. Both the existence and the duration of retrograde amnesia after hippocampal lesions has been hotly debated (Rosenbaum *et al.*, 2001; Nestor *et al.*, 2002). Haist *et al.* (2001) have used fMRI and the famous faces task to generate data indicating that the hippocampus proper may be involved only in the retrieval of memories that go back a few years. The entorhinal cortex, in contrast, demonstrates temporally graded changes in activity when viewing and identifying faces that extend back up to 20 years. Ryan *et al.* (2001) also carried out an fMRI study while subjects were asked to recall recent or distant past events in their lives. They found equivalent activation for both ages of events, which they argue disputes the notion of the hippocampus playing a role in long-term consolidation. These investigators, however, did not specifically examine the entorhinal cortex.

Another issue that has been profitably explored with fMRI is the role of the hippocampal formation in memory retrieval. It has been clear for some time that damage to the hippocampus impairs formation of new memories, but it was not thought that the hippocampus was an essential component of memory retrieval. However, a number of investigators have observed that the hippocampus is activated during the recollection of recently occurring facts and events (Stark and Squire, 2000). Lepage *et al.* (1998) carried out a meta analysis of PET activations of the hippocampus during encoding and retrieval on new information and found that encoding activations were predominantly in the anterior hippocampus and retrieval activations predominantly, in the posterior hippocampus. As attractive as this notion is, more

recent high-resolution fMRI studies have not been able to confirm this regions localization (Reber *et al.*, 2002).

Functional imaging technologies will undoubtedly become increasingly more powerful. Perhaps during the next decade, the functional significance of the complex yet elegant hippocampal neuroanatomy that has been the subject of this chapter will be determined.

Acknowledgments

Original work cited in this chapter was supported by NIH grants NS-16980 and MH-41470 to DGA and Grant FIS 86/1129 and 01/0688 from the Ministry of Health (Spain), and grant GC-02-022 of the Department of Science and Technology, Junta de Comunidades de Castilla-La Mancha (Spain) to RI. We would like to thank Janet Weber and Mary Ann Lawrence for superb histological assistance, Kris Trulock for splendid photographic help, and Belle Wamsely for secretarial and editorial help. We are also indebted to the Human Neuroanatomy Laboratory and CRIB components, Mª del Mar Arroyo, Pilar Marcos, Emilio Artacho, Alino Martínez, Mónica Muñoz, Xavier Blaizot, Alicia Mohedano, Sandra Cebada, Isabel Úbeda, and Carmen Ruiz for assistance in the elaboration of this chapter. Human brain material from which the histological preparations were made was obtained through the generous assistance of J. Martinez-Peñuela, T. Tuñon, A. Insausti, and T. Urrutia of the Department of Pathology, Hospital of Navarra, Pamplona, Spain.

The *cingulate gyrus* is the most prominent cortical feature on the medial surface of the human brain. It forms a cingulum or belt that extends from the lamina terminalis rostral to the anterior commissure, around the genu of the corpus callosum, over the body of the callosum, and just ventral to the splenium. The cingulate gyrus forms the dorsal component of the grand limbic lobe of Broca (1878) and has a major role in most theories of emotion (MacLean, 1993). Although it forms a single and continuous structure, the cingulate gyrus is structurally and functionally heterogeneous. Efforts to identify a structural motif that is responsible for the role of cingulate cortex in emotion and a limbic system have failed as have efforts to characterize a single cingulate function such as attention and its allocation. Because the structure of human cingulate cortex may uncover organizational principles that pertain to the entire brain, characterizing the structural heterogeneity of human cingulate cortex has been a major challenge for neuroscience.

The *cingulum bundle* is a white matter tract that underlies the cingulate cortex, and all connections entering and exiting the cingulate gyrus pass through this bundle. In addition, there are axons of passage that neither arise in the cingulate cortex nor terminate there. These pathways include projections between prefrontal and parahippocampal cortices (Nauta, 1964; Goldman-Rakic *et al.*, 1984) and projections to the median raphe nucleus that terminate in the dorsal

hippocampus (Azmitia and Segal, 1978). The cingulum bundle has been the target of neurosurgical procedures for the alleviation of chronic pain and psychiatric disorders including anxiety, major depression, and obsessive-compulsive disorder. When the primary target of the procedure is the cingulum bundle, the procedure is a *cingulumotomy*, and when the target is cingulate cortex itself and damage to the cingulum bundle is secondary to the procedure, the ablative technique is a *cingulotomy*. Finally, the term "cingulum" was used in the early part of the last millennium when Roman soldiers and clerics wore a belt or sash and woman wore an undergarment for breast support termed a cingulum. In the context of modern neuroanatomy, the cingulum bundle is the longitudinally oriented aggregate of myelinated axons that underlies cingulate cortex and looks like a belt or sash surrounding the corpus callosum when the overlying gray matter has been removed.

A *four-region neurobiological model of cingulate organization* incorporating key structure/function correlations requires the full armamentarium of neuroscience because no single methodology or theoretical framework has proven adequate to model it. Indeed, one of the jewels of cingulate neurobiology is evolving from imaging human cerebral activation under carefully controlled neuropsychological testing conditions. Even this body of work, however, cannot stand in a vacuum and must become part of a larger structure/function model. In the context of this model, regional designations are not simple statements of where activation sites are located on the gyrus. Instead, each region implicates specific cytologies, connections, functions, and disease vulnerabilities. For example, the designation perigenual anterior cingulate cortex is more than a location around the genu of the corpus callosum as is often stated in imaging studies. This region has differential inputs from the amygdala and parietal lobe, has unique projections to autonomic motor nuclei, a specific role in affect, and is selectively damaged in major depression. All these observations are an explicit part of the regional model.

The first and traditional model of the cingulate gyrus sought to localize key functions within a tripartite morphology of cortex with anterior cingulate, posterior cingulate, and retrosplenial cortices (Vogt *et al.*, 1992). In subsequent years that included a spate of human imaging research, this model was extended to the current four-region model (Vogt, 1993; Vogt *et al.*, 1997). These evolving models of medial cortical structure seek to identify the unique contributions of each of the 20 cingulate areas to particular functions. In the long run, such studies will yield a wealth of information about the mechanisms of neurodegeneration in brain diseases, the mechanisms of action of new drugs, and neurosurgical outcomes and for modulating consciousness with alternative mind/body methods.

The primary goal of this overview of the human cingulate gyrus is to characterize the cytoarchitectural features of each of its regions. In decades past, the cingulate gyrus was viewed as a relatively simple region with anterior and posterior divisions, and studies often assumed that Brodmann's (1909) maps of the medial surface were essentially correct. Recent macaque monkey connection studies, human functional imaging, and the cytoarchitectural work of Braak (1976, 1979a, b) have shown that the primate cingulate gyrus is more complex than envisioned by Brodmann. In most instances, the Brodmann areas are not cytologically uniform and do not perform a single function. This review begins with a consideration of the variations in the surface morphology of the cingulate gyrus and comments on brain maps that had a significant influence on current views of cingulate cytoarchitecture. Brodmann area "centroids" are identified, and histological features of each area shown in Nissl preparations to accommodate the lack of a full documentation supporting his maps. Most of the remaining text defines the cytological criteria for each area based on new human cases prepared for this review with immunohistochemical techniques not previously applied to the entire cingulate gyrus. During this analysis, new observations were possible, and they substantiated the evolving four-region neurobiological model of the cingulate gyrus. The cytological criteria for each area in the human cingulate gyrus are now available as are the patterns of transition that lead from adjacent allocortical areas to the fully developed isocortex. The heterogeneity of cingulate structure and function that baffled neuroscientists for generations is close to resolution, and this will provide a clear path to elucidating mechanisms of disease and their therapeutic amelioration through the study of the cingulate cortex.

SURFACE MORPHOLOGY

The surface features of human cingulate cortex are quite variable, and it is possible that each individual has his or her own "fingerprint" of medial surface features. To the extent that deep sulci are the most consistent, superficial or tertiary sulci may be excluded from surface feature classifications. Although Retzius (1896) performed the first systematic assessment of the surface cerebral morphology, the work of Ono *et al.* (1990) is more readily available and provides high-quality macrophotographs of the 25 postmortem

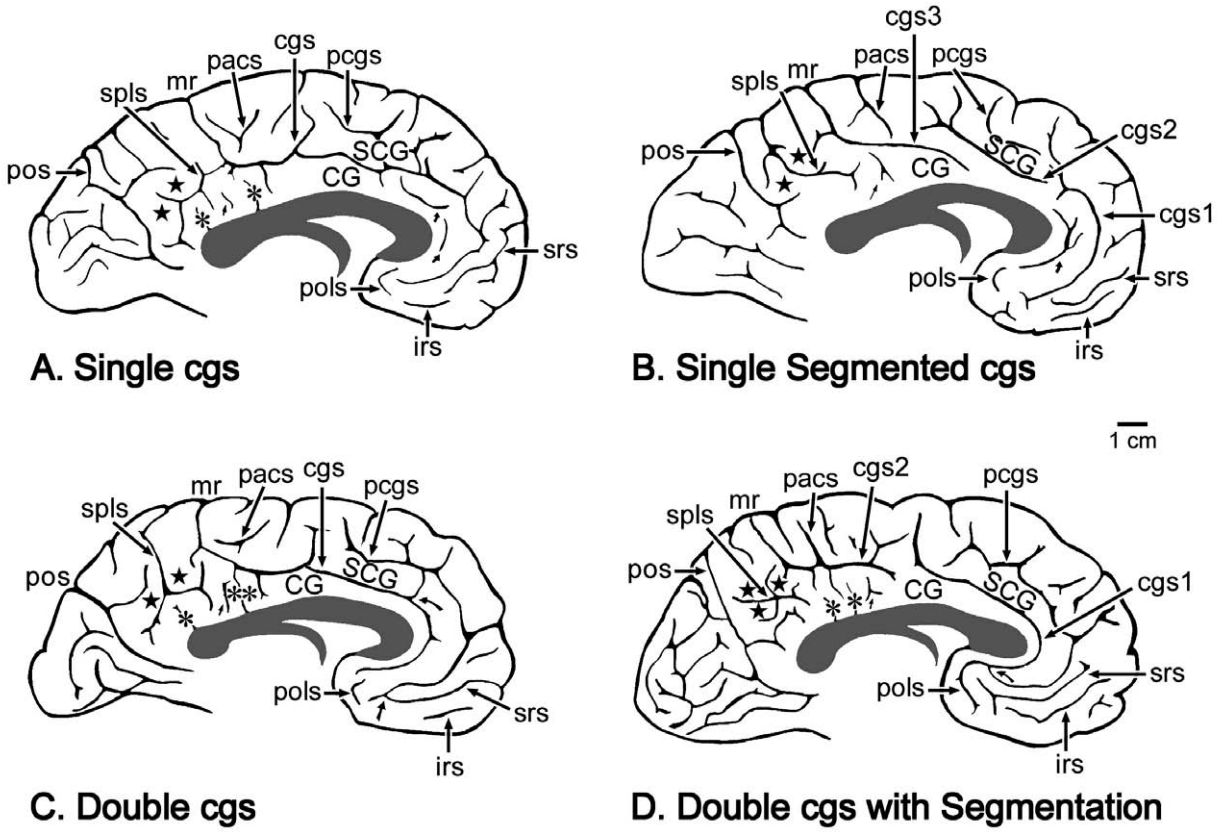

FIGURE 24.1 Sulcal patterns on the medial surface for the left hemispheres of four cases. The double parallel pattern differs from the single cgs in the extent of elaboration of pcgs. When there are just of few short branches of the pcgs, SCG cannot be identified, however, when the pcgs is fully developed, the double parallel pattern is well formed. Tertiary sulci in the anterior cingulate cortex (ACC) tend to lie parallel to the cas as shown by the short and curved arrows in A. In contrast, tertiary sulci in the posterior cingulate gyrus (PCG) are vertically oriented. Many of these sulci project directly from the callosal sulcus (cas, asterisks) and some are free (short, straight arrows). There are many connections between various sulci, however, none appear to be consistent. For example, the spls can connect with the cgs (A), the srs can connect with the pcgs (C, curved arrow), and the pcgs and cgs can attach (D). The stars around each spls identify the parasplenial sulci and are on the parasplenial lobules.

specimens in their analysis, which includes the cingulate gyrus. Ono *et al.* (1990) reported that the only large, main sulcus on the medial surface is the cingulate sulcus, which in usually not interrupted (58% of cases). The medial surface has a number of short, main sulci including the heavily branched splenial sulcus (spls) and the superior (srs) and inferior rostral (irs) sulci. Although Ono *et al.* use the term "subparietal sulcus" for the former sulcus, spls is used here because it is surrounded by dorsal and posterior cingulate area 31 and suggests an appropriate relation with the splenium. Parietal area 7m lies dorsal to area 31; thus, this sulcus is not subparietal, but rather it is intraposterior cingulate, and the cortex surrounding the spls forms folds called splenial lobules.

Although the single cingulate sulcus, with or without interruptions, is the most common form (76% on right or left hemispheres; Ono *et al.*, 1990), there are other patterns. The other most frequent pattern is the double parallel pattern where the paracingulate sulcus (pcgs) forms a long path dorsal to the cingulate sulcus (cgs). Ono *et al.* observed this in 24% of either hemisphere. Figure 24.1 presents a number of examples of these various patterns observed in our postmortem series. These include a single cgs without (Fig. 24.1A) or with (Fig. 24.1B) segmentation and the double parallel cgs without (Fig. 24.1C) or with (Fig. 24.1D) segmentation. Finally, even when the pcgs is not robust, there is a superior cingulate gyrus (SCG; Fig. 24.1).

The presence or absence of the pcgs is the primary basis for defining the single and double parallel sulcal patterns. In light of this variability, Paus *et al.* (1996) generated probabilistic maps for each hemisphere in 247 individuals and observed that the pcgs is more frequent in the left than right hemispheres. Ide *et al.* (1999) confirmed this observation by showing a significant hemispheric difference in the incidence of these two sulcal patterns. The single sulcus is more

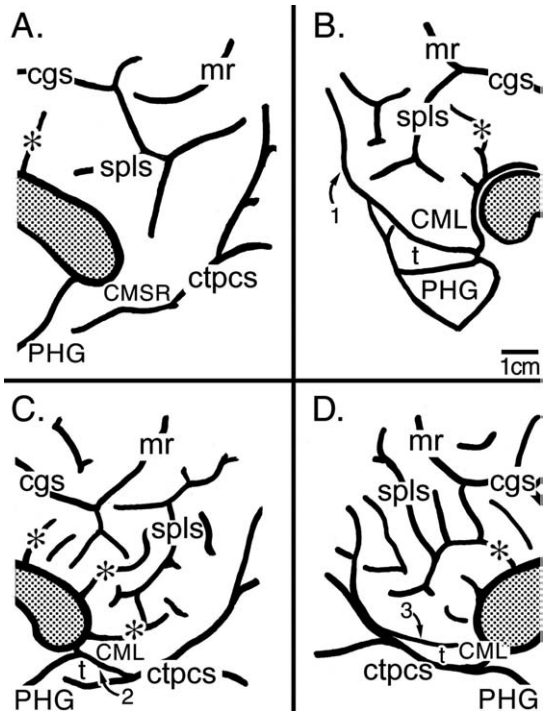

FIGURE 24.2 The perisplenial surface is shown for four cases. The asterisks identify some of the tertiary sulci that project directly from the cas and the splenium of the corpus callosum is shaded. (A) The PCG is continuous with the parahippocampal gyrus (PHG), and the caudomedial subregion (CMSR) is noted along this transition, but there is no identifying feature for the border between cingulate and parahippocampal areas. (B) Cortex below the ctpcs was removed at the arrow shown with #1, and this exposed the caudomedial lobule (CML), which is composed of the posterior cingulate areas 23 and 31. It also exposed a transitional PHGt, which contains the posterior divisions of the parahippocampal area 36′, and the PHG can be observed ventral to the PHGt. (C) Without dissection of the ventral bank of the ctpcs, the CML, PHGt, and PHG can be observed. The PHGt is formed by a branch of the ctpcs and is noted with the #2. (D) The CML is formed by the ctpcs; however, the PHGt is formed by a postsplenial dimple marked here, with the #3 and the posterior parahippocampal areas located ventral to this dimple.

frequent in the right (69%) than left (31%) hemispheres, while the double pattern is more frequent in the left (68%) than right (32%) hemispheres. Finally, Yücel *et al.* (2000) showed that males have a greater sulcal asymmetry in the left hemisphere with more prominent pcgs in 20% of males than is true for females who had a prominent pcgs in only 11% of left hemispheres.

The patterns of sulci in the posterior cingulate and caudomedial subregion are also quite variable. The angle or knee at the cgs and inflection of the marginal ramus (mr) is probably one of the deepest points in the cgs. The spls usually has two main vertical/oblique branches that are connected to form an H that can itself be connected to the cgs (Fig. 24.2A). The H form occurs in about 65% of spls in right or left hemispheres (Ono *et al.*, 1990), but many other variations have been reported including two or three branches projecting dorsally (Fig. 24.2D), connections with the cgs (Figs. 24.2A, B, D), free side branches, and branches that connect with the callosal sulcus (Cas; Figs. 24.2C, D). In light of the many vertical sulci, some projecting from the cas into the posterior cingulate gyrus, the specific morphology of the spls is of little note. Vertical sulci are a feature of most cases, and they provide for numerous interconnections between the cas, spls, and cgs. The patterns of these many vertical sulci may contribute to a relatively stable total cortical volume in this region. Brodmann (1909) used a case in which the spls had a typical pattern and showed that area 31 completely surrounds it. The vertical branches of this sulcus, however, are variable in length and can extend beyond the limits of area 31 to penetrate area 23b and sometimes area 23a. Thus, although all cases have a clear though variable spls, it does not mark the limits of particular cytoarchitectural areas. Indeed, the only gross structural feature in posterior cingulate cortex that consistently delineates a cytoarchitectural border is the cas at the apposition of the ventral apex of the CG and the cc where the border occurs between areas 23a and 30.

The surface of the posterior cingulate gyrus extends ventrally to form an isthmus with the posterior parahippocampal cortex, and the variable structure of this region is shown in Figure 24.2. In one case, a tongue of cortex provides no landmarks for transition from posterior cingulate cortex to the parahippocampal gyrus and the junctional cortex is simply termed the caudomedial subregion (Fig. 24.2A). In another case, a clear fold of tissue at the terminal part of the PCG may not be observed unless the ventral bank of the common truck is removed as at "1" (Fig. 24.2B). Upon removal of the ventral cortex, the ventral border of a lobule is noted as is a transitional fold of cortex termed the transitional PHG (PHGt or "t" in Fig. 24.2). Goldman-Rakic *et al.* (1984) referred to this consistent and terminal part of the monkey cingulate gyrus as the caudomedial lobule. When a CML is present in human cases, the common trunk of the parietooccipital and calcarine sulci (ctpos) often appears to interrupt the isthmus to form the CML (Fig. 24.2B). In other cases a branch of the ctpos extends to the cas to form a CML ("2" in Fig. 24.2C is the caudomedial branch of the ctpos). The PHGt lies ventral to the CML, in this instance, where it is formed by the terminal branch of the ctpos. In a fourth variant of CMSR, a postsplenial dimple ("3", Fig. 24.2D) extends into the CML and defines the border between posterior cingulate cortex and the transitional parahippocampal areas.

REGIONAL MORPHOLOGY: FOUR FUNDAMENTAL CINGULATE SUBDIVISIONS

Each part of the cingulate gyrus is designated according to the entire gyral surface and by its particular cytoarchitectural composition. The divisions are not based on a standardized coordinate system because each region cannot be defined with structural images. Rather, each region has specific architectures and this forms the basis for a neurobiological, structure/function model of the cingulate cortex. Traditionally, investigators identify an anterior cingulate region comprised of areas 25, 24 and 32, a posterior cingulate region with areas 23 and 31, and a retrosplenial region composed of areas 29 and 30. This approach failed to account for many observations gleaned over the past two decades and is undergoing major revisions. In the early 1990s it became clear that anterior cingulate cortex is not a single structural entity because amygdala and parietal projections into this region distinguished between its rostral and caudal parts. Figure 24.3 provides the two monkey cases that were pivotal to differentiating the organization of these two regions in primate brain. These reconstructions of the medial surface show the distribution of anterogradely labeled axon terminals throughout the CG following tritiated amino acid injections into the amygdala (Fig. 24.3A) and inferior and posterior parietal cortex (Fig. 24.3B) (Vogt and Pandya, 1987). Although the amygdala has widespread cortical connections including primary and secondary visual areas, the primary distribution of this input on the medial surface is to areas 25 and 32 and rostral area 24. There is little input to the midcingulate cortex (MCC; noted in Fig. 24.3 with two arrows) and none to the posterior cingulate cortex (PCC). In contrast, the parietal projection is massive throughout PCC and MCC but does not appreciably extend into the perigenual part of ACC. In view of the fundamentally different roles that the amygdala and parietal cortex play in brain function, it is likely that their differential projections to ACC represent a watershed boundary in ACC.

Another pivotal series of observations leading to new views of ACC were made by Heiko Braak. His primitive gigantopyramidal field (1976) was in the caudal part of ACC, and it was the first demonstration of a motor area in the cgs. This finding was corroborated in the macaque monkey when Biber *et al.* (1978) described its corticospinal projections, and later the details of somatotopically organized projections of cingulate motor cortex were described to the spinal cord (Dum and Strick, 1993) and motor and limbic cortices (Morecraft and Van Hoesen, 1992; Van Hoesen *et al.*, 1993). Heiko Braak (1979b) also detailed the pigmentarchitecture and location of the anterogenual magnoganglionaris area in the rostral sector of ACC and the visceromotor functions of subgenual cortex, and their projections to autonomic motor nuclei in the brainstem were identified by Neafsey *et al.* (1993). These cytoarchitecture and connection observations were considered from the overall perspective of cingulate organization; it was proposed that ACC be divided into a perigenual ACC (pACC) and a MCC (Vogt, 1993), the cytoarchitecture of ACC was assessed in each region in the human brain (Vogt *et al.*, 1995), and the rationale for functional distinctions along these lines was considered (Vogt *et al.*, 1997; Vogt and Sikes, 2000). The ACC duality was strengthened with numerous functional imaging studies reporting that the rostral and caudal parts of ACC provide substrates

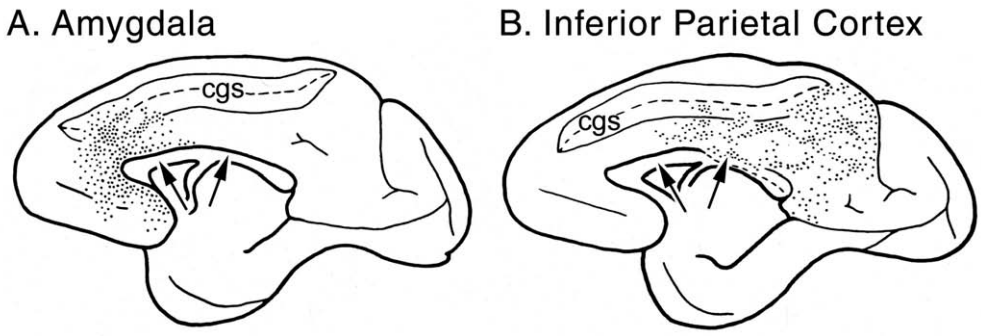

FIGURE 24.3 Differentiation of pACC and MCC by amygdala and inferior parietal cortex projections in the monkey shown with tritiated amino acid injections that label axon terminals in different parts of ACC (small dots emphasize limits of main terminal labeling). The midcingulate region is identified with two large arrows. **(A)** An injection mainly into the lateral and accessory basal nuclei of the amygdala heavily labels axon terminals throughout area 25 and the rostral part of area 24 or pACC. **(B)** An injection into inferior parietal cortex labels axon terminals throughout most of posterior cingulate cortex, and there is substantial termination in midcingulate cortex including the ventral bank of the cingulate sulcus. The details of injection location and laminar patterns of terminal labeling has been shown (Vogt and Pandya, 1987).

for different brain functions. An important delineation of these functional units was provided by Whalen *et al.* (1998) and Bush *et al.* (1998). In the former study, it was shown that the emotional-counting Stroop task activated pACC, while in the latter the counting Stroop activated MCC or their cognitive/motor region. Thus, the border between the rostral and caudal parts of ACC reflects important cytoarchitectural, connection, and functional differences. At the present time, pACC is equivalent to anterior ACC, MCC equates to posterior ACC, and each region has its own morphology. In the future the "p" will be removed and the term ACC will be used alone to refer only to the rostral part of ACC, and the four fundamental regions of cingulate cortex will be the following: ACC, MCC, PCC, and retrosplenial cortex (RSC).

The four primary cingulate regions and associated cytoarchitectural areas are shown in Figure 24.4. The pACC abuts the genu of the corpus callosum (gcc) and includes areas 25, 33, 32, and 24. Cortex ventral to the genu has also been termed subgenual or infragenual cortex and is comprised mainly of area 25 and caudoventral extensions of areas 12, 32, and 33. Because this region is likely engaged in expression of autonomic states through projections to the nucleus of the solitary tract and the dorsal motor nucleus of the vagus and the amygdala (Neafsey *et al.*, 1993), a separate subgenual subregion (SGSR) designation is provided. In view of its direct autonomic regulation and simple cytoarchitecture noted later, this region is true limbic cortex and the term "infralimbic" is not appropriate on functional or cytoarchitectural criteria.

The MCC is the middle one-third of the CG and includes the caudal parts of areas 33, 24, and 32, which are designated areas 33′, 24′, and 32′. Braak's primitive gigantopyramidal field is a caudal subdivision of area 24′ referred to as area 24d by Matelli *et al.* (1991). The MCC terminates before the inflection of the mr of the cgs. The PCC includes areas 23 and 31 on the PCG and the spls and surrounding cortex or suprasplenial lobules. The most caudal and ventral part of these areas forms the caudomedial subregion. Although the exact functions of this subregion are not known, it does have interesting connections with pACC (Vogt *et al.*, 1987; Fig. 24.5E, F, H) and is co-activated with the latter region in auditory-verbal memory tasks (Grasby *et al.*, 1993). RSC is areas 29 and 30, and they extend around the splenium of the corpus callosum (scc) and abut parahippocampal areas ventral to the ventral edge of the scc. Finally, PCC is not equivalent to the PCG because the ventral bank of the PCG contains RSC. Thus, the PCG comprises retrosplenial areas 29 and 30 in the cas, PCC on the posterior gyral surface with areas 23a/b and area 31 surrounding the spls,

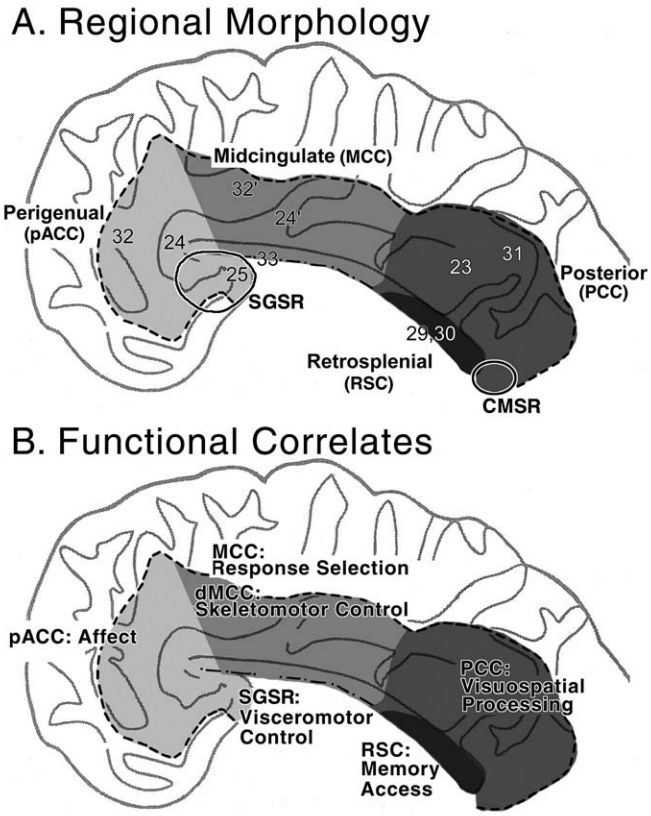

FIGURE 24.4 Four-region neurobiological model of the organization of the human cingulate gyrus. The model requires close correlations among the topology of cytoarchitectural areas, major afferent connections, regional composition, and functional properties. **(A)** pACC is comprised of areas 25, 33, 24, and 32 and includes a subgenual subregion. MCC includes areas 33′, 24′, 24d, and 32′, the PCC is areas 23 and 31 and the caudomedial subregion, and the RSC is areas 29 and 30. **(B)** The functional correlates are not derived from a single class of research, but rather a range of studies including electrical stimulation, stroke case reports, neuropsychological studies in monkey, and human functional imaging. In addition to the four regions, there are two subregions in pACC and MCC. These include the visceromotor control cortex in SGSR and the skeletomotor control subregion in dorsal MCC (dMCC). The dMCC includes area 32′ and the cingulate motor areas on the dorsal and ventral banks of the cingulate sulcus.

and area 23c in the depths of the PCG (i.e., the ventral part of the mr). Posterior cingulate cortex in the human refers to cortex on the gyral surface and that in the caudal part of the CG.

FUNCTIONAL CORRELATIONS OF THE FOUR CINGULATE REGIONS

The neurobiological model of cingulate cortex requires that each cytoarchitectural area and region be associated with different functions or structure/

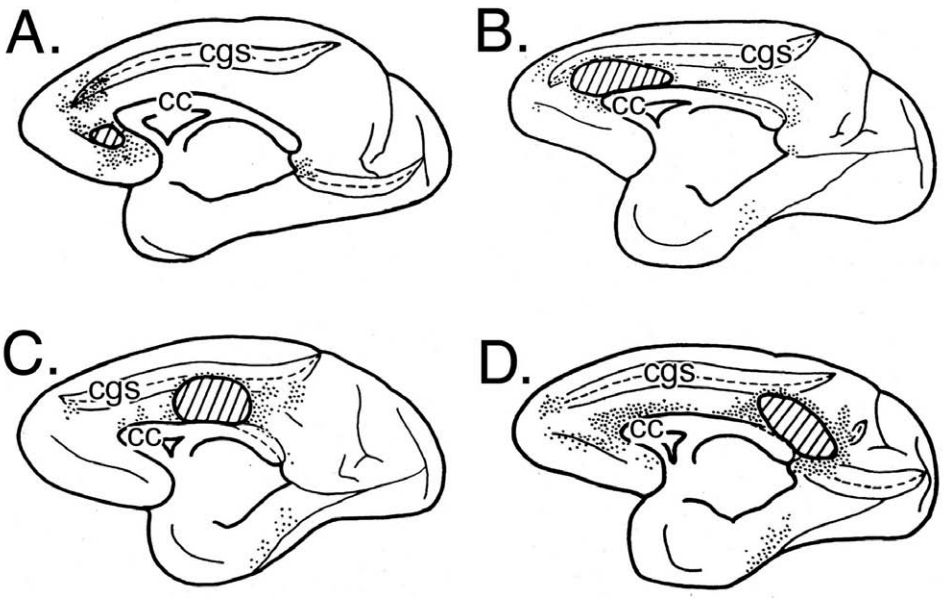

FIGURE 24.5 Four cases in which horseradish peroxidase was injected into the monkey cingulate gyrus and retrogradely labeled neurons plotted on the medial surface (each dot ≈ 3–5 labeled neurons). The intracingulate connections support substantial interactions between pACC and PCC (A, B, D), while the MCC (C) tends to have much less interaction with either of these regions.

function correlations. This does not imply that there is no functional overlap; rather, it means that each structurally distinct area makes a functionally unique contribution to brain activity. Identification of the cytoarchitectural border between areas 24 and 24′ (Vogt *et al.*, 1995) followed by its identification with functional imaging (Whalen *et al.*, 1998; Bush *et al.*, 1998) validates the importance of the neurobiological model based on structure/function correlations. Figure 21.4B presents the neurobiological model in the morphological context of four cingulate regions. As previously suggested (Vogt *et al.*, 1997), pACC is involved in affect, SGSR in visceromotor control, MCC in response selection including dMCC in skeletomotor control, PCC in visuospatial processing, and RSC in memory access.

Perigenual ACC and Subgenual Subregion in Affect

The perigenual areas are associated with affective experiences and are directly engaged in autonomic regulation. Electrical stimulation of dorsal perigenual cortex in humans produces fear, pleasure, and agitation (Meyer *et al.*, 1973). The most frequent response in this series was intense or overwhelming fear including one individual who reported the feeling that death was imminent. Electrical stimulation of different parts of ACC evokes different responses in epilepsy patients (Bancaud and Talairach, 1992). Stimulation of pACC produced the report, "I was afraid and my heart started to beat," whereas stimulation of MCC evoked the report, "I felt something, as though I was going to leave." The former report is of pure fear, while the latter is one of an early premotor planning with motivational characteristics. In another series of experiments, the SGSR had elevated blood flow when healthy women recalled sad experiences (George *et al.*, 1995) and the dorsal pACC had elevated blood flow when subjects were involved in a face recognition task and the faces expressed emotional content (George *et al.*, 1993). Finally, autonomic activity is a frequent correlate of emotional behaviors, and visceromotor changes are the most consistent responses evoked by electrical stimulation of areas 24 and 25. In humans these responses include increases and decreases in respiratory and cardiac rate and blood pressure, mydriasis, piloerection, and facial flushing (Pool, 1954; Escobedo *et al.*, 1973; Talairach *et al.*, 1973). Visceral responses include nausea, vomiting, epigastric sensation, salivation, or bowel or bladder evacuation (Pool and Ransohoff, 1949; Lewin and Whitty, 1960; Meyer *et al.*, 1973).

Perigenual ACC has important connections with structures that directly regulate autonomic activity. Area 25 projects to brainstem autonomic nuclei and has been termed the visceromotor control region by Neafsey *et al.* (1993). Projections of area 25 include those to the nucleus of the solitary tract, the dorsal motor nucleus of the vagus, and the sympathetic thoracic intermediolateral cell column. There are also projections to the periaqueductal gray and reciprocal connections with the amygdala, and detailed references for each projection have been provided (Vogt *et al.*, 1997); each of these connections likely contributes to the role of pACC in affect and autonomic regulation.

MCC in Response Selection

The MCC has a pattern of organization similar to pACC. Thus, pACC is primarily involved in affect, and it implements emotionally relevant, autonomic activity directly through the projections of area 25 to the various brainstem autonomic motor nuclei. In a similar way, MCC has a general role in response selection based on the motivational relevance of particular behaviors, and it implements these behaviors through cingulospinal and cortical motor and supplementary motor projections that arise in the cingulate motor areas. It is this fundamental dichotomy in which pACC regulates autonomic function and MCC regulates skeletomotor function that underpins the division of ACC into two parts.

Different functions have been ascribed to the MCC including attention-for-action (Posner *et al.,* 1988), response selection (Corbetta *et al.,* 1991; Bench *et al.,* 1992; Paus *et al.,* 1993), error detection (Gemba *et al.,* 1986), competition monitoring (Carter *et al.,* 1998), anticipation (Murtha *et al.,* 1996), and working memory (Petit *et al.,* 1998). Although it may be possible to accommodate all these functions with a single model of one area that incorporates many separate populations of neurons, the facts of cingulate cortex organization that suggest these various functions represent the activity in at least two divisions of MCC. Thus, MCC itself is composed of two subregions: the dMCC in the cgs that extends onto the superior cingulate gyrus and another on the surface of the CG.

The dMCC areas in the cgs have very large layer Vb neurons (Braak, 1976), project to the spinal cord (Biber *et al.,* 1978; Dum and Strick, 1993) and supplementrary and primary motor and limbic cortices (Morecraft and Van Hoesen, 1992; Van Hoesen *et al.,* 1993) and account for the many skeletomotor responses evoked by electrical stimulation. These latter responses include gestures such as touching, kneading, rubbing, or pressing the fingers or hands together and lip puckering or sucking (Escobedo *et al.,* 1973; Meyer *et al.,* 1973; Talairach *et al.,* 1973). These movements are often adapted to the environment; they can be modified by sensory stimuli and, at times, resisted. These areas contain neurons with premotor discharge properties (Shima *et al.,* 1991) that are coded according to the changing reward properties of particular behaviors (Shima and Tanji, 1998). Functional imaging studies show altered blood flow in this region during sequences of finger apposition movements (Schlaug *et al.,* 1994; Kwan *et al.,* 2000).

The dMCC, however, is not limited to regulating discrete motor activities, and functional imaging studies show that it has a major role in cognitive activity associated with the response selection process and not necessarily resulting in movement. Cognitive processes associated with divided attention (Corbetta *et al.,* 1991), selecting verbs to novel lists of nouns (Raichle *et al.,* 1994; Raichle, 2000), and Stroop interference tasks (Pardo *et al.,* 1990; Bench *et al.,* 1992) elevate blood flow in dMCC. Furthermore, generation of verbs to novel lists of nouns not only elevates flow in MCC but, as the task is practiced, blood flow returns to baseline in MCC, it is decreased in pACC, and PCC and medial parietal area 7m show an increase in activity (Raichle, 2000). Most importantly, altering the reward properties of particular outcomes elevates blood flow in dMCC (Bush *et al.,* 2002), and we predict that dMCC plays a pivotal role in reorganizing activity in a host of motor structures to produce new behavioral outputs that adapt to changing rewards. Thus, patterns of neuronal activity in the cingulate cortex reflect the differential contributions of each region to different aspects of task acquisition and performance as well as cognitive processing in the absence of movement.

Posterior Cingulate, Caudomedial, & Retrosplenial Cortices in Visuospatial/Memory Functions

Valenstein *et al.* (1987) presented a case with extensive anterograde and retrograde amnesia following removal of an arteriovenous malformation near the splenium and referred to the syndrome as *retrosplenial amnesia*. Since involvement of the fornix may have contributed to the presentation in this case, Parker and Gaffan (1997) placed massive cingulate cortical or anterior thalamic lesions in monkeys and tested object-in-place memory. Although cingulate lesions failed to show a significant deficit, there was substantial impairment in the anterior thalamic group. Because the anterior thalamic nuclei have as their primary projection to the RSC (Vogt *et al.,* 1987), it is surprising that no deficit was observed following cortical lesions. Explanations for the negative finding in the monkey are that the cortical lesions of RSC were incomplete owing to the effort to remove the entire gyrus in anterior and posterior cortices and/or the task was not sensitive to a cortical impairment. Other evidence links these cingulate gyral areas to memory and visuospatial functions.

Working memory tasks elevate glucose metabolism in the anterior thalamic nuclei (Friedman *et al.,* 1990), one of the highest levels of basal glucose metabolism in the monkey brain is in RSC, and glucose metabolism in RSC is elevated when performing a delayed-

response task (Matsunami *et al.*, 1989). We have compared the distribution of anterior thalamic inputs to RSC and basal glucose metabolism in the monkey, and there is a striking correlation between both (Vogt *et al.*, 1997). The tight link between anterior thalamic projections to RSC, high levels of basal glucose metabolism, and its modulation in both structures suggest that the anterior thalamic/RSC system is a pivotal player in memory.

Area 23a and RSC are adjacent to each other and reciprocally connected (Vogt and Pandya, 1987), and relationships between perigenual and perisplenial cortices are profound. Area 23a is heavily labeled following a horseradish peroxidase injection into pACC (Fig. 24.5A), and pACC is labeled after injections of anterograde tracers into posterior area 23 (Pandya *et al.*, 1981). Thus, the perigenual and perisplenial connection is reciprocal and involves only a small part of MCC as shown by tracer injections into different parts of the CG (Fig. 24.5B–D). It appears that the most profound intracingulate connections in these cases are reciprocal connections between pACC and PCC/CMSR, and it is possible that activation of both of these regions with a common auditory input (Grasby *et al.*, 1993) is strengthened by these reciprocal intracingulate connections. The linkage between pACC and the CMSR is even tighter when other cortical connections are considered. A limbic convergence zone in area 11m receives major inputs from both perigenual and perisplenial cortices with none from MCC (Carmichael and Price, 1995). Pericallosal cortex in both regions also receives direct subicular inputs that do not terminate appreciably in MCC (Rosene and Van Hoesen, 1977). Thus, primary sensory inputs, reciprocal intracingulate connections, and connections among limbic association areas preserve the functional integration of perigenual and perisplenial cortices to the exclusion of MCC.

The RSC and PCC are also involved in topographic and topokinetic memory. Olson *et al.* (1993) suggested that PCC is involved in large visual scene assessment, part of which is subserved by activity generated by the orbital position of the eye. Focal lesions that involve the right RSC impair memory of spatial positional relationships and are associated with topographic disorientation (Takahashi *et al.*, 1997). Furthermore, mental navigation along memorized routes elevates blood flow in PCC (Berthoz, 1997; Ghaem *et al.*, 1997; Maguire *et al.*, 1998). Thus, PCS, CMSR, and RSC have many interconnections that subserve memory and visuospatial functions, and their close relations to pACC suggest a coupling of the activity in these regions. It is possible, for example, that memories associated with emotional states are stored in pACC but their release for conscious consideration is mediated by the activity of RSC, PCC, and/or CMSR that have no specific role in emotion.

MAPS OF CINGULATE AREAS

Four maps of the areas on the human CG have been published over the past century that have been particularly important to understanding this region. von Economo and Koskinas (1925) identified areas LA2 and LA that share similarities with the distributions of pACC and MCC, and they viewed transitional changes on the medial surface as reflecting fundamental differences in the frontal lobe. Although Brodmann stated that area 32 is a dorsal and anterior cingulate area (1909), this area has transitional features that might also be termed cingulofrontal transition cortex. Areas LC1 and LC2 appear to be similar to Brodmann areas 31 and 23, although LC2 extends further rostrally than does area 23, while areas LD and LE are retrospelenial areas on the ventral bank of the CG. Finally, von Economo and Koskinas (1925) identified anterior ectogenual area LA3 and ectosplenial area LF that equate to Brodmann's areas 33 and 26, respectively.

The map of Sarkisov *et al.* (1955) identified parallel, ventral-to-dorsal subdivisions of areas 24 and 23 in human, and we observed them in monkey (Vogt *et al.*, 1987) and later in human (Vogt *et al.*, 1995). The major difference is that we observe only two gyral parts of each area (i.e., areas 24a and b and 23a and b), and the third subdivisions of each are areas 24c and 23c in the cgs. Area 23c is a caudal extension of cingulate sulcal cortex and we agree with Brodmann that area 31 surrounds the spls where this cortex forms the splenial lobules.

Brodmann (1909) discussed an intermediate cingulate area that might be similar to our MCC; however, he did not plot it on his map, he provides no unique subdivision of human area 24, and there is no histological description available comparing this region with rostral parts of ACC. Later we provide precise cytological information about the MCC region (i.e., not just a transitional zone where the cytoarchitecture is hard to define), relate this cortex to adjacent regions with immunohistochemical methods, employ a unique nomenclature, and plot the distribution of its areas.

Heiko Braak (1980) made a number of very important contributions to understanding cingulate cytoarchitecture. First, his map shows the prominent anterogenual magnoganglionic area in pACC, which suggests that the perigenual part of Brodmann's area 24 is distinct from its caudal extent. Indeed, it is

possible that the differences are responsible for a fundamental pattern of cortical differentiation as proposed by Braak. Second, the primitive gigantopyramidal field is located in the cgs and forms a cingulate motor area with corticospinal projections. Third, the retrosplenial areas are located on the ventral bank of the CG in the depths of the cas, while parasplenial isocortex surrounds RSC. It appears that parasplenial isocortex closely approximates, but is not equivalent to, area 23a.

The Brodmann map has become the most frequently used reference in human neuropathology and imaging studies partially because Talairach and Tournoux (1988) extrapolated it onto a standardized brain atlas. There are difficulties interpreting the Brodmann map because it was limited to a single case and the reconstruction was onto the convoluted cortex without delineation of areas in the sulcal depths, which accounts for about 50% of the cortical volume. To document Brodmann's views histologically, Figure 24.6 shows his map and the six circles reference points that are the topographic center of each area. These points were photographed at low magnification in the approximate center of each area in a case embedded in celloidin and stained with cresylecht violet. This centroid analysis serves as the basis for modifications made later to define structurally uniform subareas. In some instances, there is doubt as to which structure constituted a Brodmann area. For example, his area 33 could refer to an ectogenual area in the depths of the cas, it could refer to an area on the edge of the ventral bank of the CG (our area 24a), or it could be a combination of both. In this instance, we concur with Zilles (1990) in suggesting that it is an ectogenual area.

The Brodmann area centroids were located from his map by finding the approximate rostrocaudal and dorsoventral midpoint for each area and in equivalent locations in a celloidin-embedded/Nissl-stained case (Fig. 24.6). Area 33 wraps completely around the gcc and is likely an ectogenual area with a single layer of pyramidal neurons that abut the indusium griseum (IGr) and area 24 ventrally (Fig. 24.6A, B, D). Area 25 is agranular (lacks a layer IV) and has two principal layers of neurons; a superficial layer II/III that is relatively uniform in its density of medium-sized pyramidal neurons and a deep pyramidal layer of medium-large pyramids similar to those mainly in layer V; only a small layer VI is present (Fig. 24.6A). One of the most consistent features of cingulate architecture is the prominence of layer V, and the relative prominence of layer Va is most evident in area 24 (Fig. 24.6B/D, asterisks). Finally, area 32 is a dorsal, anterior cingulate area that surrounds rostral and dorsal area 24 and is dysgranular with a thin and variable layer IV (Fig. 24.6B/C).

The PCG is comprised of two regions, retrosplenial areas 29 and 30 on the ventral bank and posterior cingulate areas 23 and 31 on the cingulate gyral surface and depths of the caudal cgs. The ectosplenial area 26 is located at the fundus of the cas. Ectosplenial cortex is essentially a single, external layer of neurons that have a granular appearance and are similar to neurons in the external granular layer of retrosplenial area 29. Area 29 has a granular external pyramidal layer and undifferentiated layers V and VI (Fig. 24.6F). Brodmann referred to area 30 as "agranular," a concept that is challenged later. Finally, area 23 on the PCG surface is granular, while area 31 surrounds the spls and has the thickest and most granular layer IV in PCC (Fig. 24.6F and E, respectively). If immunohistochemical, connection, and functional studies observed homogeneity within each of these Brodmann areas, nothing more would need to be said about the architecture of the cingulate gyrus. However, almost none of the Brodmann areas are cytologically uniform, and a century of neuroscience requires a substantive modification.

CYTOLOGY OF CINGULATE AREAS

Before analyzing the details of cortical structure, a few overview comments will set the context for such an undertaking. First, although the border between areas 24 and 23 is not marked with a sulcus, this border comprises a fundamental change from an agranular anterior cortex to the granular posterior cortex. The presence of a layer IV in PCC suggests that there is an intermediate level of cortical processing between thalamic and cortical afferents that does not occur in MCC. The anterior areas have thalamic and cortical projections directly to the basal dendrites of layer III and the apical dendrites of layer V pyramidal neurons—presumably for more rapid processing and output functions (Vogt and Peters, 1981). Second, interpretation of cingulate cytoarchitecture is most productive in the context of cortical transition along the CG. This includes different cytological changes such as increases in neuron density in rostrocaudal and ventrodorsal directions, progressively greater expression of neurofilament proteins in layer IIIc pyramids and their "predecessors" in deep layer III, and elaboration of the basal dendrites of pyramidal neurons particularly in layers III and V throughout the retrosplenial areas. Third, although the Nissl stains were used productively over the past century, modern immunohistochemical techniques provide significant advancements. The antibody for neuron-specific nuclear binding protein (NeuN; Mullen *et al.*, 1992) is

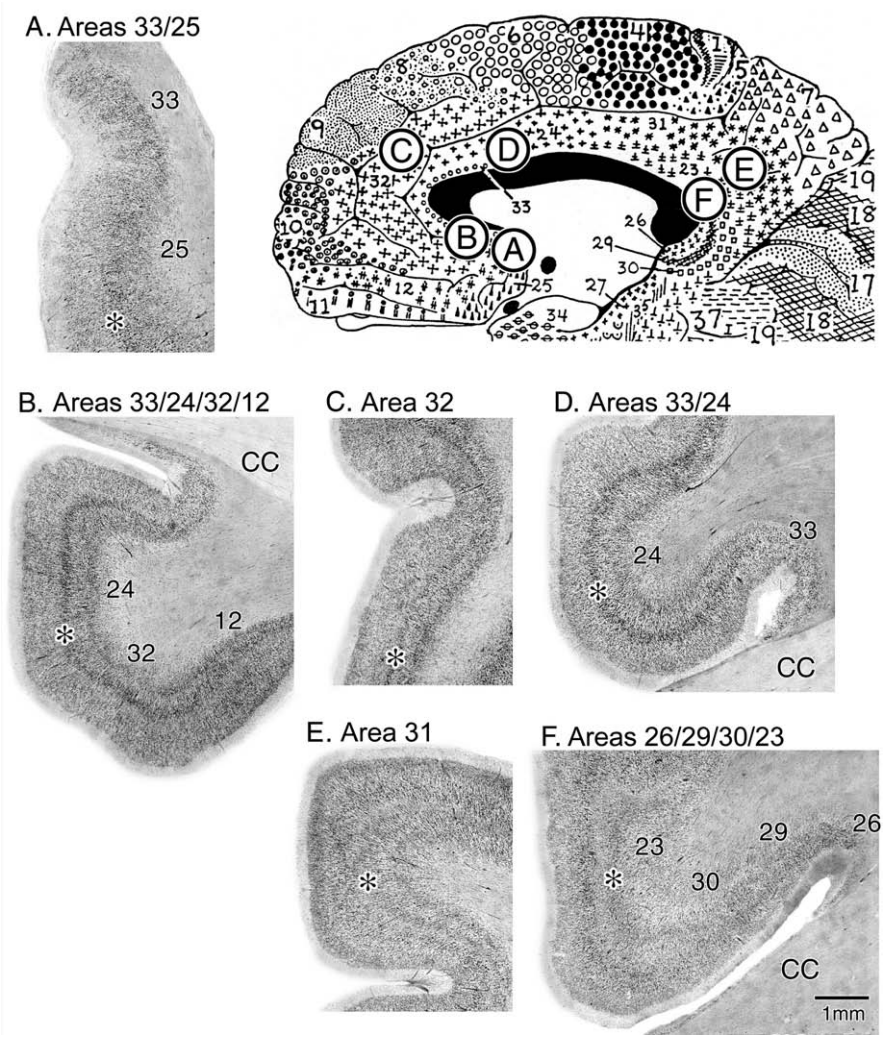

FIGURE 24.6 The Brodmann map (1909) is the most influential map of the medial surface. To assess the structure of each of these areas in celloidin-embedded and Nissl-stained sections, centroids (approximate centers) were identified for the major areas and photographed for levels A–F. The corpus callosum (cc) and layer V (asterisks) are identified and these centroid photographs provide benchmarks to which each cytoarchitectural area is compared in immunohistochemical preparations.

an important tool because it labels neurons and does not react with glial and vascular elements that add noise to the analysis of neuronal architectonics. In addition, the immunoreactivity is so intense that photographs have a high degree of contrast, and the laminar architecture can be shown with greater clarity at low magnifications than with Nissl staining. Another important antibody is SMI-32 for nonphosphorylated, intermediate neurofilament proteins (NFP-ir). This antibody is a valuable marker of unique neuronal phenotypes, and it is invaluable for identifying particular layers and area borders. It is most helpful in the granular layer of retrosplenial and ectosplenial cortices, layer IIIc in PCC, and layer Va throughout the entire cingulate gyrus including the cingulate motor areas in the cingulate sulcus.

Ectocallosal Region

The ectocallosal region is in the fundus of the entire callosal sulcus and is comprised of areas 33, 33′, and 26. Brodmann showed that area 33 surrounds the rostral one-third of the corpus callosum beginning in the subgenual subregion where it abuts area 25 and continues around the cc to terminate dorsal to the genu. Although he depicted area 26 as surrounding only the caudal end of the splenium and not abuting area 33 rostrally, these observations cannot be verified. Indeed, area 33 extends further caudally in the form of area 33′, area 26 extends rostrally above the splenium, and area 33′ and 26 abut each other at midcingulate levels in the form of an undifferentiated cortex. The ectocallosal areas are shown in Figure 24.7.

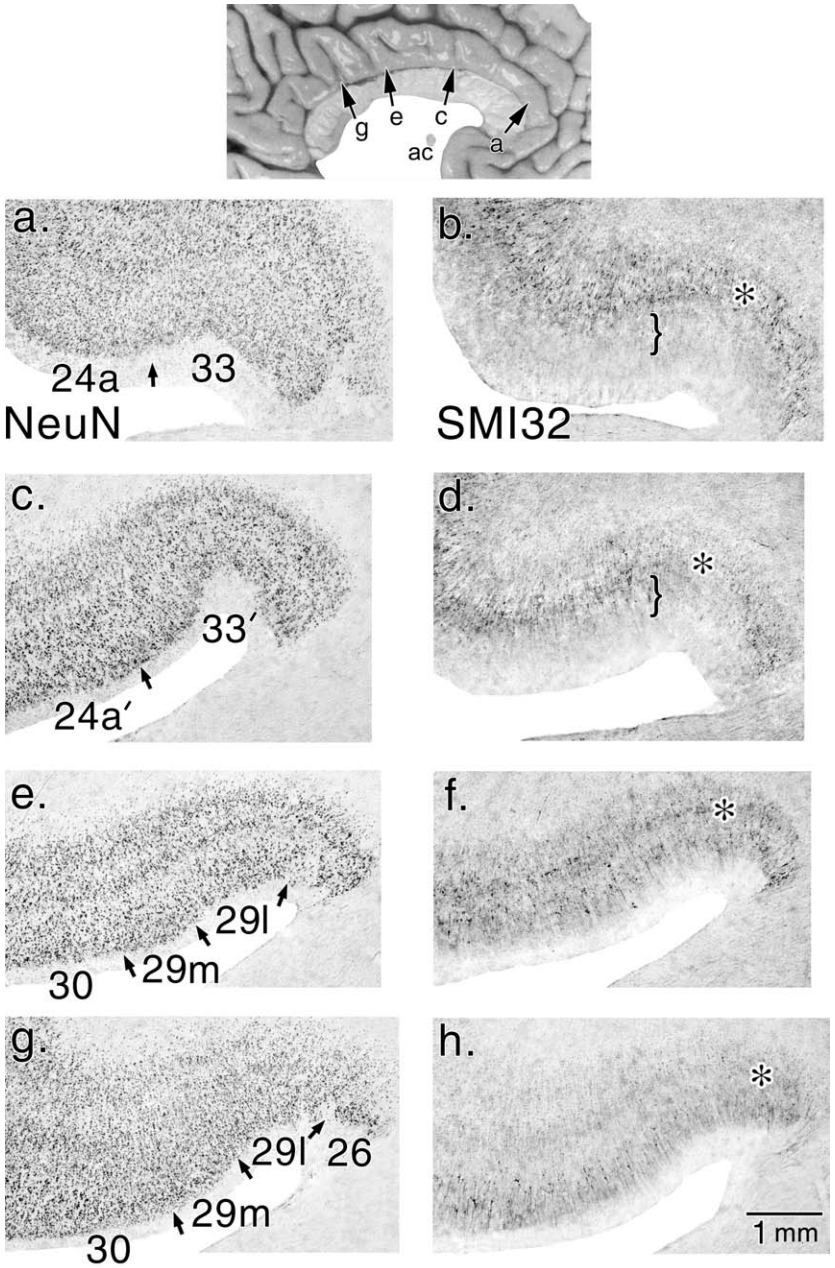

FIGURE 24.7 Ectocallosal areas immunoreacted with the NeuN and SMI32 antibodies. The levels begin rostrally just dorsal to the genu and extend to a caudal level. The asterisks indicate layer Va, and the bracket in d emphasizes that neurons in the deep part of layer III of area 33′ are NFP-ir, which serves as the basis for designating a caudal division of area 33. An undifferentiated area 29 appears in e and is identified by the substantially enhanced NFP in layer III that is not in areas 33′ or 24a′. An undifferentiated ectocallosal cortex continues along the full length of the cc.

Area 33 has broad and poorly differentiated layers II and III, a layer V with a moderate number of NFP-ir pyramids, and a layer VI of small neurons (Fig. 24.7a, b). There is an ectocallosal area in the depths of the cas at a midcingulate level (Fig. 24.7c, d.), but it has features that differentiate it from area 33. Area 33′ has a more clearly laminated structure, and layers II and III are thinner and contain somewhat smaller neurons, while the large neurons in the deep part of layer III are NFP-ir, as is not the case for area 33 (compare Fig. 24.7b and c in brackets). Finally, a small number of layer V neurons are NFP-ir, as is the case for area 33.

At a level just caudal to the midpoint in the cc (Fig. 24.7e), the external pyramidal layer contains small neurons with a granular appearance suggesting that this is one of the most rostral levels of area 29. There is a striking NFP-ir in pyramids throughout layer III of areas 29 and 30, and layer Va has many more NFP-ir pyramids than is the case for either area 33 or 33′. It is interesting that, at this rostral level of area 29, the neurons in the granular layer have not yet fully expressed NFP-ir as they do at caudal levels (e.g., Fig. 24.7h). It is also difficult at this transitional level of Figure 24.7e to identify the features of either area 33′ or area 26. Therefore, this poorly differentiated cortex lateral to area 29 is not designated in the figure. It appears that rather than a loss of ectosplenial cortex between areas 33′ and 26, there is a short distance of poorly differentiated and transitional cortex. The granular layer of area 26 and its heavily NFP-ir pyramids are shown in Figure 24.7g–h. Area 26, however, has almost no deep ganglionic pyramidal layer, and Braak (1979a) referred to these few neurons as essentially a layer VI of multiform cells. The few, deep-lying pyramids that are present express NFP-ir. The differentiation and extension of areas 29 and 30 along the ventral bank of the cingulate gyrus is also seen in Figure 24.7 but is described in more detail later as is the extension of area 26 around the splenium of the cc (Fig. 24.15). Thus, the ectocallosal areas form the fundus of the full rostrocaudal extent of the cas. Only at a level just caudal to the callosal midpoint is there a short stretch of undifferentiated cortex lacking the features of either areas 33′ or 26.

Perigenual Areas

The subgenual subregion is comprised of areas 33, 25, and 24a and the caudal extension of area 32. Area 25 is the principal component of this region and is of particular interest because of its projections to autonomic brainstem nuclei and its role as a visceromotor control region. The architecture of area 25 differentiates directly from area 33 (Figs. 24.7a, and 8A) where the broad and undifferentiated pyramidal layer of area 33 abuts area 25 and there is a broad and relatively uniform layer II/III of medium-sized pyramids. There is a slight intensification of layer Va in terms of both size and density of pyramidal neurons and a poorly differentiated layer VI. Small islands of layer II pyramidal neurons in caudal levels of area 25 have been observed (Vogt *et al.*, 1997); however, this feature is variable. Figure 24.8 shows two levels through this subgenual region. It appears that the dorsal and rostral parts of this cortex have the aggregations of neurons in layer II. Because this clumping is not a characteristic of area 24, this cortex is termed rostral area 25 (25r). Braak (1979b) referred to this as area anterogenualis simplex. There also appears to be scattered clumping of layer II neurons in area 33 in this subgenual region. Caudal to area 25r is the area Brodmann appears to have termed area 25. Figure 24.8B shows that this area has a clear layer II that is negative for NFP-ir. It has a layer III of medium-sized pyramids that are sparsely immunoreactive for NFP, a layer V of slightly larger neurons that are NFP-ir, and a layer VI of small neurons. Overall, this area is quite compact in comparison to area 25r. Because this area is caudal to area 25r, it is termed area 25c and equates to Brodmann's area 25.

Area anterogenual magnoganglionaris was identified by Braak (1979b) as a feature of cortex rostral to the genu. This provided one of the early arguments that area 24 does not surround the genu from its supracallosal position with a single architecture. Indeed, the broad layer Va of large pyramids that distinguishes this area 24b in pACC can be seen in Figure 24.9. Rostral and ventral to area 24b are areas 32 and 12. It is possible to identify components of areas 24a and 24b that have these magnocellular features, and this is one of the primary distinctions between rostral and caudal divisions of area 24 (i.e., area 24 vs. area 24′).

Area 24 architecture is shown in Figure 24.9 at a perigenual level. In the low-magnification photograph, the primary differences between areas 24a and 24b can be seen; area 24a has a less-dense layer II, thinner and less-dense layer Va, and a broad and less-neuron-dense layer VI when compared to area 24b. Each of these features are magnified where the subdivisions of layers V and VI are apparent as are a number of features of area 24b. The NeuN-ir section shows an interesting feature for both areas 24a and 24b and, as is noted later, for area 24′. Although layer III is not divisible with medium-sized neurons in the upper, large, and NFP-ir neurons in the deeper part, this layer does have neuron-dense-superficial and -sparse-deep parts. This fact is noted in Figures 24.9 and 24.10 with pairs of arrows between the NeuN and SMI32 sections. Another important feature of area 24b is that it has many small neurons intermingled with the large ones in layer Va. The neurons in layer Va tend to form aggregates and are NFP-ir. Layer Vb SMI32 immunostaining is magnified by a factor of 2 to show that neurons in this layer also form aggregates (asterisks); they are NFP-ir. Among these layer Vb neurons are the NFP-ir, spindle neurons of Nimchinsky (Nimchinsky *et al.*, 1995). These neurons are bipolar projection cells that are unique to limbic cortex including the insula; they are observed in human and great ape brains but not in monkeys (Nimchinsky *et al.*, 1999). Finally,

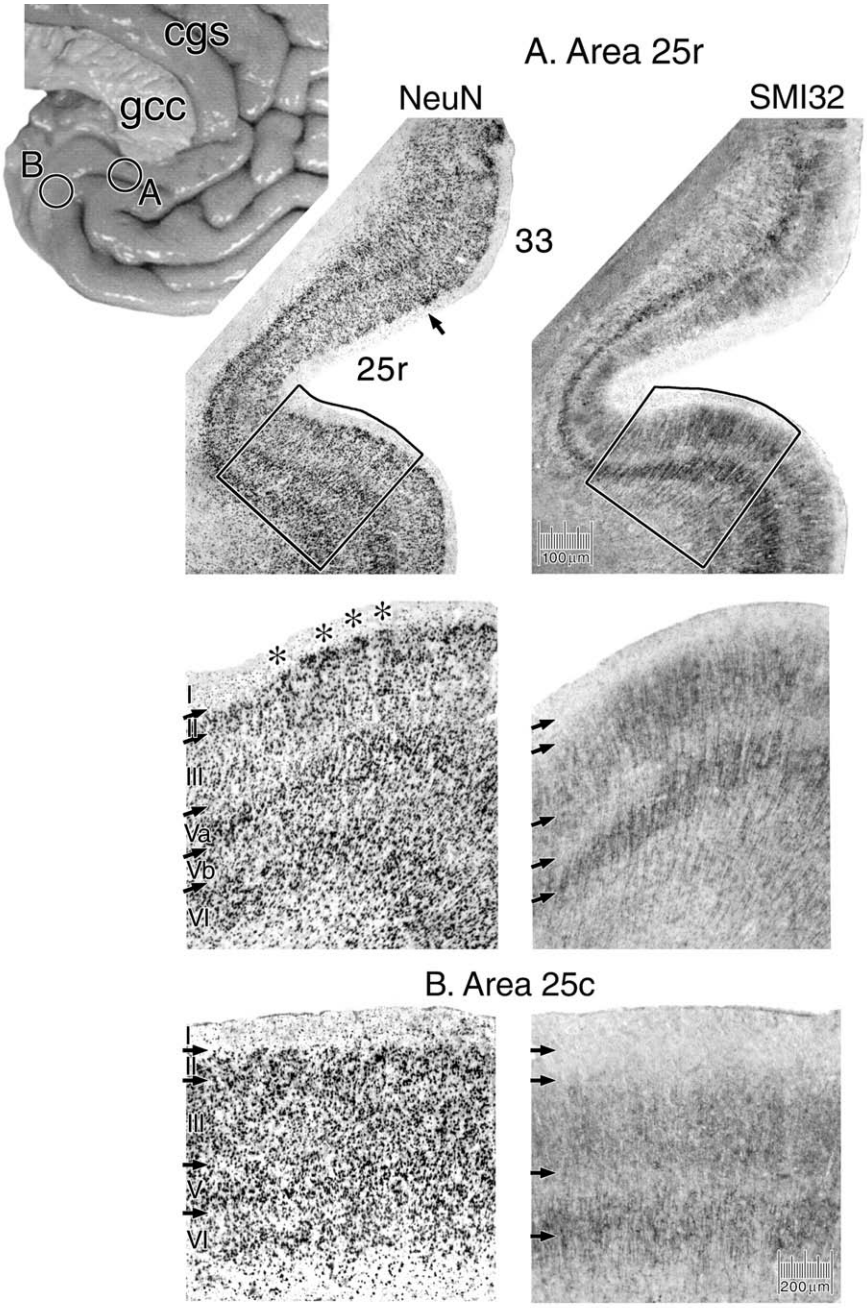

FIGURE 24.8 Area 25 is one of the main components of the SGSR, and its cytology is not uniform. The rostral part of area 25 (area 25r) is ventral to ectogenual area 33 and has some neuron aggregations in layer II and dense NFP-ir neuronal plexuses in layers III and V. Area 25c has a less differentiated structure with no subdivisions in layers III and V, a modest number of NFP-ir neurons in layer V, and few in layer III.

although layers Va and Vb are less neuron dense in area 24a, a similar clumping of NFP-ir pyramids is in both of these layers, but it is most prominent in layer Vb including the spindle neurons. These features of layer V distinguish area 24 from its caudal counterpart area 24′.

Midcingulate Gyral Areas

One of the primary features of MCC is the cingulate motor areas in the cingulate sulcus. Although this region has extensive connections with motor systems including direct projections to the spinal cord, the sulcal and gyral areas are not independent and may operate jointly under some circumstances. Pivotal to these interactions are direct and reciprocal connections identified in the monkey brain with anterograde tracer injections into gyral and sulcal areas. The greatest overall projections originate from the dorsal part of pACC, while injections into sulcal areas and midcingulate gyral cortex show limited projections primarily dorsal to the cc and rostral parts of PCC and often

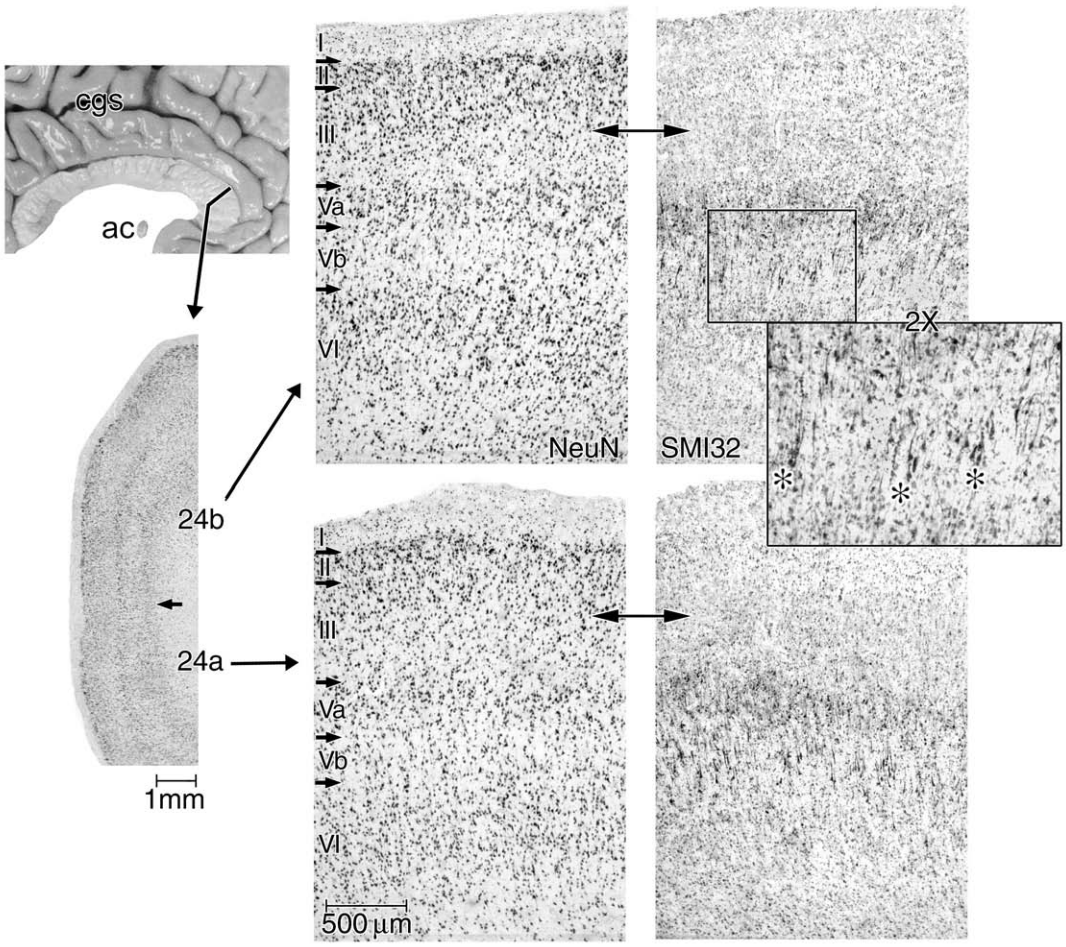

FIGURE 24.9 Although perigenual areas 24a and 24b both have a prominent layer Va and aggregations of NFP-ir neurons in layer Vb (asterisks in 2× pullout), layer Va is more dense in area 24b than it is in area 24a. Area 24b also has a more neuron-dense layer II. Although layer III is not divisible based on neuron sizes, there are fewer neurons in the deeper part of this layer in both areas (two-headed arrows).

limited to MCC itself (Van Hoesen *et al.*, 1993). Thus, even though the gyral areas do not themselves have projections to the spinal cord, the gyral areas are one step earlier in the premotor planning process—a processing stage that likely involves evaluation of the motivational consequences of particular motor outputs and, as such, is crucial in early premotor planning events.

In spite of the critical need to define the border between anterior and posterior parts of ACC in functional imaging studies, there are no objective methods to define this border with structural imaging and standardized atlases. This border can only be defined cytoarchitecturally and approximations made for the purposes of functional imaging. A comparison of the low-magnification photographs in Figures 24.9 and 24.10 makes a number of obvious points about the structure of area 24 in pACC and area 24′ in MCC. The MCC is thicker and has much broader layers II, III, Va, Vb, and VIa. A closer viewing of area 24b′ in Figure 24.10 shows that layer II neurons are in irregular groups rather than consistent islands as in area 25r. Although layer III does not have large pyramids in its deep aspect (i.e., no apparent layer IIIc), neurons are more sparse in the deep rather than superficial part of this layer, and there are a few NFP-ir cells scattered throughout deep layer III. There are, however, too few of these latter neurons to define a layer IIIc. Layer Va is broad, and the neurons have a very heterogeneous size profile with the typically large and NFP-ir pyramids in addition to many small and medium-sized pyramids. Although layer Vb neurons are sparse and NFP-ir, they do not form obvious aggregations as in area 24b. Finally, layer VI is quite broad, and about one-third of its small neurons are NFP-ir. Area 24a′ has thinner and less-neuron-dense layers II, III, and Va and it has a similar profile of NFP-ir neurons in all layers including III, V, and VI.

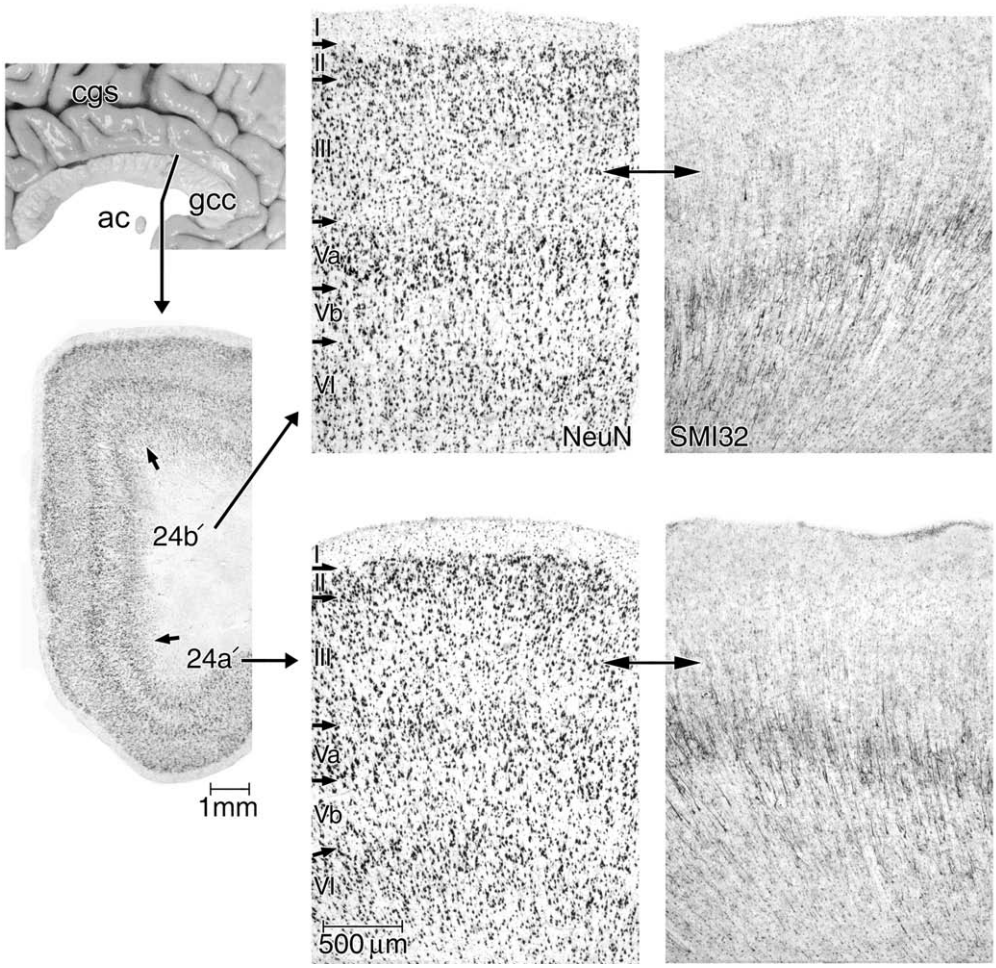

FIGURE 24.10 The gyral midcingulate areas 24a′/b′ are generally thicker than their pACC counterparts, they have a thicker layer Va, and there are more small neurons in layer Va. There also are more small neurons in the deep part of layer III and this layer does not yet have large enough neurons to specify a layer IIIc. There are almost no NFP-ir in layers II–III but quite a number in layers Va and Vb.

A study by Nimchinsky *et al.* (1997) makes a number of important points about the border between areas 24 and 24′ and that between areas 24′ and 23. First, the distribution of NFP-ir neurons in a horizontal section through the cingulate gyrus showed three levels of immunoreactivity. In pACC most staining was in layer Va, substantial staining in layer Vb, and none in layer III. In area 24′ the staining in layer Va was more focused (i.e., less in layer Vb), and there were moderate levels in layer III. In area 23 the staining was most intense in layer IIIc, less in layer Va, even less in layer Vb/VI, and nonexistent in layers II–IIIab. Second, an equally important differentiation could be made with a computer-generated map of the distribution of calretinin-ir pyramidal neurons. Most of these neurons are in the pACC and a moderate number in the rostral half of MCC, while there are none in area 23.

Perigenual and Midcingulate Sulcal Areas

Although it is well recognized that cortex in the depths of the cingulate sulcus projects to the spinal cord and has neurons with premovement discharges coding the reward properties associated with a movement, there is not complete agreement over the number and distribution of each cingulate motor area. Dum and Strick (1991, 1993) identify three areas with one in area 24c (CMAr), one in area 23c (CMAv), and one in area "6c" (CMAd). Their rostral border for area 23 extends quite far rostrally and it is unclear that the area 6c region is a CMA *per se*, particularly since a unique set of projections to primary motor cortex has not been identified for it (Nimchinsky *et al.*, 1996). Although Morecraft and Van Hoesen (1992, 1998) identify a CMA in area 23c, Luppino *et al.* (1991) and Rizzolatti *et al.* (1996) show no electrically evoked

activity from area 23c caudal to area 24d. A monkey cortex with features similar to Braak's primitive gigantopyramidal field appears to be part of the area 24d of Luppino *et al.* (1991); however, area 24d is more extensive than the primitive gigantopyramidal field and forms most of the dorsal and ventral banks of the cingulate sulcus (Nimchinsky *et al.*, 1996). It is fair to say that there is at least one, large cingulate motor area in area 24d. Finally, the concept of two motor areas with one rostral and one caudal is supported by Nimchinsky *et al.* (1996) who showed that the rostral one in area 24c' has projections to the primary motor cortex originating mainly in deep layers, while projections to the same area originate from both deep and superficial layers of area 24d. Chapter 26 discusses in fine detail the organization and functions of area 24d.

The present observations are based on a photographic series through 25 levels of the entire cingulate sulcus. Area 24c in the rostral cingulate sulcus appears to extend further caudal in immunohistochemical than in Nissl preparations. Area 24c has a thick layer II and a layer III with relatively uniform and medium-sized pyramids that thin out considerably toward its deeper part. Because there are no particularly large pyramidal neurons in deep layer III, a layer IIIc cannot be identified. Layer Va is quite dense with medium and large pyramidal neurons, many of which are NFP-ir. Indeed, there is a rich plexus of NFP-ir dendrites throughout layer Va (Fig. 24.11, SMI32). Interestingly, the architecture of area 24c is not constant in its mediolateral extent. At low magnification (Fig. 24.11A; asterisks) parts of layers Va and VI have an elevated number of larger neurons in comparison to the adjacent cortex. The edge of one of these aggregates is shown at high magnification to the right of a pair of asterisks (Fig. 24.11A, NeuN). Below layer Va there are many neurons in layer Vb, which is normally neuron-sparse. The neurons in layer VI under the layer Va/b aggregations are also larger. These subareal variations likely reflect differential organization of the innervation of different parts of the brainstem and spinal cord skeletomotor systems.

Area 24c' of MCC is cingulate motor cortex and is significantly thicker than its rostral counterpart. A number of significant changes occur in this cortex (Fig. 24.12). Layer III has more NFP-ir neurons, and relatively fewer are in layer V. Indeed, the dense plexus of dendrites characteristic of layer Va in area 24c is not in area 24'. The neurons in layer Va are generally smaller, while those in layer Vb are quite large and densely packed. In accordance with the trend in area 24 in which layer III neurons express higher levels of NFP-ir caudally, the posterior of two levels of SMI32 (Fig. 24.12B) has a higher density of large layer III neurons expressing NFP-ir than in the anterior section. The rostrocaudal trend toward increased numbers of NFP-ir neurons in layer III has been shown for sulcal (Nimchinsky *et al.*, 1996) and gyral (Nimchinsky *et al.*, 1997) cortex with full length, horizontal sections.

Very large pyramidal neurons in the deep part of layer V mark area 24d or the primitive gigantopyramidal field (Braak, 1976), and they are NFP-ir (Nimchinsky *et al.*, 1996). Area 24d has a broad layer II, relatively homogeneous layer III, deep layer Vb with the large pyramids, and a layer VI (Fig. 24.13). There are two unique aspects to layer V in area 24d. First, layer Va is parvicellular because it contains many small pyramids intermingled with larger neurons. This structure is not readily apparent in Nissl-stained preparations because of costaining of glial cells. Layer Va has many small neurons in the NeuN preparation, and it also has a dense plexus of NFP-ir dendrites and small neurons in the SMI32 preparation. Second, layer Vb contains the gigantopyramidal neurons of Braak that are NFP-ir, and aggregations of these neurons in layer Vb are particularly apparent in the SMI32 preparation of area 24d on the ventral bank of the sulcus (i.e., area 24dv). In addition, many of the large pyramids in layer III are NFP-ir, although a layer IIIc cannot be defined on the basis of neuronal size in comparison to superficial parts of layer III.

Cortex on the dorsal (area 24dd) and ventral (area 24dv) banks of the cgs share adequate similarities to be part of area 24d. The conclusion that area 24d extends onto the superior bank of the cgs means that the short extension of area 32' previously noted on the dorsal bank at this caudal level has been displaced. In this situation, area 32' inserts mainly between areas 24c' and area 6aβ. There are also some interesting differences between areas 24dd and 24dv (Fig. 24.13) that could have important functional consequences. First, area 24dd has a greater number of larger and NFP-ir neurons in layer III, and these neurons reach the point where a layer IIIc is defined. This is an important transitional feature to area 32' where layer III pyramids are a significant characteristic. Second, layer Va in area 24dd is much thicker than in area 24dv, although it appears to contain the same overall proportions of small and large pyramids. Third, layer Vb has slightly larger pyramids, and they are solitary rather than in groups as in area 24dv. Finally, the different morphologies of these two divisions of area 24d may relate to their differential involvement in skeletomotor and cognitive functions. Area 24dd mainly regulates muscles of the hindlimb and lower trunk, while area 24dv regulates mainly forelimb and upper trunk (Rizzolatti *et al.*, 1996).

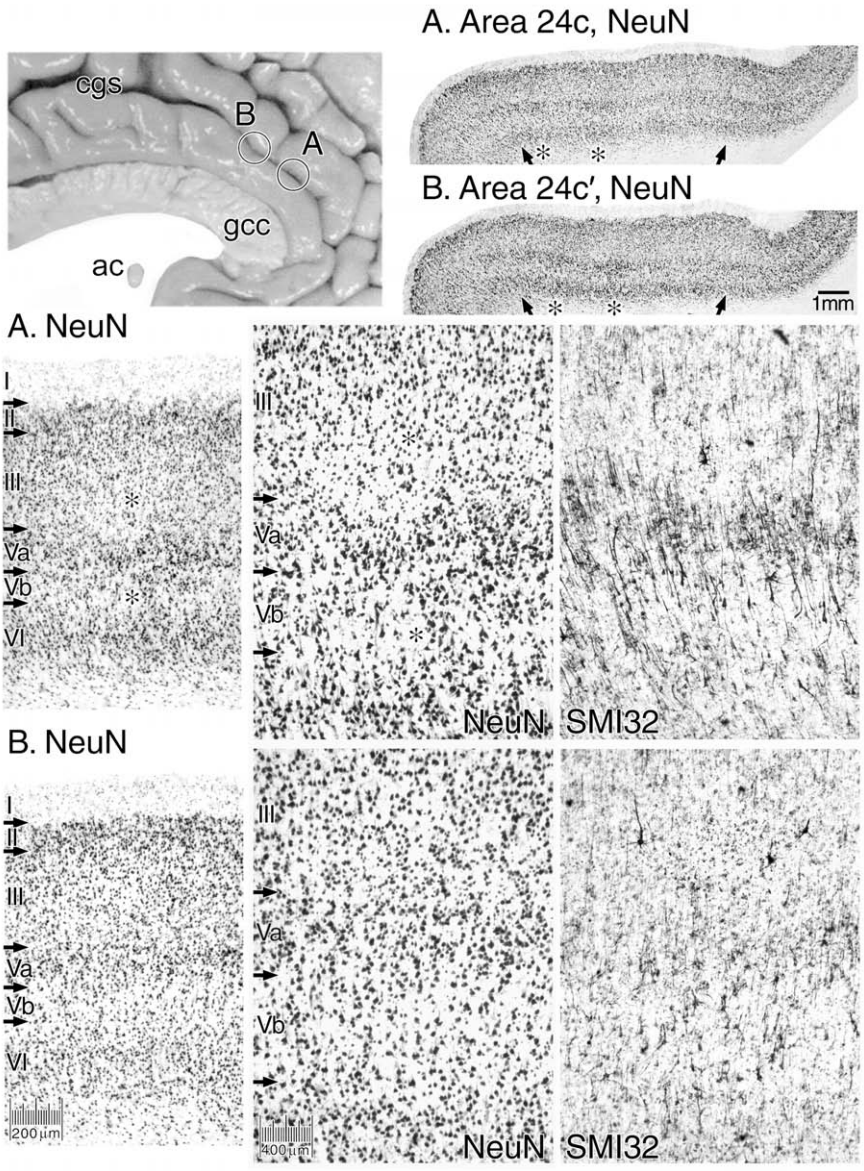

FIGURE 24.11 Areas 24c and 24c′ are shown in the depths of the rostral cingulate sulcus. In the low-magnification photographs, there are two aggregates of large neurons in layers Va and VI (above the asterisks). The NeuN section in A that is magnified further shows the border with one of these clumps with a pair of asterisks around layer Va and once again at the highest magnification. The distinction between layers Va and Vb are difficult, and many of these large neurons are NFP-ir. In this area, not only is layer III sparse in its deeper division but there are some large NFP-ir neurons therein, although an overt layer IIIc cannot be detected. Area 24c′ has a similar lamination pattern; however, layer V is substantially thicker, and the pattern of NFP-ir is quite different, as noted in Figure 24.12.

Areas 32 and 32′

Area 32 is a rostral and dorsal division of cingulate cortex that forms a belt around area 24. Although parts of it have been activated in a number of functional imaging studies associated with response selection such as generation of verbs to novel lists of nouns (Raichle *et al.*, 1994) and Stroop interference tasks (Pardo *et al.*, 1990; Bench *et al.*, 1992), its specific contributions to brain function are not fully understood. In view of its location between the cingulate motor areas ventrally and medial frontal areas dorsally, including the supplementary motor areas as well as reciprocal connections with these areas, it is reasonable to expect that this area plays a role in joining the activity of a number of frontal and cingulate motor areas. From a structural perspective, areas 32 and 32′ have features that are transitional to granular prefrontal cortex. In pACC, area 32 is transitional from area 24 to areas 12, 10, and 9, while area 32′ is transitional at

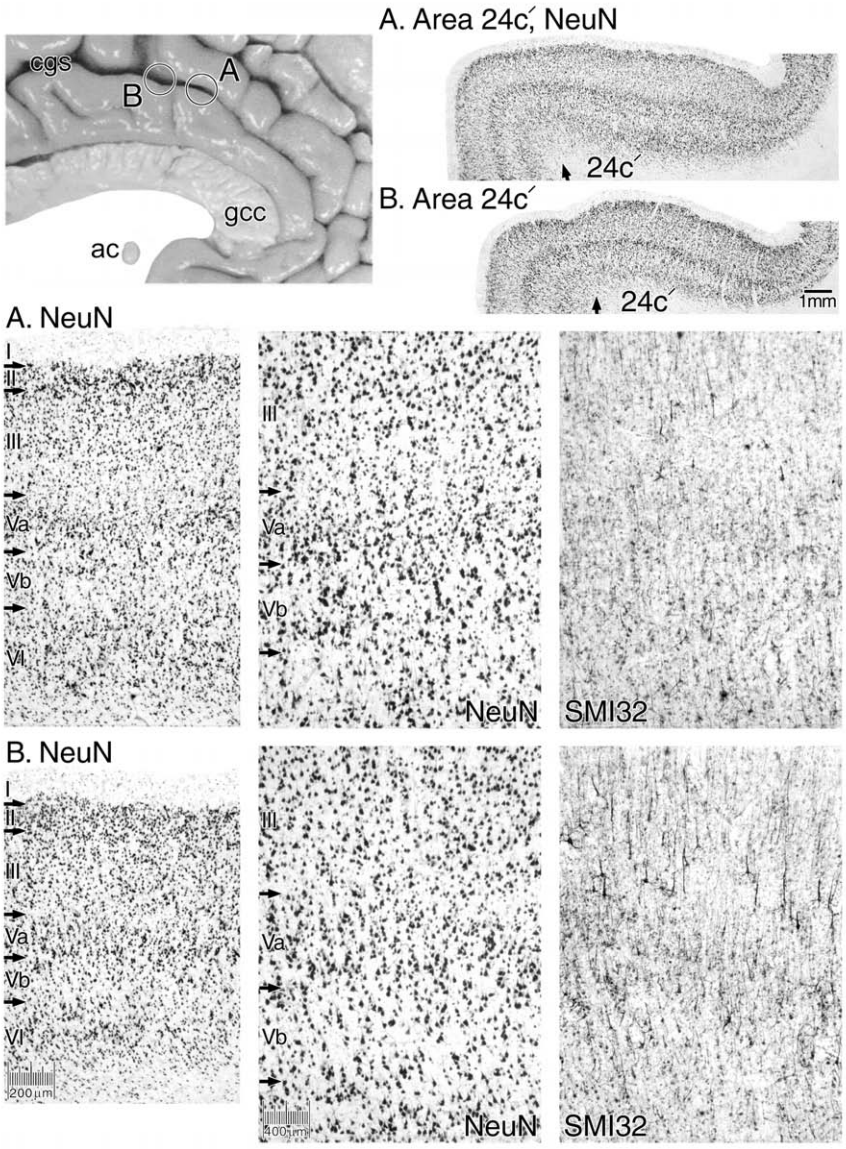

FIGURE 24.12 Two levels of area 24c′ show this area to have a very thick layer Va that is quite parvicellular. There are so many neurons in layers III-VI that are NFP-ir that the SMI32 preparations look almost homogeneous. The large though not gigantic layer Vb pyramids are clear in both preparations.

dorsal levels to area 9 and rostral area 6aβ. von Economo and Koskinas (1925) emphasized these transitional positions with adjacent frontal areas in their designations FhL, FeL, FdL, and FcL, although they did not recognize an area equivalent to area 32′. The cortex between areas 24c′ and 6ab is area 32′.

Area 32 has a well-developed layer IIIc with most large pyramids NFP-ir (Fig. 24.14A). Because these are the largest neurons in area 32, this inversion is a key transitional feature with area 24 where the largest and NFP-ir neurons are located in layer V. Layer IV is another transitional feature that contrasts sharply with the agranular areas 25 and 24. In area 32, layer IV is thin but continuous and is distinguished from the dysgranular organization of area 32′ where there are clear interruptions in layer IV. Finally, layers V and VI are unremarkable, although layer Vb seems to have more neurons than is usual in area 24.

Area 32′ of MCC inserts primarily between the supplementary motor area 6aβ and area 24c′. Area 32′ has a number of differences with area 32. Area 32′ has large layer IIIc pyramids that are NFP-ir; however, there are many fewer of these neurons (compare SMI32 for both in Fig. 24.14). Although there are fewer large layer IIIc pyramids, the overall neuron density in layer IIIc is lower than in area 32. Layer IV is more often interrupted by bridges of neurons requiring the designation of dysgranular as reported with Nissl

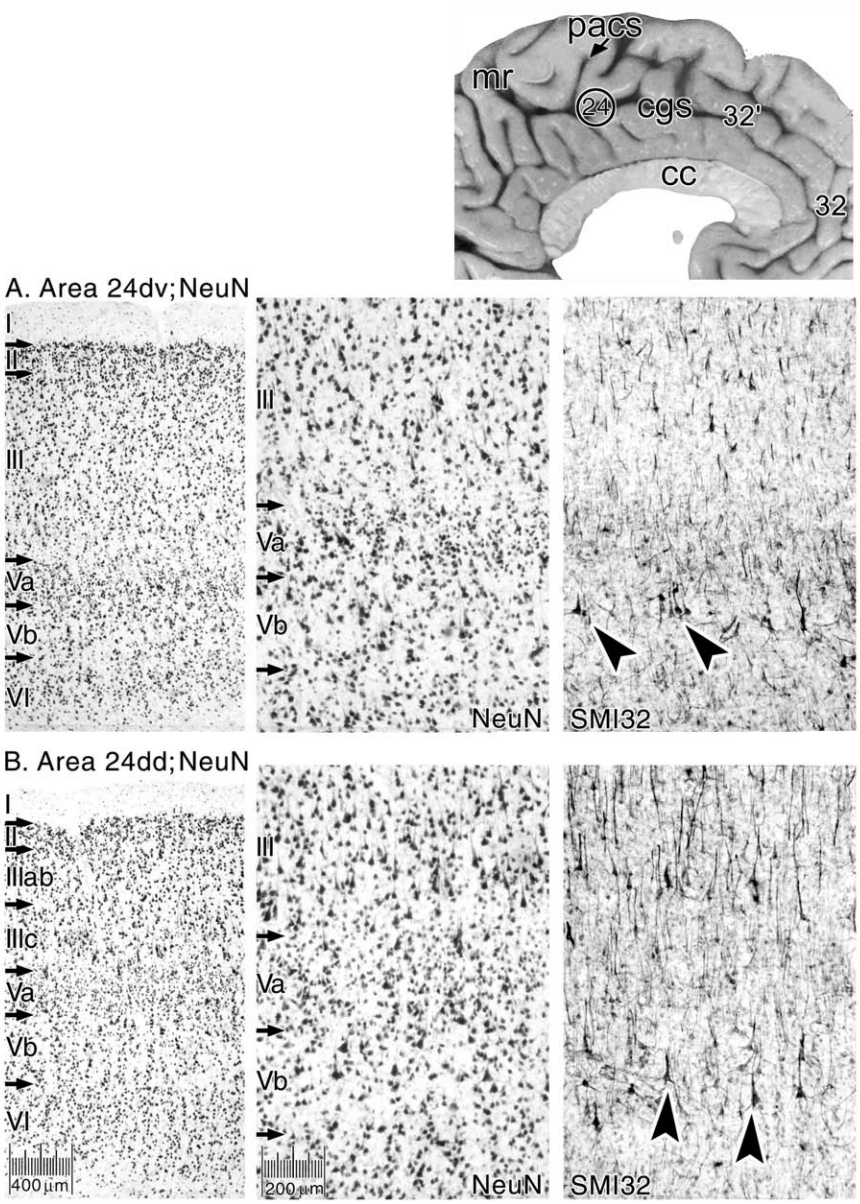

FIGURE 24.13 Electrical stimulation shows that the dorsal and ventral banks of the cingulate sulcus at this caudal level represent different parts of a somatotopically organized motor field; area 24dv (ventral) and 24dd (dorsal). Area 24d in these two locations represents an enlargement of this field from previous studies that relied on Nissl staining alone. The ventral bank has the hallmark aggregations of very large pyramidal neurons that are NFP-ir in layer Vb (A, two examples at arrowheads), while this layer in the dorsal division has solitary pyramids (B, two examples at arrowheads). There are also many more large and NFP-ir neurons in layer IIIc of area 24dd than in area 24dv.

preparations (Vogt *et al.*, 1995). In Figure 24.14B (area 32', NeuN), a level of this area is shown where one such interruption occurs at the pair of asterisks. Finally, although layers Va and Vb can be differentiated with large neurons in the former, layer Vb has a significant number of small and medium-sized neurons, and it is not neuron-sparse. This contrasts with area 24d, which has a more typically neuron-sparse layer Vb.

Ectosplenial and Retrosplenial Cortices

Each coronal section through RSC includes a segment of allocortical hippocampus and ectosplenial area 26. Above the splenium, the hippocampal rudiment (IGr) or areas LB2 and HF (von Economo and Koskinas, 1925) form a single layer of densely packed ganglion cells that are heavily NFP-ir (Fig. 24.15). Adjacent to the IGr is the subicular rudiment (Sub) or

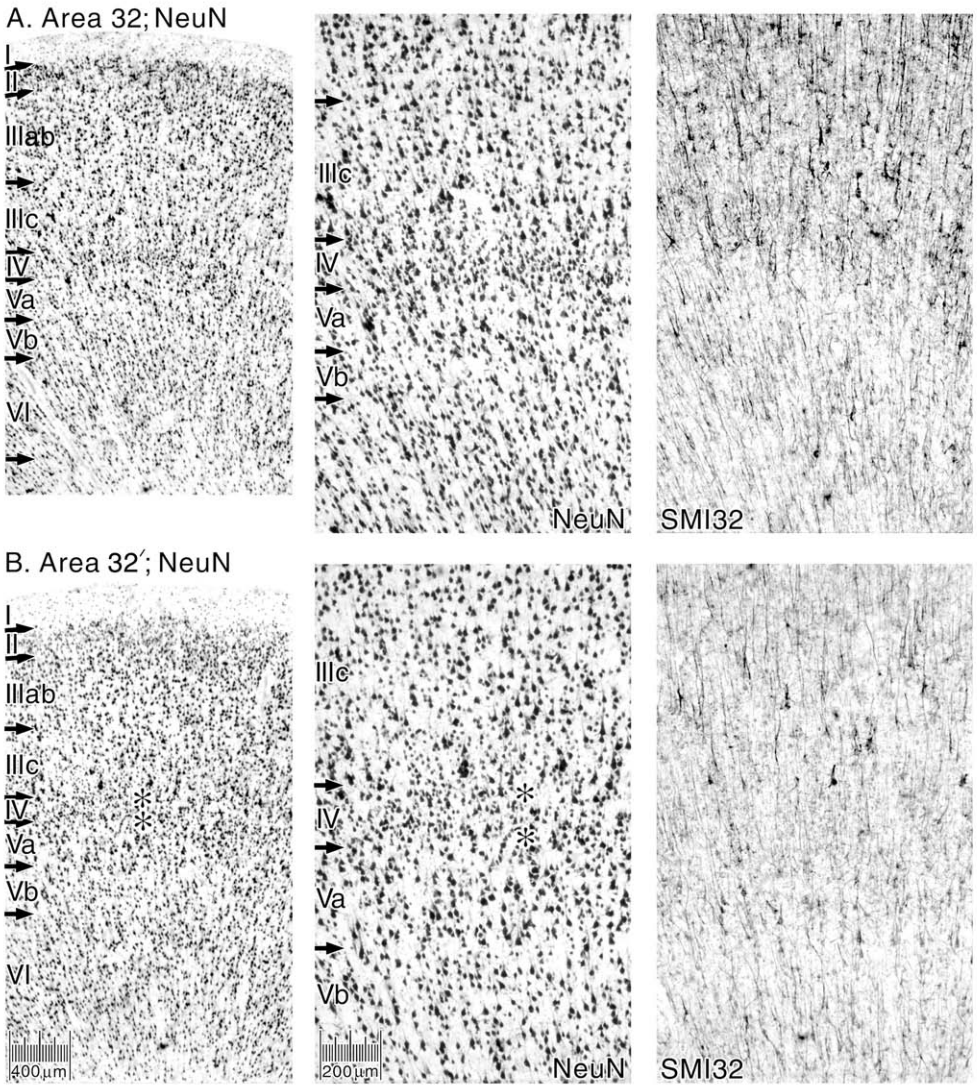

FIGURE 24.14 The rostral and dorsal cingulate areas 32 and 32′ are located in the pACC and MCC, respectively. The position of each photograph is shown in Figure 24.13. Area 32 has a continuous layer IV and large and heavily NFP-ir layer IIIc pyramids—characteristics of association areas in general (A). Area 32′ has a layer IV, but it is dysgranular because there are places where neurons in layers IIIc and Va abut each other as noted with asterisks in both magnifications of NeuN preparations (B). There are also substantially fewer layer III NFP-ir.

area HE of von Economo and Koskinas which has many fewer and more dispersed neurons. These two areas together form the fasciolate gyrus on the dorsal surface of the cc. Although the term "intralimbic" has been used for this small gyrus (Retzius, 1896), the concept of an intralimbic gyrus in this region requires that this cortex is limbic cortex; a view that has not been proven.

Ectosplenial Area 26

Area 26 of Brodmann (1909), area LF of von Economo and Koskinas (1925), and area es of Braak (1979a) have an architecture that is almost the inverse of that expressed by the IGr and subicular rudiment. Area 26 has a very dense layer of granular neurons most of which are NFP-ir, and there is a dense plexus of NFP-ir fibers in this layer (Fig. 24.15). Deep to the granular layer there are few pyramidal neurons, most of which are NFP-ir. This can be stated because the sections used for the SMI32 immunoreaction were counterstained with thionin, and there are no thionin-stained neurons that are not also SMI32+. Braak (1979a) observed that this deep layer was comprised of only the multiform neurons of layer VI.

Granular Area 29

The organization of the retrosplenial cortex presents a number of difficult problems. It undergoes many

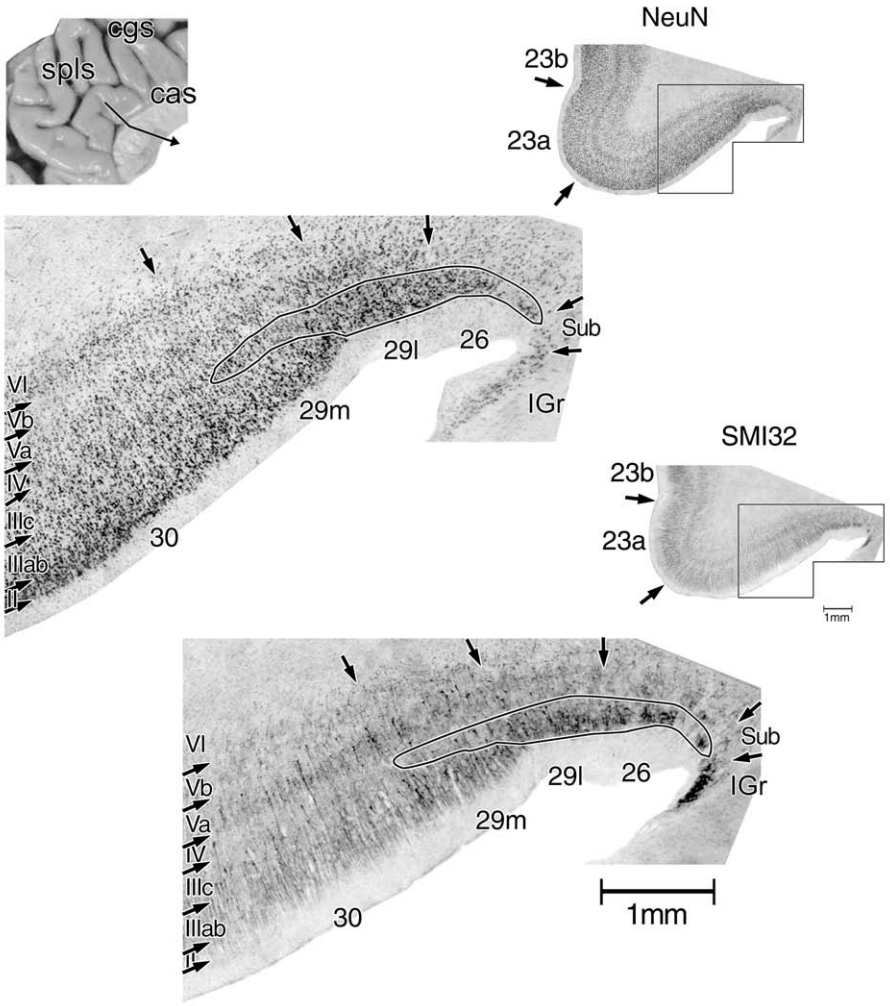

FIGURE 24.15 Coronal sections through the ventral bank of the posterior cingulate gyrus showing the posterior cingulate (23) and retrosplenial (29/30) cortices. The granular layer of areas 26 and 29 is outlined to emphasize the commonality of this layer to ectosplenial area 26 and granular retrosplenial area 29. Note that the overall density and sizes of neurons in this layer in area 29m is reduced because large neurons in layer III of area 29m separate from the granular layer, while in area 29l, such differentiation does not occur. In area 26 of both preparations, there are almost no neurons below the granular layer (i.e., there is essentially no internal pyramidal layer). Each layer in area 30 is shown to the left of the photographs including a variable layer IV.

transitions, and its structure must be interpreted in terms of differentiation trends. Also, it is convoluted around the splenium, and interpreting its organization and relationships with parahippocampal structures can be difficult. Finally, although the Brodmann map has been very influential, Talairach and Tournoux (1988) mislocated area 30 by transposing it to a posterior parahippocampal location. Although the architecture of RSC can be identified in Nissl-stained tissue (Vogt *et al.*, 1995, 1997, 2001), the details of cytological organization are more apparent with the NeuN and SMI32 antibodies, and Figure 24.15 shows a supraspleniał level of RSC. The unifying feature of the two subdivisions of area 29 is the granular layer that in lateral area 29l is directly adjacent to layer I, and in medial area 29m it is deep to a layer of medium-sized pyramidal neurons termed layer III. The granular layer is outlined in Figure 24.15 to emphasize its presence in areas 26 and 29. It is referred to as layer III/IV in areas 26 and 29l because it is an intermediate stage of differentiation of layers III and IV on the ventral bank of the cingulate gyrus (vCG). The granular layer contains many medium-sized pyramids that are NFP-ir, and the associated NFP-r dendritic plexus is prominent (Fig. 24.15, SMI32). Although this is also termed the granular layer, the neurons are not small and "granular" as they are in the monkey. In area 29m the density and sizes of neurons are reduced in layer IV because many medium-sized neurons are separated from this layer into a layer III (Figs. 24.15, 24.16, 24.21,

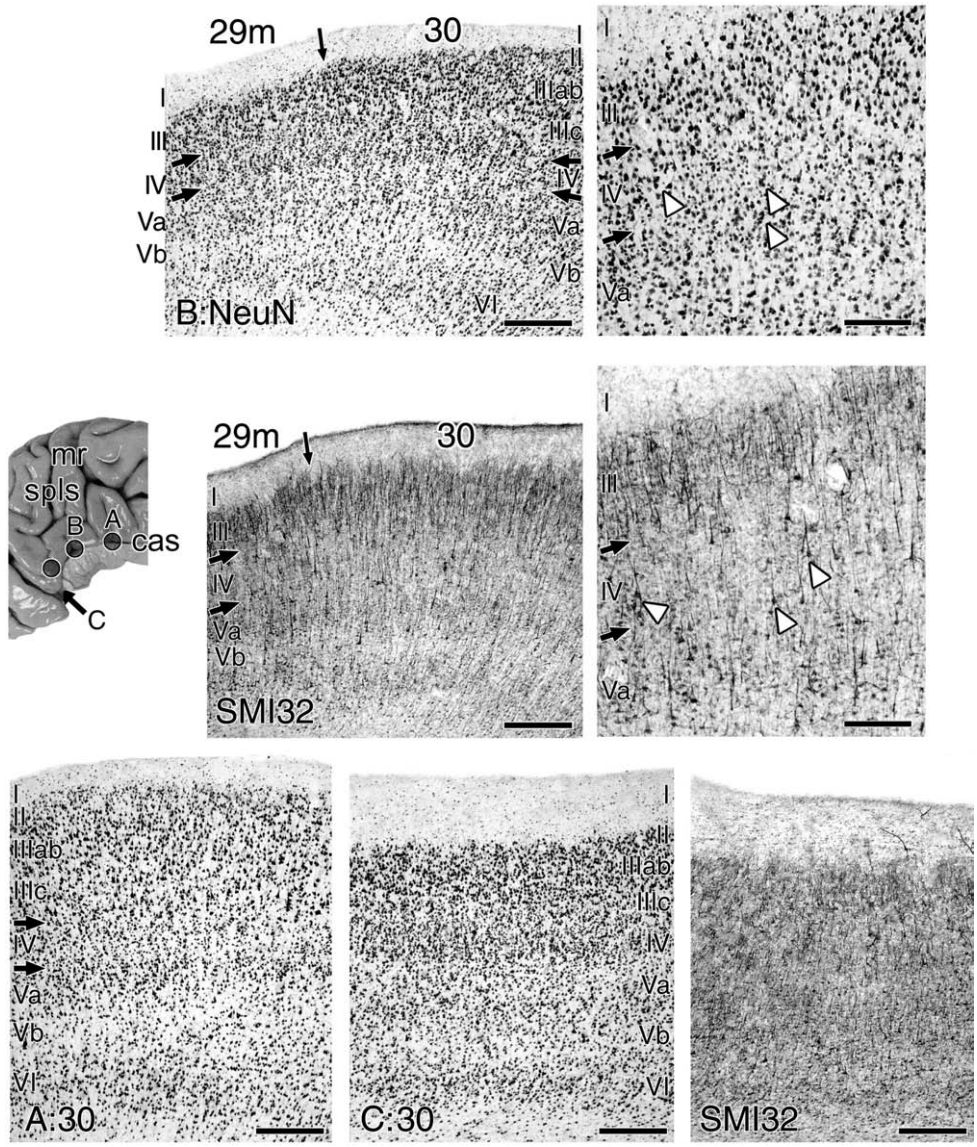

FIGURE 24.16 Three rostrocaudal levels of area 30 above the body of the corpus callosum (A), dorsal to the splenium (B), and caudal to the splenium and lateral to the CML as indicated with the arrow pointing below the CML (C). The medium-sized NFP-ir neurons in the parvicellular layer IV are demonstrated, and three in each preparation are emphasized with white arrowheads. The level of the section at C is noted with brackets in Figure 24.17: NeuN. This level of area 30 is transitional to area 29m at its most caudal level (i.e., this is the terminal end of area 30). At this point, area 30 has a more densely granular layers II and IV, and the sizes of layer III pyramids are reduced with less prominent NFP-ir dendrites. Scale bars, 1 mm.

and 24.22). Beneath the granular layer in area 29l are poorly differentiated layers V and VI, while in area 29m, layer V differentiates into layers Va and Vb. Many of the largest pyramids in area 29 are NFP-ir, and they are located mainly in the deeper part of layer V in area 29l and the deeper part of layer Va in area 29m. Finally, there are some NFP-ir neurons in layer VI throughout area 29, although the associated plexus in layer VI is much less dense than in layers IV and Va.

It may seem arbitrary to term the first neuronal layer adjacent to layer I in area 29m as layer III rather than layer II. This selection is not the result of a simple pia to white matter counting but rather is based on the facts of neuron structure and the principles of cortical transition in the posterior cingulate region. It has been suggested that this is not layer II in the monkey because these are not lancet-shaped neurons similar to those of layer II in area 23a and a distinct layer II appears only in the medial part of area 30 (Vogt, 1976). This fact is demonstrated later and confirms and extends observations in monkey RSC in the following ways. First, most neurons in layer III of area 29m are

NFP-ir, while almost none are NFP-ir in layer II of area 23a and medial area 30. Second, there is a reduction in the overall density of neurons and the NFP-ir dendritic plexus in the lateral part of area 30 that is adjacent to area 29m (Figs. 24.15 and 24.16). Third, the size and density of heavily NFP-ir neurons in layer III of area 29m contrasts with those in layer IIIc of area 30 (Fig. 24.15). It was concluded that neurons in layer III are most likely associated with layer IIIab as proposed for the monkey (Vogt, 1976). Thus, the cytoarchitecture of monkey and human cortices, Golgi studies in monkey, and immmunohistochemical studies in human all point to the fact that layer III of area 29 is similar to that of layer IIIab in neocortex rather than layers II, IIIc, or IV.

The parvicellular layer IV of area 29m contains not only small and medium-sized pyramidal neurons but also a number of large and solitary pyramids. These neurons are NFP-ir and are a distinguishing feature of area 29m along its full extent to its termination on the rostral bank of the CML. Examples of these pyramids are in Figure 24.16B (white arrowheads); at this magnification, it is clear that layer III is comprised of many medium-sized and large pyramidal neurons that are heavily NFP-ir. These latter neurons likely are the undifferentiated counterparts of pyramids of layers II and IIIab in adjacent areas 30 and 23a.

Dysgranular Area 30

Area 30 (Brodmann, 1909), LD (von Economo and Koskinas, 1925), Rsag (Rose, 1928), and rsm (Braak, 1979a) have been thoroughly analyzed histologically. At each point of transition from allocortex to isocortex throughout the primate telencephalon, there is at least one area with the features of a dysgranular cortex as is the case for orbitofrontal and insular cortices. In the insula, neurons in layer IV form islands, as is characteristic of a layer that is of irregular thickness (Mufson *et al.*, 1997). In orbitofrontal cortex, the intermediate area has a thin layer IV that can be difficult to detect where the layer III and V pyramids are particularly large (Hof *et al.*, 1995). Since cortex on the ventral PCG progresses through a number of transitions beginning with the allocortical indusium griseum and culminating in the isocortical area 23, the presence of a dysgranular cortex needs to be considered.

Brodmann (1909) referred to area 30 as agranular, and von Economo and Koskinas (1925) were quite explicit that area LD is not just agranular but that the "granulous" layer of area LE (Brodmann's area 29) is not continuous with the isocortical layer of area LC2 (Brodmann's area 23). Although there is no doubt that layer III/IV in area 29 is not equivalent to layer IV in area 23a, von Economo (1929, Fig. 50) vacillated on the presence of a layer IV in LD and showed a layer III(IV) below layer III. Furthermore, the granular layer IV of area 29m is continuous with layer IV in area 30 and layer IV in area 23a in immunohistochemical preparations invalidating von Economo's statement that they are not continuous (Vogt *et al.*, 2001).

Area 30 architecture is shown in Figure 24.16 for three rostrocaudal levels. It has layers IIIab and IIIc that differentiate from layer III of area 29m. Although some small neurons are at the border between layers I/II, a layer II is most apparent at the medial edge of this area. Small neurons aggregate in layer IV, and there are many instances where the layer is interrupted by bridges of neurons between layers IIIc and Va or where the small neurons interdigitate with those in layers IIIc and/or Va. The variability in layer IV thickness can be appreciated in Figure 24.16 where one level has a variable layer IV (B: NeuN), one has a thin but continuous layer (A: 30), and the granular neurons are either in a separate layer or intermingled with those in layer Va at the caudal level (C: 30). Area 30 has another feature that makes it stand out from adjacent areas. It has a high relative density of NFP-ir neurons in layer IIIab when compared to other layers. Although some large neurons in layers IIIc and Va are NFP-ir, they are infrequent when compared to area 23a. Although area 23b may have a similar number of NFP-ir neurons in layer IIIab, this area has the second highest density of NFP-ir neurons in layer IIIc (second only to area 31), and this contrasts strongly with the organization in area 30 where few of the layer IIIc neurons are NFP-ir. Finally, at caudal levels of area 30 (Fig. 24.16C: 30), the cortex is thinner, and there is a more homogeneous distribution of NFP-ir neurons.

Posterior Cingulate Cortex

The first isocortical area encountered in the transition that begins with the indusium griseum is area 23a. At its rostral border with area 24a', layer IV is thin, and there is an intermingling of small neurons with large pyramids in layer Va. Recall that area 24' does not have a layer IV but rather small neurons intermingled in layer Va. This feature, therefore, is a transitional aspect of rostral area 23a architecture. Caudally in area 23a, layer IV becomes more pronounced and, although a layer Va is present, the number of large neurons in it is surprisingly low. One of the key differences between areas 23a and 23b is that the latter area has a significantly greater number of neurons in layer Va (Fig. 24.17). The greatest number of NFP-ir neurons in area 23a are in layer IIIc that is in striking contrast to area 30 where most are in layer IIIab. A moderate population of large neurons in layer Va also

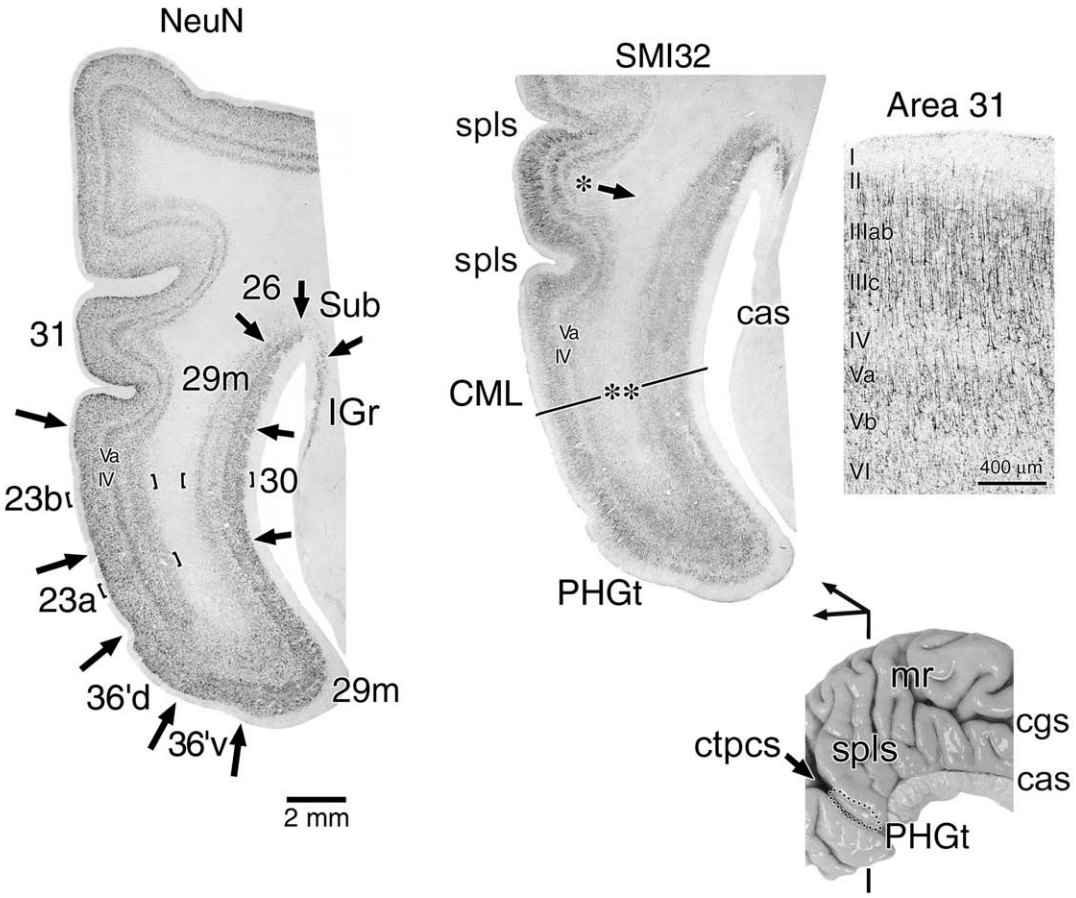

FIGURE 24.17 Microphotographs through the postsplenial posterior cingulate and retrosplenial regions and the junction with the PHGt. The surface reconstruction paradox of RSC in producing brain maps including that of Brodmann is clear because RSC is in the fundus of the cas lateral to the CML and not on the surface of the CML. The isocortical nature of areas 23a and 23b with their layer IV is apparent in both preparations and, as is true for most cingulate areas, layer Va is prominent even in isocortex. This case also demonstrates the clarity with which each area of CML can be assessed in standard coronal sections. Although area 29m does not appear on the CML, its border with parahippocampal area 36'd on the PHGt is demonstrated; the PHGt is outlined with a dotted line in the macrophotograph. Area 31 has not only the thickest layer IV of any cingulate area but also the highest level of NFP-ir in layer III that emphasizes its border with area 23b. The strip of area 31 cortex is a 3× magnification of the level in SMI32 marked with one asterisk and an arrow.

expresses NFP-ir and there is a fine mesh of NFP-ir dendrites throughout deep layer V and layer VI. As is the case for area 30, at caudal levels of area 23a there is a greater overall dispersion of NFP-ir neurons and dendrites that also includes some in layers II and IIIab.

The border between areas 23a and 23b is clearly marked by a significant increase in the number of layer Va neurons and the thickness of layer IV as shown in the CML (Fig. 24.17, NeuN). As is the case for area 23a, the rostral part of area 23b at its junction with area 24' has a thinner layer IV and a well-formed layer Va that does not contain many small neurons (Fig. 24.18A). One of the outstanding features of the dorsal and posterior cingulate areas is the very high density of NFP-ir neurons throughout layer III. There are so many of these cells that even layers II, IV, and VI have a high density of them (Fig. 24.18B, SMI32)

Area 31 forms lobules around the spls, and its structure is identified between the primary branches of these sulci. Area 31 has the thickest layer IV on the cingulate gyrus, and this layer can be compared with the same one in area 23b in Figure 24.17 in the NeuN preparation or as a negative image in the SMI32 section. Layer Va is also well developed and has the highest density of NFP-ir neurons in the posterior cingulate region (Fig. 24.17, SMI32). Finally, area 31 has the highest density of large NFP-ir neurons in layer III in the entire cingulate gyrus, and they are obvious even at low magnification (Fig. 24.17, SMI32). As shown in the subregional, postsplenial flat map (Fig. 24.20), area 31 forms the superior and posterior border of cingulate cortex and extends ventrally and caudally to area 23b along the posterior border of the caudomedial subregion.

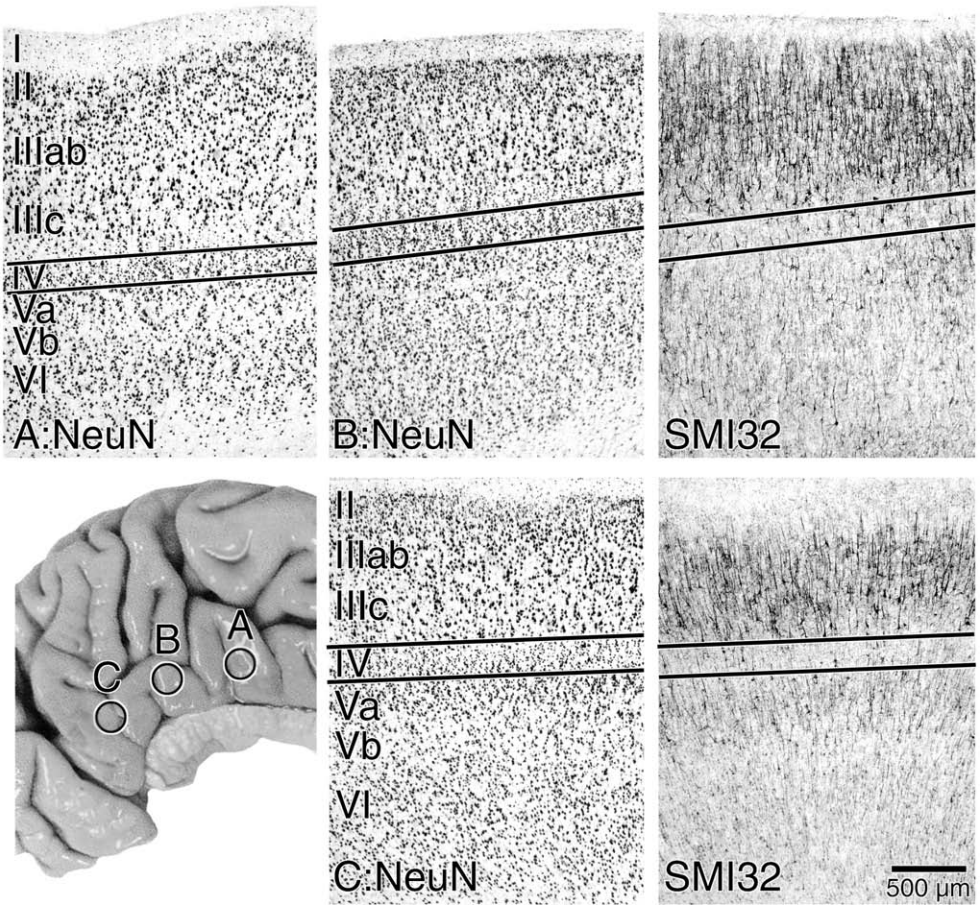

FIGURE 24.18 Three rostrocaudal levels of area 23b including a level at the dorsal part of the CML (C). Although the essential structure of area 23b is maintained throughout with heavily NFP-ir large neurons in layer III, a thick layer IV, and a robust layer Va with few NFP-ir neurons, the thickness of layer IV does decline close to the border with area 24, and a dysgranular architecture is apparent at some levels.

Caudomedial Subregion

Brodmann (1909) showed areas 26, 29, and 30 extending around the full extent of the splenium, while von Economo (1929, Fig. 58) provided a reconstruction of this region and showed that the retrosplenial areas terminated posterior to the splenium at a level just caudal to the ventral edge of the splenium rather than fully embracing it *per se*. Although there is no doubt about the von Economo conclusions because of his carefully drawn map of the region, the same cannot be said of the Brodmann map because it was reconstructed on the convoluted surface of the entire brain and represents compromises to show the topology of each area in sulci and on gyral surfaces. We evaluated these issues and concluded that the RSC in Brodmann's map does not extend far enough anteriorally, it does not extend onto the surface of the CML/CMSR, nor does it extend to the most ventral aspect of the splenium (Vogt *et al.*, 2001). Each of these issues has a significant impact on how functional imaging studies localize activation sites in this region. Indeed, the use of Brodmann's localizations without histological guidance led to a mislocation of retrosplenial area 30 on the surface of the CML/CMSR (Talairach and Tournoux, 1988).

The PCC and CMSR have variable surface features as detailed in Figure 24.2. In the monkey, there is a consistent pouch of cortex in the CMSR termed the CML (Goldman-Rakic *et al.*, 1984), and its surface is comprised mainly of areas 23a and 23b, while the rostral bank contains RSC (Vogt *et al.*, 1987, 1997; Vogt, 1993). Although a similar conclusion has been reached in human brain (Vogt *et al.*, 1995), the multiple gross morphologies of this cortex need consideration as do the details of transition to parahippocampal cortex. In instances in the human where a clearly defined CML is not present, the more general term CMSR is used. An overview of the posterior cingulate gyrus is provided in Figure 24.17, and the problem of reconstructing RSC on the convoluted surface of the human cortex is apparent therein because area 23 directly overlies the ectosplenial and retrosplenial areas in the cas. The isocortical layer IV of areas 23a and 23b can be seen in cortex on the surface of the CML, while areas 29 and 30 underlie this cortex in the depths of the cas and do not express a fully differentiated layer IV. It is not possible to reconstruct these areas accurately without flattening

the cortex to show areas in the fundus of the cas. At ventral levels, the CA1 sector of the hippocampus replaces the indusium griseum, and area 29m terminates adjacent to the caudal parahippocampal areas 36'd and 36'v.

Although histological studies have not shown area 30 on the gyral surface in the CML, two essential issues are raised by the atlas interpretations of Brodmann's map (Talairach and Tournoux, 1988). Does any gyral component of the CML/CMSR share cytoarchitectonic features with area 30 in the cas? How do the features of area 30 compare with those on the CML, including that area which most closely relates to area 30 cytoarchitectonics (i.e., area 23a) which it borders? In Figure 24.17, layer IV can be clearly identified at low magnification in areas 23 and 31. Since area 30 has a dysgranular layer IV that cannot be detected at this magnification, it is unlikely that area 30 is part of the gyral surface at the isthmus. Direct comparison of a supraspleniał level of area 30 (i.e., as in Fig. 24.16B) with cortex on the CML is provided in Figure 24.19, which has higher magnifications of layers IIIc–Va of area 30, and photographs of area 23a on the CML, which has the least differentiated layer IV in this region (i.e., between brackets in Fig. 24.17, NeuN). As noted earlier, area 30 has a layer IV that is interrupted by layer IIIc/Va neurons (asterisks in Fig. 24.19A, NeuN). There are some medium-sized, NFP-ir pyramidal neurons throughout layer IV in area 30 and this reduces the clarity with which layer IV can be identified with NFP-ir. In contrast, area 23a on the CML has a clear layer IV with only a few large and solitary layer IIIc or Va, NFP-ir neurons. There also are many more NFP-ir neurons in layer IIIc in area 23a than in area 30. As noted earlier, layer IIIc of area 30 has surprisingly few NFP-ir neurons in layer IIIc but the greatest relative density in layer IIIab. Finally, there are no neuronal bridges connecting layers IIIc and Va to the exclusion of a layer IV in area 23a, although layer IV in area 23a does have some solitary, NFP-ir neurons. Thus, area 30 is not expressed on the CML.

Another major component of the CMSR is area 23b. This area has such a well-defined layer IV that it is easily observed at low magnifications as in Figure 24.17, which shows both layers IV and Va. These layers show the two most important features of area 23b: thickness and neuron densities. Many large pyramidal neurons in layer Va, most of which are NFP-ir, easily distinguish this area from areas 23a and 30. Finally, the distinctions between areas 23a and 23b are enhanced by the extensive size and number of NFP-ir neurons throughout layers IIIab and IIIc in area 23b.

The differentiation of the retrosplenial areas from parahippocampal areas has been elegantly shown

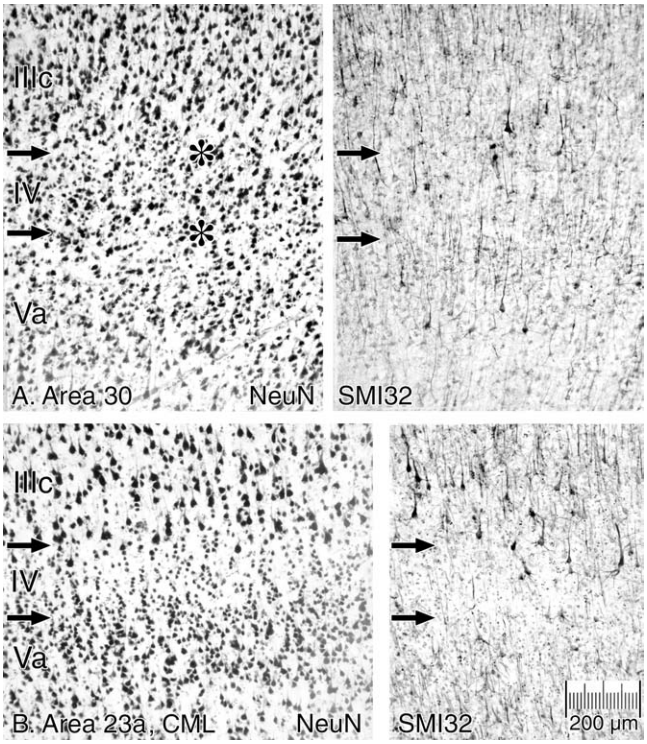

FIGURE 24.19 Area 30 dorsal to the splenium in the cas is compared with area 23a on the CML because no equivalent to area 30 has been identified in this latter region. The dysgranular nature of area 30 is emphasized at a point where layer IIIc and Va neurons intermingle (to the right of the double asterisks in A; NeuN). Area 30 also has a layer IV with many small and medium-sized NFP-ir neurons (SMI32). In contrast, area 23a has no neuron bridges across layer IV and only occasional solitary NFP-ir neurons in layer IV. Layer IIIc in area 23a has larger and more dense NFP-ir neurons than for area 30.

with immunohistochemical analyses of coronal sections in the monkey by Berger *et al.* (1997). This latter study showed that in the cas there is an arch of neurotensinergic neurons in the deep layer of areas 29 and 30, and the elaboration of these areas and their apposition to parahippocampal areas 27 and the parasubiculum. Although the retrosplenial and presubicular/parasubicular areas abut in the callosal sulcus just ventral to the splenium, in the human there is an intermediate level of transition between the posterior cingulate and more lateral parts of parahippocampal cortex. Ventral to posterior cingulate and retrosplenial cortices are two divisions of posterior parahippocampal cortex that share features with area 36. Area 36 has well-defined layers II and Va and a dense layer VI. Layer III is broad, and the pyramidal neurons are relatively uniform in size (Vogt *et al.*, 2001). The division of layer III into a superficial layer IIIab and deeper layer IIIc is possible, although

the neurons in layer IIIc do not reach the size and dispersion characteristic of the cingulate neocortical areas. The relative density of neurons in layer IV of area 29m increases around the splenium and to its termination either in the ventral part of the cas or the rostral lip of the CML/CMSR. The transition at this point is with area 36'v. The NFP-ir plexus in layers III and IV are apparent and disappear as area 29m merges with area 36'v. Area 36'v only has a NFP-ir plexus in layer V. Features of area 36'v that distinguish it from area 29m include broad layers II–III composed of more uniform, medium-sized pyramidal neurons, a poorly defined layer IV, and an infragranular layer dominated by a uniform layer V and a narrow layer VI.

Subregional Postsplenial Flat Map

Cytoarchitectural studies of human cortex require flat map reconstruction of the areas identified because 50% or more of the cortical surface is in the sulci, and this is particularly true for the posterior cingulate region. A flat map of the entire cingulate gyrus in which the fundus of the cas is represented and areas 29 and 30 are plotted on the ventral CG is available (Vogt *et al.*, 1995). As is true for flat maps of the entire brain, however, flat maps of the entire cingulate cortex result in significant distortions in all areas owing to the need to warp all areas to fit a two-dimensional space and still retain basic gross morphological relationships. Subregional flat maps alleviate this problem because they are limited to a subsector of cingulate cortex, flattening is performed in only one direction rather than two, and it is not influenced by flattening in other parts of cingulate cortex to form a full map. von Economo (1929, Fig. 58) provided the first posterior cingulate subregional map, although it was not flattened.

Figure 24.20 shows a case in which postsplenial cortex was sectioned in the plane of the flat map reconstruction to ensure precision in relating features on the map to histological observations. Asterisks on the convoluted surface on the left are used to orient the flat map at the right. The first one is at the cas and emphasizes that flattening was started at the fundus of the cas, while the second asterisk shows the rostral edge of the transitional PHG in both drawings. The depth of the cas was determined according to the curvature of the splenium and each area was represented according to the length of a line drawn through each area at a midcortical level between layers IV and V. Heavy lines in Figure 24.20 represent cortex on the ventral PCG (i.e., cortex in the cas) and the caudal edge of the CML, while in the ventral part of the map they represent the rostral and caudal limits of the

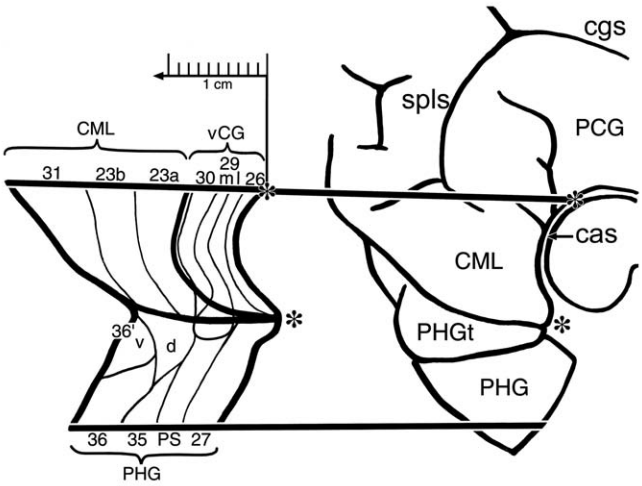

FIGURE 24.20 Subregional postsplenial flat map including the entire CML. This is a linear (one-dimensional) expansion of posterior cingulate, retrosplenial, and parahippocampal cortices in a single direction noted by the arrow on the scale bar (i.e., caudal from the fundus of the cas). The dorsal asterisk in the drawing on the right extends from the depths of the cas to an equivalent starting point on the flat map on the left, and the same is true for the rostral edge of the PHG/PHGt. Areas on the vCG are enclosed by thick lines on both sides of the callosal sulcus, while those on the gyral surface are extended to the left on the CML. The locations and interrelationships of RSC and transitional parahippocampal areas are clear with a transitional PHG.

PHGt and PHG. The direction and calibration of flattening in this case is shown with the arrow and scale bar, respectively. This map shows that almost all of RSC is on the ventral PCG in the cas. Area 30 ends just dorsal area 29m, and this case has a small termination of area 30 on the rostral edge of the CML. Because standardized atlases based on Brodmann's map show that most of the CMR is comprised of area 30, it is of interest to determine the actual extent of area 30 on the CML in this case. Because the map was flattened in only one dimension, it accurately represents the relative surface area for each area on the CML and cortex on the ventral CG. The surface area occupied by each cortical area was calculated directly from the flat map (Vogt *et al.*, 2001). Area 30 comprises 0.8% of CML, while it is 33% of area on the ventral CG at the level of the CML. In contrast, area 29m comprises 2.8% of the rostral edge of the CML, while it is 26% of cortex on the ventral CG. Thus, both areas 30 and 29m are almost entirely located within the cas, and all of areas 29l and 26 are in this sulcus. Finally, the PHGt contains a small rostral extension of area 29m and areas 36'd and 36'v, and neither area 29m or 30 appeared on the CML. Thus, area 30 does not comprise a substantive part of the CML.

COMPARISON OF THE BRODMANN AREAS WITH RECENT MODIFICATIONS THEREOF

Because only about 50% of the human cortical surface is represented on the convoluted brain surface, Brodmann had to make many compromises to render his interpretations of the entire cortex. The ectogenual, ectosplenial, and retrosplenial areas are buried within the callosal sulcus on the ventral bank of the cingulate gyrus. Indeed, area 24a extends into the callosal sulcus as well. Although one might imagine that Brodmann's area 24 extends into the cingulate sulcus, is that also true for area 32? What is the relationship between area 32 and the depths of the anterior cingulate sulcus? Area 24 is not uniform in either rostrocaudal or ventrodorsal orientations, and this has been documented in a number of species with architectural, connection, immunohistochemical, ligand binding and transmitter systems, and functional imaging analyses. Although the composition of the dorsal and ventral banks of the cingulate sulcus are a matter of conjecture for the Brodmann map, the assessment provided over the past 25 years by many investigators shows that it is comprised of areas 32, 32', 24c, 24c', 24d, and 23c. Each of these areas has a precise definition that is not just morphologically correct but also exacting in terms of their projections to the spinal cord and throughout the cerebral cortex, and the neuropsychological conditions under which they are most active.

Even when the same numerical designation has been used in the Brodmann and Vogt maps, there can be important differences in the topology of each area. Consider area 31 as an example. Although the centroid for area 31 is located on the splenial sulci and its architecture is easily defined, the monkey area 23 differentiates beyond the a/b designation on the gyral surface and forms area 23c in the ventral bank of the caudal cingulate sulcus that was not recognized by Brodmann. In this situation, the rostral border of area 31 is extended caudally, and area 23b extends dorsally to the level at which the marginal ramus is emitted from the cinguate sulcus. Thus, our area 31 does not extend as far rostral as does Brodmann's area 31. In another example, Brodmann's areas 29 and 30 completely surround the splenium and abut the parahippcampal areas, while our areas 29 and 30 extend more rostrally dorsal to the splenium and terminate caudally at a level that is adjacent but not ventral to the splenium. Finally, the structure of caudomedial cortex is very important, particularly in light of its reciprocal connections with pACC and functional imaging findings. One interpretation of Brodmann's area 30 is that it forms much of the CML and that areas 23 and 31 are excluded from this region. Our analysis of the cytoarchitecture of this region shows that areas 23a, 23b, and 31 form the surface of the CML, while the rostral bank of the CML is formed by areas 29l, 29m, and 30.

In conclusion, when an area of activation or other functional entity fully encompasses the location and extent of Brodmann's areas, "BA" designations are appropriate. However, when functional sites reflect a–c divisions of areas 24 or 23 or an area not recognized by Brodmann such as areas 23c, 24c', 25r/c, 32', 33', 29m, 29l, it is appropriate to use the designation "A" for area without the "BA." This provides a flexible nomenclature that can be modified over the coming decades in light of new anatomical and functional studies.

CORTICAL DIFFERENTIATION IN POSTERIOR CINGULATE GYRUS

Descriptions of a cortical region are most helpful when considered in terms of fundamental patterns of organization rather than only the unique features of a particular area. For example, area 29 has fewer than six layers, and simply counting from I to IV does not indicate which layers contain large ganglionic neurons similar to those in layer V, which layers contain primarily corticocortical projection neurons and are similar to layer III in other areas, nor which are most likely to receive thalamic afferents. Although one might speculate that such layers have no continuity or relationship with those in isocortex, this does not appear to be the case because layers of cortical neurons share common embryonic origins and axonal projections. From a developmental perspective, Nowakowski and Rakic (1981) showed that neurons in the hippocampus and deep layers of entorhinal cortex are generated in the subventricular zone. Thus, neurons throughout the indusium griseum and deep layers of the ventral bank of the cingulate gyrus likely share a similar origin. Furthermore, common projection sites provide another means of associating neurons in two different areas. The projections of layer VI neurons throughout the cingulate gyrus and including the retrosplenial areas are to the thalamus as shown in the monkey (Baleydier and Mauguiere, 1985). Thus, the deep layers of retrosplenial cortex share similarities in origin and projections that allow one to conclude that they are part of a similar differentiation scheme. Indeed, the concept of cortical differentiation is based on the principle that a common motif can be identified for all cortical areas such as layer V upon which

cortical differentiation proceeds to culminate in a fully elaborated isocortex.

Each area on the cingulate gyrus is transitional in nature because every area shares the cytoarchitectural features of its two or more neighbors. When there are transitions between cingulate and adjacent frontal or parietal cortices, the term transition designates the cingulofrontal transitional area 32 and the cingulo-parietal transitional area 31, respectively. Rather than speak in terms of transition from the perspective of single areas, we use this concept in relation to broad trends of cortical differentiation. Many students of cytoarchitecture have considered cortical trends of differentiation in the cingulate gyrus (e.g., von Economo and Koskinas, 1925; Vogt, 1976; Braak, 1979a; Braak and Braak, 1993), and this includes progressive alterations throughout the ectosplenial, retrosplenial, and posterior cingulate regions. The process begins with a substratum of densely packed neurons in the internal pyramidal layer. This stage is followed by the addition and differentiation of a granular external pyramidal and ends in the parietal and occipital association areas. A second trend includes the rostral agranular cortex and begins with the ectogenual areas and progresses through a differentiation pattern leading to the cingulate motor and supplementary motor areas. Here we consider some of the main issues related to transition on the posterior cingulate gyrus. The concepts of cortical differentiation are difficult conceptual issues as is their relation to ontogenetic events. Consult Chapter 27 for a thorough consideration of these issues.

Dysgranular Concept and Transition

At each point of transition from allocortex to isocortex throughout the primate telencephalon, there is at least one area with the features of a dysgranular cortex, and this is why the character of area 30 is important. In the insula, neurons in layer IV form islands as is characteristic of a layer that is of irregular thickness (Mufson *et al.*, 1997), while orbitofrontal cortex has an intermediate area with a thin layer IV, which can be difficult to detect where the layer III and V pyramids are particularly large (Hof *et al.*, 1995). Since we view area 30 as the dysgranular equivalent in posterior cingulate cortex, early perspectives need to be considered. Brodmann (1909) referred to area 30 as agranular, and von Economo and Koskinas (1925) were quite explicit in stating that area LD is not just agranular but that the "granulous" layer of area LE (Brodmann's area 29) is not continuous with the isocortical layer of area LC2 (Brodmann's area 23). Although there is no doubt that layer III/IV in area 29 is not equivalent to layer IV in area 23a, the following three points need to be considered. First, von Economo (1929, Fig. 50) vacillated on the presence of a layer IV in LD and showed a layer III(IV) below layer III therein. Second, the granular layer IV of area 29m is continuous with layer IV in area 30 and layer IV in area 23a with both NeuN and a negative image in an SMI32 preparation (Vogt *et al.*, 2001, Fig. 8). This does not mean that layer IV in each area is equivalent; however, von Economo's statement that they are not continuous is not supported. Finally, the dysgranular concept for a cortical area was not established during the early years of cytoarchitectonic analysis nor were immunohistochemical techniques available to clarify the concept. It is not surprising, therefore, that the dysgranular structure of area 30/LD was not appreciated by early neuroanatomists.

The dysgranular nature of area 30 in monkey and human brains has been documented with Nissl, Golgi, and immunohistochemical techniques (Vogt, 1976; Vogt *et al.*, 1995, 1997). Figures 24.15 and 24.19 show that layer IV is of variable thickness with points at which layers IIIc and Va join via neuronal bridges across layer IV, and a recent study demonstrated the dysgranular structure of layer IV in RSC using photomontages along the full lateromedial extent in area 30 (Vogt *et al.*, 2001). Another example of a dysgranular cortex is in ACC where area 32, which sits at the juncture of anterior cingulate and prefrontal cortices, was shown to have islands of neurons in layer IV (Vogt *et al.*, 1995). Thus, dysgranular cortices are both part of the transition of PCC as well as transitions to frontal cortical areas.

Retrosplenial Differentiation Pattern

The pattern of retrosplenial cortical differentiation is obvious in both the human and macaque monkey, and SMI32 preparations are particularly useful in demonstrating these patterns of change because the large pyramidal neurons are often NFP-ir. To the extent that NeuN preparations do not react with glial and endothelial elements, it is possible to analyze selectively small neurons in layers II and IV that contribute to the patterns of differentiation. Figure 24.21 provides a series of photographs through each area on the ventral bank of the PCG that are aligned at the border of layers III/IV and V or layers IV and V. The cell-dense layer of the indusium griseum and subiculum are NFP-ir. The addition of layer III/IV in area 26 is as prominent a change as is the overall reduction in the number of neurons in the deep layer. In area 29l, layer III/IV becomes less neuron-dense and the neurons are larger. The deep layer V is also

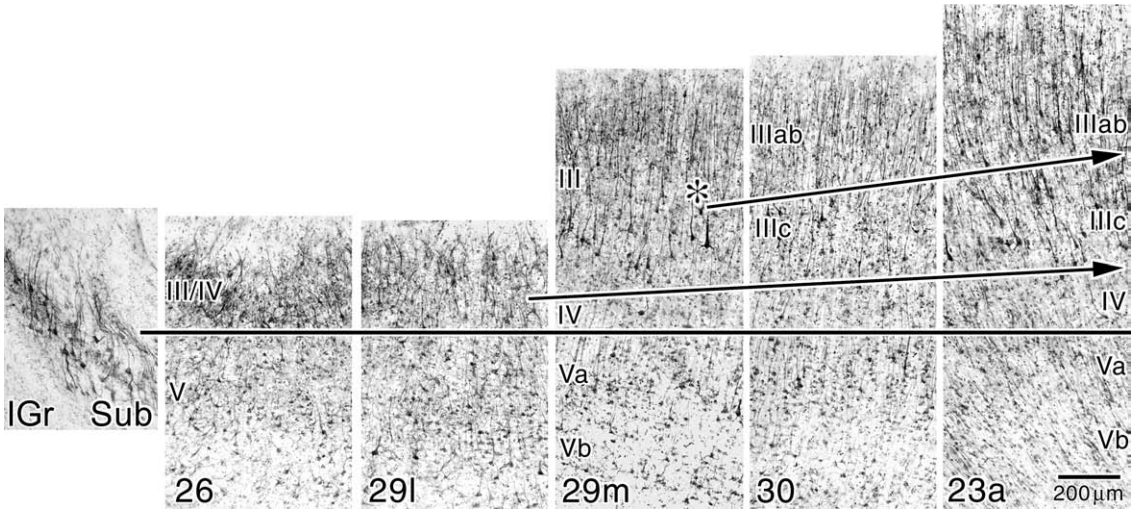

FIGURE 24.21 Cortical transition in humans is best shown for large neurons that are NFP-ir. Area 26 has an external granular layer and only a modest number of pyramids in deep layers. Differentiation of layer III/IV into layers III and IV occurs in area 29m. The asterisk marks the medial part of area 29m where a few large layer IIIc pyramids are first observed. The arrows in superficial layers draw the eye through the transitional events in areas 29m, 30, and 23a as discussed in the text.

populated by many more large and NFP-ir neurons than is true for area 26. Radical changes in morphology occur in area 29m including the addition of a thick layer of medium-sized to large pyramids in layer III, definition of a layer IV, and elaboration of layer Va. Some of the neurons in layer III are so large in the medial part of area 29m that they may presage those of layer IIIc in area 30 as shown in Figure 24.21 at the asterisk. Finally, layer III differentiates in area 30 in parts ab and c and in area 23a layer IV thickens to form an isocortical granular layer.

Elaboration of neuronal architecture and packing in layers II and IV are evident in the NeuN preparations where all neurons are immunoreactive rather than just a subset of large, NFP-ir pyramidal neurons. Figure 24.22 shows the ectosplenial, retrosplenial, and posterior cingulate areas aligned at the top of layer Va. The progressive elaboration of layer III/IV is evident, and it is even possible to identify a layer IV in area 29l that has not been done previously. It appears this differentiation is apparent in Figure 24.22 because a higher level of contrast was applied to the photographic reproduction to highlight neuronal somata. A parvicellular layer is clear in area 29m, and it becomes more pronounced in areas 30 and 23a. The demonstration of layer II addition over layer III is made by selecting the point in area 30 where layer II first appears as indicated with the asterisk. The lancet shape of these neurons appears in area 23a where layer IIIc also reaches a high degree of differentiation in contrast to the plump layer II neurons in area 30. The highest level of differentiation of layers IIIc and IV occurs in area 31. Although not shown in this figure, an SMI32 preparation of area 31 is magnified in Figure 24.17, as noted later. Thus, a combination of immunohistochemical techniques provides a compelling view of different aspects of cortical transition in the human posterior cingulate gyrus and provides a rationale for the nomenclature of each layer.

Area 31: Pinnacle of Cingulate Isocortical Differentiation

Area 31 represents the culmination of two important trends in cingulate cortical transition. The first differentiation trend is that of layer IIIc with a unique neuronal phenotype, and it is observed in the rostrocaudal dimension on the cingulate gyrus. Beginning with the anterior region, there is a progressive increase in the number of large layer III pyramidal neurons. Area 24 has only an undifferentiated layer III; area 24′ has more large neurons in this layer with progressively higher numbers of NFP-ir neurons, but there is only a decrease in neurons density and not a well-defined layer IIIc with large pyramidal neurons. Area 23 has a fully developed layer IIIc and a moderate to high density of NFP-ir neurons in this layer. Area 31 caps this trend with the most extensive layer IIIc and the highest density of NFP-ir neurons on the medial surface (Fig. 24.17). The second differentiation trend is that of layer IV, which occurs in the ventrodorsal dimension on the cingulate gyrus. This trend starts with layer III/IV of area 26. Layer III/IV of areas 26 and 29l differentiate into

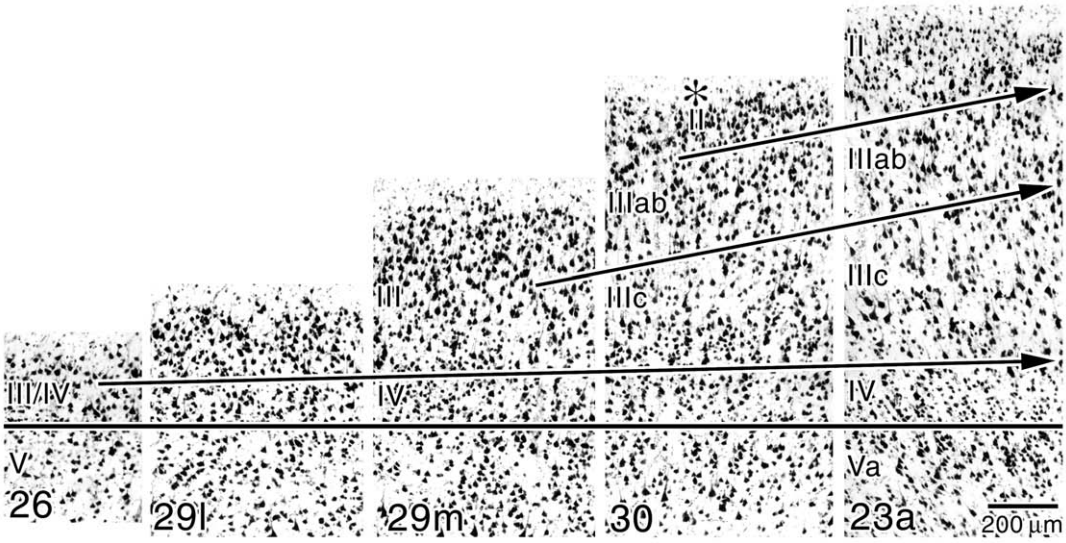

FIGURE 24.22 High-contrast prints of NeuN-immunoreacted tissue show changes in the superficial layers of the human retrosplenial areas that are not evident in SMI32—particularly layers II, IIIab, and IV that have few or no NFP-ir neurons. The rationale for not terming the granular layer of areas 26 and 29 layer II–IV is apparent; layer II is not present until the medial part of area 30 (asterisk, II). Differentiation of the superficial layers in terms of neuron densities and cell shapes is noteworthy in layer II where the plump versus lancet-shaped pyramids of areas 30 and 23a, respectively, are shown. Arrows are oriented to emphasize the direction of cortical transition and do not always fall on each laminar border.

layers III and IV in area 29m, while in area 30 there is the dysgranular layer IV. In area 23, layer IV reaches the isocortical thickness, but in area 31, layer IV is at the maximal thickness and overall neuron density. Thus, area 31 is the final and most differentiated form of granular cingulate cortex, and it forms the superior and caudal parts of the posterior cingulate gyrus.

THE FUTURE FOR CINGULOCENTRIC HYPOTHESES AND RESEARCH

One of the most frequently asked epistemological questions for a neuroscientist with interests in the structure and functions of cingulate cortex is: Why study cingulate cortex and what can be learned from such an undertaking? This question belies the fundamental sampling bias that pervades modern neuroscience with its emphasis on regions with neuronal discharges that are apparently simple and related to single sensory or motor events. For decades neurosurgeons ablated parts of cingulate cortex for the relief of pain and various psychiatric disorders such as obsessive-compulsive disorder and depression, yet research into the physiology of pain and premotor processing was limited to assessing the coding of noxious somatic stimuli in primary and secondary somatosensory cortices and the movement in primary and secondary motor cortices that have no known role in affect and motivation. The cingulocentric viewpoint brings new hypotheses to the scientific enterprise that are not possible in areas where motivation and affect are of little or no relevance. In another example, it is often striking to students of Alzheimer's disease that the cingulate gyrus would be of any interest to uncovering the etiology of this disease. Indeed, the first region to show glucose hypometabolism in patients suffering with their first memory deficit is posterior cingulate cortex (Minoshima *et al.*, 1997)—not entorhinal cortex as most would predict. At this point, the question might be reversed: Why would one study entorhinal cortex in individuals who have early signs of memory loss? Furthermore, there are cases of definite Alzheimer's disease with early signs of frontal lobe damage. Might it not make sense to study prefrontal cortex in these cases (Johnson *et al.*, 1999) and the cingulate motor areas (Vogt *et al.*, 1999)?

Indeed, the long-term consequences of precision anatomy and neurophsyiological studies of cingulate cortex are an understanding of many neurological and psychiatric diseases. There is substantial evidence that cingulate cortex is involved early in many diseases including Alzheimer's disease, schizophrenia, chronic pain, obsessive-compulsive disorder, irritable bowel syndrome, trigeminal neuralgia, post-traumatic stress disorder, and depression. Therefore, the challenge for research with a cingulocentric bias is to find the fundamental mechanisms of neurodegeneration and, ultimately, identify therapies that will stop disease progression by acting directly on the primary cause of each disease, possibly expressed in cingulate cortex.

Dedication and Acknowledgments

Dr. Brent A. Vogt would like to dedicate this work to his intellectual mentors: Dr. Helen Mahut at Northeastern University, Drs. Deepak N. Pandya and Gary W. Van Hoesen at the Harvard Neurology Unit of Boston City and Beth Israel Hospitals, and Drs. Alan Peters and Douglas L. Rosene at Boston University School of Medicine. Each provided the challenge, intellectual framework, resources, and understanding needed to undertake a lifetime study of the structure, functions, and pathologies of cingulate cortex.

The materials prepared, analyzed, and illustrated in this chapter were supported in part by NIH NINDS grants #NS38485 and #NS44222 (BAV) and NIA grant #AG05138 (PRH). We are grateful to Linda Arcure and Will Safrit for their assistance preparing the illustrations.

In primate brains, the frontal cortex is the part of the cerebral mantle that lies anterior to the central sulcus and superior to the lateral (Sylvian) fissure. The sulcal and gyral morphology of the human cerebral cortex was the subject of intense investigation in the late 19th century culminating in the excellent surveys of Eberstaller (1890) and Cunningham (1892). It continued to be the focus of research during the first half of the 20th century (e.g., Landau, 1911, 1914; Shellshear, 1926, 1937; Connoly, 1950) but was relatively neglected during the latter part of this century, with some exceptions (e.g., Ono *et al.*, 1990). While standard textbooks of neuroanatomy and neuroradiology usually provide an adequate description of the sulci that define the precentral gyrus and the caudal part of the inferior frontal gyrus (i.e., the motor and premotor cortex and Broca's speech region, respectively), large parts of the remaining frontal cortex are described in terms of only a few sulci and gyri (e.g., superior frontal sulcus and inferior frontal sulcus).

The development of functional neuroimaging in recent years, leading to the demonstration of specific activation foci in many different parts of the human cerebral cortex, has given rise to the need for a more detailed description of the sulcal and gyral patterns of the human cerebral cortex than has typically been provided in recent textbooks of neuroanatomy. Consequently, the first part of this chapter will provide a description of the sulcal and gyral pattern of the cortex of the human frontal lobe. This description is based on the classical studies, as well as recent investigations in our laboratory of the sulcal and gyral patterns of the sulci of the frontal lobe. The second part of this chapter will provide a description of the cytoarchitectonic organization of the human prefrontal cortex. For a description of the motor and premotor cortex, see Chapter 26, and for the cingulate region, see Chapter 24. Finally, the third part of this chapter will briefly summarize current knowledge of the corticocortical connection patterns of the different prefrontal areas

based on experimental anatomical studies on the macaque monkey.

SULCAL AND GYRAL MORPHOLOGY OF THE FRONTAL CORTEX

Lateral Surface of the Frontal Lobe

The Precentral Region

The caudal limit of the frontal lobe is defined by the central sulcus (Figs. 25.1 and 25.2), a sulcus that runs in a primarily dorsoventral but more-or-less oblique direction, its dorsal end lying in a more posterior location than its ventral end. The superior (sprs) and inferior (iprs) precentral sulci that lie rostral to the central sulcus (cs) and, like the central sulcus, maintain a primarily dorsoventral direction define the rostral limit of the precentral gyrus (PrG). The central sulcus does not usually reach the lateral fissure and is separated from it by a short gyrus, the subcentral gyrus (SCG), which is formed by the fusion of the precentral and postcentral gyri in their ventralmost parts. This gyrus is also known as the central (Rolandic) operculum

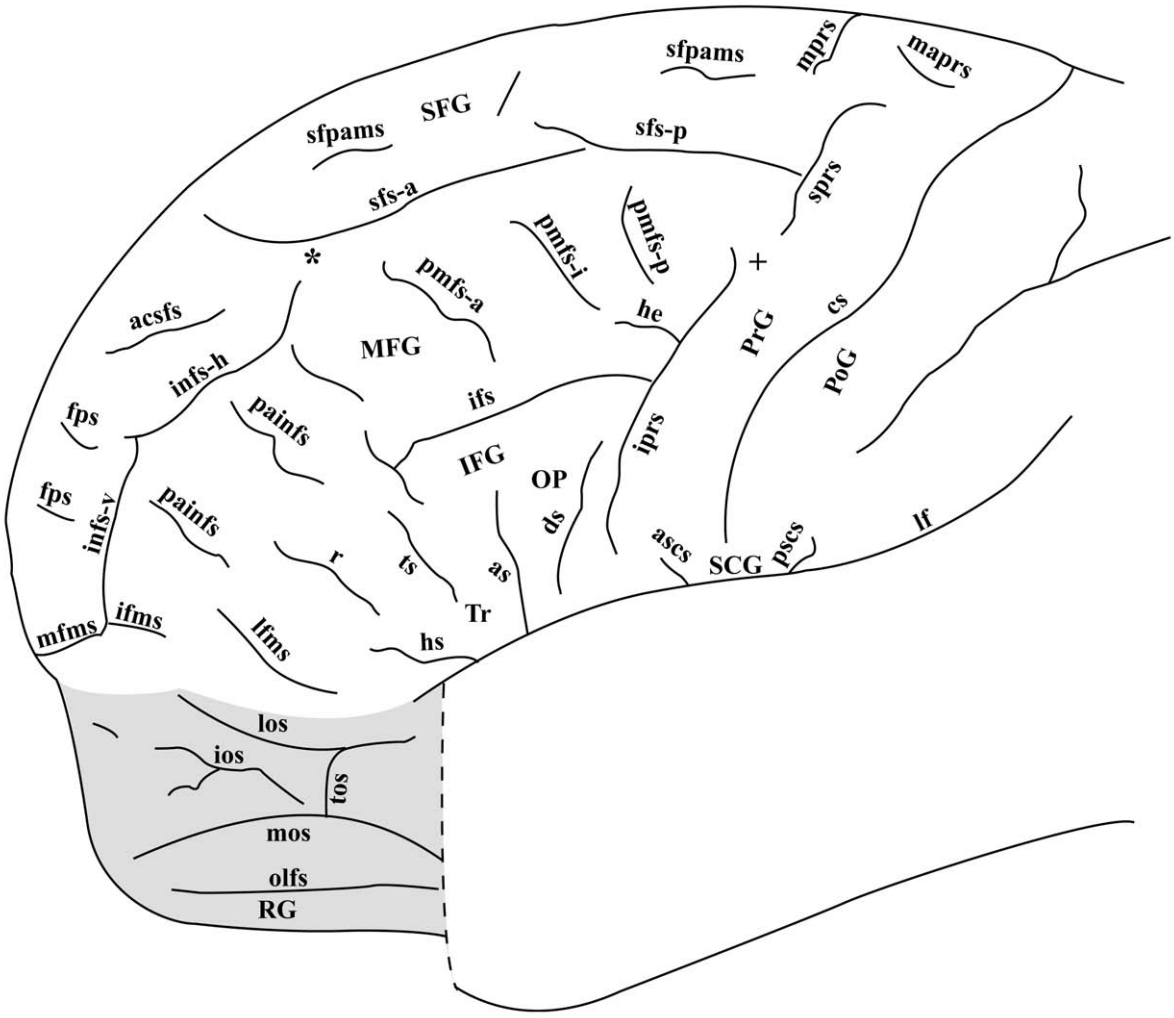

FIGURE 25.1 Diagrammatic representation of the lateral and orbital surfaces of the frontal lobe of the cerebral hemisphere to illustrate the location of the various sulci. The orbital surface is shaded in gray. Abbreviations: as, ascending sulcus (ascending ramus of the lateral fissure); acsfs, accessory superior frontal sulcus; ascs, anterior subcentral sulcus; cs, central sulcus; ds, diagonal sulcus; he, horizontal extension of the inferior precentral sulcus; hs, horizontal sulcus (horizontal ramus of the lateral fissure); infs-h, horizontal part of the intermediate frontal sulcus; infs-v, vertical part of the intermediate frontal sulcus; IFG, inferior frontal gyrus; ifms, intermediate frontomarginal sulcus; ifs, inferior frontal sulcus; ios, intermediate orbital frontal sulcus; iprs, inferior precentral sulcus; lf, lateral fissure; lfms, lateral frontomarginal sulcus; los, lateral orbital frontal sulcus; mfms, medial frontomarginal sulcus; mos, medial orbital sulcus; mprs, medial precentral sulcus; maprs, marginal precentral sulcus; MFG, middle frontal gyrus; pscs, posterior subcentral sulcus; olfs, olfactory frontal sulcus; OP, opercular part of inferior frontal gyrus (pars opercularis); RG, gyrus rectus; SFG, superior frontal gyrus; painfs, paraintermediate frontal sulci; pmfs-a, anterior posterior middle frontal sulcus; pmfs-i, intermediate posterior frontal sulcus; pmfs-p, posterior posterior frontal sulcus; PrG, precentral gyrus; SCG, subcentral gyrus; sfpams, superior frontal paramidline sulci; sfs-a, anterior branch of superior frontal sulcus; sfs-p, posterior branch of superior frontal sulcus; sprs, superior precentral sulcus; tos, transverse orbital sulcus; Tr, triangular part of inferior frontal gyrus (pars triangularis); ts, triangular sulcus; r, radiate sulcus of Eberstaller.

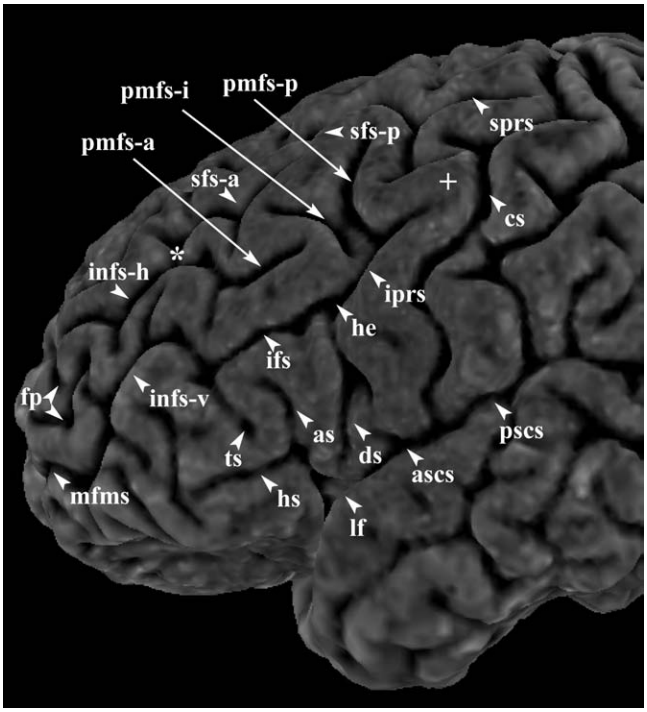

FIGURE 25.2 Three-dimensional reconstruction of the lateral surface of the frontal lobe based on a magnetic resonance image of a single human brain to illustrate the sulci. Abbreviations as in Figure 25.1.

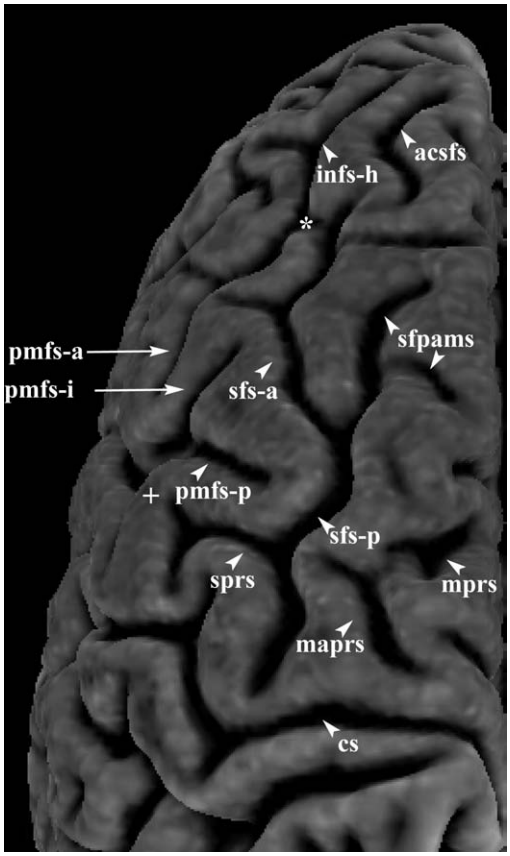

FIGURE 25.3 The dorsal view of the brain illustrated in Figure 25.2 to show the sulci in the dorsal frontal region. Abbreviations as in Figure 25.1.

or the inferior frontoparietal pli de passage. The subcentral gyrus is delimited in front and behind by the anterior (ascs) and posterior (pscs) subcentral sulci, respectively (Figs. 25.1 and 25.2). In some hemispheres, the subcentral gyrus is situated deep within the lateral fissure; in those cases, the central sulcus gives the impression of joining the lateral fissure (Fig. 25.2).

The superior and inferior precentral sulci form the rostral limit of the precentral gyrus and the caudal limit of the superior, middle, and inferior frontal gyri (SFG, MFG, IFG in Fig. 25.1). The inferior precentral sulcus, which is the longer one of the two precentral sulci, originates near the lateral fissure and courses dorsally for a considerable distance reaching the posterior margin of the middle frontal gyrus. The superior precentral sulcus lies, generally, caudal to the dorsalmost point of the inferior precentral sulcus and is often separated from it by a narrow gyral passage that joins the caudal part of the middle frontal gyrus with the precentral gyrus (see + in Figs. 25.1 and 25.2). In a few cases, this narrow gyral passage may be submerged; in those cases, the inferior and superior precentral sulci may fuse superficially giving the impression of a single uninterrupted sulcus. Frequently, there is a more or less horizontally directed extension (he) of the inferior precentral sulcus projecting into the middle frontal gyrus just above the caudal part of the inferior frontal sulcus (see Fig. 25.1). This short ramus sometimes merges with one of the adjoining sulci. In the brain shown in Figure 25.2, the horizontal extension (he) veers medially and merges with the inferior frontal sulcus (ifs) and can only be distinguished in coronal and horizontal sections through this region.

The superior precentral sulcus is shorter than the inferior precentral sulcus and frequently merges with the superior frontal sulcus. In some brains, a part of the superior or the inferior precentral sulcus may be separated; in these cases, one may speak of an intermediate precentral sulcus. However, this is not a useful distinction, and the separated part is best considered as belonging to either the superior or the inferior precentral sulcus.

Dorsal to the superior precentral sulcus, there is often a small dimple that Cunningham labeled the "sulcus precentralis marginalis" (maprs in Figs. 25.1 and 25.3). Rostral to this dimple and often cutting into the medial surface of the hemisphere is the "sulcus precentralis medialis" of Eberstaller. The medial precentral sulcus (mprs in Figs. 25.1 and 25.3) is not

really a medially located sulcus but rather a small sulcus located at the midline of the hemisphere that may extend for a variable distance onto the medial surface of the brain.

The Superior Frontal Gyrus

Anterior to the precentral gyrus, the gross morphology of the lateral surface of the frontal lobe is characterized by three horizontally directed gyri: the superior, middle, and inferior frontal gyri. The superior frontal sulcus is the lateral limit of the superior frontal gyrus (Figs. 25.1, 25.2, and 25.3). Rostral to its point of intersection with the superior precentral sulcus, the superior frontal sulcus runs in a more or less horizontal direction and in its rostral end approaches the midline of the hemisphere. Thus, the rostral end of the superior frontal sulcus is more medially located than its caudal end. The superior frontal sulcus is not a continuous sulcus but consists of two main branches that are either separated on the surface of the brain by an anastomotic fold or can be separated in the depths of the sulcus as can be seen in coronal or horizontal sections. Thus, one can speak of a posterior (sfs-p) and an anterior (sfs-a) superior frontal sulcus (Figs. 25.1, 25.2, 25.3). Rostral to the anterior branch of the superior frontal sulcus, there may be an additional short sulcus that we have called the accessory superior frontal sulcus (acsfs in Figs. 25.1 and 25.3).

The superior frontal sulcus is a deep sulcus that can clearly be identified in coronal or horizontal sections of the brain. Within the superior frontal gyrus, a number of shallow sulci are located approximately halfway between the midline of the brain and the superior frontal sulcus. Sometimes these shallow sulci have been referred to as the "medial frontal sulci" (e.g., Ono *et al.*, 1990), but this is a misnomer as these sulci are *not* lying on the medial surface of the hemisphere. We refer to them as the superior frontal paramidline sulci because they are located next to the midline of the hemisphere in the superior frontal gyrus (sfpams in Figs. 25.1 and 25.3).

The Middle Frontal Gyrus

The middle frontal gyrus is a wide gyrus that lies between the superior and the inferior frontal sulci, rostral to the precentral gyrus. The sulci of the middle frontal gyrus have generated a lot of confusion in the anatomical literature. In the anterior part of the middle frontal gyrus lies a deep sulcus that has been referred to as the middle frontal sulcus or the intermediate frontal sulcus. This sulcus was studied in detail by Eberstaller (1890). It originates in the rostral part of the middle frontal gyrus and runs in a horizontal direction initially (infs-h) and then veers ventrally (infs-v) to reach the medial frontomarginal sulcus (mfms) at the lower edge of the frontal pole (see Figs. 25.1 and 25.2). The horizontal and the vertical branches can be separate is some cases. The caudal end of the middle frontal sulcus begins close to the rostral end of the superior frontal sulcus. There is usually a narrow gyral passage that separates them (see * in Figs. 25.1, 25.2 and 25.3). In several cases, this narrow gyral passage may be collapsed; in these cases, the intermediate frontal sulcus may give the impression of joining the superior frontal sulcus. The superficial joining of these two sulci may lead to confusing the middle frontal sulcus as a continuation of the superior frontal sulcus when one relies on surface inspection of a brain. For instance, Ono *et al.* (1990, p. 51) reported that the superior frontal sulcus connects with the frontomarginal sulcus in 16% of the cases in the right hemisphere and 44% of the cases in the left hemisphere. In our studies, the superior frontal sulcus was never observed to join the frontomarginal sulcus, and we could always distinguish the anterior end of the superior frontal sulcus from the posterior end of the intermediate frontal sulcus in coronal or horizontal sections. Therefore, the statement that the superior frontal sulcus joins the frontomarginal sulcus in some cases has probably resulted from confusion of the intermediate frontal sulcus as a continuation of the superior frontal sulcus.

The anterior part of the middle frontal gyrus can be thought of as being divided into a dorsal and a ventral middle frontal tier by the horizontal part of the intermediate frontal sulcus. The caudal part of the middle frontal gyrus is divided into several smaller gyri by various short sulci that have not been the focus of an investigation before. In our recent examination of the sulcal patterns of the frontal lobe, three short sulci could usually be identified in the posterior middle frontal gyrus. These posterior middle frontal sulci are quite variable in their directions and may merge with each other creating confusing patterns. We have referred to these three sulci as the posterior (pmfs-p), the intermediate (pmfs-i), and the anterior (pmfs-a) posterior middle frontal sulci, proceeding in a caudorostral direction (Figs. 25.1, 25.2, and 25.3). The posterior and intermediate posterior middle frontal sulci can be more or less vertically oriented and directed toward the inferior precentral sulcus (Figs. 25.1, 25.2, and 25.3). It should be noted that a considerable extent of the frontal cortical region lies in the depth of the horizontal extension of the inferior precentral sulcus. Eberstaller (1890) noted that this is the deepest part of the lateral frontal cortex. The anterior posterior middle frontal sulcus is a sulcus that varies considerably in its direction and may approach the superior frontal sulcus and merge superficially with it.

Another set of short sulci can be identified in the anterior part of the middle frontal gyrus running next

to and lateral to the intermediate frontal sulcus. These sulci we refer to as the paraintermediate frontal sulci (painfs in Figs. 25.1 and 25.2). The dorsal one runs in a more or less vertical direction and lies just behind or below the caudal end of the intermediate frontal sulcus.

The Inferior Frontal Gyrus

The inferior frontal gyrus constitutes a large part of the ventrolateral surface of the prefrontal cortex. It is delimited dorsally by the horizontally directed inferior frontal sulcus (ifs) and ventrally by the rostral part of the lateral fissure (Figs. 25.1 and 25.2). In a caudorostral direction, the inferior frontal gyrus can be divided into three parts: the pars opercularis, the pars triangularis, and the pars orbitalis. The pars opercularis is delimited caudally by the inferior precentral sulcus and rostrally by the ascending sulcus (as; i.e., the ascending ramus of the lateral fissure). The pars triangularis lies between the ascending sulcus and the horizontal sulcus (hs), also known as the horizontal ramus of the lateral fissure. The pars orbitalis lies ventral to the horizontal sulcus as far as the lateral orbital sulcus. The pars opercularis is seen usually as a vertically oriented gyrus that is subdivided into a rostral and a caudal part by the diagonal sulcus (ds). In different brains, a variable extent of the caudal part of the pars opercularis is submerged into the inferior precentral sulcus (see Tomaiuolo *et al.*, 1999). Depending on the curvature of the pars opercularis and how much of it stays on the surface of the brain, the diagonal sulcus may appear to lie in the middle of the pars opercularis clearly separating it into two parts, or it may appear to join any of the surrounding sulci.

Within the pars triangularis, there is usually a small sulcus, the triangular sulcus (ts), also known as the incisura capitis. There may be an additional more rostrally located sulcus that is directed toward the pars triangularis, which Eberstaller (1890) named the sulcus radiatus (r). The inferior frontal sulcus originates, caudally, close to the inferior precentral sulcus; in many cases, there is a clear separation between these two sulci. In other cases, the narrow bridge of cortex that separates them may be submerged, and the inferior frontal sulcus and the inferior precentral sulcus merge superficially. Eberstaller (1890) pointed out that the inferior frontal sulcus extends rostrally until about the midportion of the dorsal edge of the pars triangularis of the inferior frontal gyrus. Our recent investigation of the frontal sulci in 80 cerebral hemispheres has confirmed Eberstaller's observations. In some textbooks (e.g., Ono *et al.*, 1990), the term "inferior frontal sulcus" has been used loosely to include additional sulci, such as the sulcus radiatus and the lateral frontomarginal sulcus, that lie anterior to it and, sometimes, abut superficially with it. The tendency to treat these distinct sulci as rostral extensions of the inferior frontal sulcus introduces considerable confusion in the identification of the frontal sulci. For instance, we observed that, although in some cases the sulcus radiatus and the lateral frontomarginal sulci may anastomose and appear to join superficially the rostral end of the inferior frontal sulcus, these three sulci could be clearly separated by careful examination of sections of the frontal lobe.

The Frontopolar Region

The term "frontomarginal sulcus" was first used by Wernicke (1876) to refer to a deep sulcus that is found at the ventralmost part of the frontal pole (Figs. 25.1, 25.2, and 25.4). Eberstaller (1890) and Economo and Koskinas (1925) recognized a complex of three distinct frontomarginal sulci that are running in the ventralmost part of the rostral frontal lobe along the edge with the orbital surface. These sulci are the medial frontomarginal sulcus (mfms), the intermediate frontomarginal sulcus (ifms), and the lateral frontomarginal

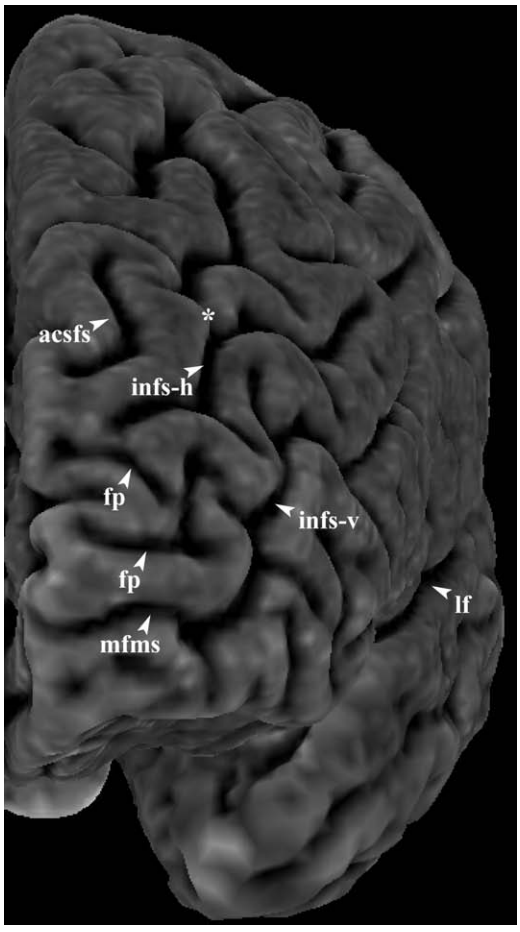

FIGURE 25.4 The frontopolar view of the brain illustrated in Figure 25.2 to show the sulci in this region. Abbreviations as in Figure 25.1.

sulcus (lfms) (Figs. 25.1, 25.2, and 25.4). The medial and intermediate frontomarginal sulci abut the ventralmost extension of the intermediate frontal sulcus (infs-v). The lateral frontomarginal sulcus lies rostral and lateral to the horizontal sulcus and is directed dorsally. In a recent atlas by Duvernoy (1991), the lateral frontomarginal sulcus was labeled as the lateral orbital sulcus. The term "lateral orbital sulcus" has been classically used by several investigators to refer to the lateral part of the H pattern of the sulcal complex that is lying on the orbital surface of the frontal lobe (e.g., Economo and Koskinas, 1925, pp. 28–31; Bailey and Bonin, 1951, p. 45). It must be emphasized here that the lateral frontomarginal sulcus lies lateral and dorsal to the lateral orbital sulcus and has been recognized as such by several major investigators such as Eberstaller (1890, p. 84) and Economo and Koskinas (1925, pp. 28–31).

The Orbital Surface of the Frontal Lobe

At the medialmost part of the orbital surface of the frontal lobe, one can identify the olfactory sulcus which is running in a rostrocaudal direction and delimits the gyrus rectus (RG), which lies medial to it (Figs. 25.1 and 25.5). Typically, the posterior end of the olfactory sulcus lies more lateral than its anterior end (Chiavaras and Petrides, 2000). Lateral to the olfactory sulcus, there are two longitudinally directed sulci, the medial (mos) and lateral (los) orbital sulci, which are joined together by the transverse orbital sulcus (tos) to form the impression of an H or a K pattern. The medial and lateral orbital sulci can be divided into rostral and caudal parts relative to the transverse orbital sulcus. The gyrus that lies between the olfactory sulcus and the medial orbital sulcus is often referred to as the medial orbital gyrus. The cortex lying rostral to the transverse orbital sulcus and between the medial and lateral orbital sulci can be referred to as the anterior orbital gyrus, and the cortex that lies caudal to it, as the posterior orbital gyrus. Lateral to the lateral orbital sulcus lies the orbital extension of the ventrolateral prefrontal cortex (i.e., the pars orbitalis of the inferior frontal gyrus).

One or two longitudinal sulci, named the intermediate orbital sulci (ios), may be lodged within the anterior orbital gyrus between the rostral parts of the medial and lateral orbital sulci. Similarly, in some cases one or two posterior orbital sulci can be observed behind the transverse orbital sulcus within the posterior orbital gyrus between the caudal parts of the medial and lateral orbital sulci. In some brains, a small dimple known as the sulcus fragmentosus can be identified between the olfactory sulcus and the medial orbital sulcus (Fig. 25.5).

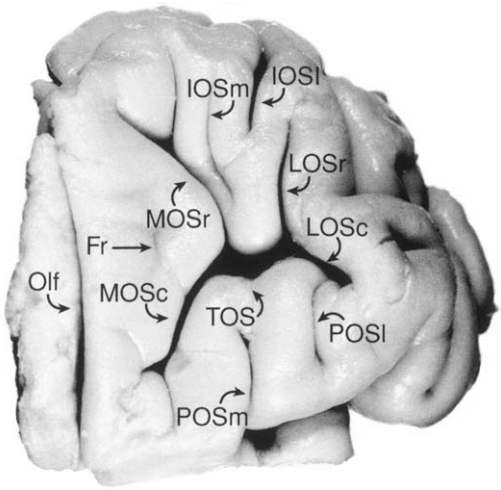

FIGURE 25.5 Photograph of the orbital frontal surface of a brain to show the sulci in this region. Abbreviations: Fr, sulcus fragmentosus; IOSm, medial intermediate orbital sulcus; IOSl, lateral intermediate orbital sulcus; MOSc, caudal part of medial orbital sulcus; MOSr, rostral part of medial orbital sulcus; LOSc, caudal lateral orbital sulcus; LOSr, rostral lateral orbital sulcus; Olf, olfactory sulcus; POSm, medial posterior orbital sulcus; POSl, lateral posterior orbital sulcus; TOS, transverse orbital sulcus.

ARCHITECTONIC ORGANIZATION

The cerebral cortex is not uniform in structure, but it can be divided into several distinct areas based on differential patterns of the neurons in the cortical layers. Cytoarchitectonic studies of the human cerebral cortex were initiated at the beginning of the 20th century. The first complete map to be published was that of Campbell (1905), who divided the cortex into a few general regions. A little later, Brodmann's map appeared in which a large number of cortical areas were identified (Brodmann, 1908, 1909, 1914) and labeled with distinct numbers (Fig. 25.6A). In 1925, Economo and Koskinas published a major atlas of the human cerebral cortex in which the different architectonic areas were labeled with letters (Fig. 25.6B), described in detail, and documented with excellent photomicrographs. In the 1950s, the maps of Bailey and Bonin (1951) and Sarkissov *et al.* (1955) (Fig. 25.6C) appeared. The map by Sarkissov is a modified version of the Brodmann map based on a survey of the cytoarchitecture of several brains. In 1962, Sanides published a monograph focused on the architecture of the human frontal lobe. The architecture of selected parts of the prefrontal cortex of the human brain has also been studied by Beck (1949), Rajkowska and Goldman-Rakic (1995), Amunts *et al.* (1999), and Semendeferi *et al.* (1998). Apart from these studies, other investigators have described the architecture of the cerebral cortex based on myelin (Vogt, 1910; Vogt and Vogt, 1919) or on pigment architecture (Braak, 1979).

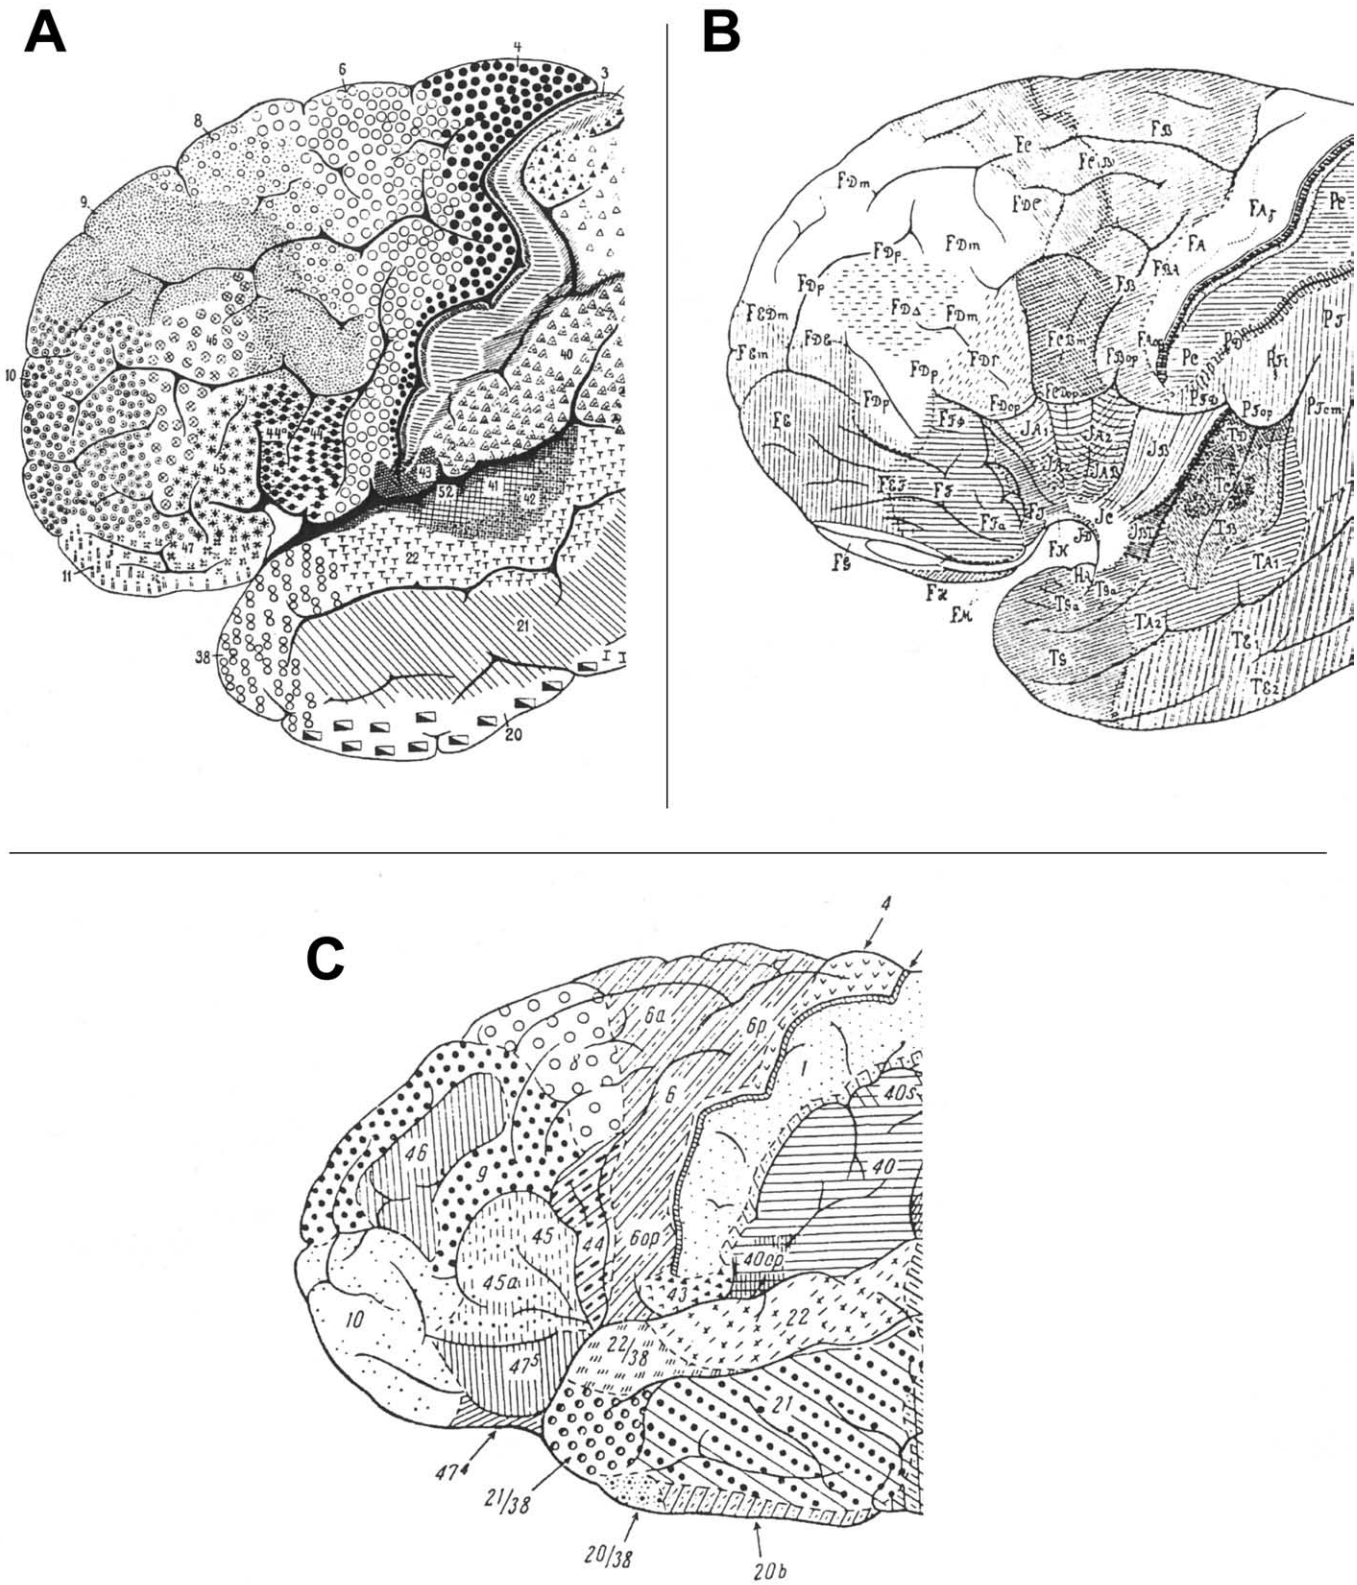

FIGURE 25.6 Cytoarchitectonic maps showing the human frontal cortex as parcellated by **(A)** Brodmann (1914), **(B)** Economo and Koskinas (1925), and **(C)** Sarkissov *et al.* (1955).

We have recently reexamined the architecture of the prefrontal cortex of the human brain in the context of a comparison with the architecture of the prefrontal cortex of the macaque monkey (Petrides and Pandya, 1994, 1999, 2002). Based on this comparative architectonic study, we modified somewhat the Brodmann scheme (Figs. 25.7 and 25.8). The description of the architecture of the human frontal cortex presented in this chapter follows our investigation. The present architectonic description is limited to the prefrontal cortex, namely the large region that lies rostral to the precentral motor region.

Dorsolateral Prefrontal Cortex

Area 8

Area 8 lies on the posterior part of the superior and middle frontal gyri and extends medially as far as the paracingulate sulcus (Fig. 25.7). Posteriorly, it abuts rostral area 6 and, anteriorly, area 9 on the superior frontal gyrus and area 9/46 on the middle frontal gyrus. Area 8 can be divided into two major subdivisions: area 8A and 8B. Area 8A lies on the middle frontal gyrus. It is characterized by a dense layer II that is clearly separated from layer III (Fig. 25.9). Layer III consists of medium and large pyramidal cells, as well as very large and darkly stained pyramidal neurons that occupy the lower part of this layer. Layer IV is also well developed. Layers V and VI contain medium to small pyramidal neurons, and Layer Va has a few darkly stained large pyramidal cells. The separation between layers Va and VI is marked by a thin and cell-sparse layer Vb. Area 8A can be divided into a ventral part (i.e., area 8Av), which occupies a small portion of the caudalmost middle frontal gyrus, and a dorsal part (i.e., 8Ad) extending into the superior frontal sulcus.

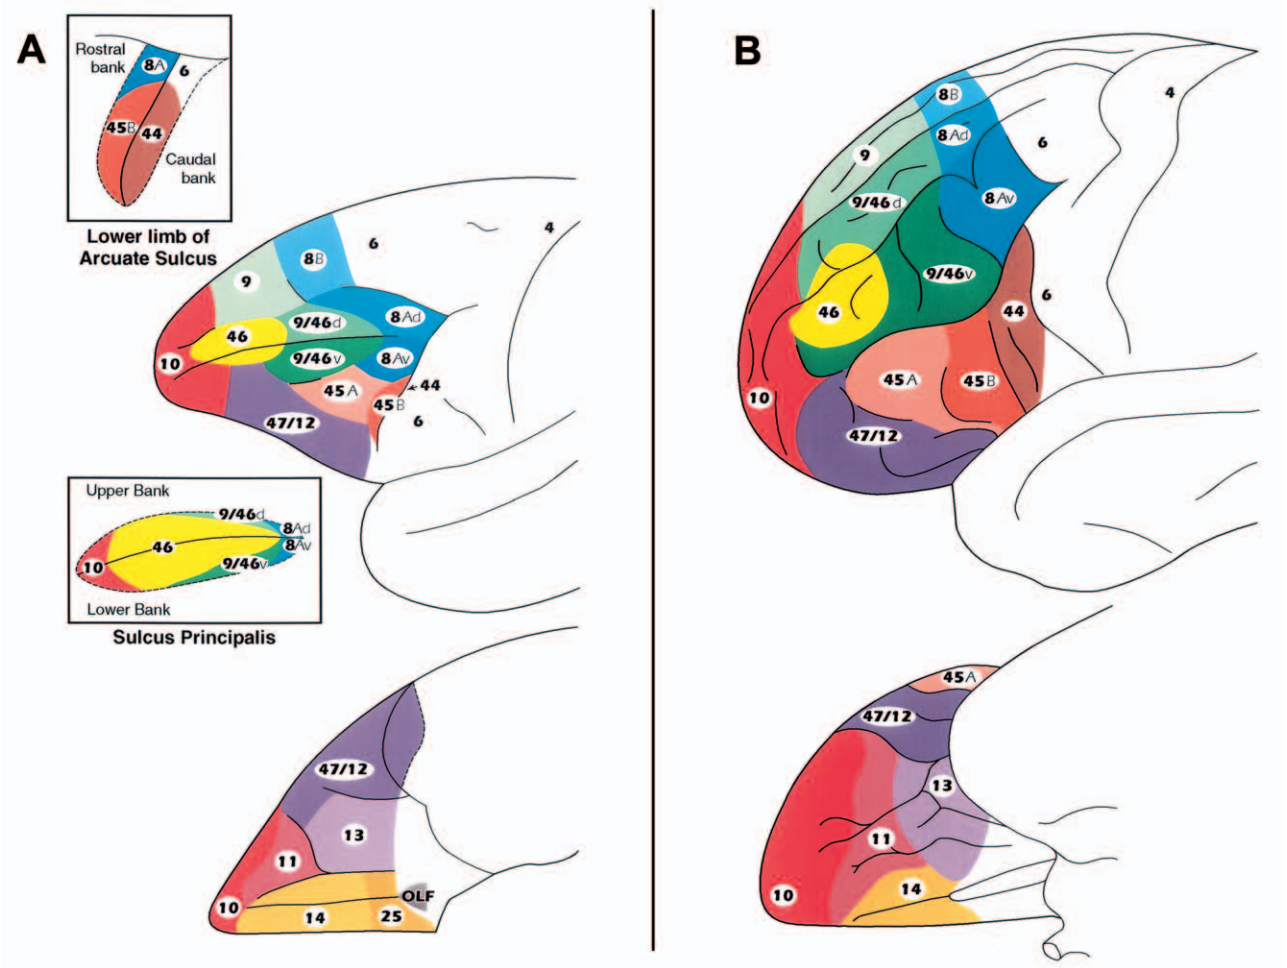

FIGURE 25.7 Cytoarchitectonic maps of the lateral and orbital surfaces of the frontal lobe of the macaque monkey **(A)** and the human **(B)** brains as parcellated by Petrides and Pandya (1994). In A, the inset diagrams display the region within the lower limb of the arcuate sulcus and the sulcus principalis to show the cytoarchitectonic areas lying within their banks.

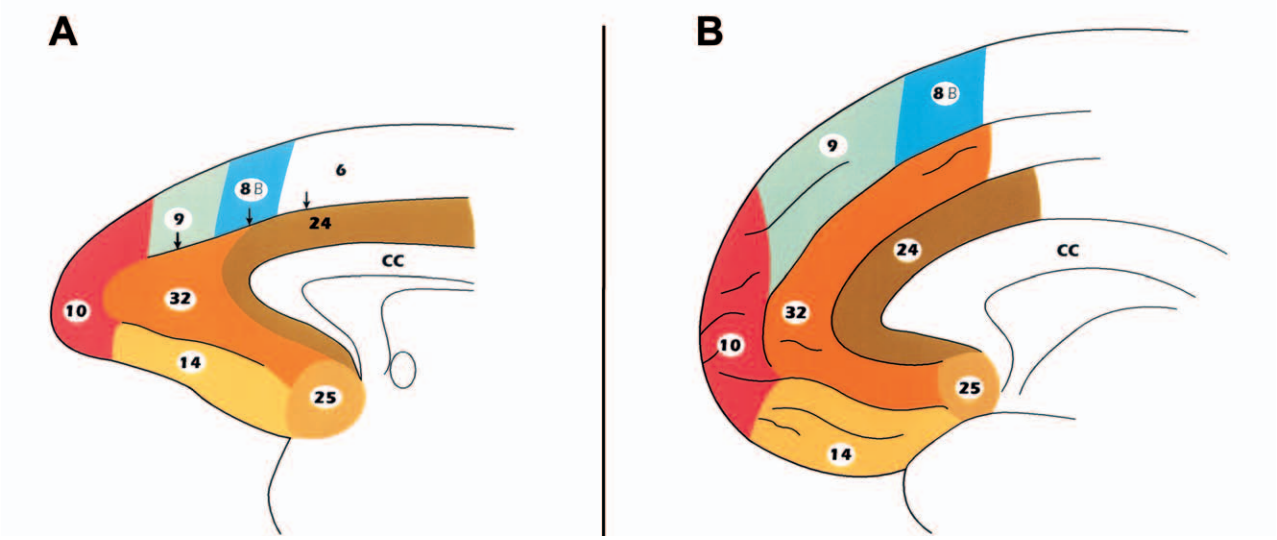

FIGURE 25.8 Cytoarchitectonic maps of the medial surface of the frontal lobe of the macaque monkey **(A)** and the human **(B)** brains as parcellated by Petrides and Pandya (1994).

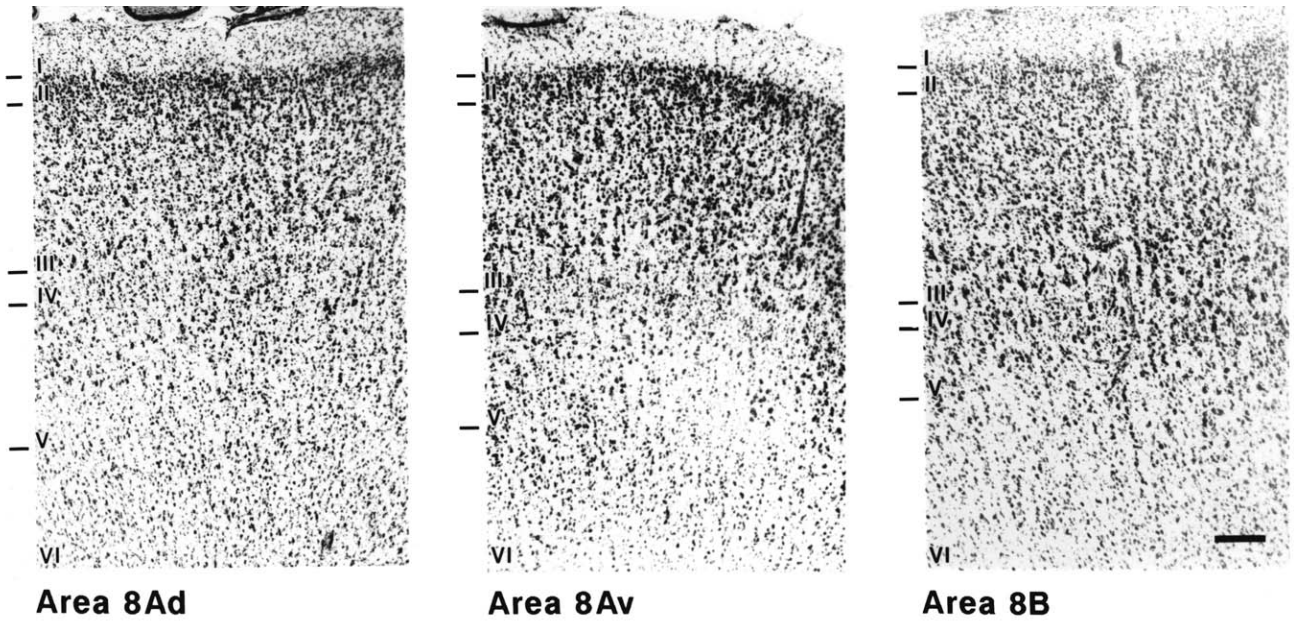

FIGURE 25.9 Photomicrographs of cortical areas 8Ad, 8Av, and 8B of the human frontal cortex. The roman numerals in each photograph indicate the cortical layers. The black bar in the photomicrograph of area 8B equals 1 mm.

The large pyramidal neurons in layer III are less dense in area 8Ad compared with area 8Av. Layer IV is somewhat more marked in area 8Av. Area 8B is located on the superior frontal gyrus and extends medially as far as the paracingulate sulcus. Area 8B has a relatively poorly developed layer IV and clusters of large neurons in the lower part of layer III. Area 8B resembles rostrally adjacent area 9 on the superior frontal gyrus that also has a poorly developed layer IV (see later).

Areas 9, 9/46, and 46

The dorsolateral frontal cortex at the midsection of the superior and middle frontal gyri is occupied by areas 9 and 46 in the map of Brodmann (1908, 1909) and Sarkissov *et al.* (1955) (Fig. 25.6A, C). In these maps, area 9 is shown to occupy both the superior frontal gyrus and a part of the middle frontal gyrus. Thus, area 46 (i.e., area FDΔ of Economo and Koskinas, 1925; Fig. 25.6B), which lies on the middle frontal

gyrus, is bordered dorsally and caudally by area 9. We observed that the architecture of the portion of the superior frontal gyrus designated as area 9 is different from that of the portion of the middle frontal gyrus also labeled as area 9 in the maps of Brodmann (1908, 1909) and Sarkissov *et al.* (1955). Indeed, the architecture of the portion of the middle frontal gyrus labeled as area 9 in the maps of Brodmann (1908, 1909) and Sarkissov *et al.* (1955) is more akin to area 46, which also lies on the middle frontal gyrus. Interestingly, this cortex corresponds in architecture to the cortex found in the caudal part of the sulcus principalis in the macaque monkey and that has been included with area 46 by Walker (1940). We have therefore labeled the portion of area 9 that lies on the middle frontal gyrus as area 9/46 (Fig. 25.7B) to acknowledge its architectonic similarity with area 46 and the fact that an equivalent cortical region was included as part of area 46 in the monkey by Walker (1940).

Area 9/46, which lies on the middle frontal gyrus, has a well defined layer II that is distinct from layer III (Fig. 25.10). Layer III contains a substantial number of large darkly stained pyramidal neurons in its lower part, a characteristic that sets it apart from area 46 (see later). Layer IV is well developed. Layer Va contains a number of medium pyramidal cells, and layer VI is separated from layer Va by a cell-sparse layer Vb. There is a slight difference between the ventral (9/46v) and dorsal (9/46d) parts of area 9/46. In area 9/46d, the large pyramidal cells in the lower part of layer III are less densely packed compared with those of area 9/46v, and layer IV is not as broad.

Area 9 lies on the superior frontal gyrus and extends medially to the paracingulate sulcus (Fig. 25.7). The main characteristic of area 9 that sets it apart from areas 46 and 9/46 is the fact that layer IV is not well developed (i.e., it is narrow and not very dense; Fig. 25.10). Area 9 has a compact layer II. The upper part of layer III is relatively dense, whereas the lower part is not as cell dense and has a number of large deeply stained pyramidal neurons.

Area 46 occupies the more anterior part the middle frontal gyrus (Fig. 25.7B). The extent of this area as seen from the surface of the brain can be deceptively small because a large part of it lies hidden in the depth of the intermediate frontal sulcus (Fig. 25.7B). In area 46, layer IV is well developed (i.e., it is broad, cell-dense, and easily identifiable; Fig. 25.10). Layer III of area 46 contains small and medium pyramidal cells, and the lower part of layer III lacks the large deeply stained pyramidal neurons found in areas 9 and 9/46. Layer Va contains pyramidal cells of medium size. Because of the relative absence of large neurons in layers III and V, and the rather even distribution of neurons in these layers, area 46 has a uniform appearance that distinguishes it from both areas 9 and 9/46.

Ventrolateral Prefrontal Cortex

Area 44

Rostral to the inferior precentral sulcus in the pars opercularis of the inferior frontal gyrus lies a cortical region labeled as area 44 by Brodmann (1908, 1909) or area FCBm by Economo and Koskinas (1925)

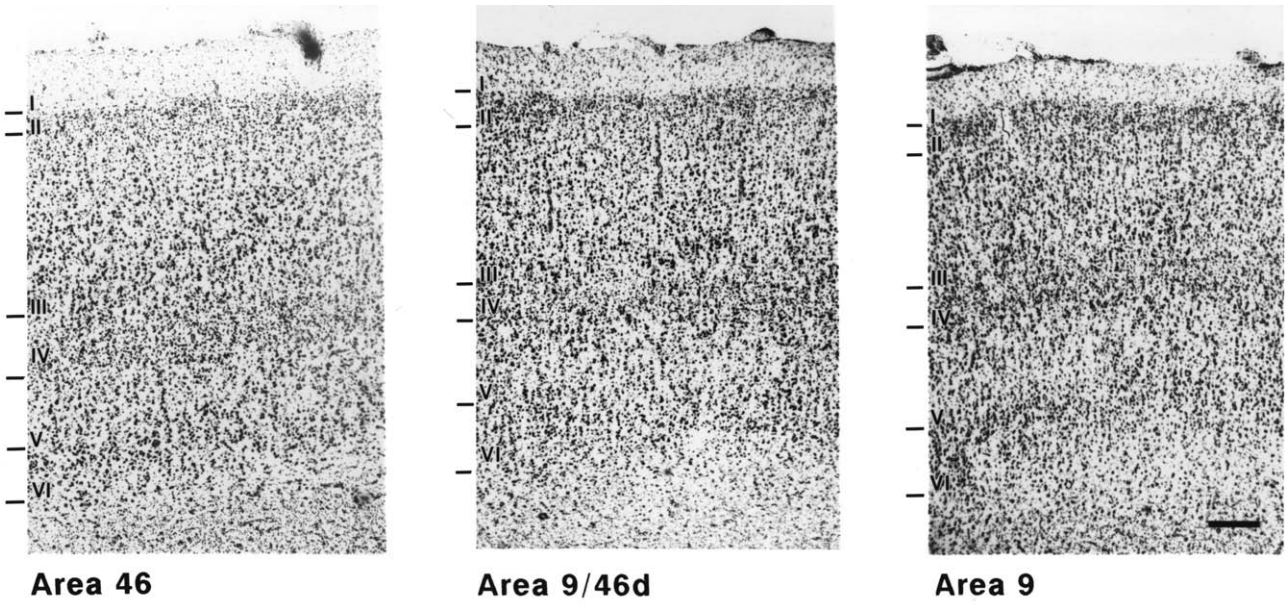

FIGURE 25.10 Photomicrographs of cortical areas 46, 9/46d, and 9 of the human frontal lobe. The roman numerals in each photograph indicate the cortical layers. The black bar in the photograph of area 9 equals 1 mm.

(Fig. 25.6A, B, and 25.7B). This area has been thought to constitute the main part of Broca's speech area. The pars opercularis often comprises two more or less vertically oriented small gyri that are separated by the diagonal sulcus. Area 44 has a densely packed layer II whose lower margin blends with layer III (Fig. 25.11). Layer III contains small and medium pyramidal cells mostly in its upper part. The lower half of this layer is occupied by deeply stained large pyramidal cells. Layer IV is dysgranular containing only a few neurons. Unlike the lower part of layer III, layer Va contains medium-sized pyramidal cells. Layer Vb contains fewer neurons than Va and layer VI is broad.

Area 45

Area 45 occupies the pars triangularis of the inferior frontal gyrus (Brodmann, 1908, 1909; Sarkissov *et al.*, 1955; Amunts *et al.*, 1999) (Fig. 25.6A, C). Economo and Koskinas (1925) have designated this area as FDΓ (Fig. 25.6B). In area 45, layer III contains small to medium pyramidal cells in its upper part and, in its lower part, has clusters of deeply stained and densely packed large pyramidal neurons (Fig. 25.11). Layer IV is well developed. The defining feature of area 45 that distinguishes it clearly from all adjacent areas are the clusters of large and deeply stained pyramidal neurons in the deeper part of layer III in combination with the well-developed layer IV. Layer Va contains medium pyramidal cells, and layer Vb is cell-sparse; therefore, layer VI is clearly separated from Va. Area 45 can be subdivided into a rostral and a caudal part, labeled areas 45A and 45B, respectively.

Area 47/12

In the classical maps of the human cerebral cortex, the cortical region rostroventral to area 45 has been labeled as area 47 (Fig. 25.6A, C). This region is shown to occupy the most rostral part of the inferior frontal gyrus (pars orbitalis), extending onto the caudal half of the orbitofrontal cortex (e.g., Sarkissov *et al.*, 1955; Beck, 1949). Brodmann (1909) pointed out that this region is heterogenous and that it can be further subdivided. Sarkissov *et al.* (1955) subdivided this large and architectonically heterogeneous region into five parts. In our comparative architectonic examination, we observed that the part of this large region that lies rostral and ventral to area 45 and extends as far as the lateral orbital sulcus has architectonic features comparable to those of Walker's area 12 in the monkey. We have therefore labeled this part as area 47/12 to denote the fact that this particular part of the previously labeled area 47 is comparable in architecture to Walker's ventrolateral area 12 in the monkey brain (Fig. 25.7A, B). By contrast, the remaining part of classical area 47 that occupies the caudal orbitofrontal cortex has different architectonic features that are similar to those of orbitofrontal area 13 of the monkey (see later).

The transition from area 45 to area 47/12 can be clearly defined. Basically, the conspicuously large and

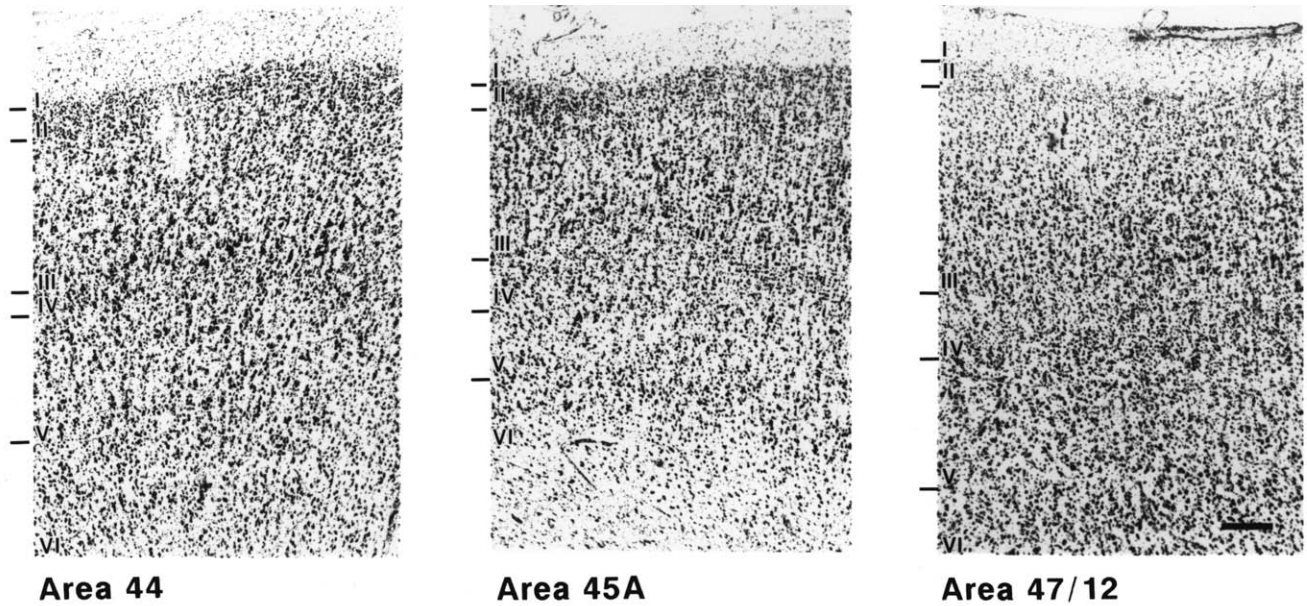

FIGURE 25.11 Photomicrographs of cortical areas 44, 45A, and 47/12 of the human frontal lobe. The roman numerals in each photograph indicate the cortical layers. The black bar in the photograph of area 47/12 equals 1 mm.

deeply stained pyramidal neurons in the deeper part of layer III, which are the defining feature of area 45, are replaced in area 47/12 by medium-sized neurons (Fig. 25.11). Thus, in area 47/12, layer III contains small and medium pyramidal cells in its upper part and medium and somewhat larger pyramidal neurons in its lower part. In area 47/12, layer IV is not as broad as in area 45. Layers V and VI contain densely packed medium to small pyramidal cells, and these infragranular layers are more prominent than those of adjacent area 45. The part of area 47/12 that extends onto the orbital surface differs slightly from the more lateral part in that layer IV is less well developed and, thus, one can speak of a lateral and an orbital part of area 47/12.

Orbital Frontal Cortex

As pointed out previously, Brodmann (1909) included a large region of the caudal orbitofrontal cortex as part of area 47 and labeled the remaining orbitofrontal cortex as area 11. He acknowledged, however, that these two large regions are architectonically heterogeneous and that they can be further subdivided. The caudomedial part of the region that Brodmann labeled as area 47 has architectonic characteristics comparable to those of Walker's area 13. We have therefore designated this region as area 13, distinguishing it from the more laterally located orbital extension of area 47/12, as well as the rostrally located area 11 and the medially located area 14 (Fig. 25.8A, B).

In area 13, layer II is clearly distinct, and layer III contains small to medium size pyramidal neurons (Fig. 25.12). The distinguishing feature of this area is the thin and irregular layer IV that characterizes it as a dysgranular type of cortex. Layer V contains mainly small pyramidal cells. Layer Vb blends with layer VI. Layer VI contains small to medium and densely packed pyramidal neurons.

Caudal to area 13 on the orbital frontal cortex lies the orbital proisocortex. This area is characterized by ill-defined layer II with an irregular outer margin. Layer III contains sparsely populated small pyramidal neurons. Layer IV is virtually absent, and layers V and VI contain deeply stained medium-sized pyramidal neurons. The orbital proisocortex has a bilaminated appearance that results from the juxtaposition of the deeply stained infragranular layers V and VI with the lightly stained sparse supragranular layers II and III.

The cortex that occupies the gyrus rectus on both its medial and orbital parts, as well as the remaining rostral part of the orbitofrontal cortex, was labeled by Brodmann (1909) as area 11 (Fig. 25.6A). Brodmann noted that, within this large region, the architecture of the cortex of the gyrus rectus is distinct from that of the remaining region. In our comparative architectonic examination, we noted that the cortex occupying the gyrus rectus has architectonic features comparable to those of Walker's cortical area 14 of the macaque monkey, which also occupies the gyrus rectus (Fig. 25.7A, B). We have therefore denoted the cortex of the gyrus rectus in the human brain as area 14. We have

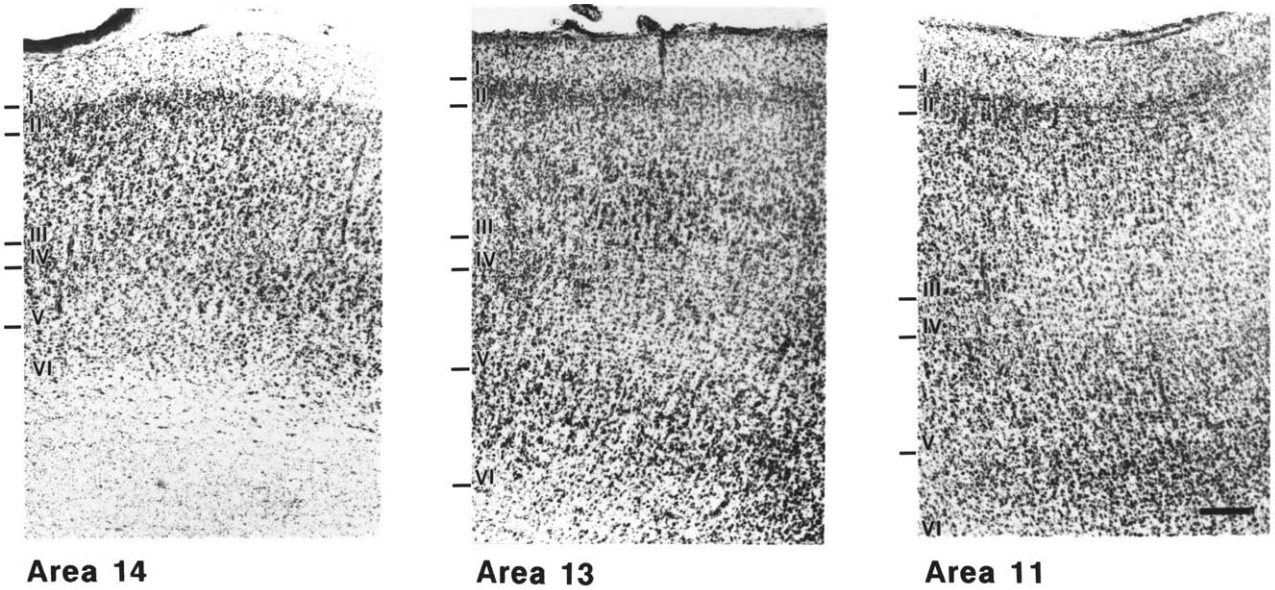

FIGURE 25.12 Photomicrographs of cortical areas 14, 13, and 11 of the human frontal lobe. The roman numerals in each photograph indicate the cortical layers. The black bar in the photograph of area 11 equals 1 mm.

restricted the term "area 11" to that part of the human orbital frontal cortex that is comparable in architecture to Walker's area 11 in the monkey (Fig. 25.7A, B).

In area 14, the outer border of layer II is irregular (Fig. 25.12). Layer III contains small to medium pyramidal cells that are uniformly distributed. Layer IV is thin but quite distinct. Layer Va contains densely packed, deeply stained medium-sized pyramidal cells, and Vb is sparsely populated with smaller neurons, clearly separating Va from VI. Layer VI contains deeply stained small and medium pyramidal neurons. Area 14 can be further subdivided into a medial and an orbital component.

Area 11 lies on the rostral part of the orbital frontal lobe in front of the transverse orbital sulcus. In area 11, layer II is thin. Layer III contains small to medium pyramidal cells that are uniformly arranged. Layer IV is well developed. Layer Va has medium-sized pyramidal cells and is somewhat denser than layer Vb. Layer VI contains small to medium-sized pyramidal cells that are faintly separated from Vb (Fig. 25.12).

Frontopolar Cortex

Area 10 occupies the frontal pole (Figs. 25.6A, C, and 25.7). On the lateral surface, it borders, caudally, with areas 9, 46, and 47/12. On the orbital surface, it borders areas 11 and 14, and on the medial surface, it borders areas 9, 32 and 14. In area 10, the cortex is overall cell-sparse and hence has a pale appearance as compared with the surrounding areas. Layer II is distinct from layer III (Fig. 25.13). Layer III is sparsely populated with small to medium-sized pyramidal neurons. Layer IV is narrow but distinct. Layer Va contains scattered medium-sized pyramidal cells, and layer VI has small to medium pyramidal neurons. The overall density of the supragranular (II and III) and the infragranular (V and VI) layers is about the same.

Medial Frontal Cortex

On the medial surface of the frontal lobe, the cingulate and paracingulate regions are occupied by areas 24 and 32, respectively (Fig. 25.8B). Dorsal to these areas, on the medial surface of the superior frontal gyrus, in a caudorostral direction, lie the medial extensions of areas 8B, 9, and 10. Ventrally, area 32 borders the medial part of area 14, and caudally it abuts area 25, which occupies the subcallosal gyrus.

In area 25, layer II has an irregular margin and is ill-defined (Fig. 25.13). Layer III contains small to medium-sized pyramidal cells that are sparsely distributed. Layers V and VI contain deeply stained neurons giving the infragranular layers a uniform appearance. Area 25, like area 24, is a proisocortical area by virtue of its prominent infragranular layers and the absence of layer IV.

In area 24, layer II has an irregular margin and is ill-defined. Layer III contains small to medium pyramidal cells that are sparsely distributed. The striking feature of area 24 is layer V, which contains deeply stained medium to large pyramidal cells. This layer abuts

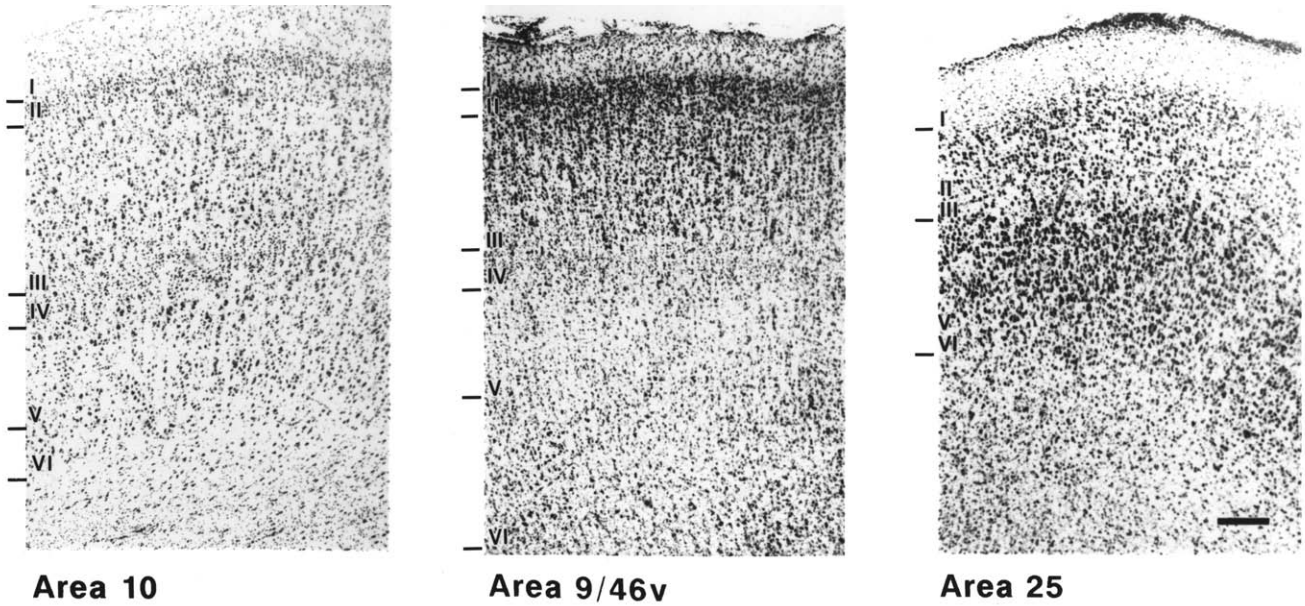

FIGURE 25.13 Photomicrographs of cortical areas 10, 9/46v, and 25 of the human frontal lobe. The roman numerals in each photograph indicate the cortical layers. The black bar in the photograph of area 25 equals 1 mm.

layer III because of the absence of layer IV. Layer Vb and VI blend and contain medium to small pyramidal cells. Like area 25, area 24 is a proisocortical region because of the overall prominence of the infragranular layers and the absence of layer IV.

Area 32 surrounds area 24 and occupies a region that is often referred to as the paracingulate gyrus (Fig. 25.8). In area 32, as in areas 24 and 25, the infragranular layers predominate. Layer III of area 32 contains small to medium pyramidal cells and is denser than that of area 24. There is an incipient layer IV in area 32. Layer Va contains deeply stained neurons that are more dispersed than those of area 24. Layers V and VI are slightly separated. Area 32 exhibits minor variations that have been recognized by both Economo and Koskinas (1925) and Sarkissov *et al.* (1955). Each subdivision exhibits some of the features of the neocortical areas adjoining it. Area 32 can be considered as a transitional type of cortex between the isocortex and the proisocortical areas 24 and 25. For a more detailed discussion of the cingulate areas, see Chapter 24.

Architectonic Trends

The prefrontal architectonic areas described previously can be conceptualized as belonging to one of two general groups or trends. This conceptualization is based on the notion of the dual origin of the cerebral cortex, which has been proposed by Dart (1934), Abbie (1940), Sanides (1969), Pandya and Yeterian (1990), and Barbas and Pandya (1989). According to this concept, one cortical architectonic trend originates from the paleocortical (olfactory) moiety, whereas the other trend originates in the archicortical (hippocampal) moiety. From each one of these two allocortical moieties, a progressive laminar differentiation can be traced, passing through periallocortex and proisocortex toward the development of the true six-layered isocortex.

For the frontal cortical areas, the sites of origin are (1) the allocortical, periallocortical and proisocortical areas in the caudal orbital frontal region and (2) the allocortical, periallocortical, and proisocortical areas in the cingulate region around the rostral part of the corpus callosum. From the proisocortex in the caudal orbital frontal region, which is characterized by a predominance of the infragranular layers and the absence of layer IV, the next stage of differentiation is area 13 which has an incipient layer IV. Next follow areas 14, 11, and orbital 47/12, which have a predominance of the infragranular layers V and VI and a better developed layer IV. Progressing further in terms of laminar differentiation are the adjacent cortical areas 10, lateral 47/12, and ventral portion of area 46, which are characterized by an approximately equal emphasis on the infra- and supragranular layers and further development of layer IV. Further differentiation within this trend can be seen in ventral area 9/46, ventral area 8 (i.e., 8Av), and area 45, all of which exhibit a predominance of the supragranular layers, prominent pyramidal neurons in layer III and highly developed layer IV.

The archicortical trend of prefrontal areas originates in the proisocortical areas 24, 25, and 32 in the anterior cingulate region. These areas exhibit a predominance of infragranular layers and virtually no layer IV. The next stage of differentiation is represented by the medial parts of isocortical areas 8B and 9, which have a poorly developed layer IV. The next stage of differentiation can be seen in lateral areas 8B, 9, and 10, which have a better developed layer IV and a relative equivalence of the infra- and supragranular layers. Finally, one observes areas 46, 9/46d, and 8Ad, which contain a highly developed layer IV and the predominance of supragranular layers. We would like to emphasize that within each stage of these two trends of architectonic differentiation, the various areas exhibit their own unique architectonic pattern. Although these two architectonic trends emerge from two distinct points of origin (i.e., the caudal orbitofrontal and the rostral cingulate regions), they come together in the region of the middle frontal gyrus.

CORTICOCORTICAL CONNECTION PATTERNS

Studies in the monkey have shown that the different architectonic areas have distinct cortical and subcortical connections. Although the connections of the different architectonic areas of the human frontal cortex cannot be studied directly, information about their connections can be inferred from experimental anatomical studies in the macaque monkey. Such an endeavor will be critically dependent on the extent to which architectonic areas have been defined by the same criteria in the monkey and the human frontal cortex. Cytoarchitectonic studies of the cortex of the monkey appeared at about the same time as those of the human cortex, but unfortunately the numerical designations employed were not always referring to areas with comparable architectonic features and location (see Petrides and Pandya, 1994, for discussion of this problem). As pointed out earlier, to circumvent this problem, we have reexamined the architecture of the human and the macaque monkey prefrontal cortex in a strictly comparative manner. Architectonic areas were defined in both species using the same criteria. Figures 25.7 and 25.8 shows the correspondence between

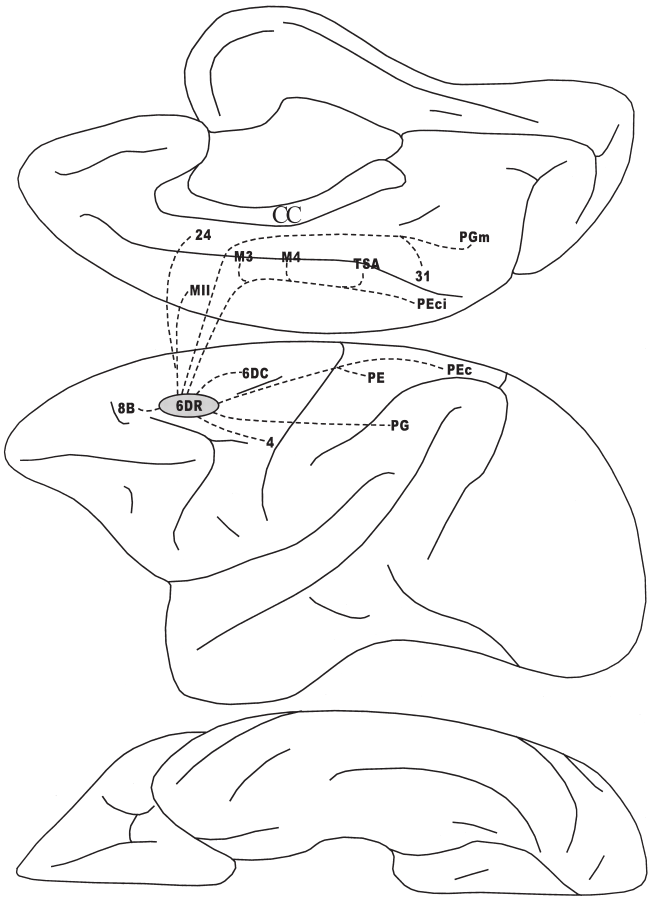

FIGURE 25.14 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of rostral dorsal area 6.

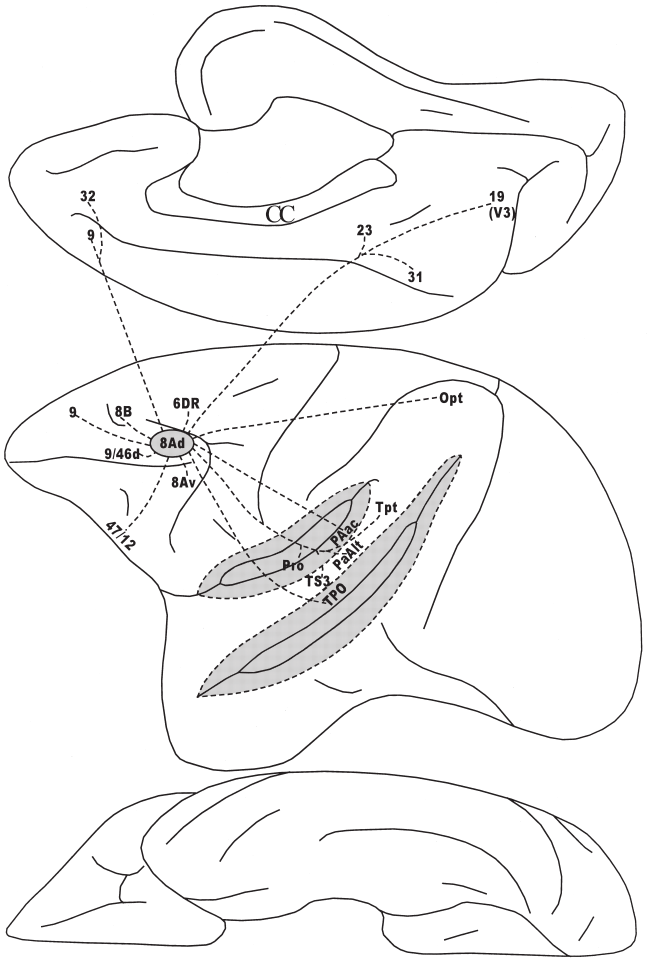

FIGURE 25.15 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 8Ad. The lateral fissure and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

the human and the monkey prefrontal cortical areas (Petrides and Pandya, 1994).

In the present description of the connections of the prefrontal cortex, data obtained from the experimental anatomical literature will be described using the architectonic areas of the prefrontal cortex as defined by Petrides and Pandya (1994). The following descriptions of the corticocortical connections of the different prefrontal areas are based on a synthesis of data presented in several studies using both anterograde and retrograde tracer techniques: Andersen *et al.* (1990), Barbas (1988), Barbas and Mesulam (1981, 1985), Barbas and Pandya (1987, 1989), Carmichael and Price (1995), Cavada and Goldman-Rakic (1989), Godschalk *et al.* (1984), Mesulam and Mufson (1982), Morris *et al.* (1999a, b), Petrides and Pandya (1984, 1988, 1999, 2002), Preuss and Goldman-Rakic (1989), Romanski *et al.* (1999), Schall *et al.* (1993, 1995), Seltzer and Pandya (1978, 1989).

Rostral Dorsal Area 6

The connections of the motor and premotor areas will not be described, except for those of the rostral part of area 6. Rostral dorsal area 6 (i.e., area 6DR) is connected with dorsal area 4, caudal area 6, supplementary motor area (i.e., MII), and cingulate motor areas M3 and M4 and, rostrally, with area 8B (Fig. 25.14). The long connections of rostral area 6 derive primarily from the posterior parietal region. There are connections from the lateral posterior parietal cortical areas PE, PEc, and PG and the medial parietal areas PEci (the supplementary sensory area, SSA), the transitional sensory area (TSA), area 31, and area PGm.

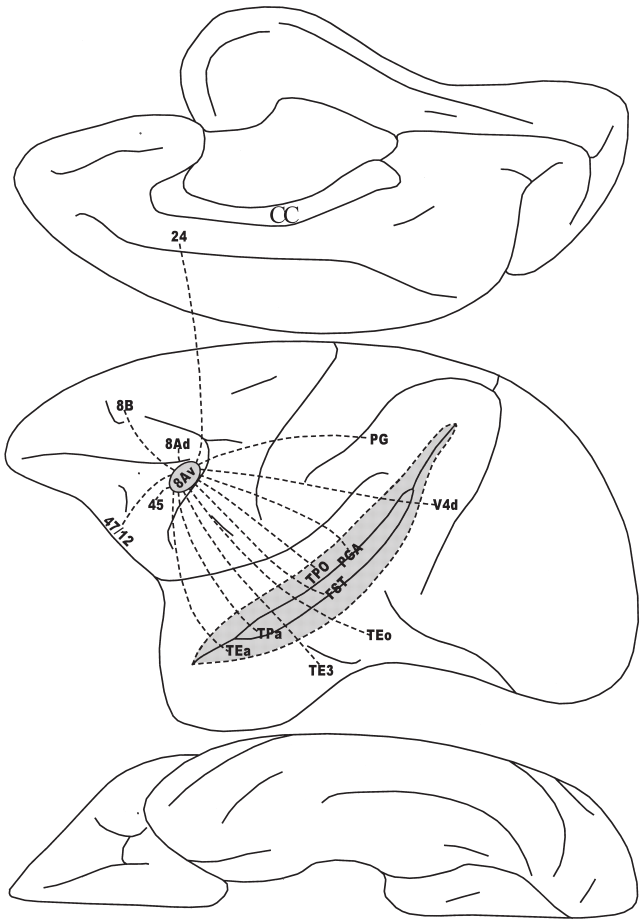

FIGURE 25.16 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 8Av. The superior temporal sulcus has been opened up (shaded area) to show the connections within its banks.

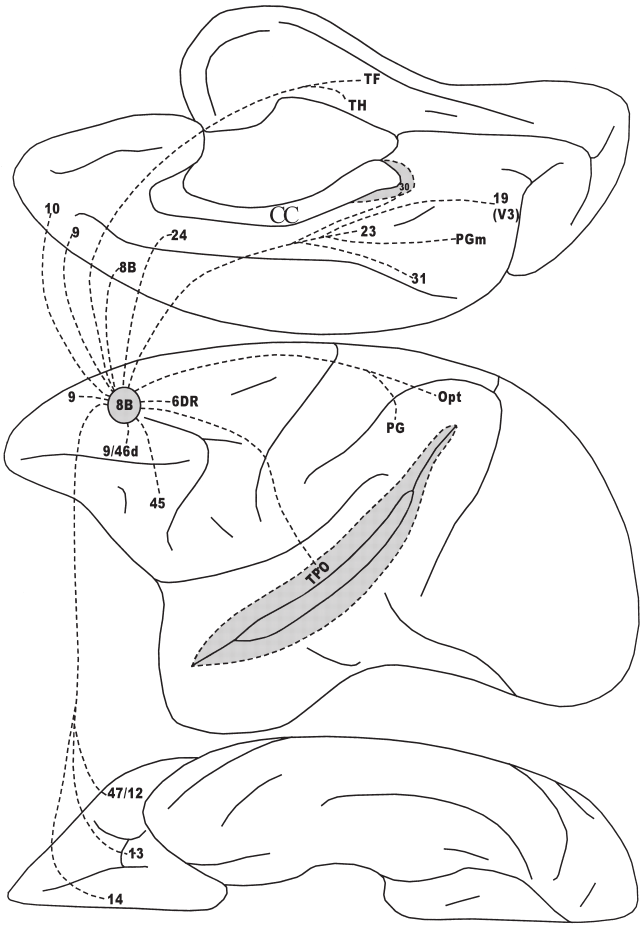

FIGURE 25.17 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 8B. The callosal sulcus around the splenium and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

Area 8Ad

Area 8Ad is connected with areas 6DR, 8B, 9, 9/46d, 8Av, and 47/12 and the cortex lying in the upper bank of the rostral cingulate sulcus (area 32 and 9) (Fig. 25.15). The long connections of area 8Ad originate from the caudalmost part of parietal cortex on the lateral surface (areas POa and Opt) and from areas 31, caudal area 23, and the medial portion of area 19 (V3). A substantial set of connections derive from the caudal superior temporal lobe (i.e., areas ProK, PAac in the supratemporal plane of the Sylvian fissure and areas Tpt, PAalt, and TS3 of the superior temporal gyrus and area TPO of the superior temporal sulcus).

Area 8Av

Area 8Av is connected locally with areas 8Ad, 8B, 45, and 47/12 (Fig. 25.16). There are also minor connections with area 24a. Its long connections are with the cortex of the multimodal cortex of the superior temporal sulcus (areas TPO and Pga) and the ventral bank of the superior temporal sulcus (areas IPa, TEa, and FST). Area 8Av is also connected with the caudal portion of inferotemporal and ventral occipital region (i.e., areas TE3, TEO, and V4d). A few connections exist between this area and area PG of the inferior parietal lobule.

Area 8B

Area 8B is connected locally with area 6DR, medial areas 10, 9, 8B, and 24; dorsolateral prefrontal areas 8B, 9, and 9/46d; ventrolateral prefrontal areas 45 and 47/12; and orbital areas 13 and 14 (Fig. 25.17). Its distant connections derive from the lateral parietal cortex (areas PG and Opt), the medial parietal areas 31

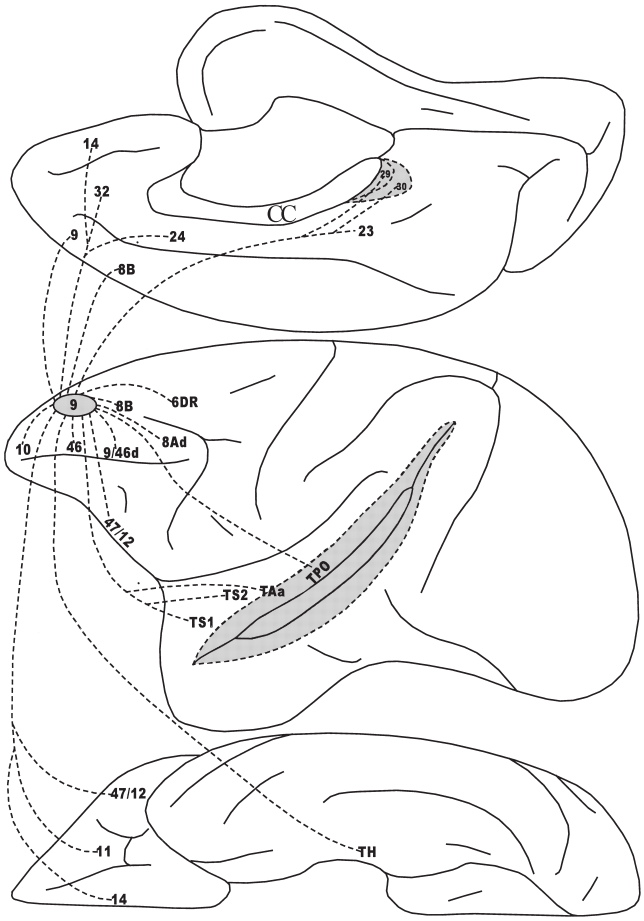

FIGURE 25.18 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 9. The callosal sulcus around the splenium and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

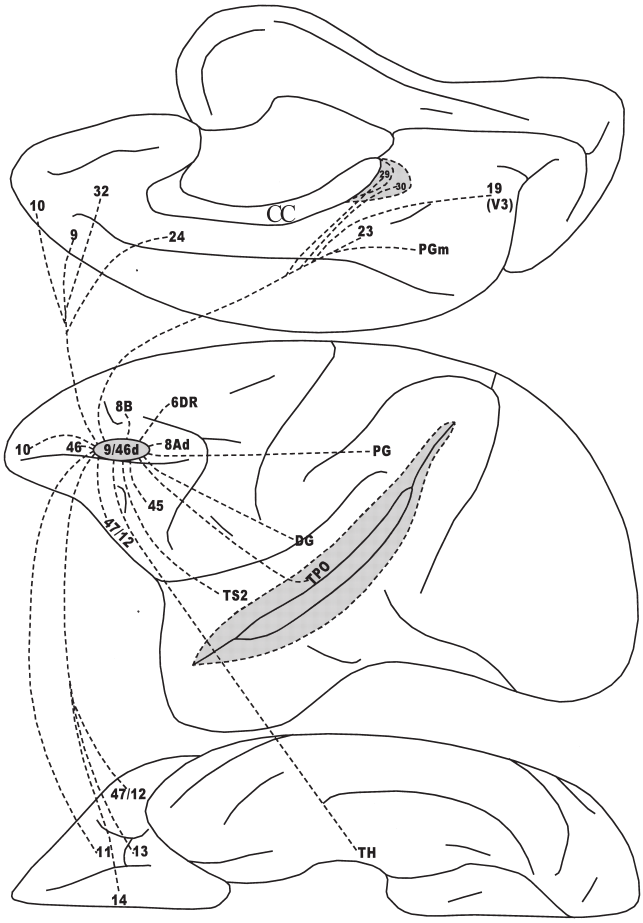

FIGURE 25.19 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 9/46d. The callosal sulcus around the splenium and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

and PGm, and the medial area 19 (V3). Area 8B is also linked with the multimodal areas TPO in the upper bank of the superior temporal sulcus. There are also connections with limbic areas, such the retrosplenial area 30, posterior cingulated area 23, and areas TH and TF of the parahippocampal gyrus.

Area 9

Area 9 has local connections with areas 6DR, 8B, 8Ad, 9/46d, dorsal 46, and 10 (Fig. 25.18). Area 9 is also linked with areas on the medial surface of the frontal lobe, namely areas 8B, 9, 32, 14, and 24. Area 9 is also connected with ventrolateral area 47/12 and areas 11 and 14 of the orbital frontal lobe. It has long connections with the rostral temporal area TS1, TS2 and TAa, as well as area TPO. Area 9 is connected with the limbic retrosplenial areas 29 and 30, caudal cingulate area 23, and the parahippocampal area TH.

Area 9/46d

Area 9/46d has local connections with areas 6DR, 8B, 8Ad, 46, and 10 (Fig. 25.19). It is linked with areas 10, 9, 32, and 24 of the medial prefrontal cortex and areas 45 and 47/12 of the ventrolateral prefrontal cortex. Area 9/46d has connections with areas 13, 11, and 14 in the orbital frontal cortex. Its long connections are with Ts2 of the superior temporal gyrus, area TPO of the superior temporal sulcus, and the dysgranular insula. The limbic connections are with areas 29, 30, and 23 in the posterior cingulate region, as well as

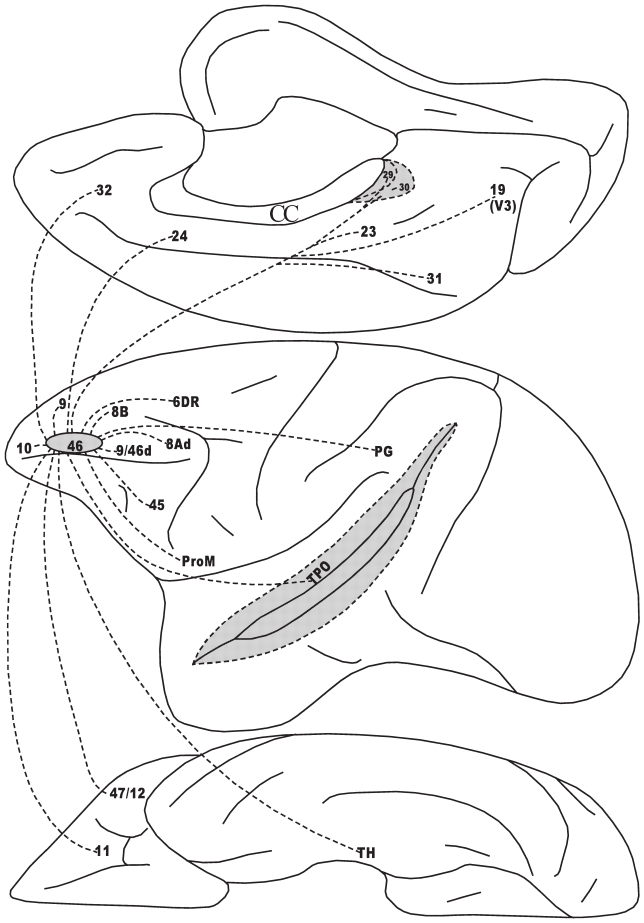

FIGURE 25.20 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 46. The callosal sulcus around the splenium and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

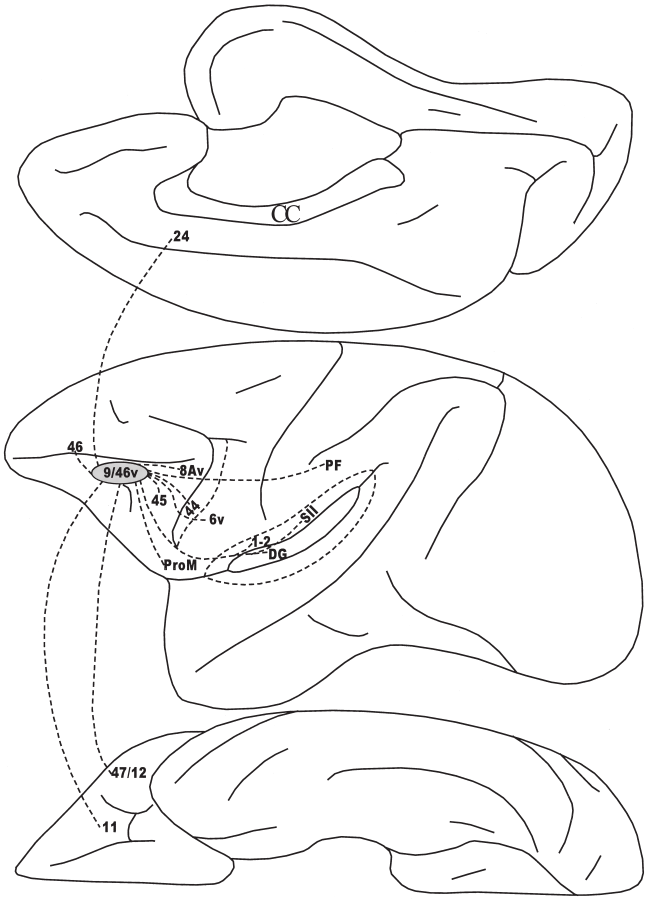

FIGURE 25.21 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 9/46v. area TH of the parahippocampal gyrus. There are also some connections with areas PG, PGm, and medial area 19. The connections of areas 46 and 9/46d are very similar, except that area 46 receives projections from ProM and is not connected with Ts2 and the insula (Fig. 25.20).

Area 9/46v

Area 9/46v is connected locally with area 8Av, ventral area 6, area ProM, and areas 47/12, 44, 45, and 46 (Fig. 25.21). It is also connected with area 11 of the orbitofrontal cortex and in a minor way with area 24. Significant long connections are with the dorsal Sylvian operculum (including area SII) and the dysgranular insula. Other areas connected with this region are the rostral inferior parietal lobule including areas PF and PFG.

Area 10

The frontopolar area 10 is connected with areas 8Ad, 8B, 9, 46, and 47/12 on the lateral frontal cortex and with areas 24, 32, and 9 on the medial surface of the frontal lobe (Fig. 25.22). Its connections with orbital frontal cortex are with areas 11, 13, and 14. Area 10 has long connections with retrosplenial area 30 and posterior cingulate area 23. Area 10 is also connected with dysgranular insula and parinsular region in the lateral fissure and temporal polar proisocortex. It also has connections with areas Ts1 and Ts2 of the superior temporal gyrus and areas TAa and TPO of the superior temporal sulcus.

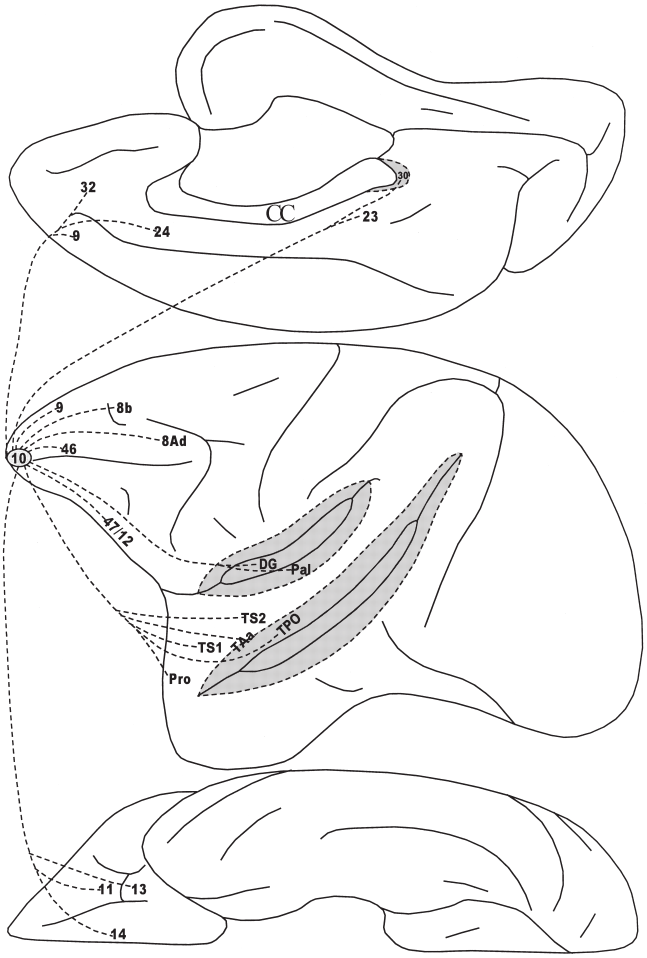

FIGURE 25.22 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 10. FIGURE 25.23 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 44. The lateral fissure has been opened up (shaded area) to show the connections within its banks.

Area 44

Area 44, which is the transitional area between ventral premotor and ventral prefrontal cortex, is linked locally with ventral area 6, area ProM, 9/46v and 47/12 (Fig. 25.23). This area also connected with areas 11 and 13 of the orbital frontal cortex and areas 24 and 23 of the cingulate gyrus, as well as the supplementary motor area. Its distant connections are with the Sylvian opercular cortex (i.e., areas 1 and 2 and SII). There are also some connections with the dysgranular insula. Strong connections exist with areas PF and PFG of the rotral part of the inferior parietal lobule.

Area 45

Area 45 is connected with many areas of the lateral prefrontal cortex: areas 8Av, 8Ad, 9/46v, 46, 10, 9, 8B, and 6DR (Fig. 25.24). Some connections exist between area 45 and medial frontal areas 10, 9, 8B, and 24. This area is also connected with area 47/12, 13, and 11 on the orbital frontal cortex. Long connections exist with dysgranular and granular insula and areas PaI and ProK of the supratemporal plane. There are major connections between the superior temporal region and area 45. These connections are with areas TS1, TS2, TS3, PAalt, and Tpt. There are also connections with areas TPO, PGa, and TEa and area FST in the superior temporal sulcus. Finally, there are connections with area SII in the parietal operculum and the midportion of the inferior parietal lobule (area PG).

Area 47/12

Area 47/12 is connected with areas 9/46v, 45, ProM, ventral area 6 and area 44, as well as with areas 11

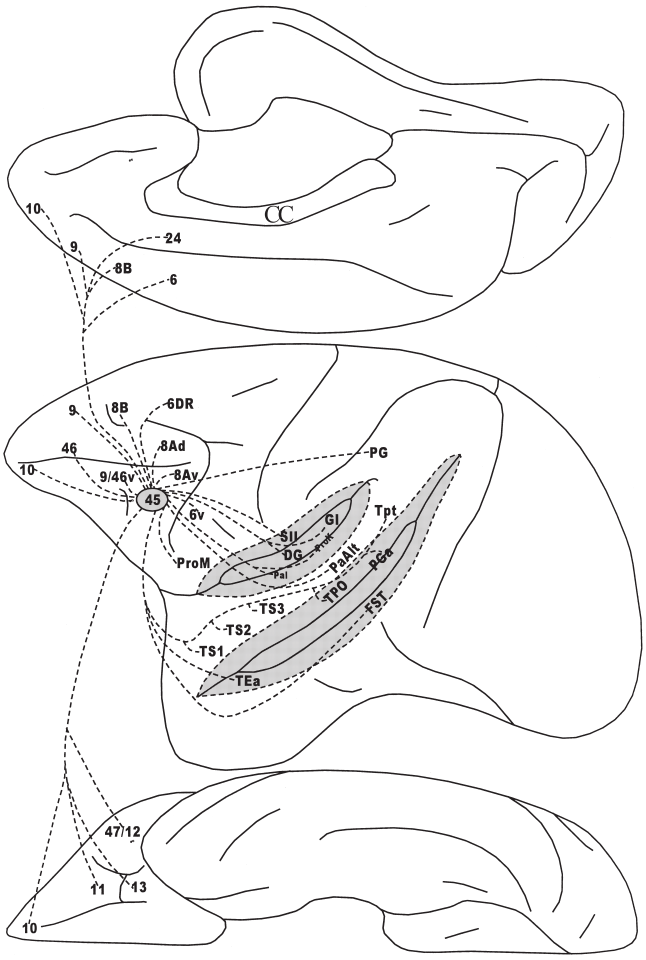

FIGURE 25.24 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 45. The lateral fissure and the superior temporal sulcus have been opened up (shaded area) to show the connections within their banks.

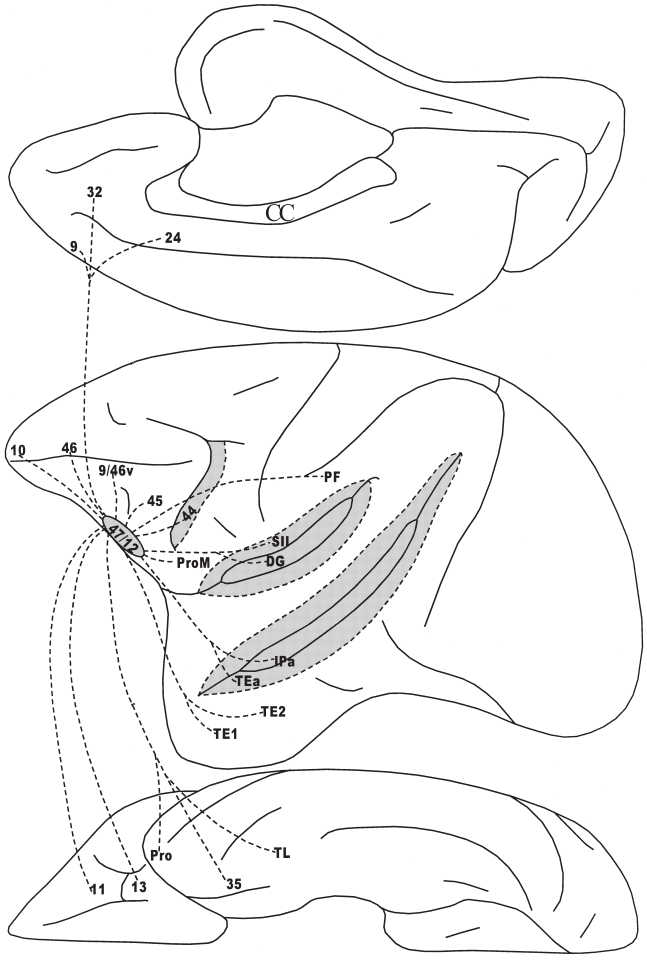

FIGURE 25.25 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 47/12. The posterior bank of the inferior limb of the arcuate sulcus, the lateral fissure, and the superior temporal sulci have been opened up (shaded area) to show the connections within their banks.

and 13 of orbital frontal cortex (Fig. 25.25). It is also connected with areas 24, 32, and 9 on the medial prefrontal cortex. Area 47/12 has long connections with area SII and the dysgranular insula. There is also a modest connection with the rostral part of the inferior parietal lobule. There are connections between area 47/12 and visual areas TEa, IPa, TE1, and TE2 of inferotemporal cortex and areas TL and 35 of the temporal proisocortex.

Area 13

The dysgranular area 13 at the caudal part of the orbital frontal cortex is connected with orbital proisocortex, areas 14, 11, and 47/12, as well as areas 46 and 10 on the lateral surface of the frontal cortex (Fig. 25.26). Area 13 is also connected with area ProM, the gustatory area, and the ventralmost parts of areas 3b, 1, and 2 around the Sylvian operculum as well as the agranular and dysgranular insula.

Area 11

Area 11 is connected locally with orbital proisocortex and areas 13, 14, 47/12, and 10 (Fig. 25.27). It is also connected with areas 46 and 10 on the lateral prefrontal cortex and areas 9, 10, 32, and 14 on the medial frontal cortex, as well as the rostral cingulate area 24 and the caudal cingulate areas 23 and 30. Long connections link area 11 with area SII and the agranular and dysgranular insula. Area 11 also receives projections from areas IPa and

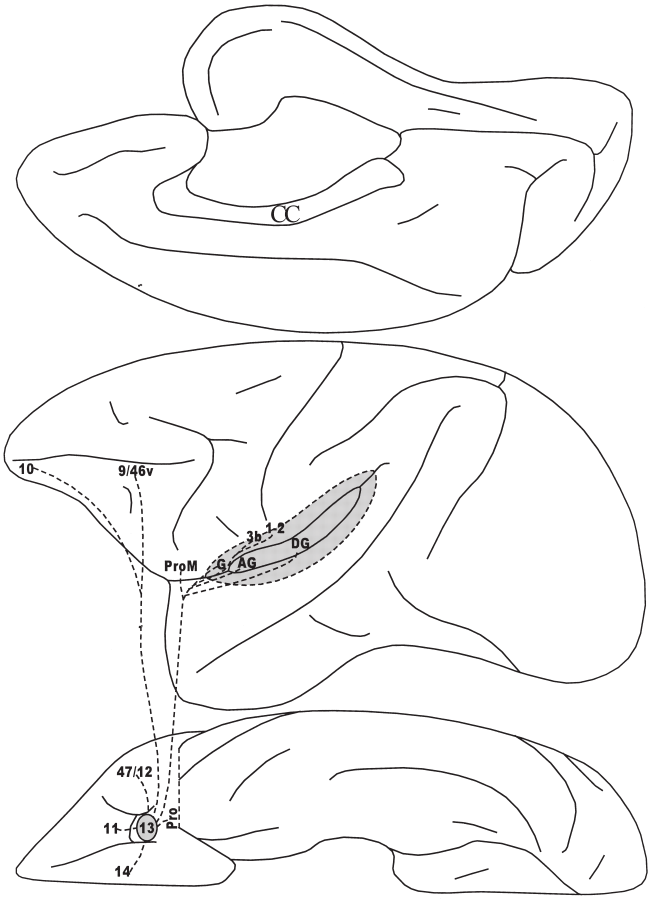

FIGURE 25.26 Diagrammatic representation of the medial, lateral, and orbital surfaces of the cerebral hemisphere of the macaque monkey to illustrate the connections of area 13. The lateral fissure has been opened up (shaded area) to show the connections within its banks.

TEa from the superior temporal sulcus as well as areas TE1 of the inferior temporal cortex. Finally, its limbic connections are derived from temporal proisocortex, area 35, and areas TF and TL.

Area 14

Area 14 on the gyrus rectus is linked locally with areas 13, 11, and the orbital proisocortex. It is also linked with medial areas 10, 9, 32, 25, and 24 (Fig. 25.28). There are also some connections with area 46. Its long connections are derived from agranular insula and the parinsular area PaI. Area 14 is also connected with the temporal polar proisocortex as well as adjoining areas TS1 and TS2. There are major connections between area 14 and the hippocampus and the presubiculum.

Orbital Proisocortex

The orbital proisocrtical area is locally connected with areas 13, 14, and 25 and the orbital periallocortex (Fig. 25.29). Its distant connections are with the gustatory area, the agranular insula, and the parinsular area PaI. The orbital proisocortex is also linked with the temporopolar proisocortex, as well as areas TS1 and TS2. It is also connected with rostral area TL and perirhinal area 35.

In the second half of the 19th century, the prevailing view of the organization of the motor system was that all movements were controlled by the brainstem and the spinal cord. The cerebral cortex was thought to be involved only in mentation and other high-order cognitive functions. In those years, the British neurologist Hughlings Jackson, on the basis of his observations on the development of somatic seizures in patients with tumors or diseases affecting the cerebral cortex, formulated his revolutionary theory. Jackson's view was that the frontal cortex controls movements in different ways and in different combinations. He differentiated the *motor cortex proper*, that is the area that contains movement representations and sends direct and indirect projections to the spinal cord, and the *superimposed cortical areas*, which, although they contain similar movement representations, are connected with the spinal motor nuclei only indirectly via the motor cortex proper. Adapting his terminology to the principle of the hierarchy of the nervous system, Jackson ranked the motor cortex proper at the *middle level* and the superimposed cortical areas at the highest levels of the motor system (Jackson, 1931). Forty years later, Campbell (1905) suggested a possible anatomical counterpart of Jackson's functional organization of the cortical motor system. According to his cytoarchitectonic map of the cerebral cortex (Fig. 26.1), the precentral cortex should mediate the executive motor functions, while the intermediate precentral cortex should represent the level of the higher motor functions. Brodmann (1909) basically agreed with Campbell's view that there are two motor areas, area 4 and area 6, but provided a more detailed map of the frontal lobe

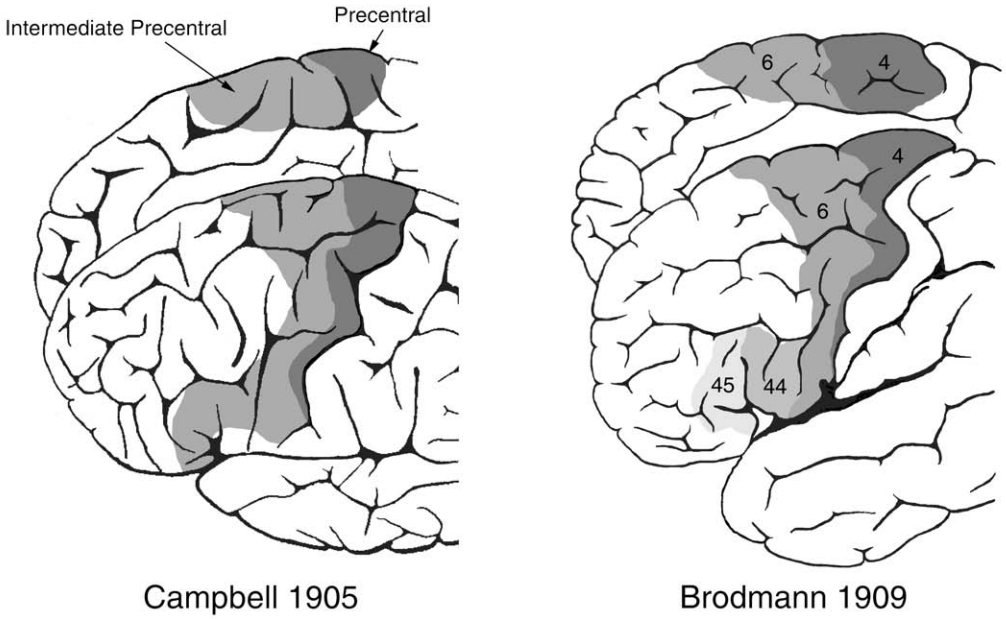

FIGURE 26.1 Cytoarchitectonic maps of the human frontal lobe, redrawn from Campbell (1905) and Brodmann (1909).

(Fig. 26.1). The notion that this architectonic subdivision could reflect functional differences was supported by Fulton (1935) who showed that ablation of area 6 (premotor cortex) produces, in addition to other symptoms, a specific deficit in the execution of skilled movements. Although these motor disturbances were described in several species of primates as in humans, some methodological weaknesses of Fulton's experiments, as well as some controversies concerning the architectonic correlates of the motor deficits hindered the acceptance of Fulton's ideas on the role of area 6.

Major criticism against architectonics arose, on the one hand, from Spanish anatomists who preferred the Golgi method in their studies of the cerebral cortex (Lorente de Nó, 1934) and, on the other hand, from psychologists (see Lashley and Clark, 1946). The idea that a boundless mind cannot be related to strictly bounded cortical areas appeared compelling for scientists devoted to understand the mind. Furthermore, in the1950s, the existence of a high-order motor area located in front of area 4 was challenged by electrophysiological studies employing surface electrical stimulation (Woolsey *et al.*, 1952). These studies, providing a detailed description of the somatotopy of the primary motor area, showed that the caudal part of area 6 is not an independent area but, together with area 4, forms the primary motor cortex (MI). In addition, the sector of area 6 located in the mesial wall of the frontal lobe was found to contain an additional somatotopically organized motor representation (the supplementary motor area, SMA). Finally, because the electrical stimulation of the rostral part of area 6 did not produce body movements, it was considered not to be involved in movement control. These data pointed against the validity of any cytoarchitectonic map, as stated by Woolsey in his influential paper: "no single cytoarchitectural area of any worker coincides with the extent of our precentral field" (Woolsey *et al.*, 1952).

A further source of skepticism on the functional validity of brain maps, derived from a large number of papers showing a great variability of the sulcal pattern among individual human brains, makes any generalization of cytoarchitectural subdivisions obtained mostly from single brains almost impossible. Given these technical and conceptual problems, the interest in anatomical research of the human brain declined, and, for a long time, the physiology of the motor system in human and nonhuman primates was largely dominated by the ideas of Woolsey. In recent years, however, neuroanatomical research in animals has significantly contributed to the study of brain circuitry and the characterization of cortical areas. Thanks to hodological and architectonic studies, there is now a general agreement that the monkey motor cortex is formed by several independent areas, each of which is identified and defined not only on the basis of its architectonic or histochemical characteristics but also on the basis of its connections, as well as its functional properties. In particular, careful studies on the descending pathways unequivocally showed that, rostral

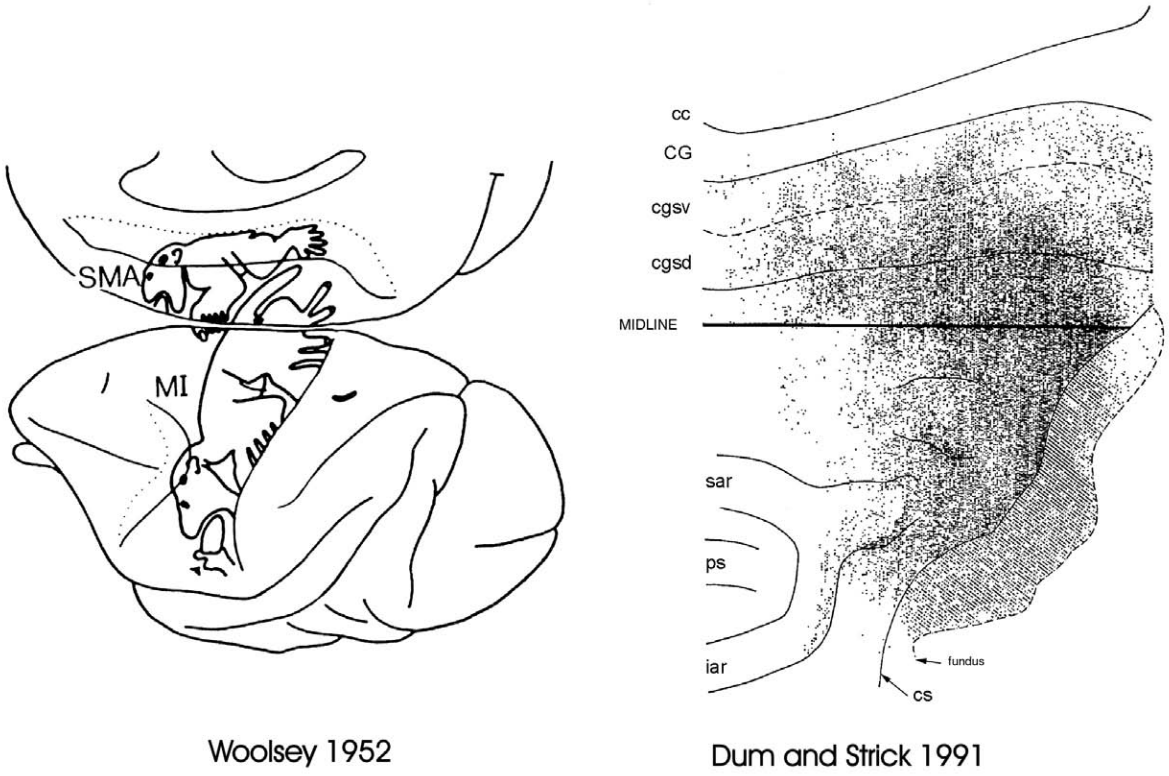

FIGURE 26.2 Mesial (top) and lateral (bottom) views of the macaque brain showing the extent of Woolsey's areas MI and SMA (Woolsey *et al.*, 1952) and a flat map of the distribution of corticospinal neurons (dots) in the frontal lobe (Dum and Strick, 1991). Abbreviations: cc, corpus callosum; CG, cingulate gyrus; cgsd, cingulate sulcus, dorsal bank; cgsv, cingulate sulcus, ventral bank; cs, central sulcus; iar, inferior arcuate sulcus; ps, principal sulcus; sar, superior arcuate sulcus.

to area 4, there are several areas projecting both to the brainstem and the spinal cord (Keizer and Kuypers, 1989). Therefore, it is quite clear today that Woolsey's MI is nothing else but a functional map of the corticospinal frontal territory and does not correspond to a single functional entity (Fig. 26.2). The aim of the present chapter is to present a modern view of the anatomical and functional organization of the agranular frontal cortex in monkeys and, by reviewing the available literature, to verify whether or not the same organizational principles are also valid for the human motor cortex.

MONKEY MOTOR CORTEX

Architectonic Subdivision of the Agranular Frontal Cortex

The agranular frontal cortex (henceforth referred to as the motor cortex) in the monkey occupies the caudal part of the frontal lobe between the fundus of the central and the fundus of the arcuate sulcus. According to the classical subdivision of Brodmann (1905), two large cytoarchitectonic areas, the caudally located area 4 and the rostrally located area 6, form the motor cortex. This subdivision was mainly based on the differential distribution, within the motor cortex, of giant pyramidal cells (Betz cells), which are abundant in area 4 but are rare or absent in area 6. Although Brodmann considered area 6 as a single entity, architectonic differences among its various parts were described in several subsequent studies (Vogt and Vogt, 1919; Bonin and Bailey, 1947; Barbas and Pandya, 1987). The possibility that architectonic subdivisions of area 6 have a functional correlate and, therefore, that architectonics can be a reliable technique for identifying functionally different motor areas has been a matter of debate for a long time. One strong argument against this possibility is the large variability among the various proposed parcellations in terms of size extent, and topography of cortical areas. Indeed, this variability results from different subjective criteria adopted by different investigators for defining borders between areas. For example, the most widely used criterion for defining

the border between areas 4 and 6 is the change in the number and density of giant pyramids in layer V. However, it is a quite common observation that these cells do not stop abruptly, but that their density decreases gradually, and that there is considerable interindividual variability among different monkeys. Therefore, if this criterion is used alone, the definition of the area 4/area 6 border becomes arbitrary. For example, this was the criterion used by Barbas and Pandya (1987) for delineating area 6DC, a cortical area, located just rostral to area 4 in the dorsal and mesial parts of the motor cortex, in which giant pyramids are scattered. Subsequent studies (see "Mesial Premotor Cortex"), however, clearly showed that this area does not correspond to any functionally independent entity and that its mesial part is nothing else but the leg field of the SMA. In contrast, when areas are defined on the basis of multiple criteria or different architectonic techniques, their definition becomes more objective and less sensitive to interindividual variability. Furthermore, it is now generally agreed that cortical areas can be identified, not only on an architectural basis but also on the basis of their connections and functional properties. If this multidisciplinary approach is adopted, maps of the monkey brain become much more reliable than they have been in the past. A clear example of the validity of this approach is the organization of the mesial sector of Brodmann's area 6. As it will be shown later in more detail (see "Mesial Premotor Cortex"), this cortical sector, once considered to be coextensive with the SMA (Woolsey *et al.,* 1952), is now almost unanimously considered to be formed by a caudal area F3 (SMA proper) and a rostral area F6 (pre-SMA, see Rizzolatti *et al.,* 1996c). The presence of an architectonic area, termed F3, occupying only the caudal part of mesial area 6 and independent from the adjoining dorsal sector of area 6, was first demonstrated by Matelli *et al.* (1985) with cytochrome-oxidase histochemistry. In a subsequent study (Matelli *et al.,* 1991), area F3 could be defined also on the basis of its cytoarchitectonic features and a new agranular area, rostral to F3, was identified and termed F6. The cytoarchitectonic border between these two newly identified mesial areas was defined on the basis of multiple criteria. For example, the caudal border of F3 with the mesial extension of area F1 (area 4) was mainly defined on the basis of clear changes in the density and arrangement of layers III and Va; therefore, the mesial part of area 6DC of Barbas and Pandya (1987) was included into a larger cytoarchitectonic entity (area F3). This subdivision of mesial area 6 was then corroborated by another completely independent approach, namely the receptor autoradiographic mapping of the binding sites of classical neurotransmitters (Geyer *et al.,* 1998). Hodological and functional data fully confirmed this subdivision and clearly demonstrated that F3 and F6 correspond to two functionally independent entities (Luppino *et al.,* 1993).

The results of the application of this kind of multidisciplinary approach to the parcellation of the whole extent of the motor cortex is represented by the map proposed by Matelli *et al.* (Fig. 26.3; Matelli *et al.,* 1985, 1991; see Rizzolatti *et al.,* 1998). This parcellation can also be found in the stereotaxic atlas of the rhesus monkey brain by Paxinos *et al.* (2000). The definition of the various motor areas of this map is mainly based on a combination of cytoarchitectonic histochemical, immunohistochemical, and neurochemical criteria but is also strongly corroborated by hodological and functional data. In this map, in analogy with von Economo and Koskinas (1925), the various areas are referred to with the letter "F." However, at variance with von Economo, numbers instead of letters, indicate the various motor areas. In this parcellation scheme, area F1 roughly corresponds to area 4, whereas each of the three main sectors of Brodmann's area 6—the mesial, the dorsal, and the ventral—is formed by a caudal and a rostral subdivision (Table 26.1).

It is quite clear, therefore, that the organization of the monkey motor cortex appears today much more

TABLE 26.1 Correspondence of Matelli *et al.*'s (1991) Nomenclature of the Agranular Frontal Areas with Brodmann's (1909) Nomenclature and the Most Widely Used Terminology in the Functional Literature

Matelli *et al.* nomenclature	Brodmann's nomenclature	Most widely used terminology in the functional literature
F1	Area 4	Primary motor cortex
F2	Dorsal sector of area 6, caudal part	Dorsal premotor cortex, caudal part (PMDc)
F3	Mesial sector of area 6, caudal part	Supplementary motor area proper (SMA proper)
F4	Ventral sector of area 6, caudal part	Ventral premotor cortex, caudal part (PMVc)
F5	Ventral sector of area 6, rostral part	Ventral premotor cortex, rostral part (PMVr)
F6	Mesial sector of area 6, rostral part	Presupplementary motor area (Pre-SMA)
F7	Dorsal sector of area 6, rostral part	Dorsal premotor cortex, rostral part (PMDr)

complex than previously thought. The motor cortex is, in fact, a mosaic of at least seven distinct areas that contains a multiplicity of body movement representations, playing a differential role in motor control.

In the next sections, the basic organizational principles of the anatomic connections of the various motor areas will be examined in order to better elucidate the functional differences among the various motor areas.

Classes of Motor Areas and General Pattern of Cortical Connectivity

Tract tracing experiments with modern neuroanatomical techniques can unravel in details the anatomic connections of each motor area with other cortical areas or subcortical structures. These data, then, provide crucial information about the functional interpretation of the role of each of these areas in motor control. Taken together, these data indicate that each frontal motor area has a specific pattern of anatomical connections. However, if the general pattern of connectivity is considered, it becomes obvious that the various frontal motor areas can be grouped into two major classes (see Luppino and Rizzolatti, 2000). The caudal motor areas F1, F2, F3, F4, and F5 form the first class. Their unifying feature is that these areas receive a primary cortical input from the parietal lobe; therefore, this class will be referred to as parieto-dependent motor areas. The rostral areas F6 and F7 form the second class. Their unifying feature is that their primary cortical input originates from the prefrontal cortex; therefore, this class will be referred to as prefronto-dependent motor areas.

Connections with the Spinal Cord and Intrinsic Motor Connections

The organization of the corticospinal projection is in agreement with the subdivision of the motor areas into two classes. Corticospinal projections originate from a large cortical territory that includes, in the frontal lobe, area 4 and the caudal part of area 6 and that, basically, corresponds to Woolsey's areas M1 and SMA. The origin of the corticospinal tract has been recently studied in great detail by Strick and co-workers (Dum and Strick, 1991; He *et al.*, 1993, 1995). These data (Fig. 26.2), when compared with the subdivision of the motor cortex, show that corticospinal projections originate from all the caudal motor areas, that is from F1, F2, F3, part of F4, and that part of F5 buried in the dorsal part of the inferior arcuate sulcus (F5 of the arcuate bank, F5ab). It is interesting to note that F2, F3, F4, and F5ab send connections also to F1 and are also connected with each other in a somatotopic manner. These data indicate that, although F1 is the only motor area provided with a rich direct access to the motor neuron pools (Porter and Lemon, 1993), all the caudal areas can be involved in movement execution, either directly, through their independent access to the spinal cord, or indirectly via F1.

In contrast, the organization of the prefronto-dependent motor areas is radically different. F6 (pre-SMA) and F7 do not project to the spinal cord, but their descending input terminates in various parts of the brainstem (Keizer and Kuypers, 1989). Furthermore, these areas are not connected with F1 and, especially in the case of F6, have more widespread connections with other motor areas. An exception is the dorsal and rostral part of F7, corresponding to the supplementary eye field (SEF; Schlag and Schlag-Rey, 1987), which has very poor connections with other motor areas but is strongly interconnected with the frontal eye field (FEF; Schall *et al.*, 1993). These data indicate that prefronto-dependent motor areas cannot control movement directly. They may control it indirectly through their subcortical relays or their connections with the parieto-dependent motor areas rostral to F1.

Connections with Other Cortical Areas

Cortical afferents to the frontal motor areas originate from three main regions: parietal cortex (primary somatosensory cortex, S1, and posterior parietal cortex), prefrontal cortex, and agranular cingulate cortex. However, as already mentioned, these projections are differentially distributed across the motor cortex (see Rizzolatti *et al.*, 1998).

The strong and reciprocal connections with the parietal cortex are the major source of input to the motor cortex, and this is especially true for the parieto-dependent motor areas. Recent functional evidence indicates that, similar to the motor cortex, the posterior parietal cortex is also formed by a multiplicity of independent areas, each of which appears to deal with specific aspects of sensory information and with specific effectors (Fig. 26.3). Furthermore, these data show that the classical distinction between an inferior parietal lobule (IPL), related to both visual and somatosensory information, and a superior parietal lobule (SPL), exclusively related to the somatosensory domain, is incorrect. Instead, both the IPL and the SPL receive somatosensory and visual input. In general, IPL areas and the posterior areas of the SPL process either visual or somatosensory and visual information, whereas the rostral areas of the SPL appear to deal almost exclusively with somatosensory information (see Caminiti *et al.*, 1996; Rizzolatti *et al.*, 1997b; Wise *et al.*, 1997). Recent studies on the organization of the parietofrontal connections indicate that motor and

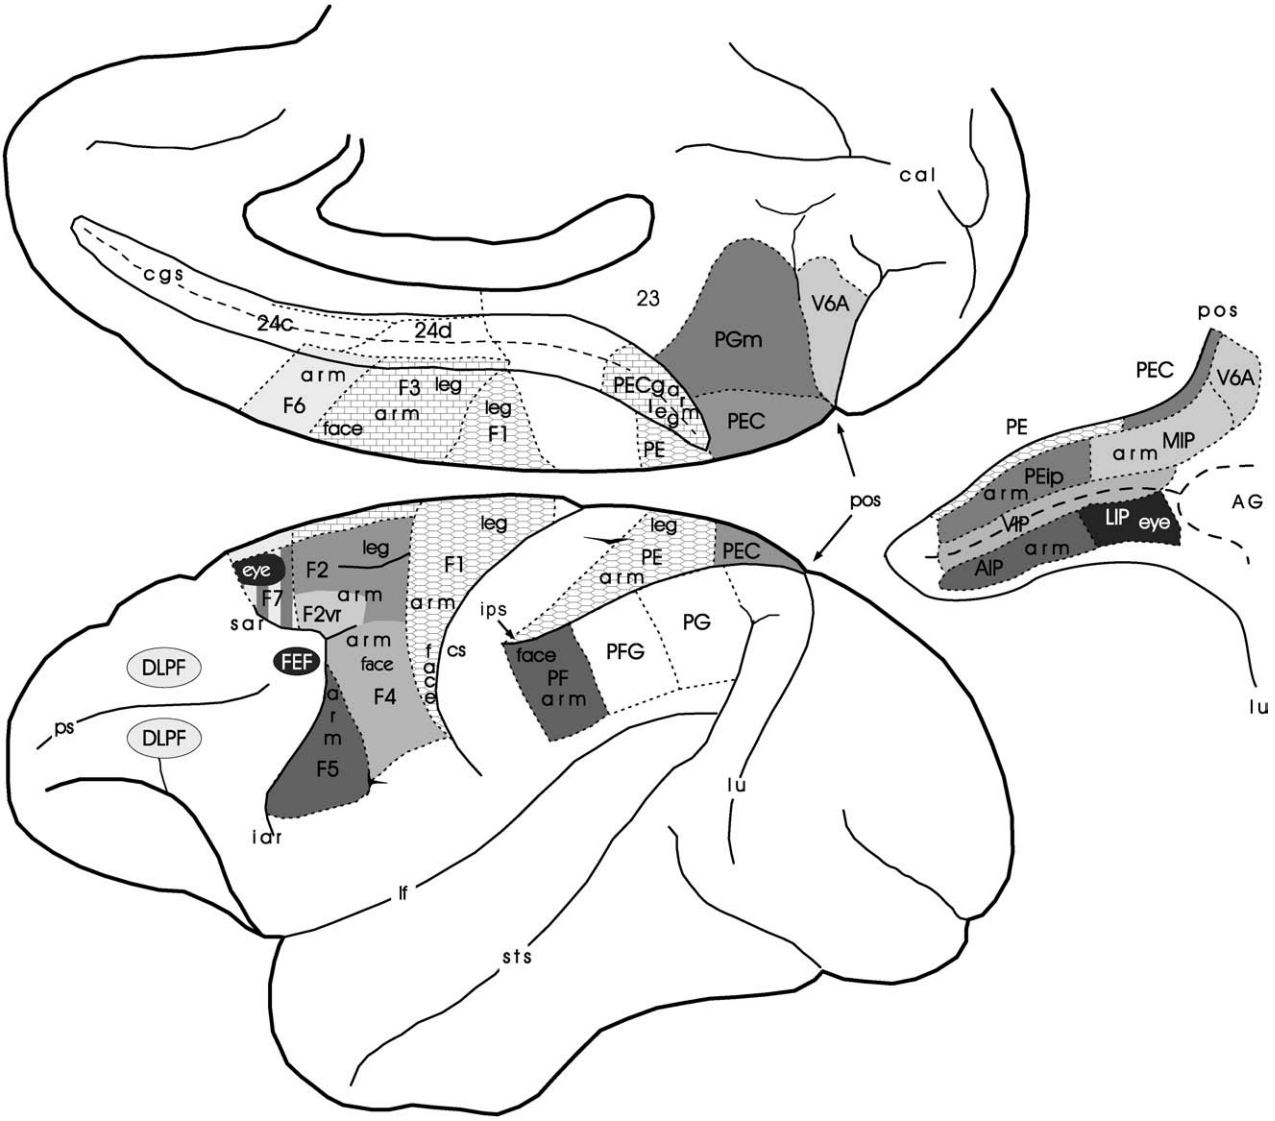

FIGURE 26.3 Mesial (top) and lateral (bottom) views of the macaque brain showing the cytoarchitectonic parcellation of the agranular frontal and posterior parietal cortex and the somatotopic representations of the body within each area. The motor areas are defined according to Matelli *et al.* (1985, 1991). The areas on the exposed surface of the parietal lobe are defined according to Pandya and Seltzer (1982), those within the intraparietal sulcus (ips) are defined according to physiological data (see text for further details) and are shown in an unfolded view of the sulcus in the right part of the figure. Frontal and parietal areas linked by predominant connections are depicted in identical gray tones or filling patterns. Abbreviations: AG, annectant gyrus; cal, calcarine fissure; cgs, cingulate sulcus; DLPF, dorsolateral prefrontal cortex; FEF, frontal eye field; lf, lateral fissure; lu, lunate sulcus; pos, parietooccipital sulcus; sts, superior temporal sulcus. Other abbreviations are as in Figure 26.2.

parietal areas are connected with each other in a very specific way (see Rizzolatti *et al.*, 1998). Each motor area is the target of a specific set of parietal areas. Typically, within such a set of parietal areas projecting to a given motor area, one area is the source of projections that are by far the strongest (predominant projections), whereas the other areas are the sources of moderate or weak projections (additional projections). Therefore, within the general framework of parieto-frontal connections, it is possible to identify a series of largely segregated anatomical circuits formed by parietal and motor areas linked by predominant connections. Functional evidence, when available, indicates that parietal and frontal areas forming each of these

circuits may share common functional properties. Therefore, the functional correlate of this anatomical organization is that each of these circuits appears to be dedicated to a particular aspect of sensory-motor transformation. The essence of this operation is the transformation of a description of the stimuli in sensory terms into their description in motor terms (Rizzolatti *et al.*, 1997b, 1998). It has been proposed that these parietofrontal circuits, and not the frontal motor areas in isolation, should be considered the functional units of the cortical motor system (Rizzolatti *et al.*, 1998).

Prefrontal projections to the motor cortex are primarily directed to F6 and F7 (Luppino *et al.*, 1993; Lu *et al.*, 1994; Luppino and Rizzolatti, 2000). However, the prefrontal input to F7 (except for the SEF) originates only from the dorsal part of the dorsolateral prefrontal cortex (DLPFd), whereas the input to F6 and the SEF originates from the dorsal and ventral parts of this prefrontal region. In addition, F6 and the SEF are also targets of strong afferents originating from the rostral cingulate cortex (area 24c). Our knowledge of the organization of the prefrontal and cingulate cortex is much less detailed than that of the parietal cortex. It is, however, widely accepted that these regions are not involved in the analysis of sensory stimuli but rather play a role in "higher order" functions such as working memory, temporal planning of actions, and motivation. Table 26.2 summarizes the sources of predominant and additional cortical afferents to each motor area. The connections among the various motor areas are not included.

From these anatomic considerations, the fact that parieto- and prefronto-dependent motor areas have a quite different functional role in motor control clearly emerges. Parieto-dependent areas, together with parietal areas, are involved in a parallel elaboration of sensory information for the transformation of it into potential motor actions. Prefronto-dependent areas, especially F6 and the SEF, appear to play a high hierarchical role in the control of body or eye movements. These areas convey inputs from the prefrontal and cingulate cortex to the parieto-dependent motor areas or to the FEF with an emphasis on motivation, long-term plans, and memories of past actions. On the basis of this information, the potential motor actions could either be implemented or remain as they are, that is that may be either cancelled or implemented later, when other contingencies allow it.

In the following sections the current knowledge of the functions of the various frontal motor areas and of

TABLE 26.2 Predominant and Additional Cortical Connections of the Motor Areas in the Macaque Monkey

Motor areas	Predominant connections	Additional connections	Proposed functional role
F1	PE	S1	Monitoring movement execution on the basis of somatosensory information
F2 dimple	PEC, PEip	CGp	Planning and controlling arm and leg movements on the basis of somatosensory information
F2vr	***MIP***	***V6A, PFG***	Planning and controlling arm trajectories on the basis of visual and somatosensory information

F5ab	*AIP,* ***PF***	***PFG,*** SII	Transforming intrinsic object properties into appropriate hand movements
F5c	***PF***	*AIP,* SII	Representing action internally for action recognition and action imitation
F6	DLPF, 24c	***PFG,*** PG	Controlling sensorimotor transformations that are processed in the parieto-dependent motor areas; controlling visuomotor associations underlying the declarative phase of motor learning
F7	DLPF	***PGm, V6A,*** CGp	Coding object locations in space for orienting and coordinating arm-body movements
F7 (SEF)	FEF	DLPF, 24c, *LIP*	Organizing eye movements in an object-centered frame of reference; monitoring the consequences of saccadic activity

For abbreviations and nomenclature of parietal and cingulate areas see Figure 26.3; parietal areas processing only visual information are appear in italic; parietal areas processing both visual and somatosensory information are appear in bold italic.

the cortical circuits in which they are involved, will be presented in greater detail.

Area F1 (Area 4)

The precentral cortex, corresponding to F1, represents a nodal point of convergence of inputs from the other parieto-dependent motor areas. It is well accepted that area F1 plays a major role in the segmentation of actions, planned by other motor areas, into elementary movements and that it is virtually unique, among the motor areas, in controlling independent finger movements (see Porter and Lemon, 1993).

The classical studies of Woolsey *et al.* (1952) showed that this area can be roughly subdivided into three main somatotopic fields: a leg field located mesially and extending also on the dorsolateral convexity, an arm field in an intermediate position, and a face field, ventrolaterally toward the Sylvian fissure. Within each of these fields, proximal movements are represented more rostrally, and distal movements, more caudally (i.e., within the anterior bank of the central sulcus). The development of intracortical microstimulation (ICMS) or spike averaging techniques revealed more detailed information on the output organization of this area and, in particular, on the exact nature of the motor representation in this area. In their pioneering ICMS study, Asanuma *et al.* (1972) proposed an organization in terms of cortical columns, each of them related to a single muscle. However, according to the study of Kwan *et al.* (1978), in awake animals, movements in the arm field of F1 are represented in terms of joints, instead of muscles. These studies suggested the existence of a "core and surround" organization with a "core" representation of digit movements located mostly within the bank of the central sulcus and surrounding concentric bands representing wrist, elbow, and shoulder movements. More recent studies proposed an organization in terms of a "fractured" somatotopy, in which arm, hand, and digit movements are represented as overlapping neuronal populations. This overlap results partly from the convergence of outputs from a wide cortical territory onto the motor neuron pools that control muscles moving a given body part. These studies suggest, therefore, that in F1 there is a cortical representation of movements that lies beyond the simple muscle or joint level (Schieber and Hibbard, 1993).

Electrophysiological studies of the functional properties of F1 neurons showed that neurons in this area are strongly activated, almost exclusively, during movement execution and can be related to a number of dynamical or kinematic parameters of the movements, such as force, velocity, and movement direction (see Porter and Lemon, 1993). According to studies of the sensory properties of F1, this area can be subdivided into a rostral and a caudal sector (Lemon, 1981) on the basis of a differential distribution of neurons responding preferentially to tactile stimulation (located more caudally, mostly within the bank) or to proprioceptive stimulation (located more rostrally, on the cortical convexity). In line with this subdivision are data on a differential thalamic input to these two regions of F1 (Matelli *et al.*, 1989; Holsapple *et al.*, 1991). However, up to now, no description of a cytoarchitectonic counterpart of this possible subdivision of F1 has been provided in the macaque monkey.

Area F1 receives a primary parietal input from area PE (see, e.g. Matelli *et al.*, 1998). It is a classical notion that area PE (area 5) is a higher order somatosensory area, mostly devoted to the analysis of proprioceptive information. The most effective stimuli for many PE neurons are specific combinations of multiple joint positions or combinations of joint and skin stimuli (Sakata *et al.*, 1973; Mountcastle *et al.*, 1975). Recently, Lacquaniti *et al.* (1995) provided evidence that many neurons in area PE code the location of the arm in space in a body-centered coordinate system. The main role of the PE–F1 circuit could be to provide F1 with information on the location of body parts necessary for the control of limb movements.

Ventral Premotor Cortex

The inferior sector of Brodmann's area 6 is generally referred to as the ventral premotor cortex (PMv) and is made up of two distinct areas: F4 and F5 (Matelli *et al.*, 1985). Recent architectonic findings indicate that area F5 is not homogeneous but consists of two major sectors (Matelli *et al.*, 1996). One is located in the posterior bank of the inferior arcuate sulcus (F5ab); the other is located on the cortical convexity immediately adjacent to the arcuate sulcus (F5 of the cortical convexity, F5c). The F5ab sector corresponds to that part of area F5 from which corticospinal projections originate. Functional data confirmed this morphological subdivision.

Area F4

Microstimulation experiments showed that in F4 there is a representation of arm, neck, face, and mouth movements. Neurons in this area fire during reaching movements directed toward the body or away from it, others discharge during orofacial movements. Neurons related to distal movements are virtually absent (Gentilucci *et al.*, 1988). F4 neurons can be subdivided into two categories according to their responses to sensory stimuli: bimodal (visual and tactile) neurons (56%) and unimodal (mostly tactile) neurons (44%; Fogassi

et al., 1996). Unimodal and bimodal neurons have the same somatosensory characteristics. Their receptive fields (RFs) are rather large and predominantly located on the face, arm, and upper part of the body. The visual RFs are located in the peripersonal space, in register with the tactile fields. In a large majority of these neurons (70%), the position of the visual RF does not change when the gaze moves; that is, regardless of where the gaze is directed, the visual RF remains in the same location with respect to the body. Similarly, the visual RF remains anchored to the tactile RF, when the body part, on which the tactile RF is located, is moved. Thus, F4 neurons appear to code space in body-parts-centered coordinates (Graziano *et al.*, 1994; Fogassi *et al.*, 1996). This particular aspect of space coding is not based on a single reference point (head, arm, or body midline), but, rather, there is a multiplicity of reference points depending on the type of movement coded by a given set of neurons (Graziano *et al.*, 1997; Rizzolatti *et al.*, 1997a).

Parietal input to F4 originates almost exclusively from area VIP, located along the fundus of the intraparietal sulcus (Fig. 26.3; Luppino *et al.*, 1999). Area VIP is the target of various visual areas belonging to the "dorsal visual stream" (among them areas MST and MT), involved in the analysis of optic flow and in motion perception (see references in Rizzolatti *et al.*, 1998). In addition, VIP receives somatosensory information from areas PEc and PFG (Seltzer and Pandya, 1986). VIP neurons fall into two main categories: purely visual neurons and bimodal (visual and tactile) neurons (for references on VIP functional properties, see Colby, 1998). Bimodal neurons respond independently to visual and tactile stimuli. Their tactile RFs are located predominantly on the face, and their visual RFs are located in those parts of the field of vision that correspond to the tactile RFs, many of them limited to the peripersonal space. In about one third of visually responsive neurons, as in F4, the visual RF is coded in egocentric and not in retinal coordinates. On the basis of these data, it has been suggested that F4, together with VIP, is part of a parietofrontal circuit involved in encoding peripersonal space and in transforming object locations into appropriate movements toward them (Rizzolatti *et al.*, 1997b, 1998; Colby 1998).

Area F5ab

Area F5 is electrically excitable and contains a movement representation of the hand and the mouth. F5 neurons typically code goal-directed motor acts of the hand, the mouth, or both. Their firing is correlated with action execution and not with the individual movements forming it. According to the coded action, F5 hand neurons were subdivided into various classes. Neurons encountered more frequently are grasping, holding, tearing, and manipulating neurons. Most "grasping" neurons code specific types of hand prehension such as precision grip, whole hand prehension, and finger prehension (Rizzolatti *et al.*, 1988).

A considerable part of F5 neurons respond to visual stimuli. Most of the visually responsive neurons located in F5ab belong to a class of neurons referred to as "canonical" neurons. These neurons discharge to the presentation of three-dimensional objects, even when no immediate or subsequent action upon the object is allowed (Murata *et al.*, 1997). These responses are most likely the result of a "pragmatic" representation of the object in which the object's intrinsic properties (size, shape, and orientation) are coded for the selection of the most appropriate way to grasp it.

Area F5 receives predominant projections from two parietal areas: AIP and PF. Recent anatomical data, however, showed that the AIP projections are selectively directed to F5ab (Luppino *et al.*, 1999). Prefrontal afferents to F5 are very weak.

Area AIP occupies the rostral part of the lateral bank of the intraparietal sulcus (Fig. 26.3). AIP neurons were studied in monkeys trained to reach for and grasp objects of different size and shape, in dark or in light (Sakata *et al.*, 1995; Murata *et al.*, 2000). Most neurons discharge when grasping specific objects and may have visual responses selective for the type of object presented. AIP neurons were classified into three groups: "motor-dominant," "visual and motor," and "visual-dominant" neurons. Motor-dominant neurons are task-related and that fire equally well in dark or in light; visual and motor neurons are less active in dark than in light; and visual-dominant neurons fire only when the stimulus is visible, but not when the task is performed in the dark. Many visually responsive neurons also discharge when objects are simply fixated and no action upon them is required. In these neurons, the visual responses appear to represent specific intrinsic properties of the object. In most visual and motor neurons, the intrinsic characteristics of the object effective in triggering a neuron and the type of grip coded by that neuron matched, suggesting that these neurons correlate the intrinsic geometric properties of the object with the appropriate hand movement for grasping it. These data clearly show that there is a part of the dorsal visual pathways, in which AIP is involved, concerned with the aspect of form, orientation and/or size perception, relevant for the visual control of grasping movements.

On the basis of these data, it has been suggested that F5ab, together with AIP, is part of a parietofrontal circuit dedicated to visuomotor transformations for grasping (Jeannerod *et al.*, 1995).

Strong support for a crucial role of the F5ab-AIP circuit in visuomotor transformations for grasping was recently provided by studies in which the two areas were separately inactivated (Gallese *et al.*, 1994; Fogassi *et al.*, 2001). The independent inactivation of AIP and F5ab resulted in a disruption of the preshaping of the hand during grasping (i.e., a mismatch between the geometrical properties of the object to be grasped and the most appropriate position of the hand and fingers in order to accommodate this object). When the monkey eventually managed to grasp the objects, the grip was achieved only after a series of corrections based on the tactile exploration of the object. Therefore, a lesion of the AIP-F5ab circuit does not disrupt the ability to perform grasping movements, but only the capacity to transform the three-dimensional properties of the object into appropriate hand movements.

Area F5c

Neurons located in F5c are indistinguishable from F5ab neurons as far as their motor properties are concerned. As in F5ab, a considerable proportion of F5c neurons respond to visual stimuli. However, the visual properties of F5c neurons are markedly different from those in F5ab. Their main characteristic is that they discharge when the monkey observes another individual performing an action similar to that coded by the neuron. For example, a neuron activated by the actual performance of a grasping movement by the monkey also fires when the monkey observes the experimenter, or another monkey, grasping the object. Object presentation alone is not sufficient to activate them. Because of this correspondence between visual and motor properties, these neurons were referred to as mirror neurons (Gallese *et al.*, 1996; Rizzolatti *et al.*, 1997b).

The existence of these neurons suggests an important cognitive role for the motor cortex: that of representing actions internally. This internal representation, when evoked by an action made by others, as is the case in the previously mentioned experiments, could be involved in two related functions: action imitation and action recognition. This hypothesis is even more interesting if it is considered that, according to the classical literature, F5 should be the homologue of at least a part of, if not the entire, human Broca's region (for a review of the data and theoretical considerations, see Rizzolatti *et al.*, 1996a; Rizzolatti and Arbib, 1998). F5c receives predominant parietal projections preferentially from area PF. Although neurons with mirror characteristics appear to be present also in area PF (Fogassi *et al.*, 1998), our limited knowledge of the functional properties of this parietal area precludes, at the moment, any speculations about the possible functional role of this anatomical circuit.

Dorsal Premotor Cortex

Superior area 6, generally referred to as dorsal premotor cortex (PMd), is made up of two areas: F2 and F7 (Fig. 26.3). Although F2 appears to be cytoarchitectonically homogeneous, recent evidence (Fogassi *et al.*, 1999) suggests that it should be subdivided into two functional sectors: one located around the superior precentral dimple (F2 dimple, F2d) and the other occupying its ventrorostral part (F2vr). Support in favor of this subdivision has also been provided by anatomical data (Matelli *et al.*, 1998, see "Area F2"). Like F2, F7 is also made up of two distinct functional sectors: a dorsorostral and a ventrocaudal one. The dorsorostral sector corresponds to the supplementary eye field (Schlag and Schlag-Rey, 1987).

Area F2

Area F2 is electrically excitable and has a rough somatotopic organization with a leg and an arm representation located dorsal and ventral to the superior precentral dimple, respectively (Kurata, 1989; Dum and Strick, 1991; He *et al.*, 1993; Fogassi *et al.*, 1999). Functional studies of F2 were mostly focused on its motor properties, by employing visually instructed motor delay tasks (see Wise *et al.*, 1997). Typically, in these tasks, a motor response (very often an arm movement) is performed after a delay from the appearance of a visual stimulus instructing the monkey which particular movement to perform. Some F2 neurons discharge in association with movement onset (movement-related activity), others become active during the delay period when the monkey is waiting for the go signal (set-related activity), and others discharge at the appearance of the instruction stimulus (signal-related activity). The percentage of these "signal-related" neurons is higher in the rostral part of F2 than in its caudal part (dimple region; see Wise *et al.*, 1997). These data indicate that F2 is not simply involved in motor execution, but plays a role also in some aspects of motor preparation (see Wise *et al.*, 1997). There is little information on the responses of F2 neurons to sensory stimuli. Many F2 neurons respond to somatosensory stimuli and, in particular, to proprioceptive input. Recent evidence indicates that there is a differential distribution of sensory properties within F2. While in F2d, most neurons respond to proprioceptive stimuli; neurons in F2vr also respond to tactile and visual stimulation (Fogassi *et al.*, 1999). Furthermore, it has been reported that in F2vr, but not in F2d, information about the target location and the arm to be used can be integrated at the single neuron level to plan a forthcoming action (Hoshi and Tanji, 2000).

Hodological data showing that F2d and F2vr are involved in different parietofrontal circuits also

supports this functional segregation within F2. While F2d receives predominant projections from areas PEC and PEip, the primary parietal input to F2vr originates from area MIP and V6A (Matelli *et al.*, 1998). Furthermore, F2vr, but not F2d, is the target of a minor but consistent projection from the dorsal part of prefrontal area 46.

Our knowledge of the functional properties of area PEC is very limited. This area is richly connected with area PE (Pandya and Seltzer, 1982); therefore, it should be basically involved in the analysis of somatosensory stimuli for movement organization. Electrophysiological studies of neighboring regions, in which occasionally PEC neurons were recorded, confirm this conclusion (Galletti *et al.*, 1996).

Area PEip was defined as that part of the medial bank of the intraparietal sulcus (roughly its rostral half) that is the source of corticospinal projections (Matelli *et al.*, 1998). Functional studies showed that neurons in this region become active in association with arm movements (Kalaska *et al.*, 1990). Typically, the discharge is stronger when the arm is projected in a certain direction. The directional tuning is usually broad. Most PEip neurons respond to somatosensory stimuli (Mountcastle *et al.*, 1975; Iwamura and Tanaka, 1996). According to these data, F2d should be the target of higher order somatosensory information. Recent observations indicate that in a restricted region, most likely corresponding to the posterior part of area PEip, there are neurons with bimodal (tactile and visual) RFs (Iriki *et al.*, 1996). The functional properties of these neurons are, for many ways, similar to those of F4 neurons, but not to those of F2d; indeed, F4 is the target of additional projections from PEip. It is, therefore, possible that some kind of visual information also reaches F2d.

Even though PEip and PEC appear to be mostly involved in the somatosensory control of movements, both area MIP and area V6A use also visual information for the same purpose. Area MIP is located in the caudal part of the medial bank of the intraparietal sulcus (see Colby, 1998). Neurons in this area are strongly activated when the monkey reaches for a visual target. Many of them show responses to pure visual stimuli or to both visual and somatosensory stimuli (bimodal neurons). Area V6A is located in the dorsal part of the anterior bank of the parietooccipital sulcus (Galletti *et al.*, 1999). About half of the V6A neurons discharge in response to visual stimuli. The remainder discharges mostly in association with eye or arm movements. In contrast to what is observed in most visual areas, there is no magnification of the foveal representation in V6A.

In conclusion, the PEip/PEC-F2d circuit appears to be involved in planning and controlling arm (and leg) movements mostly on the basis of somatosensory information. In contrast, the MIP/V6A-F2vr circuit may use both somatosensory and visual information probably for the same purpose. Monitoring and controlling arm position during the transport phase of the hand toward the target could be one of the major functions of this circuit.

Area F7

As already mentioned, area F7 is also functionally not homogeneous. The dorsal part of this area contains the SEF, an oculomotor field that can be identified with intracortical microstimulation. Anatomically, the SEF is strongly connected with the FEF, but it is also the target of strong projections from both dorsal and ventral areas of the dorsolateral prefrontal cortex (DLPF; Huerta and Kaas, 1990; Luppino *et al.*, 1990). Furthermore, the SEF receives afferents from the rostral cingulate cortex (Huerta and Kaas, 1990; Luppino, *et al.*, 1990). These anatomical data suggest that the SEF could be involved in the control of eye movements at a higher hierarchical level than the FEF. In line with this hypothesis are functional data showing that SEF is involved in encoding saccades relative to an object-centered frame of reference (Olson and Gettner, 1995) or in monitoring the consequences of eye movements (Stuphorn *et al.*, 2000).

The remaining part of F7 is scarcely excitable and has been the target of only a few functional studies. Some F7 neurons show visual responses even when the stimulus is not instructing a subsequent movement (di Pellegrino and Wise, 1991). Others show visual responses when the location of the stimulus matches with the target of an arm movement (Vaadia *et al.*, 1986). F7 is the target of predominant projections from the DLPFd, mainly dorsal area 46 and area 8b. According to some authors (Wilson *et al.*, 1993), this prefrontal region should be mainly involved in the working memory of spatial positions. Minor inputs to F7 originate mainly from parietal area PGm, whose functional role is still largely unknown. Recent studies showed that PGm neurons may discharge during eye and/or arm movements (Ferraina *et al.*, 1997). On the basis of this information, it is possible to suggest that the DLPFd-F7 circuit could be involved, with the contribution of PGm, in coding object locations for orienting and coordinating arm–body movements.

Finally, ablation studies showed that monkeys, previously trained to make arbitrary goal-directed movements, following lesions of the postarcuate cortex, were no longer able to execute the task, although no obvious motor deficit was present. If one compares the location of the lesions reported in the literature (see references in Passingham, 1993), it emerges that F7, plus the rostralmost part of F2, were the only regions

damaged in all monkeys. Therefore, a further function of area F7, possibly with the contribution of F2vr, is to play a crucial role in conditional stimulus–response association tasks (see Passingham 1993).

Mesial Premotor Cortex

The mesial part of Brodmann's area 6 is occupied by two architectonic areas: F3, or SMA proper, and F6, or pre-SMA (Matelli *et al.,* 1991, Geyer *et al.,* 1999). Classically, this cortical sector was considered to be coextensive with the so-called supplementary motor area, defined by Woolsey using gross electrical stimulation (Fig. 26.2). It was widely accepted that the SMA collaborated with the primary motor cortex in movement execution, especially for proximal and axial movements. Later, experiments in monkeys and humans yielded conflicting results on the possible role of the SMA in motor control. Some data appeared to confirm an executive role of the SMA in motor control, while others favored what was called a "supramotor" role of the SMA, that is a role in those processes that precede the actual movement execution. The discovery that, in monkeys, mesial area 6 is composed of two distinct areas (Luppino *et al.,* 1991; Tanji 1994; Rizzolatti *et al.,* 1996c) was crucial for reconciling these apparently conflicting results.

Area F3 (SMA Proper)

Intracortical microstimulation studies showed that F3 is electrically excitable with low-intensity currents and contains a complete body movement representation (Luppino *et al.,* 1991). Evoked movements mainly involved proximal and axial muscles and, typically, a combination of different joints, even at the minimal effective current intensity. Distal movements, when evoked, were often observed in combination with the proximal ones. Single-unit recordings showed that many F3 neurons exhibit somatosensory responses. Most F3 neurons discharge in association with active movements, and their discharge onset is typically time-locked to the movement onset (movement-related activity). Some F3 neurons were found to fire exclusively in relation to specific sequences of movements (see Tanji and Shima, 1996).

Area F3 appears, therefore, in many ways functionally similar to F1. Some major differences, however, distinguish these two areas. First, in F1 proximal and distal movements are anatomically segregated, while they are mixed in F3 (Luppino *et al.,* 1991). Second, ICMS typically evokes single joint movements in F1, whereas movements involving two or more articulations are often observed in F3 (Luppino *et al.,* 1991). Finally, although still controversial (see, e.g., He *et al.,* 1995), in F3 proximal movements appear to be much more represented than are distal movements (Penfield and Welch 1951; Woolsey *et al.,* 1952; Luppino *et al.,* 1991; Maier *et al.,* 1997).

F3 is the target of predominant projections from the caudal and dorsal part of area 24 (area 24d) and from parietal area PECg, located in the caudalmost part of the cingulate sulcus (Luppino *et al.,* 1993). Area 24d is architectonically distinct from the rostral cingulate area 24c (Matelli *et al.,* 1991; Nimchinsky *et al.,* 1996) and roughly corresponds to what is also referred to as "caudal cingulate motor area" (Dum and Strick, 1993). This area is electrically excitable, contains a leg and an arm representation, and is the source of topographically organized projections to the spinal cord and to F1 (Luppino *et al.,* 1991, 1993; He *et al.,* 1995). Thus, area 24d can be considered as another motor area, functionally assimilable to the caudal group of the agranular frontal areas.

Area PECg was cytoarchitectonically defined by Pandya and Seltzer (1982). Anatomical data of the same authors showed that area PECg is connected with areas PE, PEC, and PGm. In the only one functional study of this area, Murray and Coulter (1981), claimed that this area contains a complete somatosensory map of the body. Because of this finding and its anatomical location, PECg was termed the supplementary sensory area.

Taken together, these data suggest that F3 (or possibly the PECg-F3 circuit) controls the motor activity in a global way. In particular, it has been proposed that F3 may use the knowledge of the actual limb position to prepare the posture necessary for forthcoming movements, thus playing a fundamental role in predictive postural adjustments (Massion, 1992). F3 also appears to contribute to the initial stages of learning of motor sequences that improve performance (Hikosaka *et al.,* 1999). According to others, F3 is involved in the execution of certain motor sequences (Tanji *et al.,* 1996).

Area F6 (Pre-SMA)

F6 is weakly excitable with intracortical microstimulation. Motor responses can be evoked from it only with rather high current intensities and, typically, they consist of slow and complex movements restricted to the arm (Luppino *et al.,* 1991). Visual responses are common in F6, while somatosensory responses are rare. When tested during active arm movements, F6 neurons show a long leading activity during preparation for movement, and some of them fire in relation to a redirection of an arm movement to a direction opposite to one previously rewarded (shift-

related activity; Matsuzaka and Tanji, 1996). Other experiments demonstrated that F6 neurons are excited or inhibited when objects, moved toward the animal, enter into its reaching distance and, therefore, appear to be modulated by the possibility of grasping an object (Rizzolatti *et al.*, 1990).

Finally, recent data showed that F6 plays a key role in the early stages of motor learning, precisely when the cognitive aspect of the procedure to be learned is acquired. This conclusion is based on the behavior of single neurons and on inactivation experiments showing that the number of errors for learning new sequences increases after muscimol injections into this area. In contrast, the performance of learned sequences is not affected by pre-SMA inactivation (see Hikosaka *et al.*, 1999).

The cortical connections of F6 are unique among the various motor areas in that only this area receives predominant projections from the dorsal and ventral parts of prefrontal area 46 and from the rostral cingulate area 24c (Luppino *et al.*, 1993; Lu *et al.*, 1994). F6, therefore, is a privileged site of convergence of information possibly related to the working memory of objects or space locations, to the temporal planning of actions, or to motivation that is, then, distributed to the other motor areas. These data suggest for F6 a double role in motor control. A first role is the control of the sensorimotor transformations that occur in the parieto-dependent motor areas. Normally, even when parietofrontal circuits are activated, the movement does not start. Only when external contingencies and motivational factors allow it, does F6 render the movement onset possible. A second possible role of F6 is more cognitive. It is in the control of visuomotor associations underlying the declarative phase of motor learning.

HUMAN MOTOR CORTEX

Comparative Architectonics of the Human and Monkey Motor Cortex

Cytoarchitectonically, area F1 is characterized by low cell density, poor lamination, the absence of layer IV, and a very prominent layer V with giant pyramidal cells arranged in multiple rows (Matelli *et al.*, 1991). On the mesial surface, the area next to F1 in the rostral direction is F3. As F1, area F3 is poorly laminated. One of its most important distinguishing feature is the increase in cellular density in the lower part of layer III and in layer Va. Layer Vb is pale as in F1. Giant pyramidal cells are absent in most of F3. The agranular area rostral to F3 is F6. Unlike areas F1 and F3, this area is clearly laminated and has a dark and very prominent layer V, well demarcated from the less dense layers III and VI. At the rostral border of F6, an incipient layer IV becomes recognizable. More recently, receptor autoradiographic data showed that clear-cut changes in the laminar binding patterns of glutamate (AMPA and kainate) and muscarinic cholinergic receptors closely match cytoarchitectonic borders in adjacent sections stained with the Nissl method (Matelli *et al.*, 1991; Geyer *et al.*, 1998). On the lateral convexity, area F2 is poorly laminated like areas F1 and F3, but unlike F1, it contains only few, scattered giant pyramidal cells especially in its caudal part. Lower layer III is characterized by a thin row of medium-sized pyramids. Layer V is slightly denser and darker than in F1, while the density of layers III and V is slightly lower than in area F3. Area F7 is clearly laminated and differs from F2 in two ways: the presence of a prominent layer V and the subdivision of layer VI into two sublayers. Layer VIa is pale, whereas layer VIb is dark and dense. The area rostral to F7 shows an incipient layer IV, and its laminar organization is more distinct than that of the agranular frontal cortex (Matelli *et al.*, 1991). Also the ventral part of area 6 consists of two areas: area F4 rostral to F1 and area F5 in the rostralmost part of ventral area 6. Area F5 has a common border with the prefrontal cortex. Although these areas have been identified on the basis of laminar differences in the distribution pattern of cytochrome-oxidase activity, preliminary cytoarchitectonic data confirm the histochemical parcellation. In area F4, the overall cell density is low, and pyramids increase in size from superficial to deep layer III. In layer V, large pyramidal cells are scattered especially in the dorsal part of area F4, near the spur of the arcuate sulcus. Area F5 is clearly laminated, and its cell density is higher than in F4. Single large pyramidal cells in layer V are present only in that part of area F5 that is buried in the posterior bank of the arcuate sulcus (F5ab). In contrast, a layer V devoid of large pyramids (Matelli *et al.*, 1996) characterizes the part of area F5 lying on the cortical convexity (F5c).

The cytoarchitectonic features and the topography of the human precentral motor cortex are very similar to those of the macaque. Also in humans, low cell density, poor lamination, the absence of layer IV, and Betz cells in layer V characterize the precentral motor cortex (Brodmann's area 4). Scattered or absent giant pyramidal cells and larger, more elongated, and more densely packed pyramids in lower layer III characterize Brodmann's area 6. Close to the midline, the rostral border of area 4 lies on the exposed cortical surface. More ventrolaterally, it recedes in the caudal direction and eventually disappears in the depth of the

central sulcus. The mesial part of area 4 occupies part of the paracentral lobule. Recently, human area 4 has been subdivided into a caudal (area 4 posterior or 4p) region and a rostral (area 4 anterior or 4a) region, based on differences in cytoarchitecture and neurotransmitter binding sites (Geyer *et al.*, 1996). The two areas form two parallel bands within area 4 running mediolaterally from the midline to the Sylvian fissure. Clear-cut changes in the laminar binding patterns, especially of muscarinic cholinergic (revealed with [^{3}H]oxotremorine-M) and serotoninergic (revealed with [^{3}H]ketanserine) binding sites, closely match corresponding cytoarchitectonic borders. Lower layer III pyramidal cells are small and loosely aggregated in area 4p, and larger and more densely packed in area 4a. Mean regional binding densities of many neurotransmitter binding sites tend to be higher in area 4p, whereas they are lower in area 4a. At present, it is unclear whether there is any homology between human areas 4a and 4p and the two functional or hodological subdivisions described in the macaque monkey (see "Area F1 (Area 4)"). Cytoarchitectonic similarities between humans and macaques are also obvious on the mesial cortical surface. Two recent comparative studies (Zilles *et al.*, 1995, 1996) found striking architectonic similarities between macaque areas F3 and F6 and the mesial parts of human areas 6aα and 6aβ (according to the nomenclature of the Vogts, 1919), respectively. Additional similarities have been found on a neurochemical basis (Zilles *et al.*, 1995, 1996; Geyer *et al.*, 1998). For example, [^{3}H]kainate binding sites are mainly concentrated in the deep layers in both areas, in macaques and humans. Binding density in area F3/mesial 6aα is higher than in the precentral motor cortex and higher than in the lateral premotor cortex in both species. [^{3}H]oxotremorine-M binding sites show a superficial and a deep cortical band of maximal binding densities in both species. There is a caudorostral increase in binding densities from the precentral motor cortex to area F6 in macaques and to mesial area 6aβ in humans. On this basis one may speculate that human mesial areas 6aα and 6aβ are possibly homologous to macaque areas F3 (SMA proper) and F6 (pre-SMA), respectively.

In humans, the border between the primary motor cortex and mesial area 6aα coincides approximately with the VCP line (vertical through the posterior commisure). The border between mesial area 6aα and mesial area 6aβ coincides approximately with the VCA line (vertical through the anterior commisure; Zilles *et al.*, 1996). The coincidence of the borders between the primary motor cortex/SMA proper and the SMA proper/pre-SMA with the VCP and VCA lines, respectively, has also been shown by Vorobiev *et al.* (1998). In the latter study, the human SMA proper has been further subdivided into a caudal (SMAc) and a rostral (SMAr) part. This subdivision of the human SMA proper may reflect different somatotopic representations or a more fine-grained functional differentiation (see "Mesial Premotor Cortex"). What is relevant in this study and in that of Geyer *et al.* (1996) is the greater fractionation of the human agranular cortex in comparison with that of the macaque. In particular, considering the cytoarchitectonic characteristics of SMAr and SMAc, it may be speculated that these two areas evolved from a common precursor, anatomically similar to the monkey F3, as a consequence of a process of differentiation of a single field into two fields. For a description of the adjoining areas of the cingulate cortex see Chapter 24.

On the cortical convexity of the macaque, a clear anatomical landmark—the arcuate sulcus—separates the agranular frontal from the granular prefrontal cortex. In the human brain, a comparable sulcus is not evident, but the spatial distribution of the agranular cortex (Brodmann's areas 4 and 6, plus dysgranular area 44; see "Ventral Premotor Cortex" for a further discussion on areas 44 and 45) is strikingly similar. In both species, the prefrontal cortex extends caudally in the middle of the dorsolateral convexity, as if pushing back the agranular cortex; conversely, it recedes rostrally in the dorsomedial and ventrolateral parts of the convexity. The prefrontal cortex is discussed in more detail in Chapter 25.

In a recent review article (Rizzolatti and Arbib, 1998), an attempt was made to define homologies between the human and macaque premotor cortex. It was proposed that the superior frontal and superior precentral sulcus (Fig. 26.4) represent the human homologue of the macaque superior arcuate sulcus (Fig. 26.4). Accordingly, the two areas that occupy the rostral part of the precentral gyrus and the caudal part of the superior frontal gyrus (superior part of area 6aα and area 6aβ according to Vogt and Vogt, 1919) could correspond to macaque areas F2 and F7, respectively. The inferior frontal sulcus and the ascending branch of the inferior precentral sulcus could correspond to the macaque inferior arcuate sulcus, while the descending branch of the inferior precentral sulcus could correspond to the inferior precentral dimple of the macaque monkey. Accordingly, the inferior part of area 6aα and area 44 should be homologous to macaque areas F4 and F5, respectively. An open issue is the macaque homologue of Brodmann's human area 45. Walker (1940) described an area, termed area 45, which lies in the rostral bank of the inferior arcuate sulcus of the monkey. Petrides and Pandya (1994) proposed that this area is the homologue of human

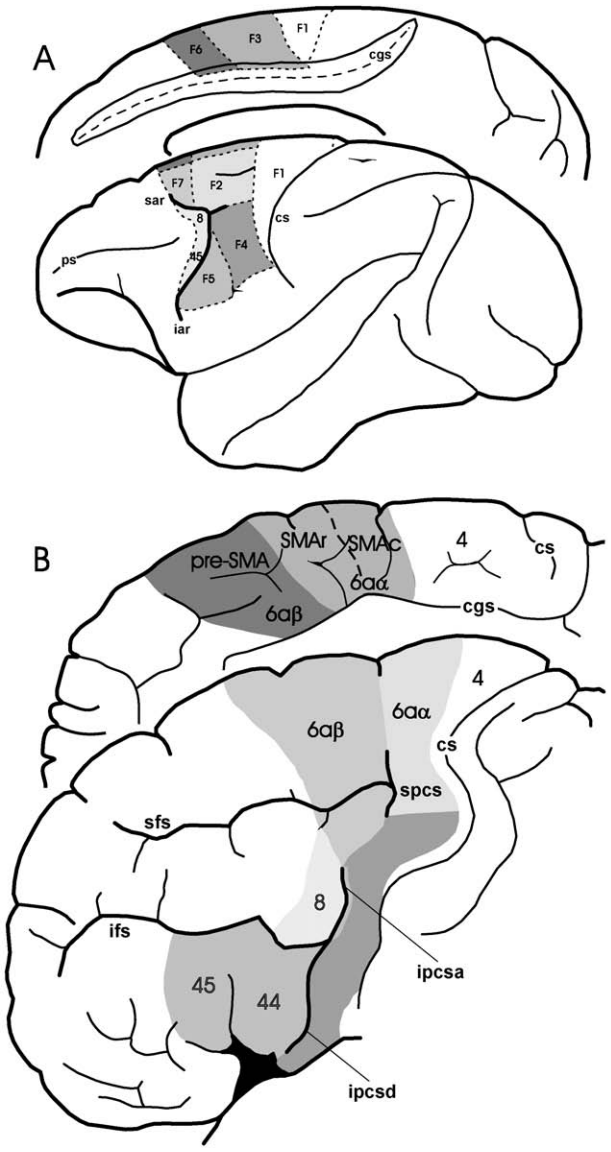

FIGURE 26.4 Proposed homologies between the monkey and human motor cortices. The monkey architectonic map **(A)** is according to Matelli *et al.* (1985, 1991). The human architectonic map **(B)** is according to Brodmann (1909); Brodmann's area 6 is further subdivided according to Vogt and Vogt (1919). Areas of the two species considered to be homologous are depicted in identical gray tones. The data are based on cytoarchitectonics, electrical stimulations, and sulcal ontogeny. The superior frontal sulcus (sfs) and the superior precentral sulcus (spcs) of the human brain are considered to correspond to the superior limb of the arcuate sulcus (sar) in the macaque. The inferior frontal sulcus (ifs) and the ascending branch of the inferior precentral sulcus (ipcsa) of the human brain are considered to correspond to the inferior limb of the arcuate sulcus (iar) in the macaque. The descending branch of the inferior precentral sulcus (ipcsd) is considered to correspond to the inferior precentral dimple (not labeled in A) in the macaque. For further details, see "Mesial Premotor Cortex." Abbreviations: cgs, cingulate sulcus; cs, central sulcus. Other abbreviations as in Figure 26.3.

area 45. However, available data suggest that, in the monkey, area 45 is mostly related to eye movements (Bruce *et al.*, 1985), while human area 45 is part of Broca's speech region. There are no reports in the literature that human area 45 might be involved in eye movements. The distinguishing cytoarchitectonic feature of human areas 44 and 45 is the presence of very large and darkly stained pyramidal neurons in layer III. As mentioned earlier, this is also a distinguishing feature of the motor areas rostral to the precentral motor cortex in both human and macaque. Area 44 is further characterized by the presence of a population of large pyramids in layer V and a barely recognizable dysgranular layer IV, which is invaded to different degrees by layer III and layer V pyramidal cells (Type 2 of general subdivision of the cerebral cortex of von Economo and Koskinas, 1925). Area 45 differs essentially from area 44 by an increase in the thickness of layer IV (Amunts *et al.*, 1999). A recent immunohistochemical study of the human inferior frontal gyrus (Hayes and Lewis, 1992) confirmed that the thickness and the cellular organization of layer IV is critical in differentiating area 44 from area 45. Therefore, if one considers the cytoarchitectonic similarities between human areas 44 and 45 and their similar age of myelinization onset (see Flechsig, 1898; Vogt and Vogt, 1919), an alternative interpretation would be that both areas evolved from the monkey area F5.

Taken together, modern architectonic studies of the human agranular frontal cortex reveal three main organizational principles: (1) the human motor cortex, as in monkeys, is formed by a mosaic of different architectonic areas; (2) in the human motor cortex, however, both the number of areas and the variability in their location and extent is larger than in the macaque; (3) in the human cortex, the spatial congruence between architectonic borders and macroscopic features (gyri, sulci) is lower than in the monkey. According to Rademacher *et al.* (1993), primary cortical areas bear a characteristic relationship to a set of sulci; therefore, their location can be predicted on the basis of sulcal patterns (class 2 variability). In contrast, it is impossible to predict with a high level of reliability the location of nonprimary cortical areas, on the basis of the sulcal pattern (class 1 variability). For an overview of the architecture of the cerebral cortex, see Chapter 27.

This spatial variability of most areal borders relative to surface landmarks is a crucial factor for the architectonic interpretation of activation foci in functional imaging studies. Classical maps, based on observations in single brains, cannot provide information on interindividual variability in the extent of cytoarchitectonic areas and their location relative to the sulcal pattern. The correlation between microstructure and

function of the agranular frontal cortex will became much more precise and valid when it will be possible to superimpose probability maps of cytoarchitectonically defined areas obtained from several brains, with activation foci obtained from functional imaging studies in the three-dimensional space of a common spatial reference system (e.g., the reference brain of a computerized atlas; Roland and Zilles, 1994).

Functional Organization of the Human Motor Cortex

Functional evidence, mostly from neuroimaging studies, indicates that the human motor cortex shares several general organizational principles with the monkey motor cortex. One important aspect is the existence of multiple representations of body movements in the human motor cortex. For example, Fink *et al.* (1997) observed that simple flexion and extension movements of the fingers induce several independent activations in the precentral motor cortex, the SMA proper, the dorsal premotor cortex, and the frontal operculum, as well as in the cingulate motor areas. Furthermore, this study showed that, in addition to the primary (S1) and secondary (SII) somatosensory areas, two further arm and finger representations are located in the superior and inferior parietal lobules. These observations fit well with the notion that multiple motor representations are also present in the posterior parietal cortex. Further evidence in favor of the existence of multiple representations of body movements in the motor and posterior parietal cortices comes from studies of motor imagery (see Jeannerod and Decety, 1995). A recent study, in which motor imagery was compared with motor execution, suggests that largely overlapping neural substrates, involving motor and parietal cortices, are involved in both aspects of motor control (Gerardin *et al.*, 2000). In this respect, one open question is the possible involvement of the precentral motor cortex in motor imagery. Several studies indicate that the precentral motor cortex is also activated during imagined movements, although to a lesser extent (Porro *et al.*, 1996; Roth *et al.*, 1996; Gerardin *et al.*, 2000).

The activation of several motor and parietal areas during motor execution and/or motor imagery is in line with the modern view, coming from monkey studies, that the basic elements of the cortical motor system are the parietofrontal circuits. Direct evidence supporting this concept also in humans comes from studies in which the issue of sensorimotor transformation for action has been specifically addressed, by using experimental paradigms similar to those used in monkey studies. Binkofski *et al.* (1999), asking subjects to manipulate complex nonrecognizable plastic objects, found activation in the ventral premotor cortex (probably Brodmann's area 44) and in a region in the intraparietal sulcus (most probably corresponding to the anterior parietal area AIP of the monkey). More recently, Bremmer *et al.* (2000), by presenting normal subjects with visual, tactile, and auditory stimuli, were able to identify an area in the depth of the intraparietal sulcus related to polymodal sensory stimulation. They suggested that this area is the human equivalent of monkey area VIP. A further activation focus was found in the dorsal part of the ventral premotor cortex, and this activation was suggested to reflect the connectivity between area VIP and area F4, as demonstrated in the monkey.

In the next sections, available functional evidence in favor of the proposed homologies between monkey and human motor areas will be elucidated in greater detail.

Precentral Motor Cortex (Area 4)

The most complete functional map of the human precentral cortex was provided in the 1930s by Penfield (see Penfield and Boldrey, 1937) who used surface electrodes to stimulate the cortex of epileptic patients during surgery. These studies gave a view of the general somatotopic organization of the human precentral motor cortex, essentially similar to what was proposed by Woolsey in the monkey. In this respect, it is important to note that surface electrical stimulation reveals mostly the origin of the spinal projection from the motor cortex that in the monkey is not restricted to area 4. Therefore, when considering that in humans the exposed convexity of the precentral gyrus is mostly occupied by area 6, it is reasonable to conclude that at least part of Penfield's homunculus belongs to premotor areas, functionally independent from area 4. Several positron emission tomography (PET) investigations confirmed the existence of a crude somatotopic organization of the human precentral motor cortex (see Grafton *et al.*, 2000). Two recent reports, taking advantage of the high spatial resolution functional magnetic resonance imaging (fMRI) technique, showed that, also in humans, multiple, partially overlapping sites of activation occur in a wide region of the precentral gyrus, in relation to wrist and single finger movements (Rao *et al.*, 1995; Sanes *et al.*, 1995). Such an organizational principle seems, therefore, to exists in both human and nonhuman primates.

In some studies, it has been found that regional cerebral blood flow (rCBF) changes in the human precentral motor cortex, as neuronal activity in the monkey area 4, is correlated with changes in the velocity

and force of the executed movements (Van Meter *et al.*, 1995; Dettmers *et al.*, 1996).

Finally, the study of Geyer *et al.* (1996) has shown that the proposed subdivision of area 4 into two areas (4a and 4p) may also have a functional counterpart. PET foci were correlated with the probability maps of areas 4a and 4p as obtained from the cytoarchitectonic analysis of postmortem brains. It was found that a roughness discrimination task activated area 4p significantly more than did a control condition of self-generated movements.

Ventral Premotor Cortex

Functional studies of this cortical region (ventral part of area 6aα, area 44, and, possibly, area 45) have been mostly devoted to investigations into the role of Broca's region in speech functions. Only recently, neuroimaging studies showed that the human ventral premotor cortex is also involved in the control of hand movements. These observations strongly support the proposed homology between Broca's region and monkey area F5.

Early studies of subjects performing grasp movements failed to identify activations in the ventral premotor cortex. Evidence in favor of the existence of a hand representation in this region can be found, however, in studies of learning finger movement sequences (Seitz and Roland 1992), of mental imagery of grasping (Decety *et al.*, 1994; Grafton *et al.*, 1996a), and of preparation of finger movements on the basis of a copied movement (Krams *et al.*, 1998). More direct evidence that the ventral premotor cortex contains a hand representation comes from a recent study of Binkofski *et al.* (1999). In this study, continuous manipulation of complex objects resulted in an activation of presumed area 44, while covertly naming manipulated objects resulted in an additional activation more rostrally in presumed area 45.

One very interesting result of this study was that object manipulation also activated a number of parietal areas, one of them located in the anterior part of the lateral bank of the intraparietal sulcus. It has been suggested that a parietofrontal circuit for manipulating objects also exists in humans and involves the homologues of area F5ab and area AIP of the monkey.

Several lines of experimental evidence indicate that an action recognition system (mirror system), described in monkey area F5c is also present in the human brain. First, experiments with transcranial magnetic stimulation (TMS) showed that, in normal subjects, the observation of hand actions produces a facilitation of the motor cortex, as shown by the increase of the amplitudes of the motor-evoked potentials in those hand muscles that are involved in the execution of the observed action (Fadiga *et al.*, 1995; Strafella and Paus, 2000). Second, electrophysiological studies showed that, when human subjects observe hand actions, there is a desynchronization of the motor cortex similar, although weaker, to that occurring during active movements (Hari *et al.*, 1998; Cochin *et al.*, 1999). Finally, brain imaging studies showed that observation of hand actions produces an activation of the ventral premotor cortex centered on the Broca's region (Rizzolatti *et al.*, 1996b; Grafton, *et al.*, 1996a; Decety *et al.*, 1997; Grezes *et al.*, 1998; Iacoboni *et al.*, 1999). The possibility that the activation of Broca's area during action observation is caused by internal verbalization rather than a mirror mechanism is ruled out by a recent study of Buccino *et al.* (2001). Taken together, these data suggest that in the human ventral premotor cortex (including Broca's region in a broad sense), as in monkey area F5, there is, in addition to the mouth representation, also a representation of hand movements. Thus, in the human brain, this cortical sector, in spite of its great development as a mouth motor field for speech, still maintains a role in hand motor control and in action recognition.

Dorsal Premotor Cortex

Electrophysiological, clinical, and neuroimaging evidence suggests that there are similarities between the human dorsal premotor cortex and its presumed homologues in the monkey. Stimulation studies showed that the electrically excitable cortex reaches beyond the anterior border of area 4 and extends approximately 2–3 centimeter rostral to the central sulcus (Uematsu *et al.*, 1992). This finding suggests that, as in the monkey, the caudal region of the human dorsal premotor cortex is the origin of a corticospinal projection.

Lesion studies pointed out an involvement of the dorsal premotor cortex in both preparation/execution of motor acts and motor learning. Unilateral damage of the dorsal premotor cortex causes an inability to perform arm or leg movements requiring temporal coordination of proximal muscles, whereas the performance of distal skilled movements was normal (Freund and Hummelsheim, 1985). PET data provide further evidence for an involvement of the dorsal premotor cortex in the motor control of arm and leg movements (Fink *et al.*, 1997). As far as arm movements are concerned, Colebatch *et al.* (1991) found an activation in the superior frontal gyrus, associated with the execution of simple movements involving proximal and distal joints. The mean rCBF increase associated with shoulder movements was significantly

higher than that associated with distal movements, suggesting that in this region, as in the monkey PMd, there is a wide representation of proximal movements. In agreement with these data are several neuroimaging reports showing that this cortical region was activated in tasks involving proximal and/or distal arm movements (Deiber *et al.*, 1991; Grafton *et al.*, 1992b, 1996b; Seitz *et al.*, 1997). As in the monkey, the human dorsal premotor cortex appears to be involved in movement preparation (Kawashima *et al.*, 1994) and in movement selection according to arbitrary rules. Learning complicated finger movement sequences (Seitz and Roland, 1992), acquiring new key press sequences on the basis of trial and error (Jenkins *et al.*, 1994), or performing reaching and pointing movements according to the internal representation of targets (Kawashima *et al.*, 1995) all produce activations in the superior frontal gyrus. Involvement of the human dorsal premotor cortex in movement selection according to arbitrary rules has recently been substantiated by two PET studies showing learning-related changes in this cortical region, as subjects learned to make an association between a cue and the direction of a movement (Deiber *et al.*, 1997) or when subjects had to select more complex movements, such as power grasp or precision grip, based on arbitrary cues (Grafton *et al.*, 1998). This particular role of the dorsal premotor cortex had already been identified in clinical studies showing that patients with lesions of this cortical region, but not patients with parietal or precentral motor cortex lesions, fail to associate hand movements in responses to arbitrary sensory cues (Halsband and Freund, 1990). A possible functional segregation within the dorsal premotor cortex has been proposed by Iacoboni *et al.* (1998). In a spatial compatibility task, these authors found an activation relatively rostral in the dorsal premotor cortex when, for both auditory and visual modalities, the incompatible condition was compared with the compatible one. In the same experiment, learning-related activation was observed in a relatively more caudal part of the dorsal premotor cortex. It was suggested that these two different parts of the human dorsal premotor cortex could correspond to the rostrocaudal subdivision into areas F7 and F2 of the monkey PMd.

Mesial Premotor Cortex

In humans, the possible role of the SMA in motor control has been a matter of debate for a long time. Electrical stimulation studies, clinical observations of deficits caused by vascular lesions or surgical ablations, recordings of the DC potential during the execution of motor tasks, and early functional imaging studies provided conflicting results (for a review of the literature, see Freund, 1996). On the one hand, the high electrical excitability of the SMA and its activation during the execution of simple aimless movements were taken as evidence in favor of an executive role in motor control. On the other hand, the presence of global akinesia or mutism in the absence of paralysis and the presence of slow negative shifts in the cortical DC potentials, long before the execution of motor tasks, as well as its activation when subjects were requested to rehearse a series of digit movements mentally, lead to the concept that the SMA is primarily involved in a so-called supramotor role in motor control. However, in all these studies no systematic attempt was made to identify anatomically the stimulated or damaged cortex, mainly because of the basic assumption that the SMA was a single functional entity. The discovery that the mesial premotor cortex in nonhuman primates is composed of two different anatomical and functional areas has been crucial for interpreting these apparently conflicting data in humans.

As mentioned in "Comparative Architectonics of the Human and Monkey Motor Cortex," recent cytoarchitectonic evidence has shown that two major architectonic areas form the mesial premotor cortex. The border between these two areas does not coincide with any macroscopical landmark but very closely corresponds to the VCA line. Using the cytoarchitectonic characteristics as a criterion, it was postulated that these two areas are the homologue of monkey areas F3 and F6 (Zilles *et al.*, 1996).

When data available in the literature are correlated with the location of the VCA line, it clearly emerges that the two areas forming mesial premotor cortex are also functionally distinct and that their roles in motor control are in many ways comparable with those proposed for monkey F3 (SMA proper) and F6 (pre-SMA). The results of electrical stimulation studies of mesial premotor cortex in humans seem, at first glance, not to be consistent with the proposed man–monkey homology because the stimulation of cortical sites on either side of the VCA line evokes relatively low threshold movements. However, by using chronically implanted subdural electrodes and a better stimulus control, it was also possible to demonstrate in humans a somatotopic organization of the SMA proper, comparable to that observed in monkeys (Luders *et al.*, 1987). In contrast, the electrical stimulation of a region spanning about 3 centimeters rostral to the region from which movements can be elicited more frequently (i.e., the SMA proper) produces an alteration of motor performance (e.g., speech arrest) or a block of the entire spectrum of motor

activities. Furthermore, the stimulation of this rostral region was also found to produce more complex responses such as the sensation of an "urge" to move the arm or the feeling of an impending movement (Fried, 1996). Such results led Fried to consider the caudal "motor excitable" zone to be comparable to the monkey SMA proper (F3) and the rostral "negative motor" or "motor arrest" zone to be comparable to the monkey pre-SMA (F6).

In a recent review of the neuroimaging literature, Picard and Strick (1996) analyzed increases in rCBF in the mesial frontal cortex in relation to a wide spectrum of motor behavior, from very simple tasks to much more complex tasks. Although the limit between simple and complex motor tasks is sometimes difficult to set, simple tasks activate, with few exceptions, sites caudal to the VCA line, whereas more complex tasks consistently activate sites rostral to it.

Simple motor tasks, such as the execution of aimless movements triggered by external stimuli produce activations only of the SMA proper (Colebatch, *et al.*, 1991; Grafton, *et al.*, 1992b, 1993; Matelli *et al.*, 1993). The same is also true for the execution of simple joystick movements in a fixed direction (Playford *et al.*, 1992). When, however, the performance of a given joystick movement requires a selection among various possibilities, the activation is located rostral to the VCA line, in the pre-SMA (Deiber *et al.*, 1991). This involvement of the pre-SMA in movement selection is also suggested by a study in which the SMA proper was activated when subjects had to move a finger in response to an instructing stimulus, while the pre-SMA was activated when subjects could freely choose a finger movement among various possibilities (Deiber *et al.*, 1996).

Another well-known role of human mesial premotor cortex is its involvement in the execution of motor sequences. Functional data indicate that the pre-SMA and SMA proper are differentially involved in the execution of this type of motor tasks. In particular, the SMA proper appears to play a role in the execution of well-learned, "automatic" motor sequences, whereas the pre-SMA seems to be crucial in the learning of new, "unfamiliar" sequences. This is the case in a study of Sergent *et al.* (1992) showing that the SMA proper is activated in professional pianists playing scales, whereas, in the same subjects, the pre-SMA is activated when playing an unfamiliar piece of music. Furthermore, functional experiments in which subjects were studied at different stages of learning motor sequences indicate a shift in the activation from the pre-SMA to the SMA proper, as the task is increasingly well practiced and eventually becomes automatic (Seitz and Roland, 1992; Grafton *et al.*, 1992a; Jenkins *et al.*, 1994; Schlaug *et al.*, 1994). Finally, data of Hikosaka *et al.* (1999) showed that the pre-SMA was involved in learning motor sequences by trial and error, while the execution of already learned sequences produced an activation only in the SMA proper. It is interesting to note that the same authors found similar results in inactivation experiments of monkey F6 and F3, thus further supporting the notion of a homology of these two mesial areas between humans and monkeys.

A further more general role of the pre-SMA in motor control, was suggested in a recent fMRI study by Petit *et al.* (1998) in which sustained activity in the pre-SMA was observed during the delay period of both spatial and face working memory tasks. The authors suggested that this activity may reflect a higher cognitive level than simple movement selection or preparation. This pre-SMA activity may be related to a state of preparedness for selecting a motor response, based on spatial and object information, held on-line. This proposed role of the human pre-SMA is very similar to that proposed for monkey F6 (see Rizzolatti *et al.*, 1996).

Finally, a set of experimental data concerns the role of the SMA proper in motor imagery. These data suggest a possible functional subdivision within the SMA proper that appears to fit well with the recently proposed cytoarchitectonic subdivision of the SMA proper into an SMAc and SMAr part (Vorobiev *et al.*, 1998). Although the physiological basis underlying motor imagery is still poorly understood, it has been suggested that this process may be functionally similar to motor preparation and that imagined movements may share common anatomical and functional substrates with actual movements (Jeannerod, 1994). Functional studies of the execution and imagination of arm movements showed two distinct activation foci, both located behind the VCA line: a more caudal one, related to motor execution and a more rostral one, related preferentially or exclusively to motor imagery (Tyszka *et al.*, 1994; Stephan *et al.*, 1995; Roth *et al.*, 1996). The location of the rostral and caudal activations appears to correspond very well to the SMAr and SMAc, respectively. Further evidence in favor a selective role of the SMAr in nonexecutive motor functions was also provided by Grafton *et al.* (1996a) and Rao *et al.* (1997). In the first study, subjects were tested while observing actions made by other individuals and while imagining themselves performing them. In both conditions, only the SMAr was activated. In the second study, subjects were instructed to perform tapping movements with their index finger, first synchronously with a tone given at constant intervals and, then, without the tone. The results showed an activation of the SMAr only in the latter

condition. These data suggest that the SMAc and SMAr are differentially involved in motor control with the SMAr being active in functions in which the representation of the movement plays a central role, irrespective of whether or not the movement is paced (Vorobiev *et al.*, 1998).

All together, these data indicate that, although the general organization of the mesial premotor cortex in humans and monkeys appears to be very similar, there is a greater degree of structural and functional fractionation in the mesial premotor cortex in humans than in monkeys.

CONCLUDING REMARKS

More than one century after Jackson's first proposal that the human cortical motor system is organized in a hierarchical way, the new empirical data still support this view. Even if our knowledge of the detailed organization of the motor cortical areas is still fragmentary, the identification of parietofrontal circuits as basic elements of the monkey cortical motor system suggests that, in addition to a hierarchical organization, there is also parallel information processing that relies on multiple neural circuits.

Over the last years, the investigation of the human cortical motor system has gained new insights into several aspects of the functional organization of motor control. The data reviewed in this chapter all seem to indicate that there are significant similarities in the basic organization of the motor cortex between humans and nonhuman primates. However, in humans, the correlation between functional data and anatomically defined cortical areas is flawed by our limited knowledge of the cortical connections and the structural organization of the motor cortex. Several cytoarchitectonists, among them the Vogts and their school (Ngowyang, 1934; Vogt and Vogt, 1919), von Economo and Koskinas and, in more recent years, Bailey and von Bonin, Sarkissov *et al.*, and Braak (see references in Braak, 1980) have proposed various subdivisions of the human frontal lobe that are indeed more congruent with our current view of the organization of the motor cortex than the Brodmann parcellation. However, this last map is still the most popular and is extensively used in neuroimaging studies. Thus, it will become extremely important to establish a reliable architectonic map of the human motor cortex in the near future, especially when considering the fact that many new histochemical and neurochemical techniques are now available. To this purpose, given the eminent role played by monkey studies for the investigation of human cortical functions, a special effort should be made to extend our knowledge of the comparative anatomy of the cortex of humans and nonhuman primates.

CHAPTER

27

Architecture of the Human Cerebral Cortex

Regional and Laminar Organization

KARL ZILLES

Institute of Medicine, Research Center Jülich, and
C. & O. Vogt-Institute of Brain Research, University of Düsseldorf
Düsseldorf, Germany

PRINCIPAL SUBDIVISIONS OF THE CEREBRAL CORTEX

The cerebral cortex of the human brain can be subdivided by microscopic anatomical ("architectonic") criteria into two major parts, *isocortex* and *allocortex* (Vogt, 1910). Despite regional variations, the largest part of the adult human isocortex is characterized by its six-layered structure visible in cell body-stained (e.g., Nissl-stained) sections.

Only two isocortical regions of the adult brain show a reduction or an increase in the number of cortical layers. Such notable exceptions are (1) the frontal agranular cortex, which does not contain a clearly visible inner granular layer (layer IV) in the adult brain and represents the anatomical correlate of the motor cortex (primary motor cortex, premotor cortex, supplementary and presupplementary motor cortices), and (2) the primary visual cortex, which displays a clearly visible subdivision of its layer IV into three sublayers (i.e., layers IVa, IVb, and IVc).

In contrast to the six-layered architecture of the isocortex, the laminar pattern of the allocortex shows a regionally highly variable appearance reaching from a hardly subdivisible single-cell band to a highly differentiated architecture with more than 10 layers (e.g., entorhinal area; Braak, 1972).

This principal cytoarchitectonic subdivision is paralleled by Brodmann's (1909) developmental classification of a *homogenetic* and *heterogenetic cortex*. The homogenetic cortex develops a six-layered structure during fetal stages, which is preserved in the adult isocortex with the previously mentioned exceptions of the primary visual cortex and agranular frontal (motor) cortex (see earlier). Therefore, the homogenetic cortex resembles the architectonicly defined isocortex. In cases of disturbed development of the cortex, the

normally occurring reduction of the motor cortex from the six-layered fetal pattern to the normal agranular five-layered cortical lamination around birth can fail as shown in children suffering from cerebral palsy (Amunts *et al.*, 1997b).

The isocortex contains *primary sensory areas* (primary somatosensory, auditory, or visual areas), which are main targets of unimodal sensory afferents originating in the ventroposterior nucleus of the thalamus, medial and lateral geniculate bodies, respectively. These primary areas project to a whole set of *higher order unimodal sensory areas* (secondary and tertiary sensory areas) in a hierarchical and parallel organization. The higher order unimodal sensory cortices border to *multimodal association areas*. Uni- and multimodal areas send projections to the motor cortex, which is again subdivided into a *primary motor area* and *nonprimary motor areas* (for a comprehensive description of the motor cortex, see Chapter 26).

The heterogenetic cortex never passes through a developmental stage with six layers nor does it show the six-layered architecture of the isocortex during adult stages. Thus, the heterogenetic cortex resembles the architectonically defined allocortex.

Finally, the allocortex precedes the isocortex during mammalian brain evolution. The isocortex has, therefore, been called *neocortex*. According to Filimonoff (1947) and Stephan (1975), the allocortex can be further subdivided into *paleocortex* and *archicortex*. The paleocortex comprises the olfactory bulb, retrobulbar (anterior olfactory nucleus), olfactory tubercle, septal (including diagonal band), and (pre)piriform regions, as well as a minor part of the amygdala. The archicortex includes the hippocampus (Ammon's horn, dentate gyrus, and subiculum), presubiculum, parasubiculum, entorhinal cortex, retrosplenial cortex, and a cortical band in the cingulate gyrus (Stephan, 1975).

A functional imaging study of the human cerebral cortex (Qureshy *et al.*, 2000) shows that the rostral parts of the allocortex mainly participate in olfactory functions *(rhinencephalon)*, whereas the more caudal and medial temporal parts are cortical portions of the *limbic system*.

Isocortex and allocortex show a stepwise transition of the architecture (histological structure) at their common border. This part of the isocortex, which forms a transition zone to the allocortex, is called *proisocortex* (Sanides, 1962; Vogt and Vogt, 1956), whereas the corresponding and adjoining part of the allocortex is called the *periallocortex* (Filimonoff, 1947). The two transition zones together are also termed *mesocortex* (Rose, 1927). According to Filimonoff (1947), the periallocortex is subdivided into *peripaleocortex* (claustral region) and *periarchicortex* (entorhinal, presubicular, retrosplenial, and parts of the cingulate gyrus).

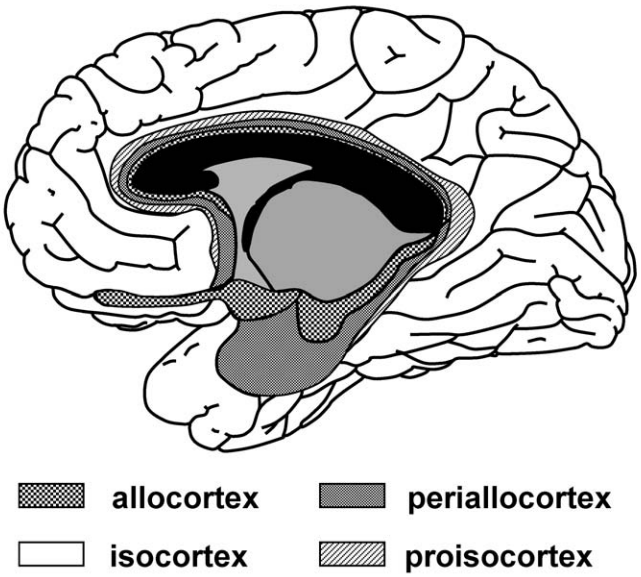

FIGURE 27.1 Medial aspect of the right hemisphere with the delineation of the principal subdivisions of the human cerebral cortex into isocortex, proisocortex, allocortex, and periallocortex. Modified after Stephan (1975).

Rose (1926) has proposed another system of subdividing the allocortex. According to this, the allocortex can be subdivided into *semicortex* (piriform and septal regions, amygdala, and olfactory tubercle), *schizocortex* (entorhinal and presubicular regions) and *holocortex* bistratificatus (retrobulbar and hippocampal regions).

Stephan (1975) has proposed a system based on his own extensive comparative neuroanatomical studies of insectivores and primates. This system is adopted here (Fig. 27.1) because it considers both the evolutionary history and the specificities of the human brain, and it does not refer to special histochemical methods. On a macroscopic level, the olfactory bulb, anterior perforate substance, paraterminal body, uncus, parts of the cingulate gyrus, lateral olfactory, semilunar, parahippocampal, and ambiens gyri contain allocortical regions. All other gyri of the human brain belong to the isocortex.

QUANTITATIVE ASPECTS OF THE CEREBRAL CORTEX

The *volume of the adult human cerebral cortex* varies between 197 and 331 cm^3 (right hemisphere: 264 ± 24 cm^3 (mean ± SD), left hemisphere 262 ± 24 cm^3; n = 43 females; age between 16 and 90 years; mean age 65 ± 2.7 years) and 242 and 358 cm^3 (right hemisphere: 292 ± 28 cm^3, left hemisphere: 291 ± 29 cm^3; n = 35 males; age between 32 and 91 years; mean age 64 ± 2.6 years) in one hemisphere (Zilles, 1972). Pakkenberg

and Gundersen (1997) reported 11–16% smaller volumes with 517 cm^3 and 440 cm^3 for both hemispheres in male and female brains, respectively. In both samples, males have a significantly larger (11–18%) cortical volume than females (Gundersen and Pakkenberg, 1997; Paul, 1971; Zilles, 1972). A similar relative gender difference of 11% is reported for the weight of male and female cerebral hemispheres in a sample of 196 male and 190 female brains (age between 70 and 79 years) (Skullerud, 1985). The larger cortical volumes in males may be explained by their larger overall brain size (Haug, 1984). Skullerud (1985) reported a 110 to 115 g smaller brain weight in women compared to men even after correction of body size using a body mass index. Both sexes show the same volumetric proportion (46%) of the cortex to the whole brain, and the same ratio (1.158 males and 1.152 females) between cortical to subcortical volumes (including amygdala, basal ganglia, and thalamus) of the prosencephalon (Zilles, 1972). A significant *hemispheric asymmetry* has been found in 109 brains of both sexes (Paul, 1971; Zilles, 1972). The cortical volume of the right hemisphere is larger than that of the left (Table 27.1). Structural hemispheric asymmetries are frequently reported (e.g., Galaburda *et al.*, 1978a,b; Galaburda and Geschwind, 1981; Geschwind and Levitsky, 1968) and have been correlated with their functional specialization (Broca, 1861; Geschwind, 1970; Zangwill, 1960). Anatomical observations describe asymmetries in the planum temporale, Sylvian fissure, inferior frontal gyrus, lateral ventricles, and temporooccipital region, all in favor of the left side. A further promising paradigm for studies of functional, structural, and developmental plasticity of right–left asymmetries is the human motor cortex, where correlations between macro- and microscopical features and functional features (motor skill, handedness) were demonstrated (Amunts *et al.*, 1996, 1997a, 1997c, 2000a). The only reported advantage of the right hemisphere is in the frontal lobe, which tends to be wider than that of the left (for review, cf. Galaburda and Geschwind, 1981). A slight right-over-left asymmetry in weight (mean 2.2 g) between both hemispheres has been described in 260 male and 207 female brains aged between 45 and 79 years (Skullerud, 1985). Thus, the wider right frontal lobe may contribute to the right-over-left asymmetry in cortical volume. Forty-two percent of the isocortical volume belongs to the frontal; 23%, to the temporal; 23%, to the parietal; and only 12%, to the occipital lobes (Pakkenberg and Gundersen, 1997).

The total *cortical surface* of both hemispheres varies between 1469 cm^2 (Blinkov and Glezer, 1968) and 2275 cm^2 (Elias and Schwartz, 1969). Pakkenberg and Gundersen (1997) reported 1900 ± 209 cm^2 for male and 1680 ± 235 cm^2 for male brains. In contrast to the cortical volumes, significant differences between the cortical surface of the right and left hemispheres have not been reported. Less than 1% of the surface is covered by paleocortex; 3.5%, by archicortex; and nearly 96%, by isocortex (Blinkov and Glezer, 1968; Stephan, 1975). Thirty-two percent of the isocortical surface belongs to the frontal; 30%, to the temporal; 23%, to the parietal; and only 15%, to the occipital lobes. As in the volumetric data (see earlier), the cortical surface data indicate a predominance of the frontal and temporal lobes, which contain beside motor and auditory cortices multimodal association areas and language-related regions.

The *depth of the human isocortex* varies between 1.5 and 5.0 mm (von Economo and Koskinas, 1925), depending on the cortical area studied (highest values in Brodmmann area 4, lowest in area 3) and position (lowest values on the sulcal floor, highest values on the gyral height). A comparison of the cortical thickness in different isocortical areas of the human brain (Table 27.2) illustrates both the variations in overall thickness and the laminar dimension. Pakkenberg and Gundersen (1997) reported a mean neocortical thickness of 2.72 ±

TABLE 27.1 Cortical Volumes in Human Male and Female Adult Brains (data from Paul, 1971 and Zilles, 1972)[a]

	Cortical volume (cm^3)	
	Male (N = 53)	Female (*N* = 56)
Right side	298.7 ± 4.2	267.2 ± 3.3
Left side	294.9 ± 4.1	263.8 ± 3.2
Right/left	3.8 ± 1.5	3.4 ± 1.7
	($p < .05$)	($p < .05$)

[a]Significance of hemispheric asymmetries is given in parentheses (the Wilcoxon matched-pair test).

TABLE 27.2 Thickness of Different Isocortical Areas and Layers in the Human Brain[a]

Layers	Area 4	Area 3	Area 41/42	Area 17	Area 18
I	200	220	260	246	272
II	100	280	280	89	92
III	1400	420	740	471	851
IV	—	280	450	653	148
V	900	220	530	218	279
VI	1250	400	640	278	395
I–VI	3850	1820	2900	1955	2037

[a]Thickness in micrometers. Data from von Economo and Koskinas (1925) and Zilles *et al.* (1986a).

0.24 mm in male and 2.61 ± 0.21 mm in female brains (significant gender difference).

According to the study of Pakkenberg and Gundersen (1997) using modern stereological methods the mean *total number of cortical neurons* in both hemispheres is $22.8 \times 10^9 \pm 3.9$ (mean ± SD) in male and $19.3 \times 10^9 \pm 3.3$ in female brains (49 left and 45 right hemispheres; age range 19–93 years). The gender difference of 15.5% is significant.

The *packing density of the cells* varies depending on the specific cortical area (Blinkov and Glezer, 1968; Haug, 1984). Pakkenberg and Gundersen (1997) reported a mean neuronal density of 44×106 per cm^3 with no significant difference between male and female brains. A two- to tenfold number of glial cells per neuron has been estimated depending on the cortical region (Blinkov and Glezer, 1968).

The midsagittal sections of the *corpus callosum* measures 6.2 ± 0.2 cm^2 in males and 6.3 ± 0.2 cm^2 in females (Zilles, 1972). While in agreement with the data of de Lacoste-Utamsing and Holloway (1982) and Witelson (1985), this difference is not significant, yet it seems remarkable that the commissural system in females reaches at least the same absolute size as in males, given that the female total cortical volume is significantly smaller. A significant correlation between the corpus callosum area and brain size has been shown (Zilles, 1972). This means a 10% larger commissural system in females, when scaled to cortical size, and indicates a gender difference in the structure of this system. On the basis of a relatively larger commissural system, it can be proposed that the female cortex shows a lesser degree of hemispheric lateralization (cf. also de Lacoste-Utamsing and Holloway, 1982).

All quantitative results mentioned in this section are highly variable between different individuals. Because these measures are correlated with total brain weight, changes in brain weight can influence cortical size. Some of the factors affecting total brain size have been reviewed (Haug, 1984). Secular acceleration (0.6 g/year), age, gender, and body size are among the most important. The volume of the cortex of a 75-year-old individual is about 4% smaller that that of a 25-year-old individual. The frontal cortex shows the largest age-dependent decrease (12%). However, these data and the frequently reported loss of cortical neurons with age must be critically reconsidered because secular acceleration may affect—at least partly—the lower cell counts in the older brains of cross-sectional studies. The age-dependent differential shrinkage during histological embedding (Haug, 1984) may also alter cell counts based on the measurement of cell numbers per volume cortical tissue.

One of the most prominent features of the human cortex is its distribution over a folded surface *(gyrification)*. Only one third of the human cortex is superficially exposed; two thirds are buried in the sulci (Elias and Schwartz, 1969; von Economo and Koskinas, 1925; Zilles *et al.*, 1988). The reasons for the gyrification of the brain are not completely understood. Because vertically oriented and side-by-side positioned cell columns represent the basic modular organization of the cerebral cortex, the cortical growth leads inevitably to a considerable enlargement of the cortical surface. A large unfolded cortical surface would require such an increase in volume of the skull, that a normal delivery would be impossible. Furthermore, the distance between cortical regions interconnected by projection fibers would increase to such a degree that information transmission between distant cortical regions would be delayed. Thus, gyrification is a solution for large brains to pack a maximal cortical surface into a minimal volume and to optimize the speed of neural transmission between neigboring cortical areas. Although all gyri and sulci are visible at birth, the depths of the sulci increase until two thirds of the cortical surface are hidden in the sulci after the 20th postnatal year (Armstrong *et al.*, 1995).

It has been demonstrated (Rakic *et al.*, 1991; Richman *et al.*, 1975) that the amount of gyrification depends on genetical and environmental constraints. Since Vogt (1910), Sanides (1962, 1972), and Welker and Campos (1963) have demonstrated that some of the sulci roughly demarcate cortical areas of different function and somatotopy, the sulcal and gyral pattern of the human cortex is both a sign of the functional, evolutionary, and individual development.

The human cortex shows the highest degree of folding, when compared with other primates (Zilles *et al.*, 1988). Moreover, the degree of folding varies over the rostrocaudal extension of the hemisphere. The highest values are found in the prefrontal and parietooccipitotemporal association cortex. The cortical regions where motor, premotor, and primary visual areas are located show the lowest degree of gyrification. The most significant increase in folding between human brains and those of nonhuman primates including gorilla, orangutan, and chimpanzee is visible in the prefrontal cortex (Zilles *et al.*, 1989). This underlines the advanced evolution of this part of the human cortex.

PALEOCORTEX

Olfactory Bulb

The olfactory bulb is not generally classified as a cortical area. Its laminar structure and comparative anatomical results, however, justify its identification as part of the paleocortex. The human olfactory bulb

shows the most extensive regression, both quantitatively and in its laminar pattern, when compared with other primates (Stephan, 1975). Nevertheless, the same laminar organization can be demonstrated in the human olfactory bulb as in most mammals, though it is less clearly visible.

The most important afferents come from the olfactory epithelium via the fila olfactoria of the first cranial nerve. In animal experiments, it has been shown that additional afferents originate in the diagonal band nuclei, the retrobulbar region, and the contralateral bulb and reach the olfactory bulb through the medial olfactory stria and the lateral olfactory tract. The lateral olfactory tract contains ipsilateral efferent fibers from the bulb to the retrobulbar and piriform region, olfactory tubercle, and amygdala (cortical amygdaloid nucleus).

Thus, the olfactory bulb is a cortical area for olfaction. The afferents from basal telencephalic regions modulate, via a complex intrabulbar system of interneurons, the information processing in the olfactory bulb. An accessory olfactory bulb, which is connected with the vomeronasal organ, cannot be found in the adult human brain, in contrast to other mammals (Stephan, 1975).

For a comprehensive description of the human olfactory system, see Chapter 32.

Retrobulbar Region (Anterior Olfactory Nucleus)

The retrobulbar region in the human brain has been demonstrated as an equivalent of a paleocortical region in other mammals (Stephan, 1975). The widely used term, anterior olfactory nucleus, is, therefore, misleading because the human retrobulbar region is a true cortical structure, despite its inconspicuous laminar pattern. Architectonic regression is a common aspect of the whole olfactory system in the human brain: A two-or three-layered structure recognizable in lower primates is not visible in the human brain (Fig. 27.2). Also, the delineation of several subareas that is possible in macrosmatic animals is hardly achievable in humans.

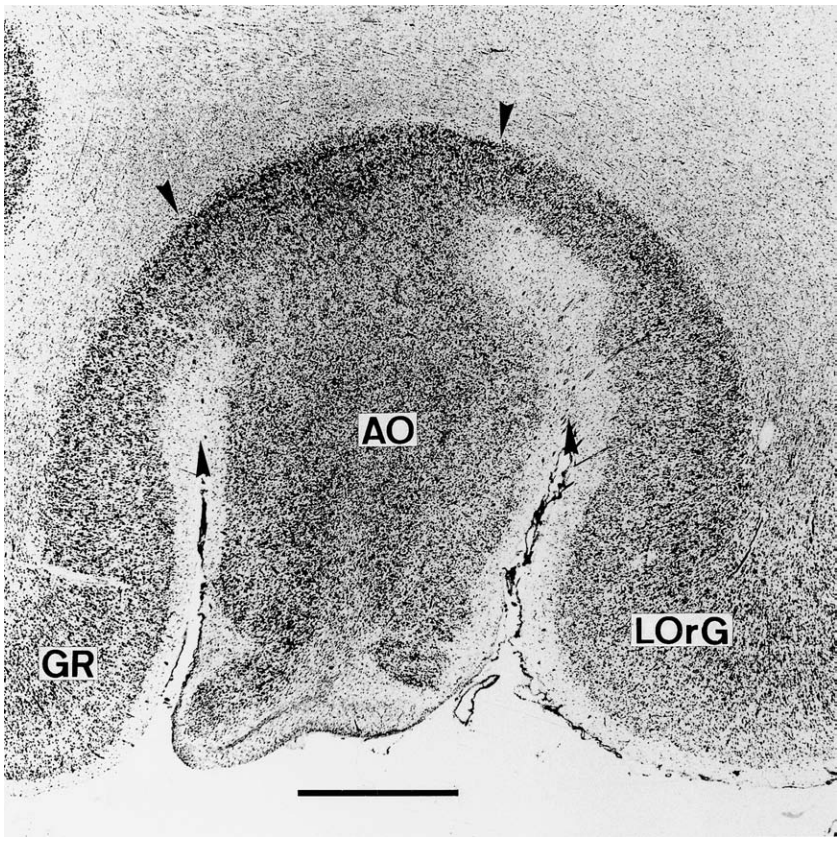

FIGURE 27.2 Coronal section through the human retrobulbar region (anterior olfactory nucleus, AO) at the basis of the telencephal. GR, gyrus rectus; LOrG, lateral orbital gyrus. Bar = 5 mm.

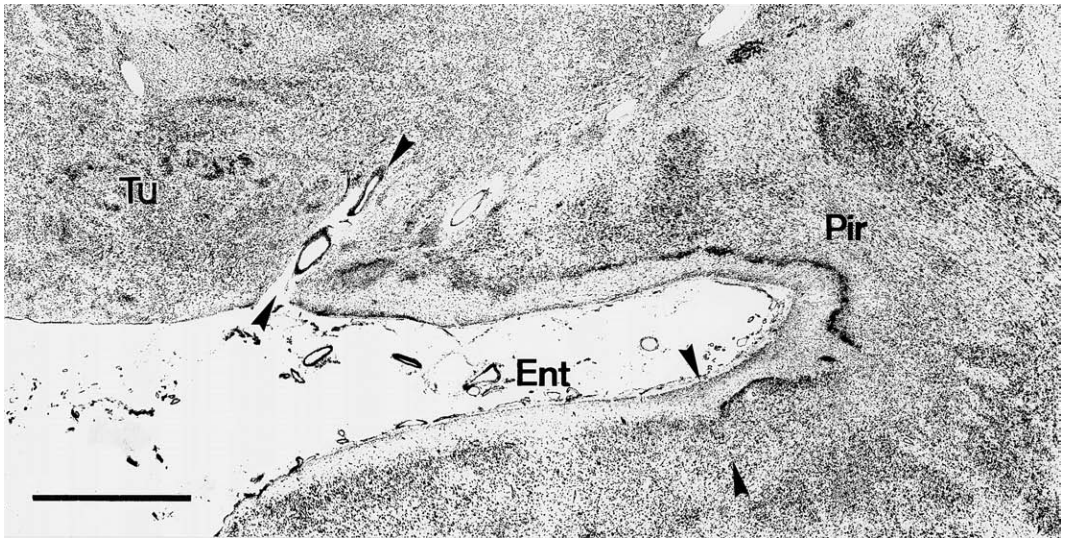

FIGURE 27.3 Coronal section through the human olfactory tubercle (Tu) and (pre-)piriform cortex (Pir). The entorhinal cortex (Ent) adjoins the piriform cortex. Bar = 2.5 mm.

The retrobulbar region is located in the caudal part of the olfactory bulb, at the place of fusion between the olfactory tract and the hemispheres, immediately rostral of the piriform cortex. It receives its main afferents from the ipsilateral olfactory bulb. At least in the rat, further afferents arrive from the piriform cortex, olfactory tubercle, and amygdala through the medial forebrain bundle and a rostrally directed system of associational fibers (Heimer, 1968, 1972). The projections from the retrobulbar region terminate, after coursing through the medial forebrain bundle, in the olfactory bulb of both sides and in the ipsilateral piriform cortex, olfactory tubercle, amygdala, mediodorsal thalamic, lateral habenular nuclei, and lateral hypothalamic and supraoptic areas (Ferrer, 1969; Lohmann and Lamers, 1967).

The retrobulbar region is an important station for processing olfactory information. A destruction of this region leads to anosmia or hyposmia and is mostly found in connection with impairment of the olfactory bulb. The retrobulbar region bilaterally modulates the information processing in the olfactory bulb.

Olfactory Tubercle

The olfactory tubercle is located immediately caudal to the retrobulbar region in the anterior perforate substance. This region is also heavily reduced in the human brain when compared with other primates (Stephan, 1975), but the homology with the same region in macrosmatic animals corroborates its classification as a paleocortical region. The three-laminar pattern of other mammals is completely obscured in the human brain. Islands of Calleja can be found within this region (Fig. 27.3). For further information about connectivity and function of the olfactory tubercle, see Chapter 32.

Piriform Cortex (Area 51 of Brodmann)

The human (pre)piriform cortex is located between the lateral olfactory tract and the temporal cortex (Brockhaus, 1940; Pigache, 1970; Rose, 1927; von Economo and Koskinas, 1925). According to Allison (1954), this region can be subdivided cytoarchitectonicly into a frontal and a temporal area. A three-layered structure is visible (Fig. 27.3) with a superficial molecular layer having only a few scattered neurons, a cell-dense second layer, and a less-dense third layer with polymorphic cells. The perikarya in the third layer are the largest. Along this layer a cell-free cleft (capsula extrema) is followed by the claustrum. The first layer contains the lateral olfactory tract in the frontal subregion of the piriform cortex.

The afferents to the piriform cortex originate in the olfactory bulb, retrobulbar region, olfactory tubercle, septal region, amygdala, orbitofrontal cortex, and contralateral piriform cortex. Commissural fibers are found in the anterior commissure. The efferent fibers from the piriform cortex reach all the areas that also have direct afferents from the olfactory bulb (Heimer, 1972; Price, 1973). Additionally, projections to the insular cortex, hippocampus, claustrum, and putamen have been described in many vertebrates (Allison,

1953; Druga, 1971; Hjorth-Simonsen, 1972), but it is not clear whether all these experimental results are also valid for the human brain.

The connectivity of the piriform cortex clearly indicates an olfactory function. Powell *et al.* (1965) emphasized the role of the piriform in sexual behavior because of the strong projections to the hypothalamus and because of behavioral experiments. For further information about connectivity and function of the olfactory tubercle, see Chapter 32.

Peripaleocortical Claustral Region (Area 16 of Brodmann)

Between the piriform cortex and the laterally adjoining isocortex, a transition zone can be demonstrated that has been called the peripaleocortical claustral region by Stephan (1975). This region is found in close topographical relation to the claustrum and constitutes the most rostral part of the insular cortex.

Brodmann (1905) has described four architectonicly different areas (areas 13–16) in the insular cortex with an increasing complexity in cytoarchitecture. These areas show a rostrocaudal sequence, with the most simply structured area rostrally (area 16). This area 16 has a position that compares well with the peripaleocortical claustral region and shows an agranular structure. Although Rose (1929) describes many more areas in the human insular cortex, he also delineates a rostral agranular area adjoining the piriform cortex. The most extensive architectonic study of the human insular cortex (Brockhaus, 1940) corroborates these earlier findings. The peripaleocortical claustral region is also comparable with the areas ID and TI of von Economo and Koskinas (1925). The laminar pattern of area 16 in humans shows a four-layered type (for further details see Stephan, 1975).

Connections of the peripaleocortical claustral region with the piriform cortex, amygdala, adjoining isocortex, claustrum, and contralateral area 16 have been described in primates (Allison, 1953; Astruc and Leichnetz, 1973; Nauta, 1961). The strong connections with the piriform cortex makes an olfactory function of the peripaleocortical insular cortex probable, but a definite statement for the human brain is presently not possible. For a comprehensive description of the amygdala, see Chapter 22.

ARCHICORTEX

The *archicortex* proper is formed by the hippocampus. The adjacent beltlike *periarchicortex* comprises the entorhinal, perirhinal, presubicular, parasubicular, retrosplenial, and the subgenual cortex as well as a part of the cingulate cortex. The periarchicortical areas are bordered by a proisocortical belt. Both regions represent together with the periarchi- and proisocortical belts of the orbitofrontal, insular, and temporopolar regions the paralimbic cortex *(mesocortex).* Thus, the forebrain contains a "hippocampocentric" (bordering the archicortex) and an "olfactocentric" (bordering the paleocortex) subdivision of the mesocortex (Mesulam and Mufson, 1985; see also "Insular Lobe"). The hippocampus can be subdivided into the retrocommissural hippocampus (Ammon's horn, dentate gyrus and subiculum), the supracommissural hippocampus (indusium griseum) and the precommissural hippocampus, which is located between the genu of the corpus callosum and the caudal end of the olfactory tract. The hippocampus, entorhinal area, presubiculum, and parasubiculum are represented pictorially and described comprehensively in Chapter 23.

Retrosplenial Region (Areas 26, 29, and 30 of Brodmann)

The retrosplenial region is located in the sulcus corporis callosi immediately behind the splenium of the corpus callosum. It is interposed between the presubiculum and the isocortical areas of the posterior cingulate gyrus. The retrosplenial region can be subdivided into a granular and an agranular part (Rose, 1928). The Brodmann classification (1909) gives three areas in the retrosplenial region: in the granular part (1) area 26 (ectosplenial cortex) and (2) area 29 (granular retrosplenial cortex), and in the agranular part (3) area 30 (agranular retrosplenial cortex). This has been confirmed by several histological studies (Armstrong *et al.,* 1986; Braak, 1979b; von Economo and Koskinas, 1925; Vogt *et al.,* 1995, 2001).

Although von Economo and Koskinas (1925) have subdivided the retrosplenial region into six different areas (LB_2, LD, LE_1, LE_2, LF_1, LF_2), a careful inspection of the figures shows that only LE_2, LE_1 and LD are comparable with the areas 26, 29, and 30 of Brodmann (1909; cf. also Stephan, 1975); LB_2, LF_1 and LF_2 belong to the supracommissural hippocampus. An architectural analysis of the whole posterior cingulate region shows an stepwise transition from a simple cortical structure to the elaborated isocortex, that is, from the supracommissural hippocampus over areas 26, 29, and 30 to the isocortical area 23 (Armstrong *et al.,* 1986, Vogt, 1985; Zilles *et al.,* 1986b). Each of the granular or agranular parts can further be subdivided according to Vogt (1993) and Vogt *et al.* (1995).

The ectosplenial area 26 has a primitive laminar pattern comprising a molecular layer, a cell-dense

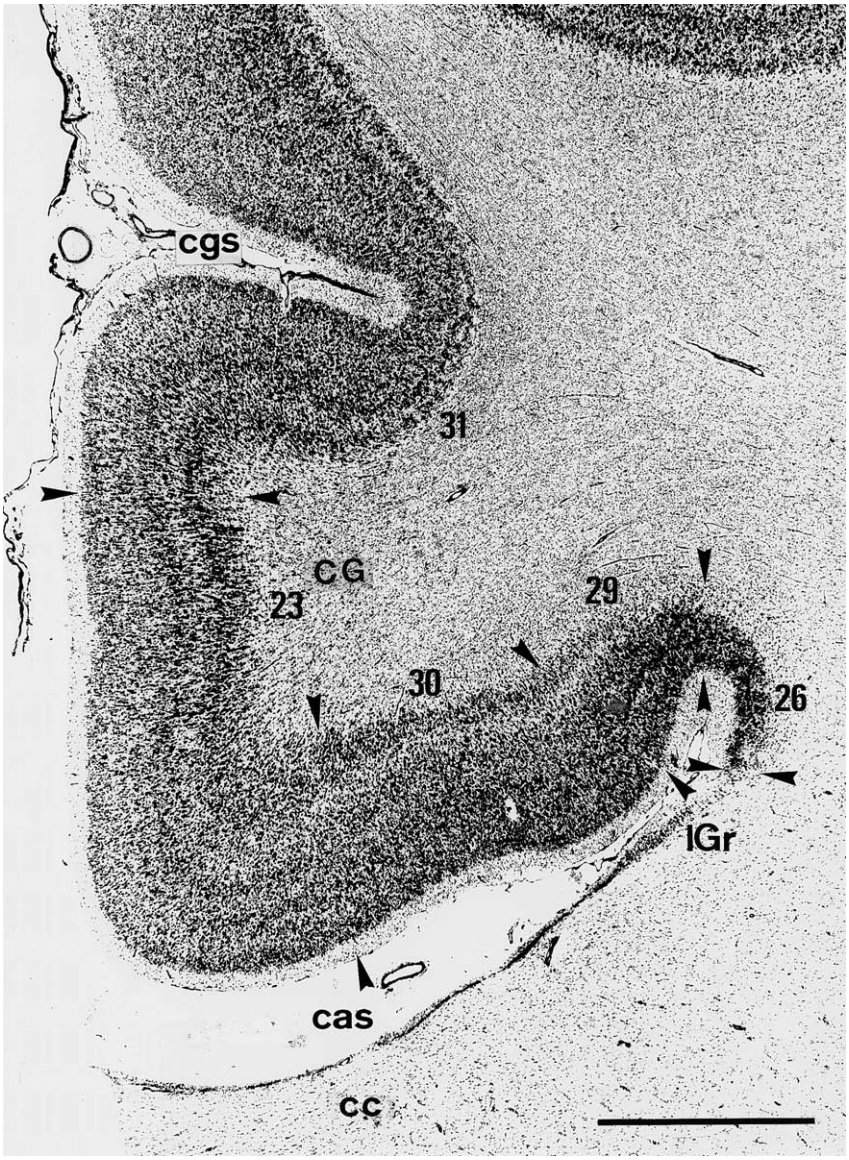

FIGURE 27.4 Coronal section through the posterior cingulate gyrus showing the transition from allo- to neocortex. Areas 26 and 29 belong to the allocortex, area 30 is part of the proisocortex and areas 23 and 31 are classified as neocortical regions. cas, sulcus of the corpus callosum; cc, corpus callosum; CG, cingulate gyrus; cgs, cingulate sulcus; IGr, indusium griseum. Bar = 3 mm.

external layer (small pyramidal cells), and an inner layer resembling the neuronal population of layer VI of the isocortex (Braak, 1979b; Vogt *et al.*, 2001). Area 29 shows a four-layered structure in Nissl-stained sections with a molecular layer, a cell-dense external pyramidal layer with small to medium-sized perikarya ("granular retrosplenial cortex"), an internal pyramidal layer with larger cells and a polymorphic layer (Fig. 27.4). Near the medial border of area 29, the laminar pattern changes. The external pyramidal layer differentiates into a cell-dense outer and a lighter inner layer (Vogt *et al.*, 2001). Area 30 shows a further progression of the laminar differentiation. Area 30 has an external pyramidal layer with a less obvious population of small ("granular") perikarya. Thus, this area has been classified as "agranular retrosplenial cortex." However, it shows also the first sign of an internal granular layer between the external and internal pyramidal layers ("dysgranular type"; Vogt *et al.*, 2001). This internal granular layer contains numerous small to medium-sized pyramidal cells and is, therefore, still different from the classical internal granular layer IV of the

isocortex (for further details, see Vogt *et al.*, 2001). Thus, area 30 can be classified as proisocortex. The adjoining area 23 has the typical isocortical structure with six layers.

The connectivity of the retrosplenial cortex further supports the principal subdivision into granular and agranular parts. In the rhesus monkey, the main cortical afferents to the granular retrosplenial areas 26/29 originate in the subiculum (Rosene and van Hoesen, 1977), whereas the agranular retrosplenial area 30 does not receive subicular axonal terminals. A main source for cortical afferents to area 30 is the extrastriate visual cortex, whereas these afferents are sparse in areas 26/29. The whole retrosplenial cortex receives afferents from area 24 and the anterior thalamic nuclei. Additionally, the intralaminar, laterodorsal, and lateroposterior thalamic nuclei (Baleydier and Mauguire, 1980; Vogt *et al.*, 1987), claustrum, diagonal band (Bigl *et al.*, 1982), locus coeruleus, raphe nuclei, and lateral hypothalamus project to this cortical region. The commissural connections are found in the corpus callosum. In the rhesus monkey, the efferent projections of the retrosplenial cortex terminate in the anterior thalamic nuclei, anterior cingulate cortex, and pons (van Hoesen *et al.*, 1993).

Periarchicortical Areas of the Cingulate Gyrus

This periarchicortical region accompanies the rostral part of the supracommissural and precommissural hippocampus.

Brodmann (1908, 1909), Vogt (1910), von Economo and Koskinas (1925), and Rose (1928) published different architectural subdivisions of the cingulate gyrus (Table 27.3). Brodmann (1908, 1909) includes in his regio cingularis the granular isocortical (Armstrong *et al.*, 1986; Zilles *et al.*, 1986b) areas 23 and 31 of the posterior cingulate gyrus, the agranular areas 24 and 32 of the anterior cingulate region, and the periarchicortical areas 25 and 33 (Fig. 27.5). The area 32 shows an isocortical structure, and area 24 represents the proisocortical part with a dorsal area medioradiata (MR) and a ventrally adjoining area infraradiata dorsalis (IRd) (for subdivisions of area 24, see Figure 27.5 and Chapter 26). According to Stephan (1975), the most rostral part of the periarchicortex is subdivided into an area infraradiata ventralis (area 33) adjoining the supracommissural hippocampus, and an area subgenualis (area 25) accompanying the precommissural hippocampus.

The common architectural feature of the anterior periarchicortical cingulate areas 25 and 33 is their reduced laminar differentiation, which includes the absence of the typical second layer (outer granular layer) of the isocortex. Thus, this region is of the transitional type between allo- and isocortex (Braak, 1980; Sanides, 1972; Yakovlev *et al.*, 1960).

Afferent fibers to area 25 of nonhuman primates have been demonstrated from the pole of the temporal lobe (Pandya and Kuypers, 1969) and from areas 7, 21 and 22 (Jones and Powell, 1970). Areas 25, 32, and 24 are interconnected by fibers running tangentially in the molecular layer (Gerebtzoff, 1939; Glees *et al.*, 1950). A further intracingulate connection exists between area 25 and the posterior cingulate cortex, including the retrosplenial region (Showers, 1959). Reciprocal connections have also been described between the prefrontal areas, the posterior cingulate cortex, and the posterior parietal gyri (Jones and Powell, 1970; Mesulam and Mufson, 1982; Mesulam *et al.*, 1977; Mufson and Mesulam, 1982; Nauta, 1964; Pandya *et al.*, 1971a, b, 1981; Petras, 1971; Vogt *et al.*, 1987).

Thalamic afferents in the monkey are differentially distributed over anterior and posterior cingulate areas. The anterior cingulate cortex receives afferents primarily from the paraventricular, reuniens, parafascicular,

The supracommissural hippocampus IGr (indusium griseum) is bordered by the periarchitectonical area 33 (IRv, area infraradiata ventralis). The adjacent area 24 can be subdivided into a proisocortical part (IRd, area infraradiata dorsalis) and an isocortical part (IMR, area mediorata). The isocortical area 32 follows rostrally. cas, sulcus of the corpus callosum; cc, corpus callosum; CG, cingulate gyrus; cgs, cingulate sulcus. Bar = 3 mm.

central superior lateral, central densocellular mediodorsal, and limitans nuclei. Further afferents to the cingulate cortex arrive from the substantia innominata, claustrum, raphe nuclei, and locus coeruleus (Vogt *et al.*, 1987). Furthermore, commissural fibers that interconnect the anterior cingulate cortex through the corpus callosum have been described (Locke and Yakovlev, 1965; Showers, 1959). Further afferents arrive from the septum and amygdala (Nauta, 1961). Efferent projections reach the amygdala, presubiculum, and retrosplenial and perirhinal cortex (Baleydier and Mauguire, 1980; Pandya *et al.*, 1981). For a comprehensive description of the cingulate region, see Chapter 24.

ISOCORTEX

Frontal Lobe

The isocortex of the frontal lobe can be subdivided cytoarchitectonicly into granular (with a clearly visible layer IV), dysgranular (with a weakly developed layer IV), and agranular (lacking layer IV) regions. The primary (Brodmann's area 4) and nonprimary (Brodmann's area 6) motor areas are agranular, Broca's speech region is dysgranular, the lateral prefrontal region is granular (except a dysgranular transitional region (Brodmann's area 8) between the motor and prefrontal cortex), and the medial prefrontal cortex (Brodmann's areas 24 and 32) is agranular. Broca's region can be further subdivided into anterior and posterior (i.e., Brodmann's areas 45 and 44; Figs. 27.8 and 27.35). The granular (lateral) prefrontal region can be further subdivided into a dorsolateral (Brodmann's areas 9, 10 and 46) and a ventroorbital part (Brodmann's areas 11, 12 and 47). The medial prefrontal cortex comprises the isocortical part of the anterior cingulate region. For a pictorial representation, see Figure 27.35. For comparison of different cytoarchitectonical terminologies in the frontal lobe, see Table 27.4.

A detailed architectonic study of the human frontal lobe has been published by Sanides (1962). This author delineates about 60 areas, which can be classified into cortical zones of different architecture (Fig. 27.6). His frontal motor zone (FmZ) resembles areas 4 and 6. The proisocortical zone (PrO) is an agranular cortex and corresponds to area 24. The dorsal and ventral paralimbic zones (PlZd, PlZv) are agranular to dysgranular regions and may be equivalents of area 32. The frontoopercular zone (FoZ) resembles areas 44, 45 and 47. The granular paraopercular zone (PoZ) corresponds to area 46; the paramotor zone (PmZ), to areas 9 and 8; the granular frontopolar zone (FpZ), to area 10; and the granular orbitomedian zone (OmZ), to areas 11–12.

Hopf (1956), Ngowyang (1934), Strasburger (1937), and Vogt (1910) have presented even more detailed cyto- and myeloarchitectonical studies of the human frontal lobe.

Prefrontal Region

The prefrontal cortex contains a larger granular (Fig. 27.7) and a smaller dysgranular part (Cavada and Goldman-Rakic, 1989a, b; Fuster, 1989; Goldman and Schwartz, 1982; Goldman-Rakic, 1984; McGuire *et al.*, 1991; Petrides and Pandya 1999; Preuss and Goldman-Rakic, 1990; Schwartz and Goldmann Rakic, 1988; Selemon and Goldman-Rakic, 1988; Walker, 1940). The inner granular layer in the prefrontal cortex is most obvious in its rostral part, whereas the more caudal part shows a transition to the dysgranular type (area 8) with a visible, but less remarkable inner granular layer. The granular part is unique in primates and reaches its largest expansion in humans (Preuss and Goldman-Rakic, 1991; Semendeferi *et al.*, 2001). For subdivisions of the prefrontal cortex of nonhuman primates see Paxinos *et al.* (2000).

A detailed study of the human prefrontal granular areas 9 and 46 (Rajkowska and Goldman-Rakic, 1995a, b) demonstrates cytoarchitectonic differences between both areas and the intersubject spatial variability of the areal borders. Area 9 extends along the middle third of the superior frontal gyrus and adjacent regions of the middle frontal gyrus. Area 46 is partially or completely surrounded by area 9 on the middle frontal gyrus. Rajkowska and Goldman-Rakic (1995b) clearly describe the lack of correlation between macroscopical landmarks (fundi of gyri, etc.) and areal borders and emphasize the considerable intersubject variability of the borders of these areas. Lamina IV is wider and contains more densely packed neuronal cell bodies in area 46 than in area 9; the sublamination of layers III and V is more differentiated in area 9 than in area 46. Area 46 is less myelinated than area 9.

The prefrontal cortex of primates receives major thalamic input from the mediodorsal nucleus, with the magnocellular part of this nucleus projecting to the ventroorbital, and the parvocellular part, to the dorsolateral prefrontal areas (Divac *et al.*, 1978; Fuster, 1989; Goldman, 1979, 1981; Kievit and Kuypers, 1977). Important cortical afferents to the prefrontal cortex in nonhuman primates arrive from various cortical areas of the same (ipsilateral associational) and of the opposite hemisphere (callosal connections) (Cavada and Goldman-Rakic, 1989b; Goldman and Nauta, 1977a, b; Jacobson and Trojanowski, 1977a, b; Künzle, 1978; Pandya *et al.*, 1971a, b; Preuss and Goldman-Rakic, 1989). The callosal connections are reciprocally organized (Goldman and Schwartz, 1982; McGuire *et al.*, 1991; Schwartz and Goldman-Rakic, 1988). Cortical afferents to the dorsolateral prefrontal cortex originate in the parietal (Petrides and Pandya, 1984; Cavada and Goldman-Rakic, 1989b) and premotor cortices (Barbas and Pandya, 1987; Lu *et al.*, 1994; Pandya and Yeterian, 1998). Contrastingly, the ventral prefrontal cortex receives its input from the temporal cortex (Bullier *et al.*, 1996; Pandya and Yeterian, 1998; Webster *et al.*, 1994). Ventral and dorsal parts of the prefrontal cortex are interconnected (Barbas, 1988; Pandya and Yeterian, 1998; Petrides and Pandya, 1999). The temporal pole and the anterior insula project to the ventroorbital part of the prefrontal cortex, which in turn is connected with the amygdala, basal forebrain,

[a]The classification schemes of various authors are compared with Brodmann's (1909) parcellation of the human cortex. Because the areal maps of the authors show incompletely matching patterns, often only parts of the areas are included in one Brodmann area.

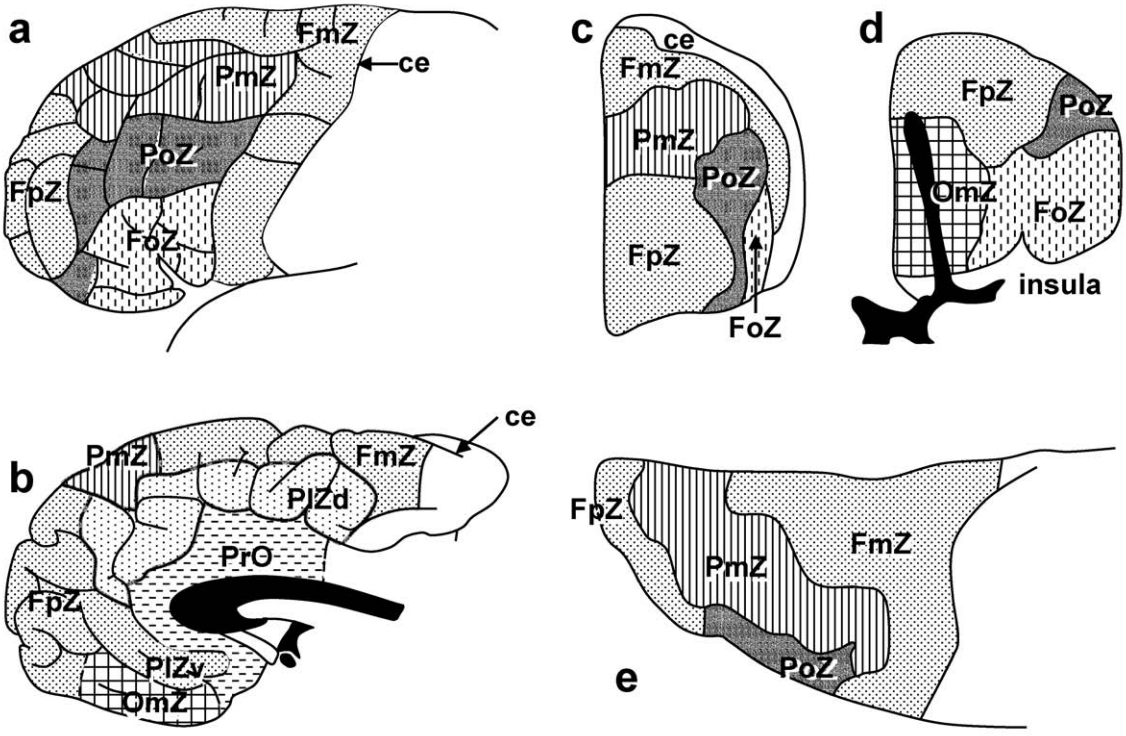

FIGURE 27.6 Areal map of the frontal lobe modified from Sanides (1962) in **(a)** lateral, **(b)** medial, **(c)** frontal polar, **(d)** basal, and **(e)** dorsal views. ce, central sulcus; FmZ, frontal motor zone; FoZ, frontoopercular zone; FpZ, frontopolar zone; OmZ, orbitomedian zone; PlZd, dorsal paralimbic zone; PlZv, ventral paralimbic zone; PmZ, paramotor zone; PoZ, paraopercular zone; PrO, proisocortex.

and magnocellular part of the mediodorsal thalamic nucleus (Barbas and DeOlmos, 1990; Goldman-Rakic and Porrino, 1985; Mesulam and Mufson, 1982, 1985; Pandya and Yeterian, 1985).

A major part of the prefrontal efferents projects to the striatum (Selemon and Goldman-Rakic, 1985). Further details on the connection can be found in Goldman and Nauta (1977a), Künzle (1975), and Johnson *et al.* (1968). Other efferents end in the dorsal thalamus (Goldman, 1979) and the superior colliculus (Goldman and Nauta, 1976). The dorsolateral prefrontal cortex is connected to the pulvinar, through which it can influence the cingulate and multi- as well as unimodal sensory areas (Goldman-Rakic and Porrino, 1985). Various other cortical and subcortical areas are further targets of the prefrontal efferent fibers (Selemon and Goldman-Rakic, 1988).

Studies in nonhuman primates (Goldman and Nauta, 1977b; Goldman-Rakic, 1984) have shown a remarkable columnar organization of the prefrontal cortex that is based on vertical units of neurons with special input–output relations and intrinsic synaptic connections. These columns are organized by alternating columns of ipsilateral and callosal corticocortical connections (Goldman and Schwartz, 1982). A two-dimensional reconstruction of the columns in the frontal section reveals a distribution in the form of stripes, which can bifurcate and show cross linkages and blind endings. The columns have a width of 300–700 μm and extend across all cortical layers. Since this structural pattern can be found in a variety of mammals (Goldman-Rakic, 1984) its existence in the human cortex is highly probable. The large increase in gyrification (Zilles *et al.*, 1989) and surface (Brodmann, 1912) of the human prefrontal cortex during evolution is, therefore, associated with an increasing number of cortical columns. While the interdigitating columnar pattern is shown for callosal and ipsilateral cortico-cortical systems, the same pattern has also been found for the cells constituting the efferent fibers for these connections (Schwartz and Goldman-Rakic, 1984). Thus, afferent terminals and efferent cell bodies of the same system are found in identical columns.

Since the corticocortical connections are only one part of the input and output of the prefrontal cortex, the corticostriatal and corticothalamic projections have been analyzed with respect to columnar organization. For both systems, a compartmentalization has been demonstrated. The corticothalamic neurons projecting to the mediodorsal nucleus form regularly spaced

FIGURE 27.7 Horizontal section through Brodmann's (1909) area 10, which belongs to the granular part of the prefrontal cortex. The Roman numerals indicate the six isocortical layers. Bar = 3 mm.

clusters in layer V of the prefrontal cortex. A further example of the modular organization in the primate prefrontal cortex is given by the efferents to the parahippocampal gyrus and the presubiculum (Goldman-Rakic, 1984).

The prefrontal cortex is a major anatomical substrate of various cognitive processes. The dorsolateral prefrontal cortex plays an important role in mnemonic encoding of visual space (Funahashi *et al.*, 1989). The columnar segregation of afferent systems may be the prerequisite for the various associative functions of this region. A great number of columns with different, well-segregated connections may allow for an even greater number of associative combinations by interaction between different columns. Destroying parts of the prefrontal lobe leads to disturbances of initiative and planning of activities, emotional status, social behavior, and memory functions (Milner and Petrides, 1984; Sawaguchi and Goldman-Rakic, 1991; Selemon and Goldman-Rakic, 1988). Destruction of the most rostrally and basally located areas leads to restlessness and hyperactivity (Jacobsen, 1935) and autonomic and emotional reactions (Kaada, 1960). Reduction of intellectual ability and ethical standards are immediately apparent phenomena after bilateral destructions of the human prefrontal cortex (Brodal, 1969). The orbitoprefrontal cortex is active during the processing of social behavior and the judging of the social consequences of actions (Fletcher *et al.*, 1995; Frith and Frith, 1999; Moll *et al.*, 2002). Additionally, visual object categorization is correlated with neural activity in the orbitoprefrontal cortex (Vogels *et al.*, 2002).

Atrophy of the frontal cortex is found in Pick's and Alzheimer's disease. Prefrontal leucotomy, a neurosurgical intervention introduced by Moniz (1936) has frequently been performed in the past in an attempt to cure symptoms of various mental disorders (schizophrenia, obsessions, etc.). Leucotomy has induced a controversal debate about the ethical problems involved with this procedure because, aside from influencing the symptoms of mental disorders, it severely changes personality.

More specific data about the function of granular prefrontal areas in the human brain is provided by imaging studies. A region comparable with the dorsal part of area 10 (Brodmann, 1909) shows the highest

metabolism and regional cerebral blood flow in conscious, wakeful subjects. These signs of activity ("hyperfrontality") disappear during sleep. Discrimination of tone sequences, mental calculation, and object categorization are associated with an increase of neuronal activity in this region. Working memory, learning, detection, association, discrimination, recognition, anticipatory tuning, and regulation of attention and abstraction are subserved by the granular prefrontal cortex. In summary, this part of the isocortex controls and regulates the operation of different sets of other cortical areas; that is, it is active whenever tasks require organization by the brain itself (for review, see Roland, 1993).

Recent functional imaging work shows a considerable segregation of the neural correlates of emotion, episodic memory retrieval, and working memory. The left dorsolateral areas seems to subserve monitoring operations during memory tasks, rostral and ventrolateral areas of both hemispheres are contributing to retrieval and cue-specific episodic memory retrieval operations, and the left ventroposterior as well as the bilateral dorsoposterior regions of the prefrontal cortex are subserving phonological and generic working memory operations, respectively (Cabeza *et al.*, 2002). The hippocampal and parahippocampal regions are active both during episodic memory retrieval and working memory. The medial prefrontal cortex plays a general role in emotion processes (for review, see Phan *et al.*, 2002).

Area 8 represents the dysgranular part of the prefrontal cortex. Sanides (1962) has delineated a paramotor zone PmZ (Fig. 27.6) which has a similar location but probably also includes parts of area 9. The FC area (Fig. 27.37) of von Economo and Koskinas (1925) seems to have a larger size than Brodmann's area 8. More recent functional observations have identified a frontal eye field in primates (Bruce and Goldberg, 1984), including humans (Roland, 1984), which is in good agreement with the ventrolateral part of area 8. Although earlier observations questioned the functional identification of area 8 as the frontal eye field, it has been demonstrated in a comparable region of nonhuman primates that this part of the dysgranular prefrontal cortex contains cells responsive to visual stimuli, which discharge before saccadic eye movements and in anticipation of saccadic behavior (Bruce and Goldberg, 1984). The saccadic direction is elicited in specific cell columns. Excitation in neighboring columns leads to different directions. As stated earlier, callosal and acallosal bands alternate (Goldman-Rakic, 1984), horizontal eye movements are controlled by acallosal columns, while vertical movements are controlled by callosal columns.

Clinical reports in humans suggest presaccadic activity in area 8 with metabolic activation during ocular fixation, pursuit eye movements, and various visual discrimination tasks (for review, see Roland, 1984). A dominance of the right frontal eye field is found when nonverbal signals are analyzed. For a comprehensive description of the prefrontal cortex, see Chapter 25.

Anterior Cingulate Region

Areas 24 and 32 constitute the proisocortical and isocortical parts of the anterior cingulate region. The agranular area 24 has been subdivided into several subareas in humans, monkeys, and rats (Matelli *et al.*, 1985, 1991; Vogt, 1993; Vogt *et al.*, 1995). Subarea 24d occupies the most caudal and dorsal part of human area 24. It is followed rostrally by subarea 24c′ at the level of the anterior commissure and by subarea 24c at the level anterior to the genu of the corpus callosum. Subareas 24d, c′, and c represent the dorsal subregion of area 24. Subareas 24b′ and b constitute the intermediate subregion, and subareas 24a′ plus 24a make up the ventral subregion (Vogt *et al.*, 1995), which is buried in the callosal sulcus (for figures and further details see Chapter 24). The anatomical correlate of the functionally defined human cingulate motor area (CMA; Paus *et al.*, 1993) comprises subarea 24d as caudal cingulate and subareas 24c′ and c as rostral cingulate motor areas (Roland and Zilles, 1996a; Zilles *et al.*, 1995, 1996). The motor function of the cingulate cortex has convincingly been demonstrated by microstimulation of the monkey cortex (Luppino *et al.*, 1991). It is presently not clear to what extent human area 32 or parts of it must also be interpreted as part of CMA.

CMA sends efferent fiber to the primary motor cortex (area 4) and the spinal cord (Luppino *et al.*, 1994). CMA appears to be activated during self-paced movements and controls the execution of motor responses (Naito *et al.*, 2000; Paus *et al.*, 1993). Vocalization and fear reactions also seems to be controlled by CMA. Ablation of areas 24 and 32 leads to increased tameness and reduction of social contacts in animals, together with a lowered performance in delayed alternation tasks (Divac, 1971; Glees *et al.*, 1950). For a comprehensive description of the cingulate region, see Chapter 24.

Broca's Speech Region

The caudal part of the left inferior frontal gyrus has been shown to represent the motor speech center (Broca, 1861; Penfield and Rasmussen, 1950; Roland, 1984) in 95% (Branche *et al.*, 1964) of right- and left-handers. A destruction of the dominant Broca area is accompanied in most cases by a loss of fluent speech, though language comprehension may not be affected.

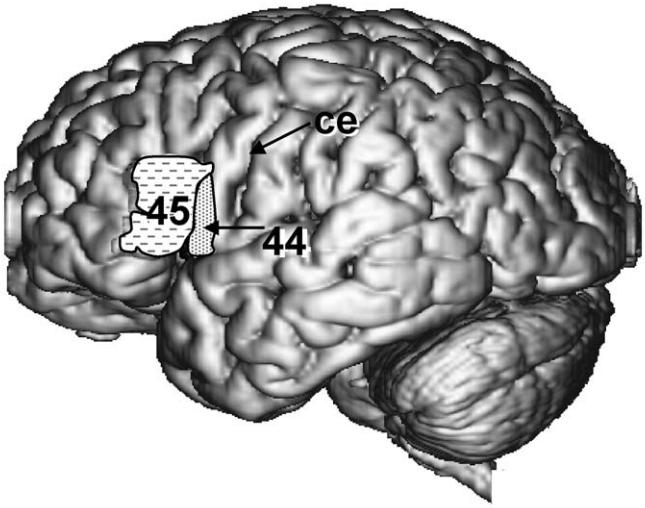

FIGURE 27.8 Areas 44 and 45 in a three-dimensional reconstructed human brain. The borders of both areas were determined using a quantitative cytoarchitectonic method (Schleicher *et al.*, 1999), which allows an observer-independent definition of the areal borders. ce, central sulcus.

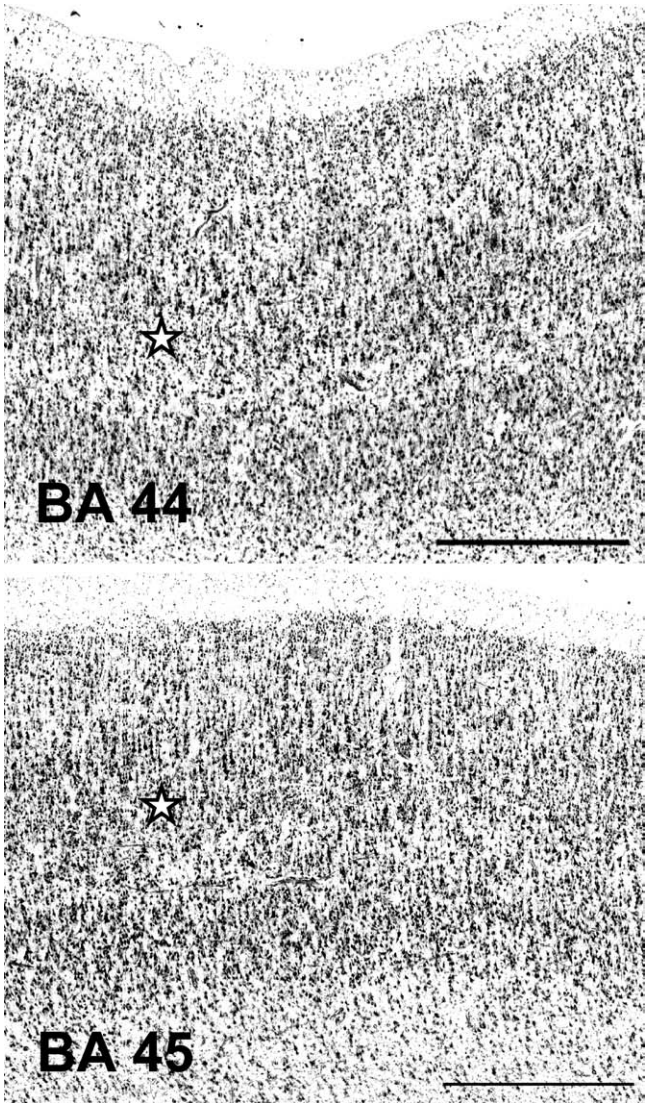

FIGURE 27.9 Cortical lamination in the dysgranular areas 44 and 45. The incipient layer IV is labeled by asterisks. Bar = 1 mm.

Detailed functions of Broca's region were examined by authors using different verbal tasks and functional imaging (Buckner *et al.*, 1996; Fox *et al.*, 1996; Frackowiak, 1994; Mazoyer *et al.*, 1993; Mazziotta and Mettner, 1988; Paulesu *et al.*, 1996; Petersen *et al.*, 1988, 1990; Petrides *et al.*, 1993; Zatorre *et al.*, 1996), and electrical stimulation (Penfield and Rasmussen, 1950; Ojeman, 1991). The homologous region in the right hemisphere is involved in prosodic aspects of speech (Botez and Wertheim, 1959) and the detection of syntactic errors (Bradvik *et al.*, 1991; Nichelli *et al.*, 1995).

Areas 44 and 45 (Fig. 27.8) are the cytoarchitectonic correlates of Broca's motor speech region (Amunts *et al.*, 1999; Brodmann 1909, 1914). Macroscopically, both areas are located bilaterally in the opercular (area 44) and triangular (area 45) region of the inferior frontal gyrus. Both areas reach the adjoining lower surface of the frontal operculum. An incipient inner granular layer (with an increasing granularity from caudal to rostral) is found in areas 44 and 45 (Amunts *et al.*, 1999; Brodmann, 1909; Sanides, 1962; Fig. 27.9). Layer IV of area 45 is still less clearly visible compared with the rostrally adjoining lateral prefrontal areas. Thus, the cortex of Broca's speech region can be classified as dysgranular (Amunts *et al.*, 1999). Further descriptions of cyto- and myeloarchitectonic aspects were published by Knauer (1909), von Economo and Koskinas (1925), Stengel (1930), Riegele (1931), Kononova (1949), Strasburger (1938), and Rabinowicz (1967). Considerable differences in the extent, location, and sizes of areas 44 and 45 are evident between the different maps, and the architectonic features were reported to be highly variable among subjects (Amunts *et al.*, 1999; Kononova, 1935). It is still a matter of discussion whether or not cytoarchitectonic features are associated with functional lateralization of speech (Galaburda, 1980; Hayes and Lewis, 1995, 1996; Scheibel *et al.*, 1985; Simonds and Scheibel, 1989). The functional segregation between areas 44 and 45 is presently not clear. In some neuroimaging studies, functional activation covered both areas (Demonet *et al.*, 1992; Hinke *et al.*, 1993; Hirano *et al.*, 1996; Mazoyer *et al.*, 1993), but in others activation was found to be restricted to area 44 or 45 or distributed over areas 44 and 6 (Fox *et al.*, 1996; Herholz *et al.*, 1996; Kim *et al.*, 1997; Paulesu *et al.*, 1996; Sergent *et al.*, 1992). These ambiguous results regard-

ing the precise anatomical location of neural activity may be caused not only by differences between the actual tasks in the different observations but also by differences in spatial resolution of the various functional imaging techniques. Furthermore, the warping of functional imaging data to anatomical atlases without architectonicly defined borders of cortical areas and without indications of the degree of intersubject variability of those borders may be a further confounding factor.

A series of studies report a possible architectonical homology (Petrides and Pandya, 1994; Rizzolatti *et al.*, 1996b, 1998) between Brodmann's areas 44/45 in the inferior frontal opercular part of the human brain (Brodmann, 1909; Amunts *et al.*, 1999) and the frontal premotor area F5 in monkeys (Matelli *et al.*, 1985, 1986, 1991). Area F5 contains mirror neurons (Di Pellegrino *et al.*, 1992; Rizzolatti *et al.*, 1996b), neurons that are active not only during grasping or tearing but also during the observation of another monkey performing the same action. Area F5 is, therefore, active during matching of observed and executed actions. Observation of actions and motor imagery tasks (Binkofski *et al.*, 2000; Grafton *et al.*, 1996; Iacoboni *et al.*, 1999; Krams *et al.*, 1998; Parsons and Fox, 1998; Rizzolatti *et al.*, 1996c) as well as imitation of target-directed actions are correlated with neuronal activity in the opercular part of the human inferior frontal gyrus (Koski *et al.*, 2002). Thus, functional similarities between the human opercular cortex of the inferior frontal gyrus and the monkey area F5 have been observed.

Recently, Amunts *et al.* (1999) published a quantitative cytoarchitectonic study that provides not only a three-dimensional representation of the microscopically defined borders of areas 44 and 45 but also population maps of these areas based on a sample of ten (five males and five females) human brains. The cytoarchitectonic borders of both areas did not consistently coincide with the sulcal pattern. Thus, macroscopical landmarks are not reliable indicators of cytoarchitectonic borders. Although the volume of area 44 varies considerably between subjects, the volume of area 44 was larger on the left than right side in all ten brains. All five male and three of the female brains had higher cell-packing densities on the left than on the right side (Amunts *et al.*, 1999). These morphological asymmetries of area 44 may represent a correlate of the functional lateralization of speech production (Galaburda, 1980). An ontogenetic study in six female and five male brains indicated a left-over-right asymmetry in the volume of area 45 in the male group (Uylings *et al.*, 1999). Further studies on a larger number of male and female subjects are needed to substantiate morphological asymmetries in Broca's region.

Major input to Broca's region arrives through corticocortical fibers of the arcuate fascicle, which originates in Wernicke's area of the temporal lobe. Efferents from areas 44 and 45 terminate in the face region of the primary motor cortex. Broca's region controls the complex motor pattern of neuronal assemblies in the face region of area 4, which in turn command the motor cranial nerve nuclei for the muscle activity during vocalization.

Primary Motor Cortex

Area 4 of Brodmann (1909) is the best candidate for the functionally defined primary motor cortex. Area 4 is agranular (Brodmann, 1903a; Marin-Padilla, 1970) and contains the giant Betz pyramidal cells (Fig. 27.10b). This cortical area is comparable to caudal parts of the precentral area of Campbell (1905; Fig. 27.33), caudal parts of the area precentralis A of Smith (1907; Fig. 27.34), area FAγ of von Economo and Koskinas (1925; Fig. 27.37), and the frontal ganglionic core of Braak (1980; Fig. 27.12; cf. Table 27.4).

Brodmann's (1903b) definition of the caudal border of area 4 (by the lack of an inner granular layer; see Fig. 27.10a) from the caudally adjoining area 3a (Fig. 27.11) in the fundus of the central sulcus has been widely accepted. The rostral border of area 4 was under dispute because here Brodmann's (1903b, 1909) parcellation is based exclusively on the presence of Betz cells in area 4 and their absence in area 6 (Fig. 27.10c). Most of the papers critically discussing Brodmann's delineation of the border between area 4 and area 6 are based exclusively on the drawing of his famous map (Brodmann, 1909). Here, area 4 seems to cover larger parts of the free surface of the precentral gyrus. One must understand, however, the limitations inherent in schematic representations and read the detailed description of area 4 in Brodmann's original paper (1903a; see also Zeki, 1979) for a discussion of the misuse of Brodmann's schematic drawing in other cortical regions. Area 4 is described in Brodmann's first article (1903a) as a wedge-shaped field that is very tiny on the laterobasal side and covers only the rostral wall of the central sulcus. That means that area 4 does not spread over the free cortical surface of the precentral gyrus to a considerable extent but is buried in the central sulcus. Also, the broad part of area 4 on the paracentral lobule of the medial hemispheric surface shows no major differences when compared with more recent observations (Geyer *et al.*, 1996, 2000c). Brodmann (1903a) described other characteristics of area 4 and the Betz cells (large cortical thickness, inconspicuous lamination pattern, low cell density, no clear boundary between layer VI and white matter, decreasing the size of the Betz cells along the mediolaterobasal extent).

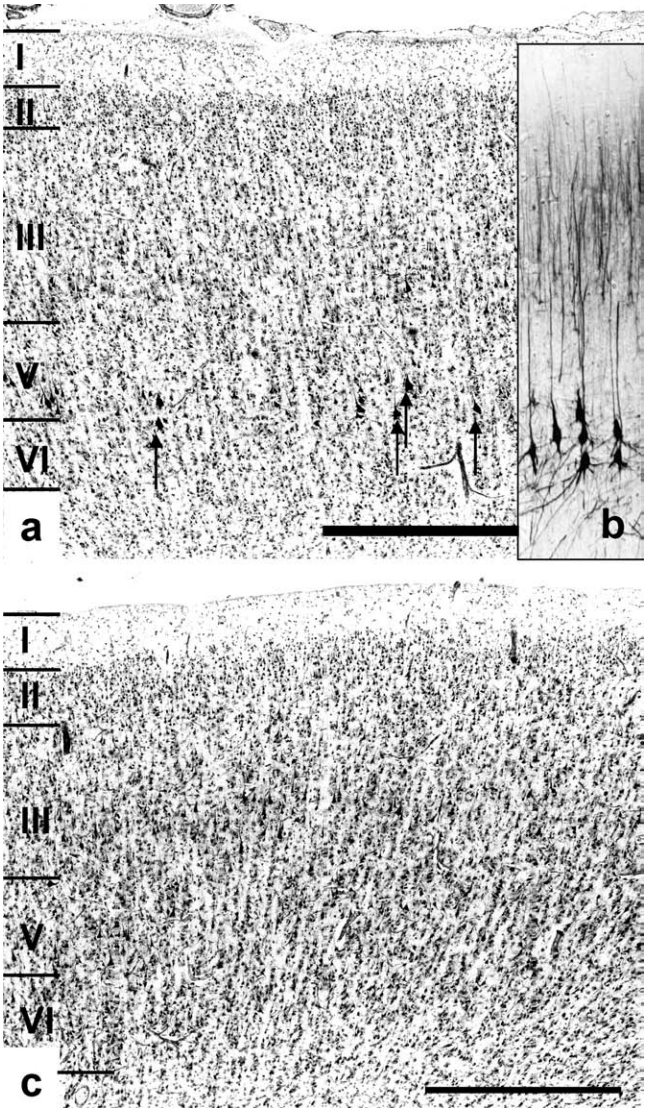

FIGURE 27.10 Cytoarchitecture of Brodmann's (1909) agranular areas 4 (a, b) and 6 (c). **(a)** Nissl-stained section of area 4. The arrows indicate several Betz-cells in layer V. **(b)** SMI-32-stained section of the macaque area 4 with prominently stained Betz cells. **(c)** Nissl-stained section of area 6. Bar = 1 mm.

Recently, Geyer *et al.* (1996) could demonstrate—by combining quantitative cytoarchitectonic mapping and transmitter receptor distributions with functional imaging data—the posterior and anterior borders of area 4, its intersubject variability and motor function, and a subdivision of area 4 into a rostral subarea 4a and a caudal subarea 4b.

Area 4 receives afferent fibers from both subcortical sources (caudal part of the ventrolateral and rostral part of the ventroposterolateral thalamic nuclei) and cortical sources (for details see Chapter 26). A major efferent pathway of area 4 is part of the pyramidal tract. However, area 4 is not the only cortical source of the pyramidal tract fibers. The nonprimary motor and the primary and secondary somatosensory cortices represent additional sources (Brodal, 1969; Kuypers, 1958; Minckler *et al.*, 1944). About 30% of pyramidal tract fibers originate from large, medium-sized, and small pyramidal cells in layer V of area 4. Whereas the volume of area 4 does not differ between the left and right side, the volume of this part of the pyramidal tract originating in area 4 is significantly larger in the left than right hemisphere (Rademacher *et al.*, 2001c). This left-over-right asymmetry of a part of the pyramidal tract may be related to the left-hemispheric dominance for handedness in more than 90% of the population. These axons terminate in motor nuclei of cranial nerves (corticonuclear tract), in pontine nuclei (corticopontine tract), on α-motoneurons, interneurons, and on γ-motoneurons of the spinal cord via interneurons (corticospinal tract). Area 4 controls the activity of both proximal and distal muscle groups, but only the motor activity of distal muscles is impaired after destruction of the lower corticospinal tract.

One of the most conspicuous aspects of organization in the primary motor cortex is its somatotopy. The studies of Penfield and Rasmussen (1950) have shown the representation of the various parts of the body in the motor cortex. The contralateral foot is found on the medial surface of the hemisphere followed by the leg and trunk around the upper margin of the hemisphere. A considerably large cortical area is covered by the hand representation in the upper half of area 4 on the lateral surface of the hemisphere. The site of the motor hand representation is visible in axial sections by a Ω-like protrusion of the precentral gyrus toward the central sulcus ("hand-knob") (Yousry *et al.*, 1997). The lower half of area 4 is occupied by the cortical representation of the face and especially the lips, tongue, pharynx, and larynx muscles.

The Betz cells differ from the other pyramidal cells of area 4 by their morphology (Scheibel and Scheibel, 1978). They show not only the major apical dendritic stem and typical basal dendrites but also the numerous additional dendrites originating from the whole circumference of their cell bodies (see also Fig. 27.10b).

Non-Primary Motor Cortex

Brodmann (1909) described the border between the primary motor cortex (area 4) and the rostrally adjoining nonprimary motor cortex, which is represented in his map by a single cortical field, his area 6. The distinction between these areas is based on the presence of Betz cells in layer V of area 4, cells that are not found in area 6 (Fig. 27.10c). However, this finding is a problematic criterion for the precise definition of the

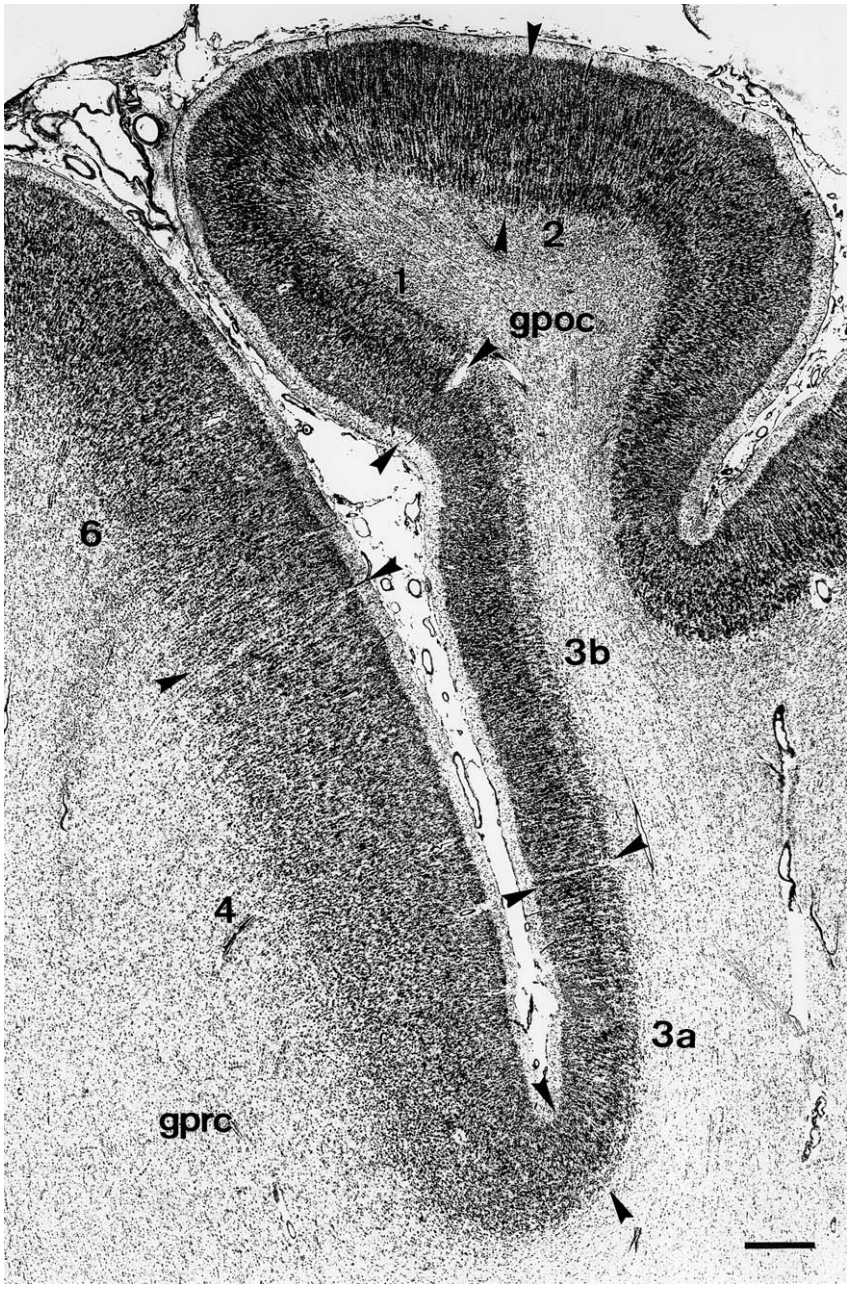

FIGURE 27.11 Horizontal, Nissl-stained section through the human precentral (gprc) and postcentral (gpoc) gyri with the agranular motor areas 4 and 6, the transition zone area 3a, and the granular somatosensory areas 3b, 1, and 2. Bar = 1 mm.

border between both areas. Wise (1985a, b) emphasized the difficulties of separating the Betz cell population from other pyramidal cells by using cell body size as the criterion. This is corroborated by Braak and Braak (1976), who used the histochemical method of lipofuscin staining ("pigmentoarchitectonics") to identify Betz cells. These cells show a vast agglomeration of lipofuscin granules in their perikarya not visible in other pyramidal cells of layer V. According to these results, the size distribution of Betz cell perikarya shows a wide overlap with that of large and medium-sized pyramidal cells. Therefore, the identification of the border between areas 4 and 6 is difficult when based exclusively on Nissl-stained sections and the criterion of cell size. Consequently, the true Betz cell area (frontal core in Fig. 27.12) delineated by Braak

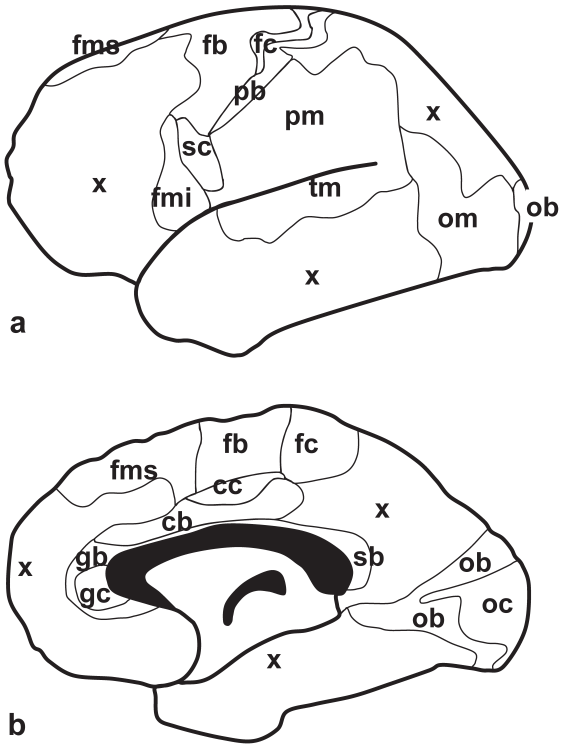

FIGURE 27.12 Cortical map based on pigmentoarchitectonic observations of Braak (1980) in **(a)** lateral and **(b)** medial views. cb, cingulate belt; cc, cingulate core; fb, frontal belt; fc, frontal core; fmi, frontal magnopyramidal region inferior part; fms, frontal magnopyramidal regions superior part; gb, genual belt; gc, genual core; ob, occipital belt; oc, occipital core; om, occipital magnopyramidal region; pb, parietal belt; pm, parietal magnopyramidal region; sb, splenial belt; sc, subcentral region; tm, temporal magnopyramidal region; x, cortical regions not parcellated.

(1979a, 1980) on the basis of pigmentoarchitectonical features is different from Brodmann's area 4 published in his famous map (Brodmann, 1909). The lateroventral part of the frontal core is completely buried in the central sulcus. According to the map in Figure 27.12, which is a simplified presentation of the detailed results of Braak's (1980) architectonic studies, Brodmann (1909) may have overestimated the extent of area 4. The area FAγ (see Fig. 27.37) of von Economo and Koskinas (1925) resembles more closely the frontal core area of Braak and area 4 as delineated by Geyer *et al.* (1996). Therefore, the architectonic delineation of the border between areas 4 and 6 needs further elaboration. The border between area 6 and the adjoining prefrontal areas is defined by the appearance of an inner granular layer (layer IV) in prefrontal areas, which is lacking in the nonprimary motor cortex. However, this criterion is not easy to recognize in Nissl-stained section.

The second feature of Brodmann's (1909) area 6, its appearance as a single cortical field, has been questioned by architectonic observations in human brains (Braak, 1976a, 1980; Sanides, 1962; Strasburger, 1937; Vogt, 1910). Comparative anatomical and functional studies substantiate the architectonical and functional segregation of area 6. Such observations in humans and nonhuman primates strongly support the concept of the nonprimary motor cortex as being composed of two major regions, the premotor and the supplementary motor cortex (for review, see Geyer *et al.*, 2000c and Chapter 26). This subdivision corresponds only partly with the frontal belt and cingulate core areas (Fig. 27.12), which have been delineated by Braak (1976a, 1979a, 1980). The premotor and supplementary cortices can be further subdivided by architectonic and functional criteria both in nonhuman primates and humans (Barbas and Pandya, 1987; Geyer *et al.*, 1998, 2000a, c; Luppino *et al.*, 1990, 1991, 1993, 1994, 1999; Matelli and Luppino, 1996; Matelli *et al.*, 1986, 1989, 1991, 1998; Paus *et al.*, 1993; Penfield and Welch, 1951; Picard and Strick, 1996; Rizzolatti *et al.*, 1988, 1990, 1996a–c, 1998; Roland and Zilles, 1996a; Roland *et al.*, 1980; Sanes *et al.*, 1995; Stephan *et al.*, 1995; Tanji, 1994; Tanji and Shima, 1994; Wiesendanger and Wiesendanger, 1984; Wiesendanger *et al.*, 1985; Wise, 1985a, b; Wise and Strick, 1984; Zilles *et al.*, 1995, 1996). A detailed description of the functional and connectional aspects of the complete motor cortex is given in Chapter 26.

Parietal Lobe

The human parietal cortex consists of the *postcentral* and *parietal regions* (Brodmann, 1909). The *postcentral region* comprises the postcentral gyrus, parts of the paracentral lobule mesially and parts of the operculum Rolandi ventrolaterally. The *parietal region* comprises the superior and inferior parietal lobules separated by the intraparietal sulcus, the most posterior part of the paracentral lobule, and the mesial extent of the superior lobule down to the subparietal sulcus and to the parietooccipital sulcus.

The cytoarchitectonic maps of Brodmann (1909) and von Economo and Koskinas (1925) still dominate the present concepts on the architectonic organization of the human parietal cortex (Fig. 27.13a–d). Brodmann's map strongly influenced the parcellation scheme of Sarkisov *et al.* (1949; Fig. 27.39), which differs only by minor details from his map. More recent architectonic studies (Bailey *et al.*, 1950; Pandya and Seltzer, 1982a, b; Eidelberg and Galaburda, 1984) further developed the Economo-Koskinas concept. However, all these maps do not reflect the high degree of functional segregation in the parietal cortex revealed by neuroimaging studies in the human brain (Bremmer *et al.*, 2001; Dong

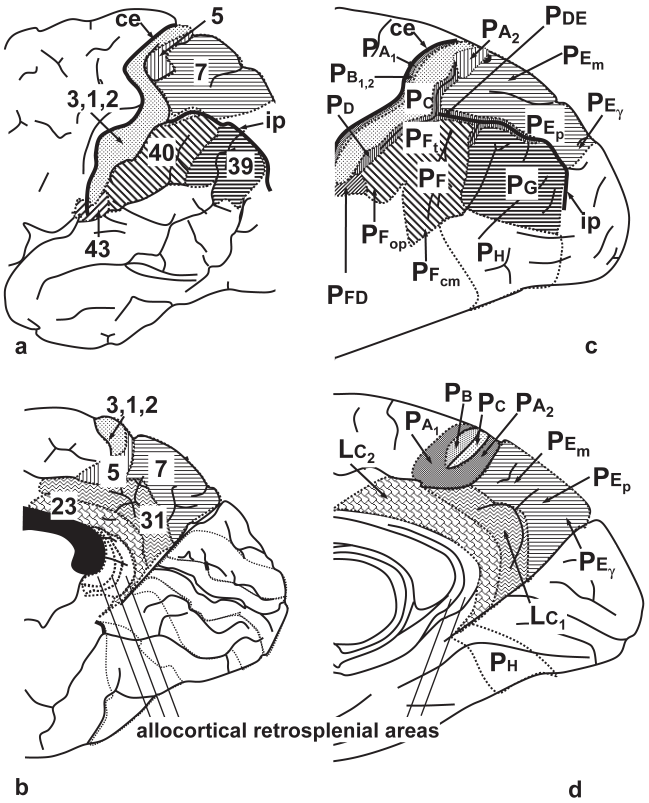

FIGURE 27.13 Cytoarchitectonic maps of human parietal areas. **(a)** lateral view and **(b)** medial view are modified after the map of Brodmann (1909); **(c)** lateral view and **(d)** medial view are modified after von Economo and Koskinas (1925). ce, central sulcus; ip, intraparietal sulcus; LC_1, area cingularis posterior dorsalis; LC_2, area cingularis posterior ventralis; PA_1, area postcentralis gigantopyramidalis sulcal part; PA_2, area postcentralis gigantopyramidalis (paracentral lobule); PB_1, area postcentralis oralis granulosa; PB_2, area postcentralis oralis simplex; PC, area postcentralis intermedia; PD, area postcentralis caudalis; PDE, transition zone between areas PE and PD; PEm, area parietalis superior magnocellularis; PE_p, area parietalis superior parvocellularis; PE_γ, area parietalis superior posterior gigantopyramidalis; PF, area supramarginalis; PF_{cm}, area supramarginalis magnocellularis columnata; PFD, transition zone between areas PF and PD; PF_{op}, area parietalis tenuicorticalis opercularis; PF_t, formatio supramarginalis tenuicorticalis; G, area angularis; PH, area parietalis basalis; PHO, area parietalis basalis limes occipitalis.

et al., 2000; Fink *et al.*, 2000a, b, 2001a, b; Grefkes *et al.*, 2002; Gurd *et al.*, 2002; Inoue *et al.*, 2001; Weiss *et al.*, 2000). Furthermore, numerous anatomical and functional (Bremmer *et al.*, 2000; Cavada, 2001; Colby and Duhamel, 1996; Galletti *et al.*, 1997; Luppino *et al.*, 1990, 1993, 1999; Matelli and Luppino, 2001; Matelli *et al.*, 1986, 1998; Rizzolatti *et al.*, 1997; Seltzer and Pandya, 1980) observations in the monkey also demonstrate a much higher degree of areal differentiation than that presented in Brodmann's (1909) maps of the human or monkey cortex. Thus, the parietal cortex is still an architectonicly insufficiently explored region of the human cerebral cortex. For a recent parcellation of the macaque parietal cortex, see Paxinos *et al.* (2000).

Postcentral Region

Brodmann (1909, 1910) divided the postcentral region into four architectonicly related areas, that is, areas 3, 1, and 2 (according to their anterior–posterior sequence; Fig. 27.13a, b), and area 43 on the operculum Rolandi, whereas von Economo and Koskinas (1925) defined six areas, that is, PA_1, PA_2, PB_1, PB_2, PC, PD (Fig. 27.13c, d) and one subarea Pcg (not shown). For a comparison of the different nomenclatural systems see Table 27.5.

The fundus of the central sulcus is a landmark of the architectonic border between the motor area 4 and the most rostral postcentral area 3a (Figs. 27.11 and 14a, b) in most human brains. In some cases, however, this border can encroach the posterior wall of the precentral gyrus or the anterior wall of the postcentral gyrus to variable distances. Furthermore, a small region displaying a mixture of the cytoarchitectonic characters of areas 4 and 3 can be found at the bottom of the central sulcus, the anterior part of the paracentral lobule, and the posterior part of the operculum Rolandi. This transitional region was identified by von Economo and Koskinas (1925) as their *area* PA_1 (Fig. 27.13c, d) and later called area 3a (for review, see Jones and Porter, 1980). The remaining and larger part of area 3 is the primary somatosensory area 3b (Fig. 27.11), which corresponds to von Economo's and Koskinas' *areas* PB_1 and PB_2. Area 3b has a conspicuous layer IV with small granular neurons invading layer III. Thus, area 3b is a typical koniocortex, that is, a heterotypical six-layered isocortex with a distinct and wide layer IV (Fig. 27.14b, c). This architectonical type is found in all primary sensory areas of the human brain. The subdivision of area 3b into PB_1 and PB_2 by von Economo and Koskinas was based on the stronger invasion of layer III of PB_1 by small granular cells compared to the reduced granularization of layer III in PB_2.

Area 3b is followed posteriorly by intermediate postcentral area 1 (Figs. 27.11 and 27.14c, d), which corresponds to von Economo's and Koskinas' *area* PC (Table 27.5). Area 1 reaches as a narrow strip (PC_γ of von Economo and Koskinas), the caudal part of the paracentral lobule on the mesial hemispheric surface and borders ventrolaterally to area 43. The cytoarchitecture of area 1 shows a homotypical six-layered isocortex with large pyramidal cells in deeper layer III and a less conspicious layer IV when compared with area 3b. Thus, area 1 fits into the general cytoarchitectonic feature of other unimodal sensory areas (e.g.,

area 18 or area 42 of the visual or auditory cortex, respectively). Subarea PC_γ differs from PC by its very large pyramidal cells in layer V and from area PA_2 by its better developed layer IV.

Area 1 is followed caudally by the postcentral area 2, which corresponds to von Economo's and Koskinas' *area* PD (Figs. 27.11 and 27.13c; Table 27.5). It is difficult to delineate area 2 from area 1 because both areas belong to the homotypical six-layered isocortex and contain large pyramidal cells in deeper layer III (Fig. 27.14d). Recently, this border between area 2 and 1 was demonstrated by using a quantitative cytoarchitectonic technique and receptor architectonic analysis (Geyer *et al.*, 1997, 1999, 2000b; Grefkes *et al.*, 2001). It was also demonstrated that area 2 is involved in somatosensory tasks of varying complexity (Bodegård *et al.*, 2000a, b; Naito *et al.*, 1999). Von Economo and Koskinas emphasized that PD can be differentiated from areas of the superior parietal lobule by numerous pyramidal-like cells in deeper layer VI of PD. In contrast to Brodmann (1909), but in accordance with von Economo and Koskinas (1925), it was demonstrated by Grefkes *et al.* (2001), that area 2 does not extend to the mesial hemispheric surface. Von Economo and Koskinas (1925) described a transition region between PD and PE, their area PDE. It continues on the upper and lower bank of the intraparietal sulcus (Figs. 27.11 and 27.13c). Thus, the intraparietal part of PDE can be compared with Brodmann's caudal part of area 2 in the intraparietal sulcus (Brodmann, 1909) and the "visuo-sensory band β" of Smith (1907). For a comprehensive description of the somatosensory system, see Chapter 28.

The subcentral area 43 (Brodmann, 1909) is located lateroventrally at the basis of the postcentral gyrus, approximately between the anterior and posterior subcentral sulci on the operculum Rolandi (Fig. 27.13a). It extends for a considerable distance along the depth of the Sylvian fissure. The most probable candidate for a comparable area in von Economo and Koskinas's map is their area PFD (Fig. 27.13c). Considering its location and extent, area 43 or parts of it may be candidates for the functionally defined second somatosensory cortex. Recently, Eickhoff *et al.* (2002) identified several cytoarchitectonic areas in the parietal operculum, which are not described in the classical cytoarchitectonic maps, but probably comprise the anatomical correlates of the functionally defined second somatosensory cortex SII and other functional areas (e.g., gustatory, vestibular; cf. Chapters 31 and 33).

The preparietal area 5 was classified by Brodmann (1909) as part of his parietal region, but von Economo and Koskinas (1925) identified their comparable area PA_2 as part of the postcentral region (Fig. 27.13). PA_2 shows extraordinarily huge pyramidal cells in layer V

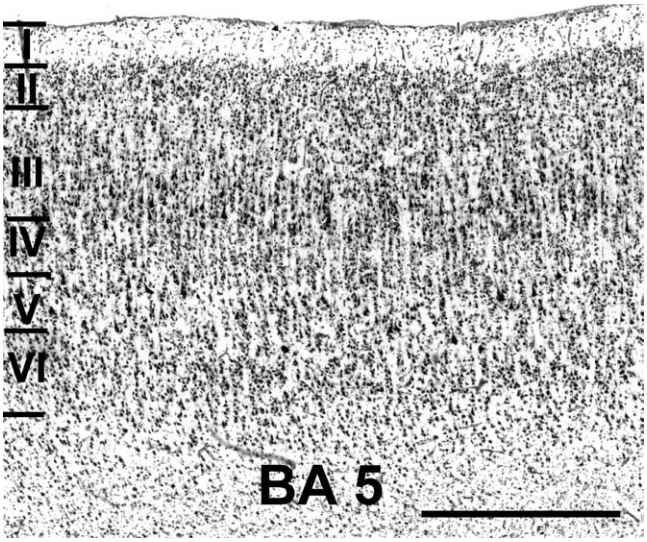

FIGURE 27.15 Cytoarchitecture of area 5 of the human parietal cortex. Bar = 1 mm.

(Fig. 27.15), which are comparable to the giant Betz cells of area 4. However, in sharp contrast to area 4, a conspicuous layer IV is visible in PA_2. Area 5 covers an area extending from the posterior part of the paracentral lobule to the rostral bank of the callosomarginal sulcus and continues laterally between the superior part of the postcentral sulcus and the anterior border of area 7.

Parietal Region

A complete architectonic map of the human parietal region compatible with the extensive regional segregation demonstrated by functional imaging is presently not available. Surprisingly, the practically forgotten myelo- and cytoarchitectonic studies by Vogt (1911), Gerhardt (1940), and Batsch (1956) indicate a much higher architectonic heterogeneity of the cortical organization than represented in the classical maps. Thus, we will briefly present here these forgotten maps, which may be of interest on the background of the high degree of functional segregation demonstrated by recent neuroimaging studies.

According to Brodmann (1908, 1909) and von Economo and Koskinas (1925), the parietal region comprises the four architectonical areas 5, 7, 39, and 40 (Fig. 27.13) or the eight areas PDE, PE_m, PE_p, PEγ, PF_t, PF_{op}, PF_{cm}, and PG, respectively. The major part of the basal parietal region PH of von Economo and Koskinas is located at the occipitotemporal transition zone, belongs to the visual cortex, and may include the functionally defined visual areas V4 and V5, among others. This area will be described later in "Temporal Lobe."

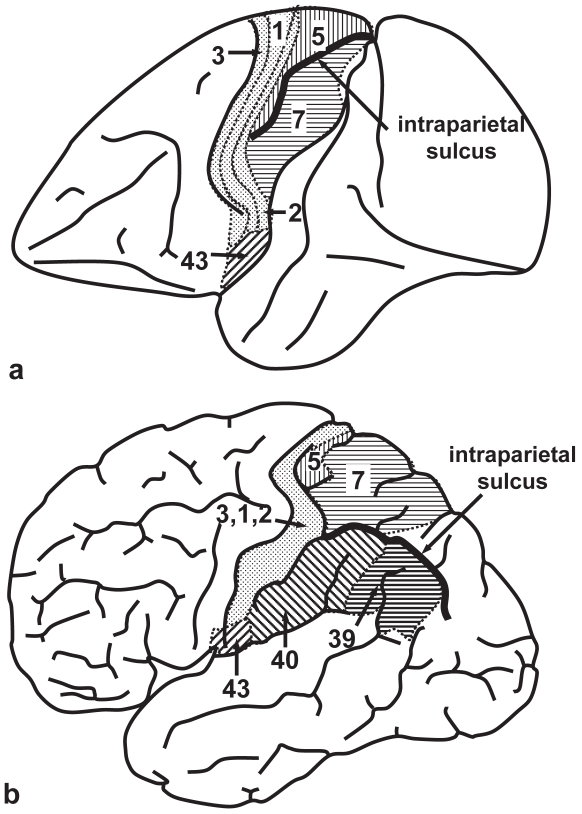

FIGURE 27.16 Areal pattern of the parietal cortex in the human **(a)** and macaque **(b)** brains after Brodmann (1909). According to these maps, the intraparietal sulcus has a different position relative to area 7 in the human compared to the macaque brain.

A major controversy concerning the architectonic organization arose from Brodmann's maps (Brodmann, 1909) of human and monkey parietal cortex (Fig. 27.16). Area 5 of monkeys covers the complete superior parietal lobule, and area 7 covers the complete inferior parietal lobule. In contrast, in the human cortex, areas 5 and 7 are found in the superior parietal lobule, whereas the inferior parietal lobule contains the "human-specific" areas 39 and 40. Vogt (1911) subdivided the superior lobule into areas 5a and 5b and the inferior lobule into areas 7a and 7b. Area 7a includes parts of Brodmann's areas 39 and 40; area 7b represents the most rostral part of area 40. Area 5 of Brodmann is a small part of the areas 5a and 5b of Vogt and Vogt (1926), which are covered almost completely by Brodmann's area 7.

Superior Parietal Lobule

The *superior parietal area 7* of Brodmann (1909) occupies most of the lateral superior parietal lobule and of the medial precuneus (Fig. 27.13a, b). A comparable location was described by von Economo and Koskinas (1925) for their PE areas (Fig. 27.13c, d; Table 27.5).

PE is characterized by a sharply delineated band of conspicuously low cell-packing density corresponding to deeper layer V (layer Vb), whereas the borders of this band are blurred in the inferior parietal areas 39 and 40. Further cytoarchitectonic criteria are provided by the generally smaller cells of inferior parietal lobule areas when compared with PE. PE was further subdivided into the anterior area PE_m, with a more pronounced magnocellular appearance compared to the posterior relatively smaller celled area PE_p. The border between PE_m and PE_p is marked approximately by the superior parietal sulcus. According to von Economo and Koskinas (1925), a transitional area PDE (or PED) is located between areas PD and PE. PDE extends into the intraparietal sulcus. A further subdivision was described in the most posterior part of PE_p, the gigantopyramidal area PE_γ. The larger part of this area is found on the anterior wall of the parieto-occipital sulcus. PE_γ is characterized by widely spaced, very large, but slim pyramidal cells in layers IIIc and V.

Inferior Parietal Lobule

The *angular area 39* corresponds broadly to the angular gyrus. Von Economo's and Koskinas' area PG is the equivalent to Brodmann's area 39 (Fig. 27.13; Table 27.5). PG is found posteriorly of the sulcus of Jensen, below the intraparietal sulcus, above area PH, and rostrally to the occipital cortex, which differs from PG by widely spaced larger pyramidal cells in lower layer IIIc, a conspicuously lighter and smaller layer V, and a more cell dense and smaller layer VI. The cytoarchitecture of PG takes an intermediate position between PE and PF. Layer III of PG is smaller than that of PE, layer V of PG appears lighter than its layer VI, and its overall cell size is smaller than in PE but larger than in PF.

The *supramarginal area 40* corresponds approximately to the supramarginal gyrus. Von Economo and Koskinas's area 40 is equivalent to area PF (Fig. 27.13; Table 27.5). PF occupies the rostral part of the inferior parietal lobule, is found on the posterior part of the operculum Rolandi and the operculum parietale, and reaches approximately to the sulcus Jensen. Von Economo and Koskinas (1925) did not describe sharp borders between PF and adjacent areas. The transitional areas PF_t, PF_{op}, and PF_{cm} are highly variable in their cytoarchitecture and size (for architectonic details of these transitional areas see Zilles and Palomero-Gallagher, 2001). The major part of PF is characterized by relatively small neurons in all layers, layers V and VI with a similar (low) cell density, wide layers II and IV, and a conspicuous, fine columnar arrangement of cells. In contrast to the occipital areas, PF shows relatively broad total cortical widths (2.5–3.6 mm). The

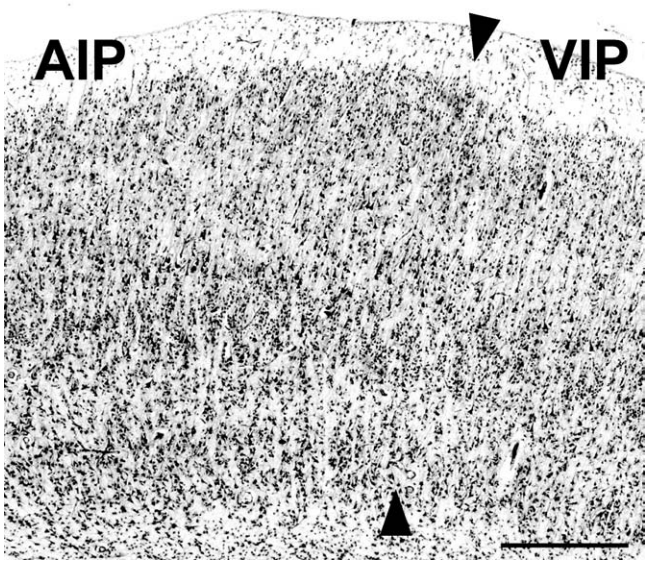

FIGURE 27.17 Cytoarchitecture of the intraparietal areas AIP and VIP of the human cerebral cortex. Bar = 1 mm.

delineation to the temporal areas is based on the higher cell density in layers V and VI of these areas in comparison to PF.

Neither Brodmann (1909) nor von Economo and Koskinas (1925) provided a distinct cytoarchitectonic parcellation of the cortex in the *intraparietal sulcus*. In monkeys, however, several areas—anterior intraparietal area (AIP; Sakata *et al.*, 1995, 1997), lateral intraparietal area (LIP; Andersen *et al.*, 1990b), medial intraparietal area (MIP; Colby *et al.*, 1988), posterior intraparietal area (PIP; Colby *et al.*, 1988), ventral intraparietal area (VIP; Colby *et al.*, 1993; Maunsell and van Essen, 1983; Ungerleider and Desimone, 1986); area PEip (Matelli and Luppino, 2001; Rizzolatti *et al.*, 1998), and area V6A (Galletti *et al.*, 1996, 1999)—were found in the intraparietal sulcus and at the junction with the parietooccipital sulcus, which have numerous connections with the frontal premotor and occipital cortices. Thus, it is highly probably that the human intraparietal sulcus can also be parcellated into equivalent cytoarchitectonic areas. Recently, Choi *et al.* (2002) delineated two areas that are the putative cytoarchitectonic correlates of the recently identified human AIP (Grefkes *et al.*, 2002) and VIP (Bremmer *et al.*, 2000) areas (Fig. 27.17).

Sufficiently precise data on the connectivity of the cytoarchitectonicly defined human parietal areas are presently not available. However, extensive studies on function and connectivity were reported in monkeys (Andersen *et al.*, 1990a, b; Blatt *et al.*, 1990; Cavada and Goldman-Rakic, 1989a, b, 1991, 1993; Cavada *et al.*, 2000; Colby and Duhamel, 1991; Colby and Goldberg, 1999; Colby *et al.*, 1988; Duhamel *et al.*, 1997; Galletti *et al.*, 1996, 1999; Hyvärinen, 1982a, b; Luppino *et al.*, 1999; Matelli *et al.*, 1998; Matelli and Luppino, 2001; Maunsell and van Essen, 1983; Mesulam *et al.*, 1977; Pandya and Seltzer, 1982a; Petrides and Pandya, 1984; Schmahmann and Pandya, 1990; Seltzer and Pandya, 1980, 1984, 1986; Sakata *et al.*, 1995, 1997; Yeterian and Pandya, 1985, 1993). The dorsal part of the premotor cortex receives afferents from the parietal area 7 (PEip and PEc; Rizzolatti *et al.*, 1998), MIP, area V6A, area 46, and the mesial posterior parietal cortex from the extrastriate visual cortex. The transformation of somatosensory and visual information for the control of hand movement toward the target and coding of object location in space for orienting and coordinated arm–body movements are possible function of these circuits (Matelli and Luppino, 2001). Further circuits are found between the ventral part of the premotor cortex and the parietal areas AIP, VIP, and von Economo's and Koskinas's (1925) area PF (area 40 of Brodmann, 1909). The VIP–premotor cortex circuit seems to encode peripersonal space according to a body part-centered frame of reference and transforms object locations into appropriate movements toward them (Matelli and Luppino, 2001). The AIP–premotor cortex circuit provides a representations of intrinsic object properties (size, shape, and orientation) for selection of the most appropriate way of grasping (Jeannerod *et al.*, 1995). The supplementary motor cortex SMA-proper and the presupplementary motor cortex pre-SMA are further targets of the areas PFG, PG, and PE of the superior and inferior parietal lobules. LIP, the frontal eye field (FEF), and the supplementary frontal eye field (SFEF) are interconnected. The LIP–FEF circuit uses eye position and retinotopic information for the transformation of the retinocentric into a craniocentric frame of reference (Matelli and Luppino, 2001).

Posterior parietal lesions in humans lead to apraxia and extinction (lesion of the left hemisphere) as well as neglect (lesions of the right hemisphere) (Balint, 1909; Denny-Brown *et al.*, 1952; Driver *et al.*, 2001; Fink *et al.*, 1997; 2000a, c, 2001b; Freund, 1987, 2001; Luria, 1959; Mesulam, 1999; Sirigu *et al.*, 1995; Tyler, 1968; Vallar, 1998, 2001). Lesions of the angular gyrus in the dominant hemisphere (areas PF and PG) lead to finger agnosia (inability to recognize, distinguish, and name one's fingers or those of other persons), pure agraphia, right–left disorientation, and dyscalculia (inability to recognize the value of a number). These symptoms have been summarized as Gerstmann's syndrome (Gerstmann, 1930).

The maintenance of a spatial reference system for goal-directed movements seems to be a major function

of the posterior parietal region. This function is a prerequisite for important human activities (i.e., tool use and conceptualization of actions). Recent functional imaging and other mapping studies (Bodegård *et al.*, 2000a, b; Bremmer *et al.*, 2001; Ehrsson *et al.*, 2000; Geyer *et al.*, 1996; Larsson *et al.*, 1999; Naito *et al.*, 1999, 2000; Roland and Zilles, 1994, 1996a, b, 1998; Zilles *et al.*, 1995, 1997) demonstrate that areas in the inferior parietal lobule and intraparietal sulcus were activated during imagining (Jeannerod, 2001) and executing (Binkofski *et al.*, 1999) grasping (Decety *et al.*, 1994; Grafton *et al.*, 1996), evaluation of the possible motor significance of sensory stimuli ("motor intention irrespectively of the likelihood of providing a response"; Toni *et al.*, 2001), perceptually based decisions and prospective action judgement (Parsons *et al.*, 1995), action observation (Buccino *et al.*, 2001), and visual presentation of graspable objects (Chao and Martin, 2000).

In a recent event-related fMRI study, the contribution of the parietal-temporal-premotor circuit to sensorimotor transformations was analyzed "where behavior is guided by rules rather than objects or places" (Passingham and Toni, 2001; Toni *et al.*, 2001; White and Wise, 1999). It could be shown, that (1) activation of the posterior parietal cortex can be correlated with motor intention, (2) the premotor cortex can be correlated with movement preparation, and (3) the posterior part of the superior temporal gyrus can be correlated with the extraction of contextual and intentional cues during goal-directed behavior. Finally, it has been shown that the superior posterior parietal cortex of the human brain is a multimodal region implicated in task switching, even when no visual or spatial component is part of the task (Gurd *et al.*, 2002).

Forgotten Maps of the Human Parietal Cortex

Detailed cyto- (Gerhardt, 1940) and myeloarchitectonic (Vogt, 1911; Batsch, 1956) parcellations of the human parietal lobe are available. Vogt (1911) proposed a map of the human parietal cortex displaying 28 different myeloarchitectonic areas. However, these three studies of the Vogt School are practically forgotten. Here, a brief review of the detailed maps (Figs. 27.18–27.20) will be given (see Table 27.5 for comparison with other nomenclatures).

Major criteria in the myeloarchitectonic studies are interareal differences in the length, thickness, and spacing of the radial fiber bundles, the visibility or lack of the Kaes-Bechterew stripe (i.e., tangentially oriented myelinated nerve fibers in the most superficial part of layer III), the visibility or lack of the outer and inner Baillarger stripes (i.e., tangentially oriented myelinated nerve fibers in layer IV and deeper layer V, respectively), and the merging or separation of the outer and inner Baillarger stripes (Fig. 27.21).

The parcellation in the maps of Vogt (1911) and Batsch (1956) is quite comparable. Differences between both maps are only found when the sizes of equivalent areas are compared between the studies. This, however, is not surprising because the sizes of equivalent cortical areas in different brains show a considerable degree of intersubject variability (Amunts *et al.*, 1999, 2000b; Geyer *et al.*, 1996, 1999, 2000b; Grefkes *et al.*, 2001; Rademacher *et al.*, 2001b; Roland *et al.*, 1997; Zilles *et al.*, 1997). Thus, the two myeloarchitectonic studies provide a concordant map of the human parietal cortex. The myeloarchitectonic maps are further supported by

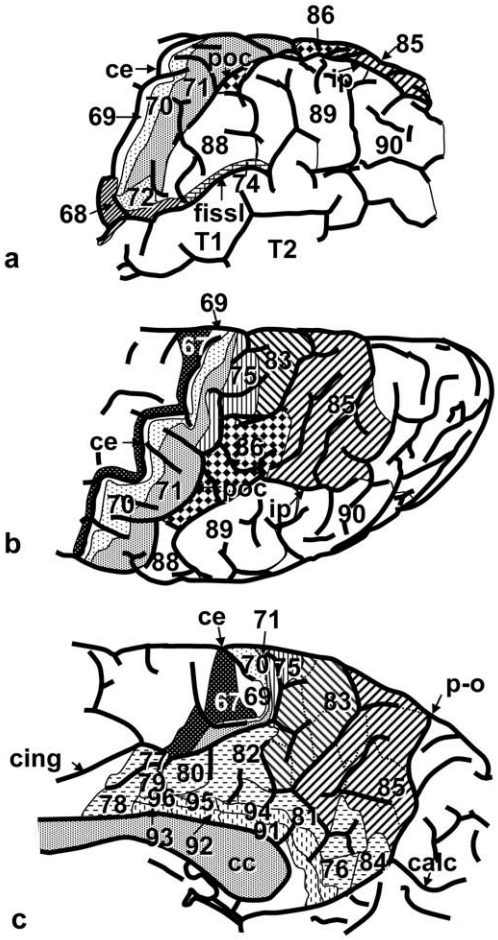

FIGURE 27.19 Cytoarchitectonic map of the human parietal cortex (modified after Gerhardt, 1940). **(a)** Lateral view, **(b)** dorsal view, and **(c)** mesial view. calc, calcarine sulcus; cc, corpus callosum; ce, central sulcus; fissl, lateral fissure; ip, intraparietal sulcus; p-o, parieto-occipital sulcus; poc, postcentral sulcus; T1, superior temporal gyrus; T2, inferior temporal gyrus. The Arabic numerals indicate the cytoarchitectonic areas of Gerhardt, which are not identical the numerical scheme of Brodmann but comparable to the myeloarchitectonic classification of Vogt as shown in Figure 27.18.

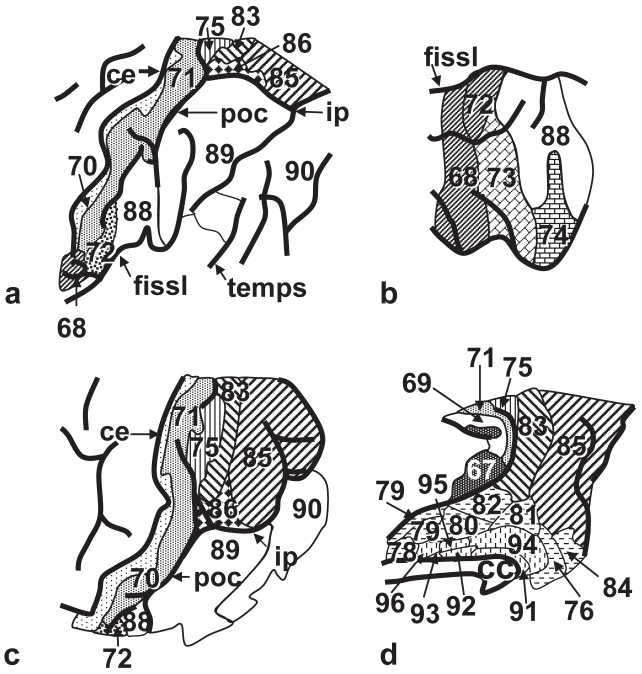

FIGURE 27.20 Myeloarchitectonic map of the human parietal cortex (modified after Batsch, 1956). **(a)** Lateral view, **(b)** surface of the parietal operculum, **(c)** dorsal view, and **(d)** mesial view. cc, corpus callosum; ce, central sulcus; fissl, lateral fissure; ip, intraparietal sulcus; poc, postcentral sulcus; temps, superior temporal sulcus. The Arabic numerals indicate the myeloarchitectonic areas of Batsch, which are not identical the numerical scheme of Brodmann but comparable with the myeloarchitectonic classification of Vogt as shown in Figure 27.18.

the cytoarchitectonic observations of Gerhardt (1940). This study provides an even more detailed map; however, the parcellation was based on only one hemisphere. Thus, not all of Gerhardt's subareas may be found in other brains. Only the major areas of this cytoarchitectonic map are reproduced here (Fig. 27.19) and show an areal pattern very similar to those observed by Vogt (1911) and Batsch (1956) in their myeloarchitectonic studies. These three studies indiate that the areal parcellations of Brodmann (1909) and von Economo and Koskinas (1925) do not give a sufficiently complete picture of the architectonical organization in the human parietal lobe.

Temporal Lobe

The temporal lobe consists of a large number of cortical areas differing in structure (isocortical to allocortical) and function (unimodal auditory, unimodal visual, multimodal association). The superior (transverse gyri, planum temporale) and dorsolateral (superior temporal gyrus) zone of the temporal lobe contains various isocortical areas, which are the structural correlates of the unimodal auditory cortex and the multimodal language area (i.e., the Wernicke region). The unimodal visual and multimodal isocortical areas of the inferior lateral and ventral zones of the temporal lobe—medial and inferior temporal gyri, fusiform (= lateral occipitotemporal) gyrus, rostral part of the lingual (= medial occipitotemporal) gyrus—are summed up here as the inferotemporal zone. This zone is followed most medially by allocortical regions, which comprise the multimodal medial zone of the temporal lobe. This latter zone consists of the periallocortical entorhinal, perirhinal, parasubicular, and presubicular areas as well as the allocortical regions of the hippocampus (dentate gyrus, Ammon's horn,

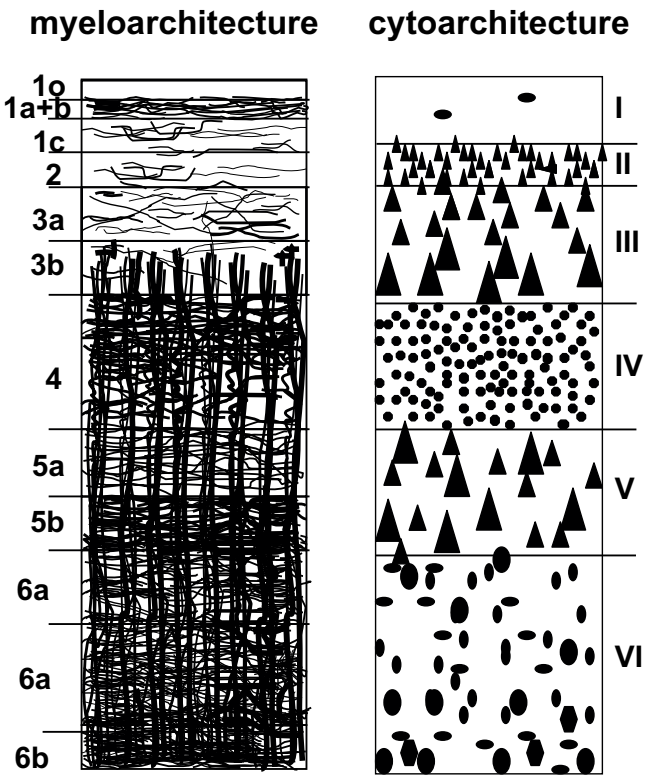

FIGURE 27.21 Schematic drawing of the myelo- and cytoarchitectonic lamination patterns in the human isocortex. Arabic numerals indicate the cortical layers in myelin-stained sections; Roman numerals indicate the cortical layers in cell body-stained sections. The myelinated fibers are running vertically or horizontally to the surface of the cerebral cortex. Only a few fibers are obliquely oriented. The vertical fiber bundles contain myelinated axons and are called radial fibers. This term may give rise for confusios because the same term is used for vertically oriented *glial* fibers in the fetal brain. The thickness, length, and packing density of the myelinated fiber bundles are important criteria for myeloarchitectonic parcellations. The horizontally oriented fiber bundels also contribute as important criteria to the myeloarchitectonic studies. The most superficial horizontal fiber bundel is the Exner-stripe in layer 1a+b, followed by the Kaes-Bechterew-stripe in layer 3a, the outer Baillarger-stripe in layer 4, and the inner Baillarger-stripe in layer 5b.

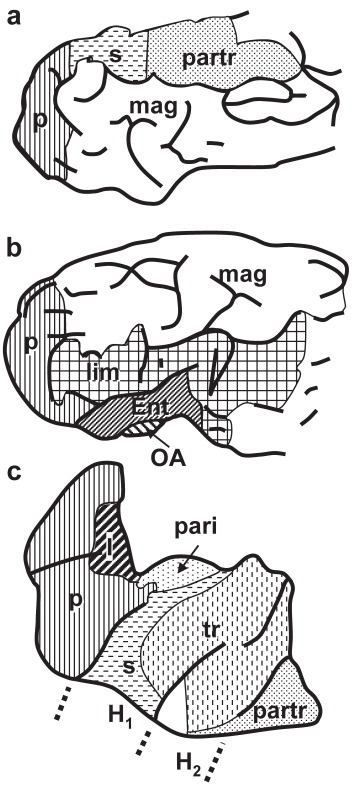

FIGURE 27.22 Areal map of the temporal lobe based on the myeloarchitectonic observations of Hopf (1954). **(a)** Lateral view, **(b)** basal view, **(c)** dorsal view. subiculum) and the small cortical part of the amygdala. The areas of this allocortical zone are described in detail in Chapters 22–24 and 32. The polar zone of the temporal lobe (Brodmann's area 38) consists of a multimodal region with a proisocortical architecture and was interpreted as part of the paralimbic belt by Mesulam (1998).

The most detailed anatomical studies of the human temporal isocortex are based on myeloarchitectonic observations (Hopf 1954, 1955, 1968). This author identified 7 regions, which were further subdivided into 20 subregions and 60 cortical areas. Figure 27.22 provides an overview of the different regions as described by Hopf (1954). A detailed comparison of the parcellation by Hopf (1954, 1955, 1968) with the cytoarchitectonic studies of Smith (1907), Brodmann (1909), and von Economo and Koskinas (1925), however, reveals considerable differences (cf Table 27.6). Braak's (1978) pigmentoarchitectonic observations (Fig. 27.23) are also at variance with all the other studies. Thus, it is presently not possible to provide a conforming and sufficiently detailed architectonic map of the temporal isocortex, that reconciles the different parcellation schemes.

Despite these controversies in detailed parcellation, a general pattern of the architectonic segregation of the temporal isocortex, which is based on the parcellation scheme of Brodmann (1909), can be described. The human temporal lobe comprises three main iso- or proisocortical regions: (1) a proisocortical polar (Brodmann's temporopolar area 38) together with a mediobasal (Brodmann's ectorhinal area 36 on the

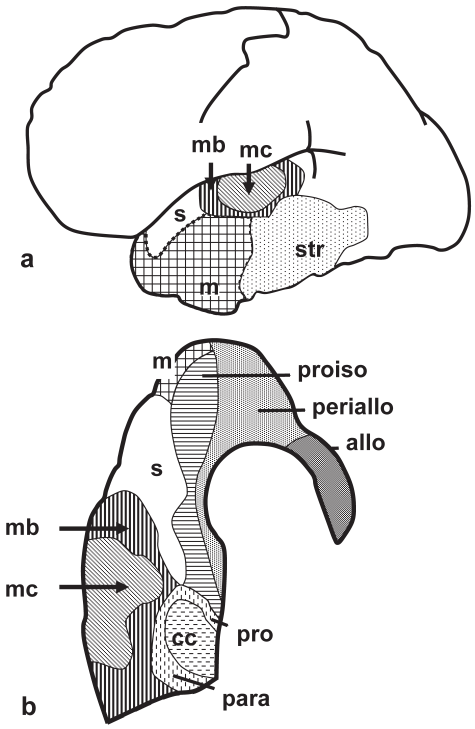

FIGURE 27.23 Areal map of the temporal lobe based on the pigmentoarchitectonical observations of Braak (1978). **(a)** Lateral view, **(b)** dorsal view. allo, allocortex; cc, koniocortial core area; m, area temporalis magna; mb, magnopyramidal temporal belt; mc, magnopyramidal temporal core; para, posterior part of the parakoniocortex; periallo, periallocortex; pro, prokoniocortex; proiso, proisocortex; s, area temporalis simplex; str, area temporalis stratiformis.

rostral prolongation of the lingual gyrus and adjacent parts of the parahippocampal gyrus) proisocortical region (p and lim in Fig. 27.22), which is very poor in myelinated fibers and is part of the paralimbic region of Pandya and Seltzer (1982b) and Mesulam (1998), (2) a large region on the middle temporal gyrus (Brodmann's middle temporal area 21) and inferior temporal and fusiform gyri (Brodmann's inferior temporal area 20 and occipitotemporal area 37), which is poor in myelinated fibers (mag in Fig. 27.22), and (3) an isocortical region on the superior and transverse temporal gyri and the planum temporale (Brodmann's area 42 and superior temporal area 22; s and partr in Fig. 27.22) surrounding rostrally, laterally and posteriorly the primary auditory area 41. These three areas are rich in myelinated fibers. According to Pandya and Seltzer's (1982b) studies in the rhesus monkey, the ptr region may project to the premotor cortex and the s and m regions to the prefrontal cortex. All these regions (ptr, s, m) project also to the paralimbic association cortex, parts of which are represented by the p region of Hopf (1954).

A small proisocortical region, immediately adjacent to the insular cortex, poor in myelinated fibers and of small cortical width (pari in Fig. 27.22), is architectonicly defined as Brodmann's parainsular area 52. This latter area is part of the temporal paralimbic cortex of Mesulam (1998) and of a proisocortical stripe (Fig. 27.23) described by Braak (1978).

Auditory Cortex

The human auditory cortex consists of various unimodal areas located on the dorsal surface of the temporal lobe and the superior temporal gyrus. A conspicious architectonic feature of the auditory cortex is its high content of myelinated fibers (Hopf, 1954, 1955, 1968) and the arrangement of neuronal perikarya in distinct vertical columns ("organ pipes" and "rain shower" formations of von Economo and Koskinas, 1925). The average column width and the interval between columns in all temporal auditory areas are

smaller in the right than in the left hemisphere (Seldon, 1981).

The principal structure of the connectivity of the auditory cortex supports the concept of three parallel streams of areas running in a rostrocaudal direction as proposed by Pandya (1995). The medial stream is represented by the parainsular cortex, the interposed (core) stream occupies the supratemporal plane, and the most lateral stream is located on the superior temporal gyrus. The areas of each stream have feedforward connections originating in layer III of one area and terminating in layer IV of the rostrally adjacent area. The feedback connections originate in the infragranular layers and terminate in layer I. The areas of the most medial and most lateral streams are connected with the prefrontal multimodal association areas and limbic areas. Additionally, the areas of the most lateral stream show a detailed connectivity according to their rostrocaudal sequence. The most rostral areas of this stream are connected with the orbital and medial prefrontal cortices; the intermediate group, with the lateral prefrontal areas; and the caudal group, with the caudal prefrontal cortex. The areas of the intermediate stream are preferentially related to the ventral nucleus of the medial geniculate body, whereas the areas of the medial and lateral streams are connected with the magnocellular and dorsal nuclei of the medial geniculate body, pulvinar, dorsomedial, and intralaminar thalamic nuclei.

Magnetic resonance imaging (Binder *et al.*, 1994; Schmid *et al.*, 1998; Strainer *et al.* 1997; Talavage *et al.*, 1999), magnetoencephalographic (Hari *et al.*, 1984; Langner *et al.*, 1997; Pantev *et al.*, 1995; Romani *et al.*, 1982), and electroencephalographic (Liegeois Chauvel *et al.*, 1991, 1994) studies have demonstrated auditory functions such as the response to pure tones and to acoustic frequency patterns that map onto the medial two thirds of the Heschl gyrus. A considerable function-depending plasticity of the representation in the auditory cortex was also demonstrated (Pantev *et al.*, 1998b; Rauschecker, 1999). In contrast to the established functional lateralization of language, asymmetries following acoustic stimulation are still a matter of discussion (Belin *et al.*, 1998; Lauter, 1992; Nicholls, 1998; Pantev *et al.*, 1998a; Poeppel *et al.*, 1996; Zouridakis *et al.*, 1998).

Primary auditory cortex (core region) The cytoarchitectonic areas 41 of Brodmann (1909) and TC of von Economo and Koskinas (1925) (Figs. 27.35 and 27.37) represent the putative cytoarchitectonic correlates of the human primary auditory cortex, which neurons are tuned to pure tones and pitch. Several studies demonstrated a tonotopic organization of the primary auditory cortex with responses to low-frequency stimuli originating more laterally and high-frequency stimuli originating more medially (Bilecen *et al.*, 1998; Hari *et al.*, 1984; Howard *et al.*, 1996; Lauter *et al.*, 1985; Pantev *et al.*, 1995; Reite *et al.*, 1994; Talavage *et al.*, 1997; Tiitinen *et al.*, 1993; Verkindt *et al.*, 1995; Yamamoto *et al.*, 1992). Area 41 has the typical koniocortical structure of primary sensory areas (i.e., a well-developed layer IV with densely packed small neurons, and a high cell density invading the supragranular layer III). Area 41 is located deep in the Sylvian fissure on the temporal transverse gyrus (Heschl) gyrus and is surrounded caudolaterally by the secondary auditory area 42, rostrally and laterally by areas 22 and 42, and medially by the area 52.

Rademacher *et al.* (1993) described two transverse gyri of Heschl separated by an intermediate transverse sulcus in 7 out of 20 hemispheres. In hemispheres with two transverse gyri, area 41 is located most frequently on the first transverse gyrus. Only in two of the seven cases with two transverse gyri does area 41 overflow across the intermediate sulcus and also cover the rostral part of the second transverse gyrus.

Braak's (1978) "granulous core field" (demonstrated by his pigment-staining technique) was identified as putative primary auditory cortex (Fig. 27.23) but covers only the rostral half of the first transverse gyrus of Heschl. Thus, his anatomical correlate of the primary auditory cortex seems to be smaller than shown in the classical maps of Brodmann (1909) and von Economo and Koskinas (1925). Galaburda and Sanides' (1980) temporal koniocortex (primary auditory cortex) shows also a much greater rostrocaudal extent compared with Braak's (1978) granulous core field. However, a considerable intersubject variability in size and shape of the transverse gyrus (gyri) must be considered (Leonard *et al.*, 1998; Penhune *et al.*, 1996; Steinmetz *et al.*, 1989; Thompson *et al.*, 1996). This makes a straightforward comparison between different maps difficult. Moreover, the maps of Brodmann (1909), von Economo and Koskinas (1925), and Braak (1978) do not allow—because of their schematic two-dimensional representation—a reliable spatial transformation into a common reference brain or stereotaxic system.

Recently, Morosan *et al.* (2001) and Rademacher *et al.* (2001a, b) published a cytoarchitectonic map of the primary auditory cortex. Because their maps are transformed into a three-dimensional reference system, the intersubject variability of this cortical area was defined by presenting probability maps, and the auditory function of the subareas could be corroborated using functional imaging (Johnsrude *et al.*, 2000). Most importantly, Morosan *et al.* (2001) and Rademacher *et al.* (2001a, b) demonstrated that the borders of the

cytoarchitectonicly defined primary auditory cortex cannot be assigned reliably to macroscopicly visible landmarks of the Heschl gyrus. Because this lack of coincidence between the borders of architectonic areas and macroscopic landmarks was found also in other cortical regions (Amunts *et al.*, 1999, 2000b; Geyer *et al.*, 1996, 1997, 1999, 2000b; Rademacher *et al.*, 1992; Roland and Zilles, 1996b, 1998; Zilles *et al.*, 1995, 1996, 1997), this finding seems to be a general caveat for any attempt to infer the position of cytoarchitectonic borders from macroscopic landmarks.

In contrast to Brodmann (1909), other authors identified two or more areas representing the primary auditory cortex (Economo and Koskinas, 1925; Galaburda and Sanides, 1980; Morosan *et al.* 2001; Rivier and Clarke, 1997; Sarkissov *et al.*, 1955). Morosan *et al.* (2001) subdivided their primary auditory area Te1 (equivalent to Brodmann's area 41) into the three subareas Te1.1 (caudomedial), Te1.0 (central), and Te1.2 (rostrolateral) (Fig. 27.24) using an observer-independent, quantitative cytoarchitectonic technique (Schleicher *et al.*, 1999). The functional meaning of this parcellation of the primary auditory cortex remains to be elucidated. The area Te1.0 shows the cytoarchitectonic features of the koniocortex (Fig. 27.25a), which is typical for primary sensory areas.

Secondary auditory cortex (belt region) Brodmann's (1909) area 42 (Fig. 27.35) and von Economo's and Koskinas's (1925) area TB (Fig. 27.37) are the putative architectonic correlates of the secondary auditory cortex. Area 42 is less granular (clearly visible but less densely populated and smaller layer IV; see Fig. 27.25b) when compared with area 41. In comparison to the adjoining area 22, area 42 is characterized by a higher cell density of layer II, a smaller layer IIIc, a more prominent layer IV, and a sharper layer VI/white matter boundary. Area 42 of Brodmann (1909) has correlates in the maps of Braak (1978) and Galaburda and Sanides (1980), which are named as pro- and parakoniocortical areas. Braak's (1978) pro- and parakoniocortical areas (putative secondary auditory cortex) surround completely the core field (putative primary auditory cortex). Area 42 (and area 22) represent phonological representations of words (Binder *et al.*, 1994; Howard *et al.*, 1992; Price and Giraud, 2001).

Stimulation by longer sound durations leads to an activation of a field in the most lateral part of the Heschl gyrus, which may correspond at least to parts of Brodmann's area 42 or the parakoniocortical field of Rivier and Clarke (1997). This field shows a mirror tonotopic organization (mediolateral low- to high-frequency gradient; Engelien *et al.*, 2002) compared with the primary auditory cortex (latero-medial low- to high-frequency gradient).

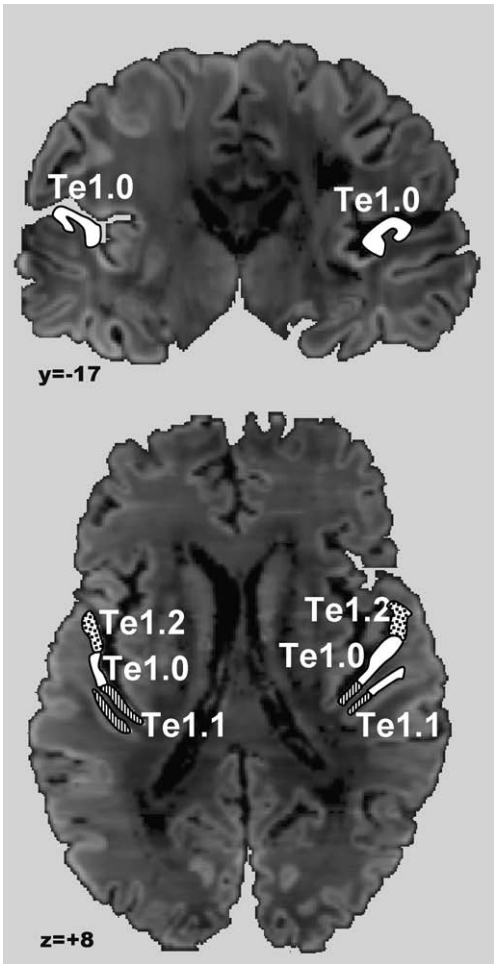

FIGURE 27.24 Areas Te1.2, Te1.0, and Te1.1 of the human primary auditory cortex Te1 on the Heschl gyrus in coronal *(upper part)* and horizontal *(lower part)* sections after spatial normalization to the corresponding postmortem magnetic resonance images (after Morosan *et al.*, 2001). Using the reference brain of the Human Brain Atlas (Roland and Zilles, 1996b, 1998) corresponding Talairach coordinates are calculated. The borders of the areas were identified (Morosan *et al.*, 2001) in cell body-stained sections using a quantitative cytoarchitectonic method (Schleicher *et al.*, 1999).

Further unimodal auditory areas The homotypic isocortical area 22 of Brodmann (1909) is found adjacent to the secondary auditory cortex (area 42) on the posterior two thirds of the superior temporal gyrus up to the beginning of the vertical branch of the lateral fissure. Most rostrally, area 22 is bordering the areas 41 and 52 (see Fig. 89 in Brodmann, 1909). The superior temporal gyrus processes phonologic word forms (Booth *et al.*, 2002). The neurons of the anterior and central parts of area 22 seem not to respond readily to

pure tones but are preferably responsive to specific phonetic parameters (Zatorre *et al.*, 1994) at a presemantic level because they are active both during exposition to meaningful words and to nonsense words (Creutzfeld *et al.*, 1989). Thus, the major part of this area is a higher order, but unimodal auditory cortex. Consequently, at least its rostral two thirds should not be lumped together with the posteriorly adjoining Wernicke region, which is a multimodal association cortex subserving complex language functions. In conclusion, at least the major part of area 22 constitutes together with the areas 41 and 42 the functionally defined human auditory cortex. This was already implicitly postulated by Brodmann (1909) on the basis of his microscopic observations. He stated that the cytoarchitecture of area 22 differs clearly from that of the isocortical areas 21 and 20 and the paralimbic (Mesulam, 1998) temporopolar area 38 and is more similar to that of the auditory areas 41 and 42.

Recent own quantitative cytoarchitectonic observations (Morosan *et al.*, unpublished) and studies of the regional distribution of transmitter receptors argue for further subdivisions of area 22. Area Te 3 (Fig. 27.25b) is found at the lateral border of the secondary auditory cortex. Te 3 is only a part of area 22, which seems to be a complex of several higher order auditory areas. This would correspond to the situation in the visual cortex provided by recent parcellations of Brodmann's area 19 into various functionally and architectonically definable higer order unimodal visual areas in the human brain (for review Zilles and Clarke, 1997). For a comprehensive description of the auditory system, see Chapter 34.

Wernicke Region

The free surface of the cortex on the superior temporal plane caudal to the first transverse gyrus and extending to the end of the lateral (Sylvian) fissure is defined as *planum temporale*. The left planum was found to be larger than its equivalent in the right hemisphere in most cases of a large human sample (Galaburda *et al.*, 1978a, b; Geschwind and Levitsky, 1968; Steinmetz *et al.*, 1989). Von Economo and Horn (1930) interpreted this gross anatomic asymmetry as a larger extent of the left auditory "association" cortex. Steinmetz *et al*. (1991) analyzed this asymmetry and its relation to handedness in 26 right and 26 left handers using magnetic resonance imaging. A correlation with handedness was found; a left-over-right asymmetry could be registered for the whole sample, but it was less strongly expressed in left handers compared with right handers. Thus, the overall left-over-right asymmetry has been interpreted as a morphological substrate for language lateralization.

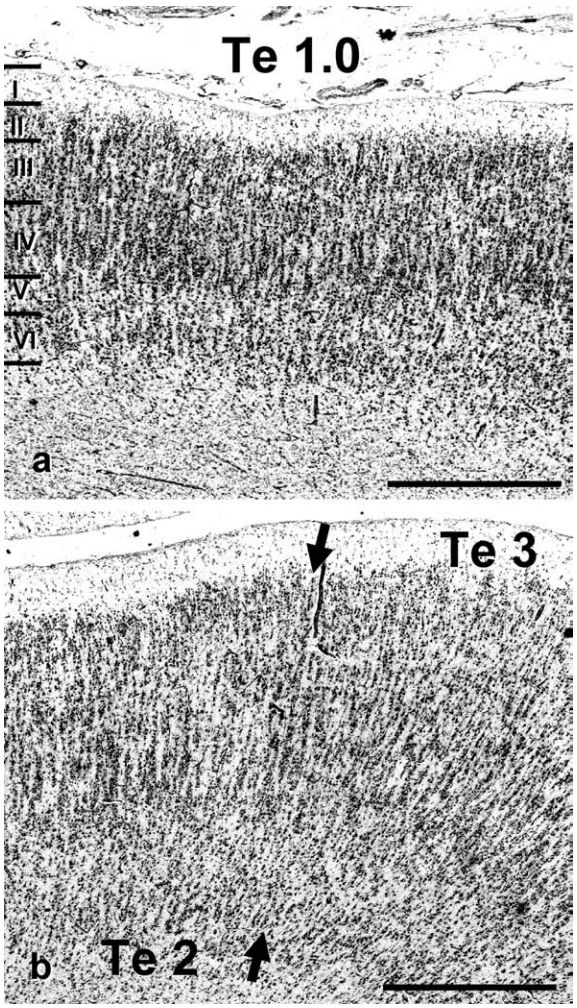

FIGURE 27.25 Cytoarchitecture of the primary auditory area Te 1.0 (a), secondary auditory area Te 2 (b), and surrounding unimodal sensory cortex Te 3 (b). This parcellation is based on a quantitative cytoarchitectonic study by Morosan *et al.* (2001). Bars = 1 mm.

The precise position of the architectonic borders of Wernicke's region (Wernicke, 1874), however, is presently not known. This multimodal language area covers at least the planum temporale of the superior temporal gyrus (Aboitiz and Garcia, 1997; Grabowski and Damasio, 2000). Thus, this area is commonly related to the most posterior part of area 22 (Brodmann, 1909), to area TA_1 of von Economo and Koskinas (1925), or to area Tpt (Galaburda and Sanides, 1980). Tpt (Fig. 27.26) includes posterior and lateral temporal regions in which lesions cause Wernicke's aphasia. Tpt was larger on the left side in all four cases measured (Galaburda *et al.*, 1978a) with relative differences between both sides showing an enormous variability between 14 and 626%.

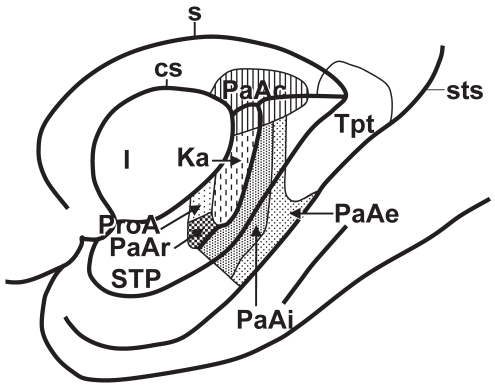

FIGURE 27.26 Areal map of the temporal lobe (lateral view, with a schematic opening of the insula) based on the cytoarchitectonic observations of Galaburda and Sanides (1980). cs, circular sulcus; I, insular cortex; Ka, koniocortex; PaAc, caudal parakoniocortex; PaAe, external parakoniocortex; PaAi, internal parakoniocortex; PaAr, rostral parakoniocortex; ProA, prokoniocortex; s, Sylvian fissure; STP, superior temporal plane; sts, superior temporal sulcus; Tpt, temporoparietal area.

Braak (1978) delineated magnopyramidal regions laterally adjoining the belt region of his auditory cortex (mb and mc in Figure 27.23). The most conspicuous indicators of this magnopyramidal temporal area are the large pyramidal cells in the lower part of layer III. Braak (1978) considers this field to represent the structural basis of the sensory speech region of Wernicke. The magnopyramidal area is surrounded by three isocortical areas on the rostromedial ("area temporalis simplex"; s in Figure 27.23), rostrolateral ("area temporalis magna"; m in Fig. 27.23), and posterolateral sides ("area temporalis stratiformis"; str in Fig. 27.23).

In contrast to area 42 (see previous discussion), the cortex resembling most probably the core of the Wernicke region has a rather cell-sparse layer II. The pyramidal cells of layers IIIc and V are of prominent size and density. The size of layer IIIc pyramidal cells seems to be increased compared with area 42. Layer IV is rather thin. The putative Wernicke region is separated from the neighboring area on the ventral wall of the superior temporal sulcus, which has a rather conspicuous cell layer II, a "cluster-like" arrangement of medium-sized IIIc pyramidal cells, a small layer IV, and rather cell-dense layers V and VI. Posteriorly, the here-described putative homologue of Wernicke's region borders the supramarginal cortex. The cytoarchitecture of this cortex is characterized by smaller and less densely packed pyramidal cells in layer IIIc, a small layer IV, and rather cell-dense layers V and VI.

The classical myeloarchitectonic maps (Beck, 1930; Hopf, 1954, 1955; Vogt and Vogt, 1919) indicate that a posterior part of Brodmann's area 22 may contribute to Wernicke's region. The putative myeloarchitectonic homologue of Wernicke's region is the area tpartr.p of Hopf (1954). This area is characterized by relatively densely packed myelinated fibers, the lack of the Kaes-Bechterew stripe (Fig. 27.21), and darkly stained outer and inner Baillarger stripes, which seem to merge to one broad stripe. In contrast, the auditory belt region has a lower fiber density than the Wernicke region, especially in layer III.

Inferotemporal Zone

The inferotemporal zone consists (in dorsoventromedial sequence) of the areas 21, 20, and 36 (Brodmann, 1909). Brodmann's area 37 is located as a transition region between the temporal, parietal, and occipital lobes (Fig. 27.35) and is included here as further part of the inferotemporal zone.

Parts of these four areas belong to the multimodal association cortices; other parts are members of the higher order unimodal visual and auditory cortices (Mesulam, 1998). Brodmann's middle temporal area 21, inferior temporal area 20, and occipitotemporal area 37 are characterized by the six-layered homotypical isocortex, whereas area 36 is found on the parahippocampal gyrus at the transition between the iso- and allocortex and shows some typical cytoarchitectonical modifications of the homotypical isocortex (see following discussion), which may justify the classification of at least parts of this area as proisocortex.

The cortex of areas 20 and 21 is very thick (3.0–3.8 mm according to von Economo and Koskinas, 1925), nearly as wide as the motor cortex. Layer III is relatively small, and its cell-packing density is very low. Layer IV is also very thin, and the cells are arranged in clearly visible vertical columns. In contrast to these more superficial layers, the deeper layers V and VI are very wide. Layer V contains conspiciously large pyramidal cells. Because areas 20 and 21 are difficult to separate by cytoarchitectonic criteria, von Economo and Koskinas (1925) classified both areas as one cortical region, their regio temporalis propria TE. The only criterion for a parcellation of this region into the subareas TE_1 and TE_2 seems to be the somewhat larger size of the pyramidal cells in layer III of TE_1 compared with TE_2. Equivalencies with the cortical terminologies of other authors are given in Tables 27.4 and 27.6.

Brodmann's ectorhinal area 36 (Fig. 27.35) is not only poor in myelinated fibers, but also shows a lower overall cell packing density compared with the adjacent isocortical area 20. The prominent appearance of large neurons in layers V and VI justifies the distinction of parts of area 36 as proisocortex from the other homotypical isocortical areas of the inferotemporal zone.

According to classical (von Economo and Koskinas, 1925) and more recent architectonic and functional imaging studies (for review Zilles and Clarke, 1997), Brodmann's area 37 is not a homogeneous cortical area. Some parts of area 37 are probably multimodal (Mesulam, 1998); others are higher order unimodal visual areas (e.g., V5/MT; see "Occipital Lobe"). It should be mentioned here that the fusiform gyrus, which contains parts of area 37 (and area 19), also displays orthographic representations of words (Fujimaki *et al.*, 1999; Nobre *et al.*, 1994; Petersen *et al.*, 1990). On the lateral cortical surface, area 37 covers the posterior parts of the middle and inferior temporal gyri and the anterior parts of the middle and inferior occipital gyri. The preoccipital incisure marks the center of area 37 at the border between the lateral and basal surface of the hemisphere. On the basomedial surface, area 37 covers the posterior part of the inferior temporal gyrus and reaches the lingual, fusiform, and parahippocampal gyri. Thus, area 37 is a region approximately comparable to the area paratemporalis of Smith (1907) (Fig. 27.34) and the area PH of von Economo and Koskinas (1925) (Fig. 27.37; Table 27.7). This area consists of small radial cell columns in layers III and IV, a narrow layer IV, and hardly delineable layers V and VI caused by relatively small cells in layer V and, thus, similar cell sizes in both layers. PH shows a sharp border between cortex and white matter. Von Economo and Koskinas (1925) emphasize that the cytoarchitecture of PH is not homogenous. It displays characteristics of the temporal, parietal, and occipital cortices depending on the region of interest within PH. Larger pyramidal cells are visible in the temporal and occipital parts of PH compared to the parietal part.

The isocortex on the medial temporal gyrus (approximately Brodmann's area 21) of the dominant hemisphere participates in short-term verbal memory (Ojemann *et al.*, 1987), verbal fluency and word generation (Petersen *et al.*, 1988; Frith *et al.*, 1991; Wise *et al.*, 1991), and tone and rhythm discrimination (parts of areas 21 and 22) as well as the ability to listen to stories (parts of areas 21 and 22) (Mazziotta *et al.*, 1982).

Parts of area 20 on the inferior temporal gyrus and at least the parts of area 37 on the fusiform gyrus belong to the "ventral stream" (Ungerleider and Mishkin, 1982; Mishkin *et al.*, 1983) of the visual cortex. Area 20 is active during imagery of route finding (Roland *et al.*, 1987). The parahippocampal gyrus (containing area 36), and the fusiform gyrus (containing parts of area 20) are found to be activated by attention to shape (Corbetta *et al.*, 1990).

In conclusion, the inferotemporal zone of the human cerebral cortex—as defined here—is a region where auditory, language, visual, and multimodal functions are represented (Nakamura *et al.*, 2000). This high degree of functional segregation supports the assumption of a parallel, much more differentiated architectonical segregation in this zone than presently shown by the available maps with only four areas (i.e., areas 20, 21, 36, and 37).

Occipital Lobe

The occipital lobe of the human brain contains most of its visual cortical areas, but visual areas are also found in the temporal and parietal lobe (see earlier discussion). These visual areas together constitute more than half of the human isocortex. This large size of the anatomical correlates reflects the importance of visual functions in the human brain.

A tripartition of the occipital lobe was proposed by Brodmann (1909) with area 17 as the primary visual cortex V1 and areas 18 and 19 as unimodal higher visual fields (Fig. 27.35). Comparable parcellations were

TABLE 27.7 Architectonic Subdivisions and Nomenclature of the Human Striate and Extrastriate Visual Cortex.

	Striate cortex	Extrastriate cortex	
Campbell (1905)	Visuo-sensory	Visuo-psychic	
Brodmann (1909)	Area 17	Area 18	Area 19
Smith (1907)	Area striata	Area parastriata	Area peristriata
Vogt and Vogt (1919)	Area 17	Area 18	Area 19 (19a, 19b)
Flechsig (1920)	Area 8	Area 23	Areas 15, 16, and 28
von Economo and Koskinas (1925)	OC	OB (OBγ; OBΩ)	OA (OA_1, OA_2, OA_m)
Filimonoff (1932–3)	Area 17	Area 18	Area 19
Bailey and von Bonin (1951)	Koniocortex	Parakoniocortex	
Sarkissov *et al.* (1955)	Area 17	Area 18	Area 19
Braak (1977–80)	Striate area	Parastriate area	Peristriate area

published by von Economo and Koskinas (1925; Fig. 27.37), Filimonoff (1932), and Sarkissov *et al.* (1949; Fig. 27.39). Von Economo's and Koskinas's area OC (Area striata) corresponds to Brodmann's area 17, their OB (Area parastriata) to area 18, and OA (Area peristriata) to area 19 (for further comparisons between the nomenclatures of different authors, see Table 27.7). Area 19 has been parcellated into numerous areas by Braak (1977) on the basis of pigmentoarchitectonic studies in the human brain. The borders of these areas exceed, however, the limits of the occipital lobe and extend into the parietal and temporal lobes (Fig. 27.27). Unfortunately, these areas cannot be directly compared with functional data because the schematic drawing of this areal pattern (Braak, 1977) cannot be warped to a stereotaxic system as used for anatomical identifications in functional imaging studies.

Brodmann's (1903b, 1909) architectonic and functional definition of area 17 is unanimously accepted. Also the location of a cytoarchitectonic area corresponding to area 18 of Brodmann (1909) could be corroborated in a recent quantitative cytoarchitectonic study (Amunts *et al.*, 2000b), which also provides an analysis of the intersubject variability of its borders. Brodmann's parcellation of the most rostral part of the visual cortex (his area 19), however, is not supported by axonal tracing and electrophysiological studies in nonhuman primates (for a recent map of the macaque occipital cortex, see Paxinos *et al.*, 2000) and does not match the results of functional imaging in the human brain (for review, see Zilles and Clarke, 1997). Therefore, it is not justified by our present knowledge to use the term "area 19" for a cortical region that is definitely not an architectonic and functionally homogeneous field. Brodmann's area 19 as well as adjacent cortical regions must be subdivided (Braak, 1980; Tootell *et al.*, 1998; van Essen, 1979; Zeki, 1969) into numerous visual areas differing in architecture and functional properties (e.g., retinotopy, direction and orientation selectivities, contrast sensitivity, motion and color preferences, and many more functional aspects; as an example of a proposed scheme, see Fig. 27.28).

Primary Visual Cortex

Area 17 of Brodmann (1903b, 1907, 1909, 1910, 1912) represents the primary visual cortex (Fig. 27.35). It extends from the occipital pole over the total length of the calcarine sulcus, and is the cortical representation of the entire contralateral visual hemifield plus a smaller part of the ipsilateral hemifield. The largest

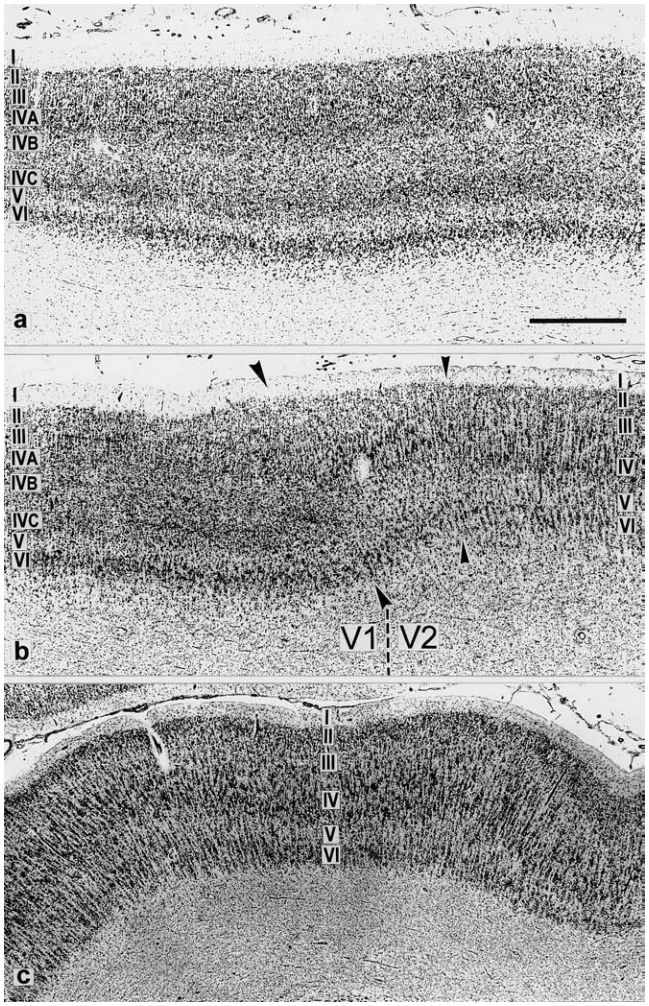

FIGURE 27.29 Cytoarchitecture of area 17 **(a, b),** 18 **(b)** and the most posterior part of area 19 **(c).** Roman numerals indicate the different layers. The large arrowheads in (b) mark the border between the areas 17 (V1) and 18 (V2). Immediately adjacent to the 17/18 border, the limes parastriatus gigantopyramidalis of von Economo and Koskinas (1925) is visible (small arrowheads). This part of area 18 contains very large pyramidal cells in the lower layer III. Bar = 1 mm.

portion of area 17 receives input from both eyes (binocular part) with the central part of the visual field at the occipital pole. The upper half of the visual field is represented in the lower wall of the calcarine sulcus and adjacent parts of the cortical surface, whereas the lower half is projected to the upper wall and adjacent parts of the cortical surface. Thus, the horizontal meridian is located in the fundus of the calcarine sulcus. The vertical meridian is located at the border between areas 17 and 18.

Area 17 shows the most differentiated laminar structure of all isocortical areas in the human brain (Fig. 27.29a, b). Human area 17 is characterized by a prominent, tripartite layer IV (sublayers IVA–C). Even these sublayers can be further subdivided. The parvocellular afferents from the lateral geniculate body reach their highest density in sublayer IVCβ (Braak, 1982). Layers III and V contain (beside the pyramidal cells) numerous small neurons, which leads to the visual impression of an extremely high "granularization" of the koniocortical area 17. Layer V is easily distinguishable from the dark layer VI. Further details of the highly differentiated laminar structure of human area 17, ultrastructure, ontogeny, and quantitative aspects have been described by E. Braak (1982), H. Braak (1976b, 1977), Brodmann (1903b), von Economo and Koskinas (1925), Filimonoff (1932), Garey (1984), Haug (1958), Horton and Hedley-White (1984), Preuss *et al*. (1999), Preus and Coleman (2002), and Zilles *et al*. (1986a). The high intersubject spatial variability of the borders of area 17 has been studied by Filimonoff (1932) and Amunts *et al*. (2000b; see Fig. 27.30). For comprehensive information about the visual system, see Chapter 35.

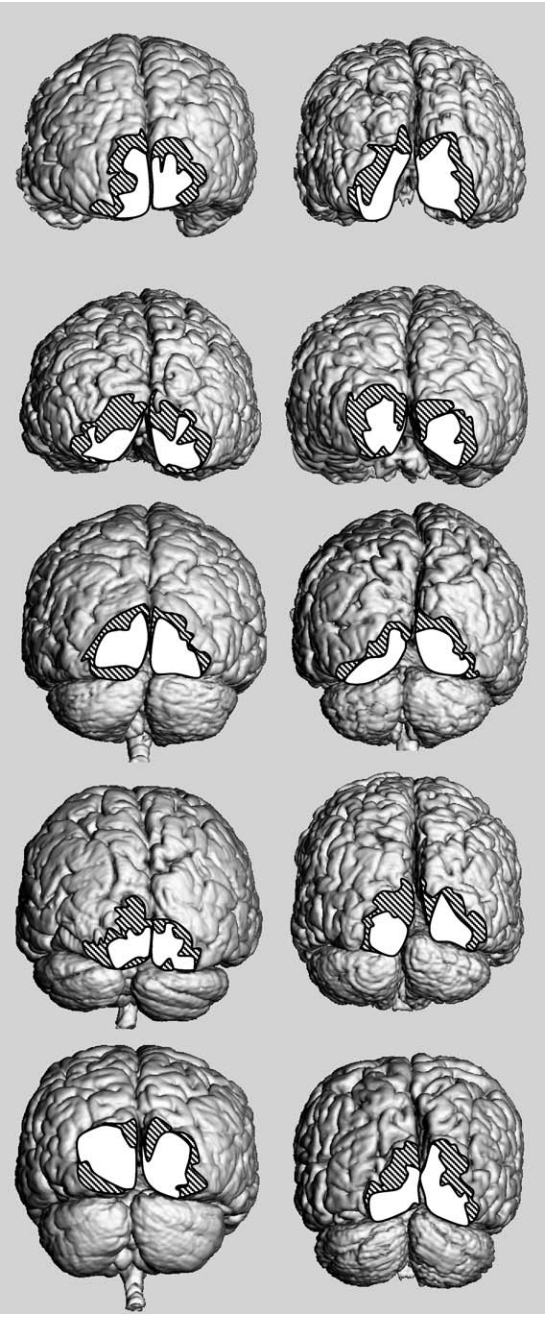

FIGURE 27.30 Intersubject variability of the primary visual cortex V1 (Brodmann's area 17) and the secondary visual area V2 (Brodmann's area 18) in ten human brains (modified from Amunts *et al.*, 2000b). V1, white area, V2, hatched area.

A comparison of area 17 with that of other nonhuman primates clearly demonstrates that the human primary visual cortex is architectonicly not the most evolved example within primates. The lamination pattern of layer IV, the major target of the retinal input via the lateral geniculate body, is much more differentiated in the prosimian *Tarsius* (Zilles *et al.*, 1982) and the areal proportions of area 17 on the total neocortex of this species exceeds that of humans by nine times (Stephan *et al.*, 1981). Also, all the other nonhuman primates have larger striate areas relative to the total neocortex. By controlling for body weight, however, Stephan (1969) showed that the human area 17 is enlarged by somewhat more than five times when compared with the prosimian *Lepilemur,* which has the smallest area in such allometric comparisons. A morphometric study in human, chimpanzee, gorilla, and orangutan (Zilles and Rehkämper, 1988) reveals no major differences in laminar pattern of the striate areas between us and our nearest relatives.

The neuropil volume of area 17, however, is much larger in the supragranular layers, in which a major part of intracortical processing takes place, in the human than in any other primate brain, including *Tarsius* (Zilles *et al.*, 1982). This dominance of the neuropil proportion in the supragranular layers is also found in extrastriate visual areas of the human brain. The human specific evolution of the primary visual cortex becomes even more evident when analyzing the termination of the magno- and parvocellular compartments of the geniculocortical input in specific layers of V1. Layer IVA of New World and Old World monkeys is characterized by a thin cytochrome oxidase-rich band in layer IVA, which is caused by parvocellular terminals (Wong-Riley, 1994). Humans and chimpanzees lack this band in layer IVA of V1 (Horton and Hedley-White, 1984; Preuss *et al.*, 1999). In contrast to nonhuman primates, human layer IVA shows a conspicuous immunoreactivity of antibodies against nonphosphorylated neurofilaments (NPNF) and an extracellular proteoglycan distributed in meshlike bands, as well as a dense irregular staining of calbindin (indicating most probably the presence of GABAergic inhibitory interneurons) in the territories between the meshlike bands of layer IVA (Hendry and Carder, 1993; Preuss and Coleman, 2002; Preuss *et al.*, 1999). Because the NPNF and the antibody-specific matrix proteoglycan are preferentially or exclusively expressed in the magnocellular pathway (Hof and Morrison, 1995; Preuss and Coleman, 2002; Preuss *et al.*, 1999), a considerable reorganization of the magno- and parvocellular pathways in human layer IVA occurs during the evolution of the human brain compared with monkeys and apes.

The border between areas 17 and 18 is very distinct, and its cyto- and myeloarchitecture displays some interesting specializations. A very myelin-dense layer (stripe of Gennari) occurs only in area 17 and stops abruptly at the border between area 17 and area 18 (Fig. 27.31a). At this site, layer IV of area 17 becomes

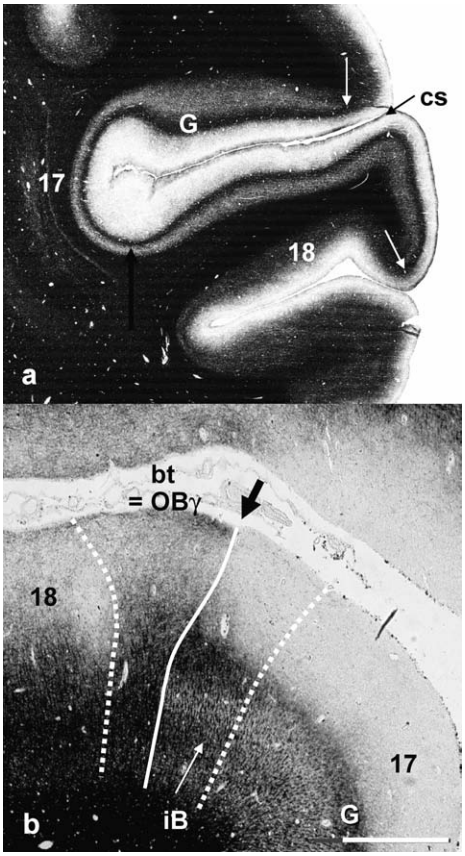

FIGURE 27.31 Myeloarchitecture of the human visual cortex at the border region between area 17 and area 18. The myeloarchitecture of area 17 is characterized by the prominent stripe of Gennari **(a). (b)** shows the various myeloarchitectonic changes at the border region. bt, border tuft; cs, calcarine sulcus; G, stripe of Gennari; iB, inner stripe of Baillarger; OBg, limes parastriatus gigantopyramidalis of von Economo and Koskinas (1925). The white arrows and the large black arrow indicate the border between area 17 and area 18. Bar = 1 mm.

considerably thinner, and the subdivision of layer IV into three sublayers A–C stops abruptly at the border to area 18 (Fig. 27.29b). A small zone with a very light layer V is found at the beginning of area 18. The neurons in this zone of area 18 are less densely packed than in the remaining part of this area. Layer IV is the broadest layer in area 17, but layer III is the most prominent layer in area 18. The packing density of cell bodies is generally higher in area 17 when compared with area 18. Thus, more space for dendrites, axons, and synapses is available in area 18 than in area 17. The border region between areas 17 and 18 is characterized myeloarchitectonicly by two small subareas (Lungwitz, 1937; Sanides and Vitzthum, 1965a, b)—one belongs to area 17 and the other to area 18. The "border tuft" subarea ("Grenzbüschel") of Sanides and Vitzthum (1965a, b) contains a distinct bundle of densely packed radial fibers (bt in Figure 27.31 b) and belongs to area 18. Very large pyramidal cells, "giant cells," are visible in layer III of this subarea. Thus, the border tuft subarea corresponds to area OBγ (Fig. 27.29b) as described by von Economo and Koskinas (1925), and adjoins a small subarea ("Randsaum") of Sanides and Vitzthum (1965a, b), which belongs to area 17. This subarea is characterized by the appearance of the inner Baillarger stripe (iB in Figure 27.31b), which is only found in this border zone, but not in the major part of area 17. The border region of area 17 with the conspicious inner stripe of Baillarger and the bt region of area 18 together are probably the architectonic correlates of the representation of the vertical meridian. This zone is the target of many callosal fibers and bridges equivalent points of the visual field on both sides of the vertical meridian in areas 17 and 18 (Clarke and Miklossy, 1990; Shoumura *et al.*, 1975; Van Essen and Zeki, 1978; Zeki, 1970; see also Chapter 35). Thus, the visualization of callosal axonal terminals provides useful landmarks for the delineation of extrastriate areas because callosal fibers are concentrated in border regions of many visual areas (Clarke and Miklossy, 1990; Van Essen *et al.*, 1982).

Layer IV of the primary visual cortex (V1) receives its major retinal input via the lateral geniculate body and the geniculocortical fibers (optic radiation). V1 projects (as shown in monkeys; e.g., Felleman and Van Essen, 1991; Van Essen *et al.*, 1986) to many extrastriate areas (V2, V3, V3A, V4, V5/MT, MST). The majority of projections terminate in V2, V3, and V5/MT. Layer V neurons of V1 give rise to connections projecting back through the superior colliculus and pulvinar to the parastriate belt (Trojanowski and Jacobson, 1976; for review, see Van Essen, 1979). Back projections from extrastriate visual areas to V1 establish together with the forward projections a complex system of reciprocal connectivity. Mostly reciprocal connections exist also between V1 and various subcortical regions (e.g., pulvinar, claustrum, amygdala, caudate nucleus, superior colliculus, pons, hypothalamus, and basal forebrain). Only a very small part of the afferents from the pulvinar projects to layers I and II of V1 (for review of the connectivity of the visual cortex in macaque monkeys, see Felleman and Van Essen, 1991).

Extrastriate Visual Cortex

The visual areas outside the striate area 17 (i.e., the extrastriate areas) have been subdivided by Brodmann (1905, 1909, 1910, 1912) into areas 18 and 19 (see Fig. 27.35). Many of the classical architectonical studies have proposed a comparable subdivision (cf. Tables 27.4 and 27.7), but more recent morphological and physiological observations have clearly demonstrated

a much higher number of cortical areas, particularly in the region of area 19 (see previous discussion). Thus, the frequently used and functionally based nomenclature of the visual areas (subdivisions into V1, V2, V3, etc.) is introduced here, whenever the comparability between functional and architectonic parcellations is demonstrated or highly probable.

Area V2 Area 18 of Brodmann (1909) is comparable with the functionally defined cortical field V2 (Fig. 27.28). It is a 10–3.4 cm wide cortical belt rostral to V1, and its surface is 1.7 times larger than that of V1 (Tootell and Taylor, 1995). The representation of the visual field in area 18 differs from that in area 17, where adjacent loci of the visual field are also located as neighboring sites in V1. In area 18, the horizontal meridian is located at the 18/19 border; this topological transformation leads to representation of the upper and lower quadrants of the visual field in separate, not adjacent, cortical places. Also, the normal point-to-point mapping of the visual field in the cortex is disrupted in area 18 (for review, Tootell *et al.*, 1998).

V2 shows a homotypical lamination pattern (six layers). Layer II and the upper part of layer III are difficult to separate in V2. The size of the pyramidal cells of lower layer III is increased compared with V1 (Clarke, 1994b). Very large cells in deep layer III are frequently found in the border region to V1 (Fig. 27.29b, c). The contrast in cell density between layers V and VI is not as distinct as in V1. Layer IV of V2 is slightly thinner than in V1, but it is thicker than in the other visual areas. The radial arrangement of cells in columns increases from V1 to V2 and from here to the other visual areas.

In contrast to the clear borderline between V1 and V2, the cytoarchitectonic border between V2 and the rostrodorsally adjoining area V3 is very difficult to detect by pure visual inspection of cell body-stained sections. Recently, this border could be reliably identified using a quantitative cytoarchitectonic technique, and the microstructural differences between V2 and V3 were statistically verified (Amunts *et al.*, 2000b). Staining of lipofuscin granules (pigmentoarchitectonic method) may also provide a reliable definition of this border as demonstrated by Braak (1977). According to the latter author, the border between area 18 and the peristriate region is defined by the unique appearance of pigmented "granule" cells in a small stripe in a position comparable with the central part of layer IV. This stripe is only visible in V2.

V2 is rostrolaterally bordered by VP in the inferior part of the occipital cortex (Fig. 27.28). VP shows a lighter myelin staining compared with V2 (Clarke, 1994b; Clarke and Miklossy, 1990; Zilles and Schleicher, 1993). A clearly visible inner Baillarger stripe is a further myeloarchitectonic sign of V2 (Clarke, 1994b). In flattened myelin-stained sections of human V2, alternating dense and light stripes are visible, and the respective stripes have a distance of 6–8 mm (Tootell and Taylor, 1995). These dark or light stripes in myelin-stained sections are not compatible in size and distance with the stripes and interstripes visible in cytochrome-oxidase (COX)-stained sections (Burkhalter and Bernardo, 1989; Hockfield *et al.*, 1990). The modular architecture of V2 visualized by the alternating pattern of COX-stripes and interstripes has also been found in nonhuman primates (DeYoe and Van Essen, 1985; Horton, 1984; Hubel and Livingston, 1987; Livingstone and Hubel, 1983; Tootell and Hamilton, 1989; Tootell *et al.*, 1993; Wong-Riley, 1994) where the COX-rich stripes are parvalbumin positive compartments (Blümcke and Celio, 1992). The thick COX-stripes of area V2 show a conspicuous immunoreactivity of the antibody Cat-301 against an extracellular matrix proteoglycan (Hendry *et al.*, 1984, 1988; Hockfield *et al.*, 1990). This proteoglycan is indicative of the magnocellular pathway of the human visual system. It is also present in the magnocellular layers of the lateral geniculate body, layer IVA of V1 (see earlier), and in area V5/MT (see later).

Area 18 receives massive input from area 17 and has reciprocal connections with many extrastriate areas. Layers III and IV of area 18 and other extrastriate areas receive also a major input from the pulvinar. The reciprocal connections from the extrastriate visual areas to the pulvinar originate in layer V (for review, see Felleman and Van Essen, 1991). Cells in layer VI of area 17, 18, and further extrastriate areas give rise to a pathway descending to the lateral geniculate body.

Over 70% of the cells in V2 of macaques are orientation selective, but only less than 15% are directionally selective, and only 8% have opponent color properties (Van Essen and Zeki, 1978; Zeki, 1978). It is difficult to get detailed information about the specific function of human V2 by older neuroimaging studies because the border between V1 and V2 as well as between V2 and V3 cannot be identified on the basis of macroscopic landmarks (Amunts *et al.*, 2000b). A reliable method, however, is now available, if the retinotopy is explored by functional imaging (Tootell *et al.*, 1998). Human V2 is activated during shape discrimination (Gulyás and Roland, 1994) by a task similar to illusory contour tasks, which reveal a V2 activation in monkeys (Peterhans and von der Heydt, 1989; von der Heydt and Peterhans, 1989). V2 and other extrastriate areas (not only V4, see following discussion) are activated by color discrimination tasks (Gulyás and Roland, 1991, 1994). V2 is also active during visual recall of real

objects (Le Bihan *et al.*, 1993). Thus, V2 is not just a region of simple perception, but it is also activated by complex perceptual, cognitive, and mnestic tasks (e.g., face and word processing; Halgren *et al.*, 1994).

Area V3 According to functional imaging studies (Sereno *et al.*, 1995; Tootell *et al.*, 1995a), area V3 is located dorsally and rostrally of V2 on the mesial and lateral surfaces of the occipital lobe, respectively (Fig. 27.28). The border between V3 and V2 represents the horizontal meridian. V3 contains the lower visual field (Tootell *et al.*, 1998).

Although it is problematic to compare the schematic drawings of classical cytoarchitectonic maps with functional imaging data, area V3 is best comparable by its location with the major part of the parvocellular posterior peristriate area O_{A_1} of von Economo and Koskinas (1925). O_{A_1} shows a very small layer I, layers II and III are difficult to separate, and layers III and V contain small pyramidal cells. Layer VI consists of particularly coarse cell columns. Nevertheless, the cyto- and myeloarchitectonic definition of the V2/V3 border by pure visual inspection is very difficult because of the high degree of microstructural similarity between both areas (Clarke, 1994b). Only recently using a quantitative cytoarchitectonic technique has this border been determined (Amunts *et al.*, 2000b).

Nearly all cells in extrastriate areas of monkeys are binocularly driven, and binocular depth cells are found in V2 and V3 (Poggio and Fischer, 1977). Most of the cells in monkey V3 are selective for orientation (Zeki, 1978). The role of human V3 in vision is not completely clear. Human V3 is less motion selective than V3 in macaques and V3A in humans (Tootell *et al.*, 1997). Dynamic form perception (Zeki and Shipp, 1988; Zeki, 1990a) and a high-contrast selectivity (Tootell *et al.*, 1995a) are functional characteristics of V3. This provides evidence for the classification of V3 as part of the magnocellular dorsal stream.

Area VP Human area VP is bordered posteriorly by V2 and dorsally by V3 on the lateral hemispheric surface, and medially by V2 on the mesial surface (Fig. 27.28). VP has been tentatively delineated by cyto- and myeloarchitectonic characteristics (Clarke and Miklossy, 1990; Zilles and Schleicher, 1993). It lacks large pyramidal neurons in both layers III and V, whereas adjacent V2 has large pyramids in layer III and adjacent area V4 in III and V. VP is lightly myelinated, and both striae of Baillarger are absent. VP differs also by its light COX staining from the adjacent, darkly stained areas V2 and V4 (Clarke, 1994a).

Human areas VP and V4 appear to be interconnected with the inferior part of medial pulvinar, while V5/MT is interconnected with the lateral pulvinar (see Table 6 in Zilles and Clarke, 1997).

Area V3A Human area V3A extends consistently below and above the lateral occipital sulcus (Tootell *et al.*, 1997) on the mesial and lateral hemispheric surface (Fig. 27.28). Its borders, however, as determined by retinotopic mapping show a considerable intersubject variability and cannot be reliably correlated with macroscopic landmarks. Sufficiently detailed architectonic descriptions of this area are presently not available.

Area V4 The cortex of the lingual and fusiform gyri seems to play an important role in color perception because lesions of this region cause achromatopsia (Damasio *et al.*, 1980; Meadows, 1974; Rizzo *et al.*, 1992; for review, see Zeki, 1990b), and functional imaging as well as electrophysiological observations demonstrate activation by color (Allison *et al.*, 1993; Corbetta *et al.*, 1991; Gulyás and Roland, 1991, 1994; Lueck *et al.*, 1989; Sakai *et al.*, 1995; Sereno *et al.*, 1995; Zeki *et al.*, 1991) and shape (Corbetta *et al.*, 1991). Thus, this region has been suggested to be the human correlate of the monkey V4, which is populated by color-, space- and shape-responsive neurons (Desimone and Schein, 1987; Desimone and Ungerleider, 1989; De Yoe *et al.*, 1994; Heywood *et al.*, 1992; Schiller and Lee, 1991; Van Essen and Zeki, 1978; Walsh *et al.*, 1993; Zeki, 1990b). Presently, however, it is controversly discussed whether this human V4 in the fusiform gyrus represents the equivalent of the monkey V4 (Heywood *et al.*, 1995; Meadows, 1974; Ungerleider and Haxby, 1994; Walsh *et al.*, 1993; Zeki, 1993).

This putative human V4 is located on the posterior part of the fusiform gyrus and abuts the rostral border of the putative human VP (Sereno *et al.*, 1995). The position and extent as well as the architecture of the area peristriata magnopyramidalis of Braak (1977) make this pigmentoarchitectonicly well-defined cortical region to an architectonic candidate for human V4. An area comparable to V4 has been called V8 by Tootell *et al.* (1998) (see also Fig. 27.28). V4 contains large pyramidal cells in layers III and V and shows a dark COX staining. Both criteria allow a delineation of this area from VP (Clarke, 1994a). The myelin density is well above average in human and monkey V4 (Zilles and Clarke, 1997).

A ventral area V4v—separable from V4—has been identified by using fMRI (Sereno *et al.*, 1995) and phase-encoded retinal stimulation. This area adjoins the ventral half of the anterior border of VP (Fig. 27.28). This border represents the vertical meridian, whereas the horizontal meridian is found at the anterior border

of V4v. Human V4v contains the upper visual field as in monkeys with a non–mirror image representation of the visual field. Architectonic descriptions of this area are presently not available.

Additional color foci were described on the human dorsolateral occipital cortex (Corbetta *et al.,* 1991). Colors as attributes of objects are also represented in a cortical region rostral to V4 (Martin *et al.,* 1995). A face and familiarity recognition area is identifiable medially of this region (Allison *et al.,* 1993, 1994; Clarke *et al.,* 1997; Nakamura *et al.,* 2000) in the posterior temporal part of the fusiform gyrus. This region is also activated by passive viewing of faces (Puce *et al.,* 1995) and by matching of unknown faces (Haxby *et al.,* 1994) in the right hemisphere, but is found more anterior and lateral in the left hemisphere. At least part of this left hemispheric region may be part of a cortical system representing working memory for faces (Haxby *et al.,* 1995).

Area V5/MT For the first time, area V5/MT was identified by functional and anatomical studies in the superior temporal sulcus of nonhuman primates (Albright, 1984; Allman and Kaas, 1971; Born and Tootell, 1992; Fiorani *et al.,* 1989; Maunsell and Van Essen, 1983, 1987; Van Essen *et al.,* 1981; Zeki, 1974, 1980).

PET and fMRI studies demonstrated a comparable area in the human brain activated by moving visual stimuli and during visual motion aftereffects (Cheng *et al.,* 1995; Corbetta *et al.,* 1990, 1991; Dupont *et al.,* 1994; Tootell *et al.,* 1995a, b; Watson *et al.,* 1993; Zeki *et al.,* 1991, 1993). This area is located close to the level of the AC–PC line and posterior to the contact of the ascending limb of the inferior temporal sulcus with the lateral occipital sulcus (Watson *et al.,* 1993). In parallel with monkey data, a retinotopic organization of human V5/MT was reported (Huk *et al.,* 2002). An even more characteristic feature of V5/MT in the monkey is the direction specificity (i.e., preference for one direction of moving visual stimuli; Zeki, 1974; Van Essen *et al.,* 1981). This property was recently demonstrated by functional imaging (Heeger *et al.,* 1999; Huk and Heeger, 2002) and focal electrical stimulation also for the human V5/MT area (Blanke *et al.,* 2002).

The putative architectonic correlate of human V5/MT is a relatively small, heavily myelinated area in the dorsal part of the ascending limb of the inferior temporal sulcus near the occipitotemporal junction on the lateral convexity (Clarke and Miklossy, 1990; DeYoe *et al.,* 1990; Tootell and Taylor, 1995). No comparable cortical area is delineated in the maps of Brodmann (1909) and Sarkissov *et al.* (1955). A small posterior part of Brodmann's area 37 (see "Temporal Lobe") and a small anterior part of his area 19 covers approximately cortical regions where V5/MT has been localized in functional imaging studies. Von Economo and Koskinas (1925) show a lateral area OAm (Fig. 27.37), which has a position approximately comparable with that of V5/MT, but the schematic presentation of their maps (and all classical architectonical maps) does not allow a direct comparison with functional imaging data. Flechsig's area 16 (subangular gyrus; Flechsig, 1920; Figure 27.36), however, was proposed to be a good candidate for V5/MT (Watson *et al.,* 1993), since it not only is found in a location (Clarke, 1994a; Tootell and Taylor, 1995) comparable to the functional imaging data but was also described as an early and heavily myelinating area during ontogeny (Flechsig, 1920). A destruction of this area leads to akinetopsia (i.e., visual motion blindness where a patient is not able to recognize moving stimuli in his visual field), although other functions of the visual system are completely intact (Mesulam, 1994; Zeki, 1991; Zihl *et al.,* 1991).

Although human V5/MT receives a major input from layer IVB of V1 and from V2 (for review, see Felleman and Van Essen, 1991), human V5/MT is activated by moving bar also in a completely hemianopic patient with a lesion in area V1 (Barbur *et al.,* 1993). The patient was consciously aware of the nature and direction of the stimulus. Thus, the input to V5/MT can bypass V1 and arrive directly from the lateral geniculate body (Benevento and Yoshida, 1981; Fries, 1981; Yukie and Iwai, 1981) and/or indirectly via the superior colliculus and the pulvinar (Benevento and Fallon, 1975; Keating, 1980; Pasik and Pasik, 1982; Standage and Benevento, 1983). Direct evidence for a component of directional motion discrimination bypassing human V1 comes from transcranial magnetic stimulation of V1 and V5/MT (Beckers and Zeki, 1995). The inactivation of V5/MT abolishes the motion perception and causes akinetopsia, whereas V1 inactivation had only marginal effects.

A further visual motion-selective area was also identified in the posterior parietal cortex using PET (Watson *et al.,* 1993) and fMRI (Tootell *et al.,* 1995a), which may be identical with the cytochrome oxidase-rich area PX described by Tootell and Taylor (1995) in macaque and human brains. Cytoarchitectonic descriptions of this area are lacking.

Medial superior temporal area MST There are functional imaging studies on the putative human homologue of the monkey area MST (Cheng *et al.,* 1995; Dupont *et al.,* 1994; Huk *et al.,* 2002). This putative human MST is located in the more anterior part of the lateral occipitotemporoparietal cortex anterior to human V5/MST in the inferior parietal lobule and on

the superior and middle temporal gyri. In contrast to V5/MT, this area does not show retinotopy but responded to peripheral stimuli in both the ipsilateral and contralateral hemifields, indicative of larger receptive fields (Cheng *et al.*, 1995; Huk *et al.*, 2002). Presently, architectonic observations of this area and further functionally identified visual areas are lacking. For a comprehensive description of the visual system, see Chapter 35.

Insular Lobe

The insular cortex of the adult brain is buried in the lateral fissure and covered by the frontal and parietal opercula as well as the temporal lobe. Its outer borders are demarcated by the circular sulcus of Reil with its superior limiting sulcus defining the border to the frontoparietal operculum and its inferior limiting sulcus indicating the border to the supratemporal plane. The inferior limiting sulcus has a lateral branch (i.e., the lateral limb of the inferior limiting sulcus), which represents approximately the border between the inferior proisocortical part of the insular cortex and its isocortical part (Fig. 27.32).

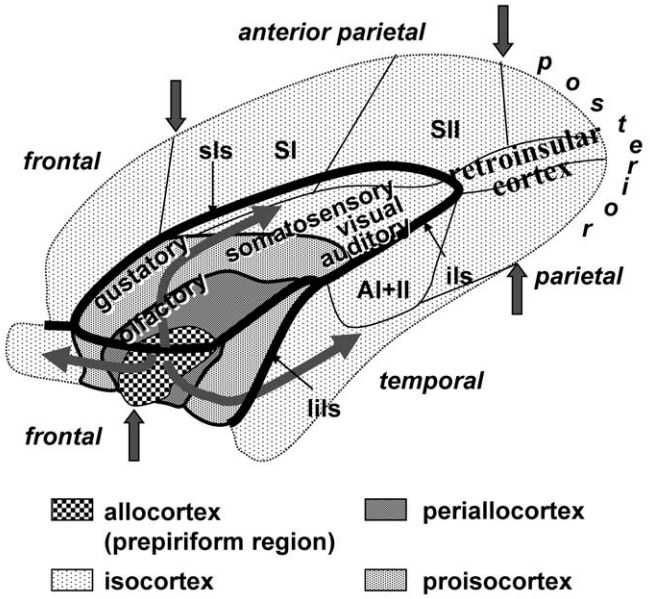

FIGURE 27.32 Schematic drawing after Mesulam and Mufson (1985) showing the principal organization of the insular cortex after opening the lateral fissure with the adjoining frontal parietal and temporal cortices. Auditory, gustatory, olfactory, somatosensory, and visual domains of the insular cortex are indicated. AI+II, primary and secondary auditory cortex; ils, inferior limiting sulcus (part of the circular sulcus of Reil); lils, lateral limb of the inferior limiting sulcus (part of the circular sulcus of Reil); sls, superior limiting sulcus (part of the circular sulcus of Reil); SI, primary somatosensory cortex; SII, secondary somatosensory cortex.

Mesulam and co-workers (for review see Mesulam and Mufson, 1985) demonstrated convincingly the radial organization of the insular cortex which surrounds the posterior part of the (pre)piriform cortex by three belt regions (Fig. 27.32). As discussed previously, the (pre)piriform cortex is part of the olfactory brain regions. The first belt consists of an agranular periallocortical region, the second belt of a dysgranular proisocortical region, and the outermost belt is true isocortex with clearly visible inner (layer IV) and outer (layer II) granular layers.

The *insular periallocortical belt* has (1) a superficial pyramidal cell layer that is a continuation of the pyramidal layer of the piriform cortex, and (2) an inner cell layer that is in continuation with the claustrum (Mesulam and Mufson, 1985). The granular layers II and IV are lacking. The agranular periallocortex of the insula shows no architectonicly detectable border to the adjacent agranular periallocortical regions of the orbitofrontal and temporopolar cortices.

The appearance of granular cells between the two cell layers of the periallocortical belt indicates the beginning of the *insular proisocortical belt*. The architecture of this cortical region is best classified by the term "dysgranular," indicating that its inner granular layer IV is not conspicous, but nevertheless detectable. Layers V and VI are also not as clearly demarcated from each other as in the true isocortex. The insular dysgranular proisocortex is also in continuation with the orbitofrontal and temporopolar proisocortical regions.

The *insular isocortical belt* is characterized by fully developed outer and inner granular layers (layers II and IV, respectively), a differentiation of layer III into sublayers and a clear demarcation of layer V from layer VI. The isocortical belt shows also the highest degree of myelination of all insular regions with a clearly visible outer stripe of Baillarger (Fig. 27.21).

Taking together the beltlike organization of periallocortical, proisocortical, and isocortical regions in the orbitofrontal, insular, and temporopolar cortex with the olfactory piriform region in the center, the insular cortex is a major part of the "olfactocentric component" (Mesulam and Mufson, 1985) of the paralimbic cortex. For the "hippocampocentric organization" (Mesulam and Mufson, 1985) of the paralimbic cortex (= mesocortex), see p. 135.

CORTICAL MAPS OF THE HUMAN BRAIN: PAST, PRESENT, FUTURE

A multitude of cyto- and myeloarchitectonic studies have been performed during the first half of the 20th century in different regions of the human cortex

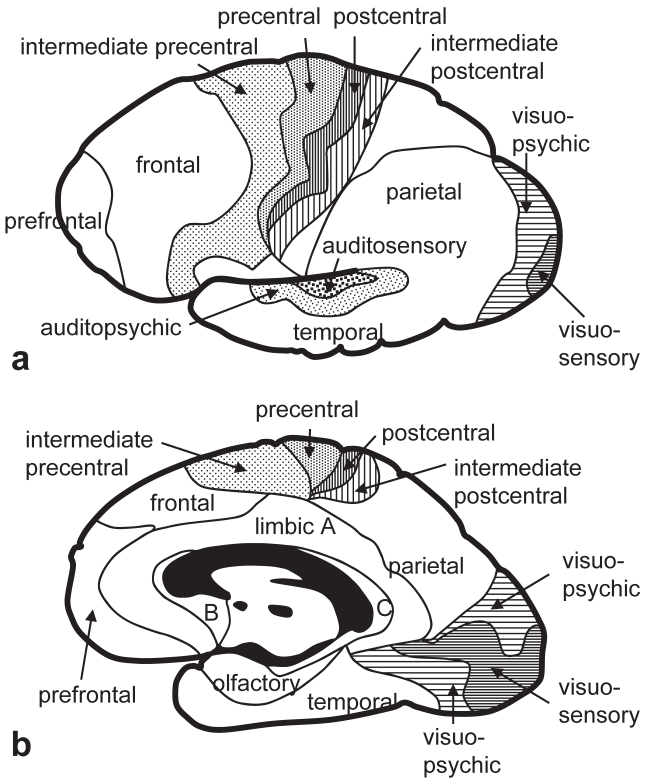

FIGURE 27.33 Areal map of the human cerebral cortex in **(a)** lateral and **(b)** medial views after Campbell (1905). For comparisons with other cortical maps, see Tables 27.4 and 27.7.

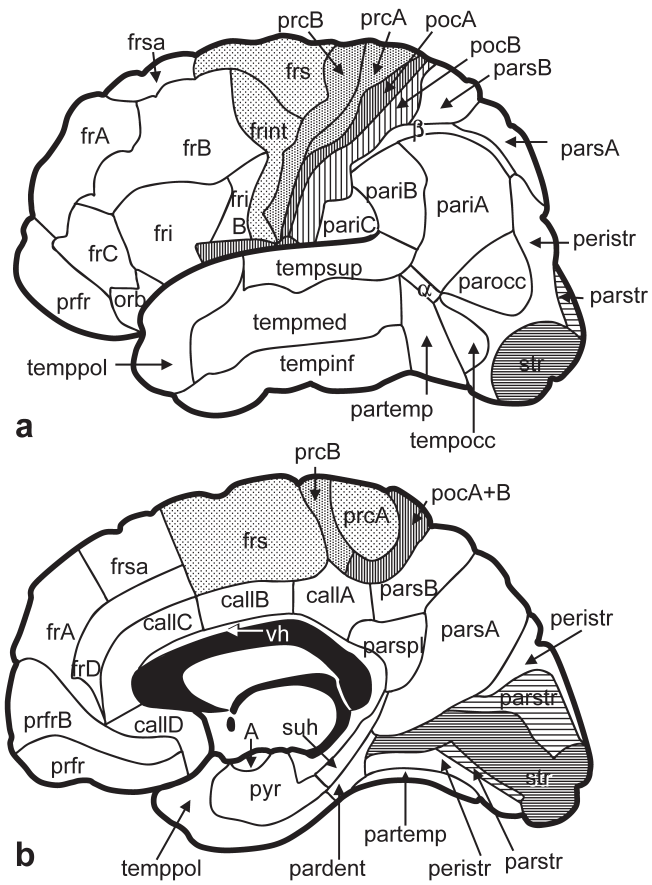

FIGURE 27.34 Areal map of the human cerebral cortex in **(a)** lateral and **(b)** medial views after Smith (1907). A, amygdala; α, visuoauditory band (probably area V5 of present functional nomenclature); β, visuo-sensory band; callA, area callosa A; callB, area callosa B; callC, area callosa C; callD, area callosa D; frA, area frontalis A; frB, area frontalis B; frC, area frontalis C; frD, area frontalis D; frs, area frontalis superior; frsa, area frontalis superior anterior; fri, area frontalis inferior; fri B, area frontalis inferior posterior; frint, area frontalis intermedia; orb, area orbitalis; pardent, area paradentata; pariA, area parietalis inferior A; pariB, area parietalis inferior B; pariC, area parasylvia; parsA, area parietalis superior posterior; parsB, area parietalis superior anterior; parspl, area parasplenialis; parstr, area parastriata; partemp, area paratemporalis; peristr, area peristriata; pocA, area postcentralis A; pocB, area postcentralis B; prcA, area praecentralis A; prcB, area praecentralis B; prfr, area praefrontalis; prfrB, area praefrontalis B; pyr, area pyriformis; str, area striata; suh, subiculum hippocampi; temppol, area temporopolaris; tempinf, area temporalis inferior; tempmed, area temporalis media; tempocc, area temporooccipitalis; tempsup, area temporalis superior; vh, vestigia hippocampi (hippocampus supracommissuralis). For comparisons with other cortical maps, see Tables 27.4, 27.6, and 27.7.

(Bailey and von Bonin, 1951; Batsch, 1956; Beck, 1928, 1930; Brockhaus, 1940; Brodmann, 1903a, b, 1905, 1908, 1909, 1910, 1912, 1914; Campbell, 1905; Filimonoff, 1932, 1947; Flechsig, 1920; Gerhardt, 1940; Hopf, 1954, 1955, 1956; Kreht, 1936; Lungwitz, 1937; Ngowyang, 1932, 1934; Riegele, 1931; Rose, 1926, 1927, 1928, 1929; Sarkissov *et al.*, 1955; Smith, 1907; Stengel, 1930; Strasburger, 1937, 1938; Vogt and Vogt, 1919, 1926, 1956; Vogt, 1910, 1911; von Economo and Horn, 1930; von Economo and Koskinas, 1925). The common goal of all these studies was the generation of a detailed and reliable map of the human cerebral cortex, which represents its regional inhomogeneity in cyto- and/or myeloarchitecture and its segregation into numerous structural–functional areas.

After more than 100 years of research, however, the architectonic parcellation of the human cerebral cortex is still not finished but is instead a work in progress. This conclusion is supported by a comparison between the classical maps—between the maps published by Bailey and von Bonin (1951), Brodmann (1909), Campbell (1905), Flechsig (1920), Sarkissov *et al.* (1955), Smith (1907), and von Economo and Koskinas (1925)—which shows a similar areal pattern only in some cortical regions, while the delineations differ markedly in other regions (Figs. 27.33–27.39). The reasons for this lack of agreement between the cortical maps of different observers are found in the morphological complexity

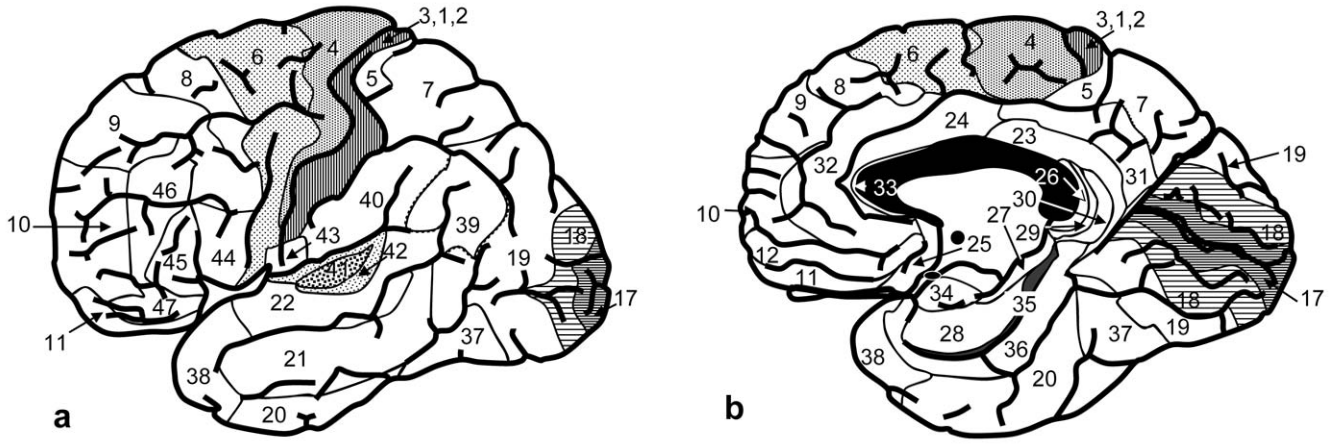

FIGURE 27.35 Areal map of the human cerebral cortex after Brodmann (1909, 1910, 1912, 1914). **(a)** Lateral and **(b)** medial views. 1, area postcentralis intermedia; 2, area postcentralis caudalis; 3, area postcentralis rostralis; 4, area gigantopyramidalis; 5, area praeparietalis; 6, area frontalis agranularis; 7, area parietalis superior; 8, area frontalis intermedia; 9, area frontalis granularis; 10, area frontopolaris; 11, area praefrontalis; 12, not explained by Brodmann; 17, area striata; 18, area occipitalis; 19, area praeoccipitalis; 20, area temporalis inferior; 21, area temporalis media; 22, area temporalis superior; 23, area cingularis posterior ventralis; 24, area cingularis anterior ventralis; 25, area subgenualis; 26, area ectosplenialis; 27, area praesubicularis; 28, area entorhinalis; 29, area retrolimbica (retrosplenialis) granularis; 30, area retrolimbica (retrosplenialis) agranularis; 31, area cingularis posterior dorsalis; 32, area cingularis anterior dorsalis; 33, area praegenualis; 34, area entorhinalis dorsalis; 35, area perirhinalis; 36, area ectorhinalis; 37, area occipitotemporalis; 38, area temporopolaris; 39, area angularis; 40, area supramarginalis; 41, area temporalis transversa medialis; 42, area temporalis transversa lateralis; 43, area subcentralis; 44, area opercularis; 45, area triangularis; 46, area frontalis media; 47, area orbitalis; 52, area parainsularis. For comparisons with other cortical maps, see Tables 27.3–27.7.

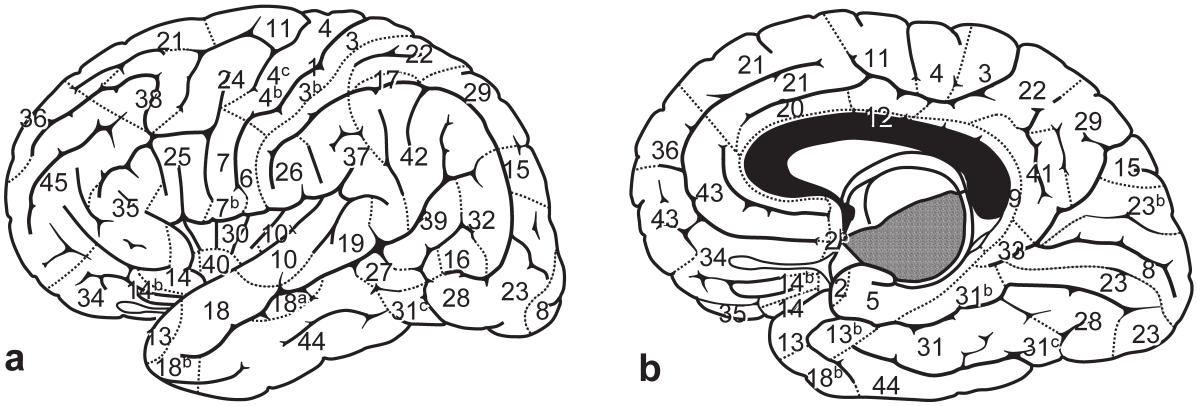

FIGURE 27.36 Areal map of the myelogenetic areas after Flechsig (1920) in the human cerebral cortex. **(a)** Lateral and **(b)** medial view. The numbers of the areas describe the sequence of myelination during fetal and early postnatal stages. The cortical regions with first signs of myelination before birth are Flechsig's primordial areas (areas 1–16), between birth and the end of the sixth postnatal week are his intermediate areas (17–28), and after the beginning of the second postnatal month are his terminal ("association") areas (29–45). For comparisons with other cortical maps, see Tables 27.5 and 27.7.

of the human cerebral cortex, the architectonic similarity of numerous isocortical areas particularly in the multimodal association regions, the interindividual variability of architectonic features (none of these maps is based on a larger sample or defines the range of variability between different individuals), the relatively simple methodical approach based on pure visual inspection of only Nissl- or myelin-stained sections, and the strong influence of the observer's criteria on delineations and definitions of areas. None of these objections denies that the classical maps, particularly Brodmann's map, represent pioneering work; however,

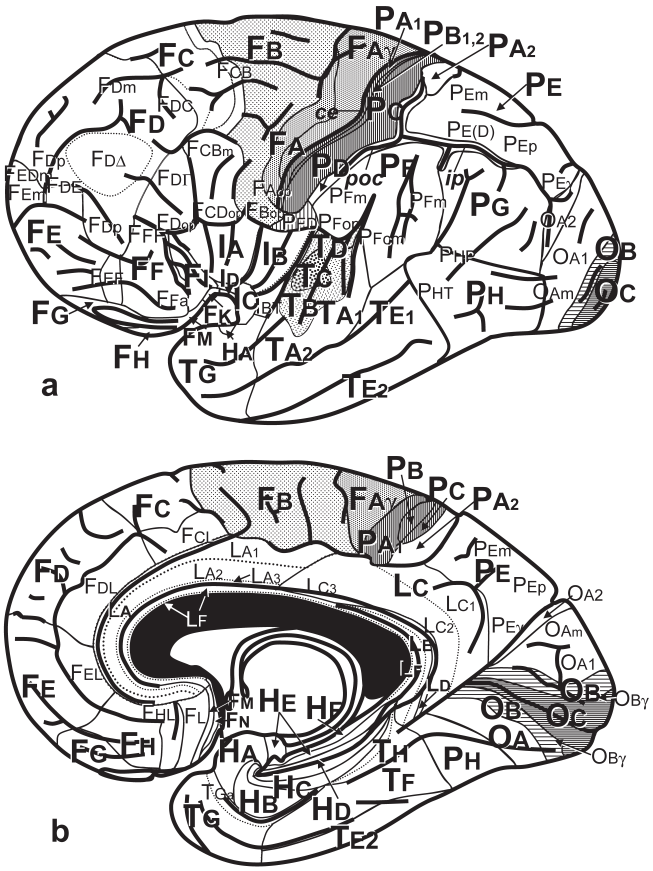

FIGURE 27.37 Areal map of the human cerebral cortex after von Economo and Koskinas (1925). **(a)** Lateral and **(b)** medial views. For comparisons with other cortical maps, see Tables 27.3–27.7.

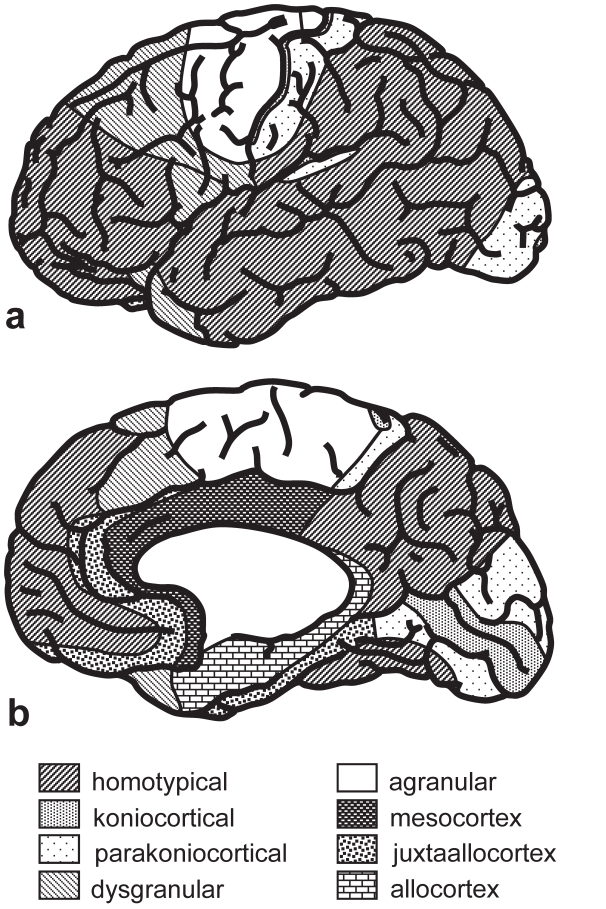

FIGURE 27.38 Areal map of the human cortex after Bailey and von Bonin (1951). **(a)** Lateral and **(b)** medial views. For comparisons with other cortical maps, see Tables 27.4 and 27.7.

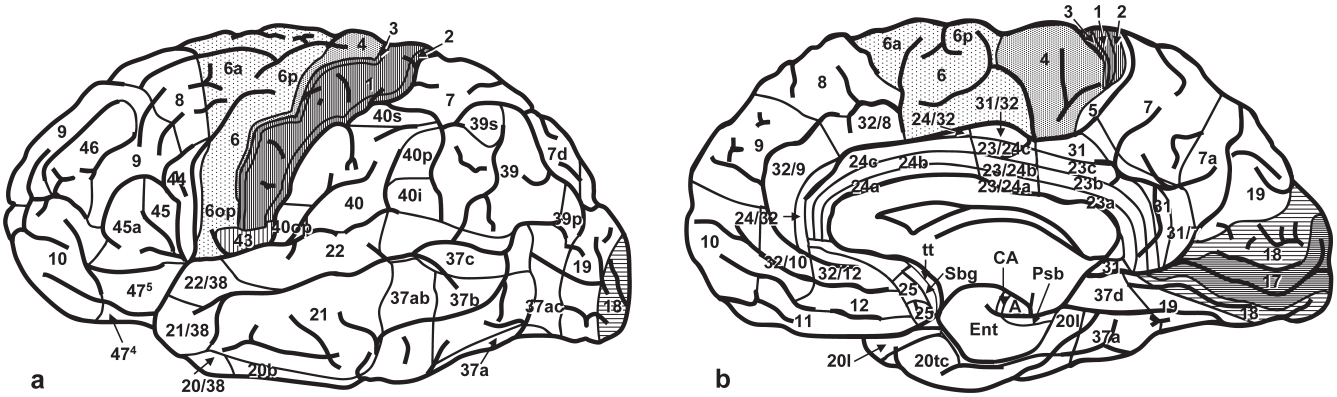

FIGURE 27.39 Areal map of the human cortex after Sarkissov *et al.* (1955). **(a)** Lateral and **(b)** medial views. The nomenclature follows Brodmann's scheme (see legend of Figure 27.35) and introduces self-explaining symbols for subparcellations and transition zones. A, amygdala; CA, Ammon's horn; Ent, entorhinal area; Psb, presubicular area; Sbg, subgenual area; tt, taenia tecta (precommissural hippocampus). For comparisons with other cortical maps, see Tables 27.4 and 27.7.

the previously listed problems can only be solved with the introduction of a novel approach to architectonics that uses various staining techniques as well as objective, observer-independent, and quantitative image analysis procedures and statistically testable criteria (Amunts and Zilles, 2001; Amunts *et al.*, 2002; Schleicher *et al.*, 1986, 1999; Zilles *et al.*, 1982, 1986a, b, 1995, 2002).

Furthermore, all the classical studies do not allow a direct comparison with three-dimensional datasets of functional imaging studies, which is a great obstacle for establishing architectonic/functional correlations. Therefore, an important aspect of present and future architectonic studies is the comparability of these microstructural data and areal borders with the results of functional imaging studies in the same spatial reference system (Amunts and Zilles, 2001; Amunts *et al.*, 1999, 2000b, 2002; Geyer *et al.*, 1996, 1999, 2000b; Grefkes *et al.*, 2001; Morosan *et al.*, 2001; Rademacher *et al.*, 1993, 2001a, b, c; Zilles *et al.*, 1997, 2001, 2002). Because the interindividual variability of the architectonic organization is a challenge for such correlations of structure and function, the novel concept of probability maps has been introduced (Roland and Zilles, 1994, 1996a, b, 1998; Roland *et al.*, 1997). Probabilistic brain mapping has meanwhile developed into a multisite international effort (Mazziotta *et al.*, 2001a, b).

CHAPTER

28

Somatosensory System

JON H. KAAS
Department of Psychology, Vanderbilt University
Nashville, Tennessee, USA

This chapter outlines the organization of the somatosensory system of humans. The emphasis is on the components of this system that are important in identifying objects and features of surfaces by touch. Even though small shapes can be perceived with information solely from tactile receptors, most discriminations involve an active process of tactile exploration with multiple contacts on the skin and an integration of cutaneous and proprioceptive information as well as efferent control. Thus, this chapter concentrates on the pathways and neural centers for processing information from the low-threshold mechanoreceptors of the skin that provide information about touch, and the deeper receptors in joints and especially muscles that provide information about position. Conclusions are based on both studies in humans and studies in other primates, especially the frequently studied macaque monkeys. At least the early stages of processing are likely to be similar in humans and monkeys, but humans appear to have a more expanded cortical network for processing somatosensory information. The important subsystems dealing with afferents coding for pain and temperature are not covered here, but they are reviewed elsewhere (e.g., Chapter 30; Casey, 1999; Craig *et al.*, 1996; Berkley and Hubscher, 1995).

The basic parts and pathways of the somatosensory system of humans are diagrammed in Figure 28.1. In brief, peripheral nerve afferents related to receptors in the skin, muscles, and joints course centrally past their cell bodies in the dorsal root and cranial nerve ganglia to enter the spinal cord and brainstem. These afferents synapse on neurons in the dorsal horn of the spinal cord, or the equivalent in the brainstem, and send a collateral to the dorsal column-trigeminal nuclear

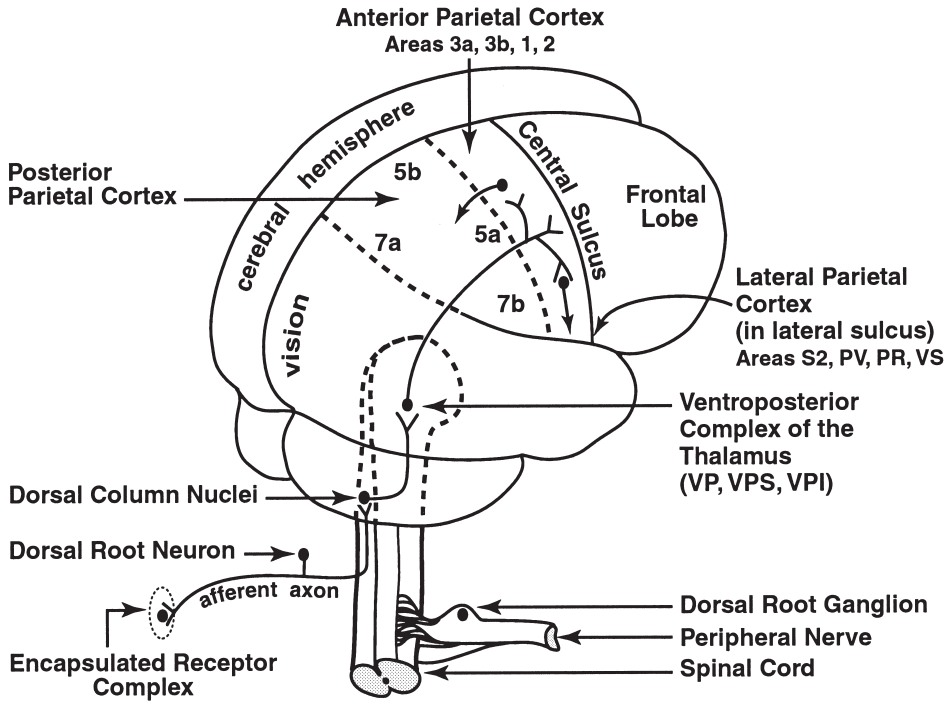

FIGURE 28.1 The basic components of the somatosensory system shown on a posterolateral view of a human brain. Receptors in the skin project to the dorsal column nuclei or the trigeminal nuclei to form the dorsal column trigeminal complex. The trigeminal complex in the brainstem provide second-order afferents, representing the face, that join those from the dorsal column nuclei, representing the body, to terminate in the contralateral ventrposterior complex of the thalamus. Third-order neurons in the thalamus project to anterior parietal cortex, where information is distributed to posterior and lateral parietal cortex.

complex. Most of the second-order neurons in this complex have axons that cross to the contralateral lower brainstem to form the medial lemniscus column of axons that ascend to the somatosensory thalamus. Second-order neurons representing the teeth and tongue project ipsilaterally to the thalamus, while other second-order neurons in the dorsal horn of the spinal cord and in the brainstem send axons to the contralateral side to form the anterolateral spinothalamic ascending pathway (Fig. 28.4). The low-threshold mechanoreceptor information from the skin and the information from muscle spindle receptors and joints course in the medial lemniscus to terminate in nuclei of the ventroposterior thalamic complex. The spinothalamic pathway carries information about pain, temperature, and touch to inferior and caudal parts of the ventroposterior complex.

The somatosensory thalamus has been subdivided in various ways (e.g., Chapter 20; Jones, 1985; Hirai and Jones, 1989; Mai *et al.*, 1997; Morel *et al.*, 1997). Because some of the earlier parcellations of thalamic nuclei were based solely on cytoarchitectonic and myeloarchitectonic criteria (e.g., Hässler, 1959) and because they do not reflect the many recent advances in understanding based on microelectrode recordings, studies of connections, and chemoarchitecture, we use more recently proposed subdivisions stemming from studies largely in monkeys (see Kaas and Pons, 1988, for review). Thus, the relay of afferents from the skin via the medial lemniscus is to the ventroposterior nucleus (VP), which has been traditionally subdivided into a ventroposterior medial subnucleus (VPM) representing the face and a ventroposterior lateral subnucleus (VPL) representing the body. The muscle spindle receptor inputs are relayed to a dorsal or superior part of the ventroposterior complex that is usually included in VPM and VPL. We distinguish this representation of deep receptors as the ventroposterior superior nucleus (VPS). The spinothalamic afferents terminate in a ventroposterior inferior nucleus (VPI). A caudal part of the VP complex that is often included in VPI or in the posterior group of nuclei has been recently distinguished as a distinct relay nucleus for pain and temperature, the ventromedial posterior nucleus (VMpo; Craig *et al.*, 1994; Blomquist *et al.*, 2000; Chapter 29). The somatosensory thalamus also includes nuclei without ascending somatosensory inputs. The anterior pulvinar (Pa) and the lateral posterior complex (LP)

receive inputs from somatosensory cortex and project back to somatosensory cortex.

The somatosensory cortex has also been variously subdivided into proposed subdivisions of functional significance. Most investigators recognize four subdivisions of the cortex of the postcentral gyrus—areas 3a, 3b, 1, and 2—stemming from the early architectonic studies of Brodmann (1909) and the Vogts (Vogt and Vogt, 1919, 1926). While all four areas were once considered parts of a single functional area, primary somatosensory cortex or S1, it has been clear for over 20 years that each constitutes a separate representation of the body, and that only area 3b corresponds to S1 of cats and rats (Kaas, 1983). Areas 3b and 1 contain parallel representations of cutaneous inputs, while areas 3a and 2 integrate cutaneous and deep receptor inputs. Yet, the term "S1" is commonly used to refer to all four areas in monkeys and humans. To avoid confusion, the architectonic terms for the four fields are used here. Thalamic projections to areas 3b and 1 are largely from VP, while VPS provides driving inputs to areas 3a and 2. VPI and Pa project widely to areas of somatosensory cortex, and LP projects to posterior parietal cortex. Areas 3b, l, and 2 form a hierarchial sequence of processing, while area 3a relates especially to motor cortex. All four areas project to somatosensory cortex of the lateral sulcus (lateral parietal cortex), especially the second somatosensory area, S2, and a more recently discovered parietal ventral somatosensory area, PV. These and other areas of the lateral sulcus relate to motor areas of cortex, and to perirhinal cortex to engage the hippocampus in a subsystem involved in object recognition and memory (Mishkin, 1979). Other connections of area 2 and subdivisions of lateral parietal cortex are with subdivisions of posterior parietal cortex that are involved with the early stages of motor guidance and control. Subdivisions of the posterior parietal cortex project to premotor and motor areas of the frontal lobe. Projections from the posterior parietal cortex also involve the medial limbic cortex of the parietal lobe in producing motivational and possibly emotional states. Aspects of this complex system are discussed in more detail later.

RECEPTOR TYPES AND AFFERENT PATHWAYS

In humans, the hand is the most important tactile organ for object identification (Darian-Smith, 1984). Receptors in the hand must convey information about texture and shape. This is done primarily from the fingerpads during active exploration; consequently, finger positions and temporal sequences are important. The glabrous (hairless) skin of the hand has the highest innervation density and tactile acuity of any body surface (Darian-Smith, 1984). Hairy skin is less important in object identification, and hairy skin is less sensitive to touch and vibration (Hamalainen and Jarvilehto, 1981). However, the hairs themselves provide an increased sensitivity to air movement and other stimuli that displace hairs (Hamalainen *et al.*, 1985).

Psychophysical, physiological, and anatomical studies on humans and other primates support the view that sensations of touch from the glabrous skin of the hand are almost completely mediated by four different types of myelinated, rapidly conducting mechanoreceptive afferents (Fig. 28.2). The afferent classes from the glabrous skin include two types of slowly adapting afferents and two types of rapidly adapting afferents. All of these types have been extensively studied physiologically in monkeys and related to receptor types. More recently, the response properties of these afferents have been characterized during recordings in humans, and sensations have been evoked by electrical stimulation in tactile discrimination. Muscle spindle receptors, perhaps aided by other deep receptors in joints and tendons and by one of the skin receptors noted earlier, play a significant role in the position sense of limbs and fingers. This sense is critical in the ability to recognize the form of objects. Afferents that are thin and slowly conducting relate to the sensations of cold, warm, pain, and crude touch. Other afferents may be related to the sensations of itch and tickle. This review concentrates on the afferents from the skin used in touch and the muscle spindle and skin receptors used in kinaesthesia (position sense). See Dykes (1983) and Willis and Coggeshall (1991) for further review.

Low-Threshold Mechanoreceptor Afferents from the Hand

Four types of low-threshold mechanoreceptors are found in the glabrous skin of primates, and afferents from these four types in the human have been studied electrophysiologically (Jarvilehto *et al.*, 1981; Johansson, 1976; 1978; Johansson and Vallbo, 1983; Johansson *et al.*, 1982a, b; Ochoa and Torebjork, 1983; Torebjork *et al.*, 1984; Vallbo, 1981; Vallbo *et al.*, 1984; Westling and Johansson, 1987). These results, together with psychophysical information on touch from humans, have led to a four-channel model of cutaneous mechanoreception (Bolanowski *et al.*, 1994, 1988). Tactile experience, according to the model, depends on various combinations of neural activity in the four channels, with particular channels providing the critical information for some sensations. Stimuli at threshold levels

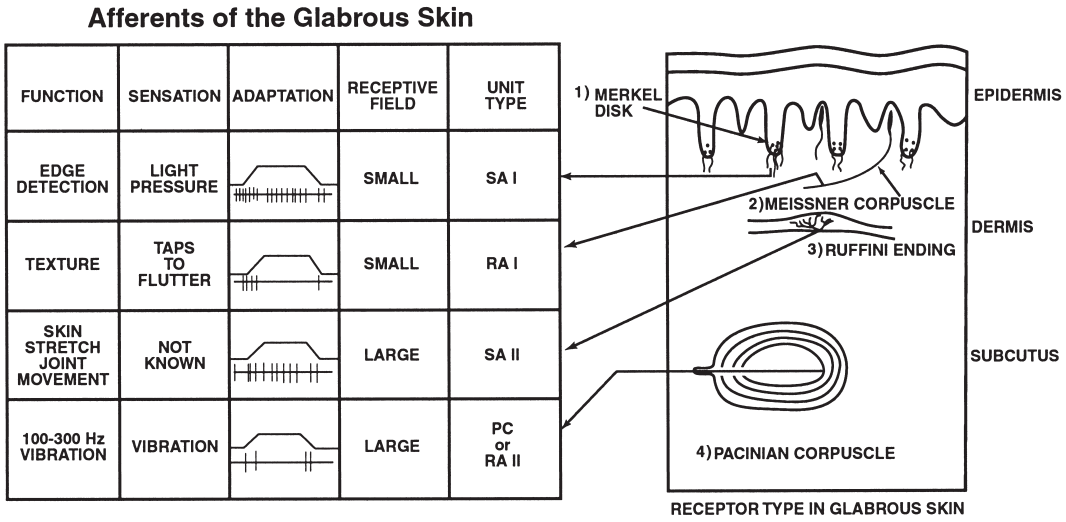

FIGURE 28.2 Receptor types (left) and afferent classes (right) of the glabrous skin of humans. four main classes of low-threshold, rapidly conducting afferents have been described as slowly adopting type I (SA I) and type II (SA II), rapidly adapting type I (RA I) and type II (RA II) or Pacinian corpuscle (PC). Each relates to a specialized receptor complex in the skin. Bsed on Johansson (1978), Johansson and Vallbo (1983), and Vallbo *et al.* (1984). The ramp in the adaptation column marks a short period of skin identation, and the vertical lines represent action potentials recorded during the indentation.

are signaled by the channel that is most sensitive to these stimuli, but suprathreshold sensations are typically the result of activity in two or more channels.

The SA-I Afferent or the Non-Pacinian III (NP III) Channel

In the superficial glabrous skin, the type I class of slowly adapting afferents (SA-I) are activated at receptor sites termed Merkel disks (see Darian-Smith, 1984). Each receptor site includes a specialized Merkel cell that is distinct from adjacent skin cells and a number of disklike nerve terminals originating from a myelinated (7–12 μm diameter) afferent fiber. SA-I receptors are densely distributed in the skin of the distal glabrous phalanges of the human hand, and they constitute about one fourth of the 17,000 tactile units of the hand (Johansson and Vallbo, 1979). Microelectrode recordings indicate that the SA-I afferents respond throughout a period of a skin indentation, even when the indentation is sustained for many seconds. Thus, they are slowly adapting to a maintained stimulus. Depending on the rate of the indentation, a large transient response also occurs during onset. The SA-I fibers have small, circumscribed receptive fields and seem especially responsive when the edge of an object indents skin within the receptive field. When stimulated by a train of electrical pulses, the single SA-I afferent signals the sensation of light, uniform pressure at a skin location corresponding to the receptive field. Single electrical impulses are not felt, and increases in stimulation frequency result in feelings of increased pressure. Thus, SA-I afferents are thought to be very important in mediating sensations of static pressure and providing information about the locations of edges and textures of held objects. SA-I afferents best preserve information about moving Braille-like dot patterns on the skin (Johnson and Lamb, 1981). After correlating human discrimination of skin indentation with the response profiles of skin afferents in monkeys, Srinivasan and LaMotte (1987) concluded that static discriminations of shape are based primarily on the spatial configuration of the active and the inactive SA afferents. In addition, under static conditions, the SA afferents provide most of the intensity information. Thus, form perception appears to be dominated by the SA-I system (Johnson and Hsiao, 1992).

The RA-I Afferent or the Non-Pacinian I (NPI) Channel

The predominant receptor afferent of the digit skin is the rapidly adapting RA-I fiber (Darian-Smith, 1984). Nearly half of the tactile afferents from the hand are of the RA-I type (Johansson and Vallbo, 1983). RA-I afferents innervate Meissner corpuscles, which are located in dermal papillae protruding into the epidermis. Meissner corpuscles are particularly dense in the glabrous skin of the distal phalanges; they are less

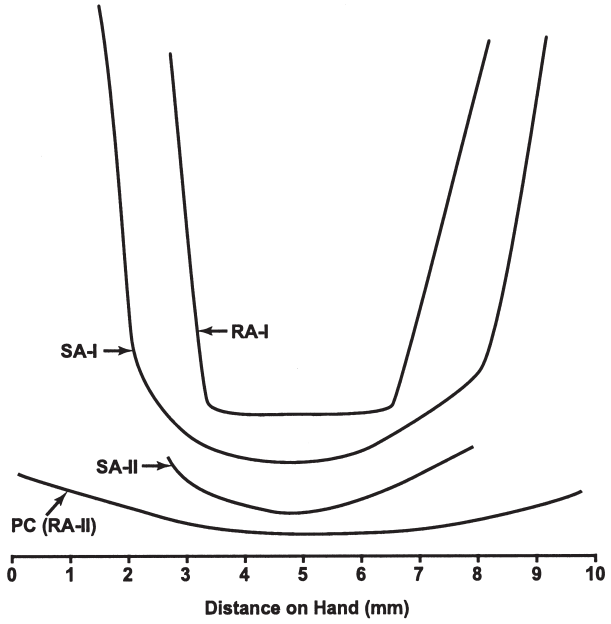

FIGURE 28.3 Changes in the sensitivity to tactile stimuli with distance across the receptive field for four classes of afferents from the glabrous skin of the human hand. Threshold levels on the vertical scale are arbitrary and do not indicate different thresholds. The rapidly adapting RA-I and the slowly adapting SA-I afferents have small receptive fields with sharp boundaries, while Pacinian (PC) or rapidly adapting RA-II and slowly adapting SA-II afferents have large receptive fields with poorly defined boundaries and a gradual change in sensitivity across the skin. Based on Johansson (1978).

common on the palm and are rare in hairy skin, being replaced by RA afferents related to hair shafts. The corpuscles consist of a core of nerve terminal disks and lamellae of Schwann cells surrounded by connective tissue extensions of the endoneural sheath. Meissner corpuscles are elongated (100 × 50 μm) perpendicular to the skin, and the outer collagen fibers of the corpuscles are linked with fibrils of adjacent epidermal cells, which allow skin deformations to stretch the corpuscle. Most corpuscles are innervated by two to six myelinated axons, and each axon innervates a tight group of corpuscles, providing a small receptive field of almost uniform sensitivity and sharp boundaries (Fig. 28.3). The RA-I afferents are thought to be responsible for the detection of movement between the skin and a surface, and for discrimination of surface texture (Johnson and Hsiao, 1992). They appear to detect microscopic slips between manipulated objects and skin to provide signals for grip control. RA-I afferents respond only to changes in skin indentation, and not to steady indentation (e.g., Srinivasan and LaMotte, 1982). Thus, RA-I afferents are capable of providing shape and intensity information during active touch (see LaMotte and Srinivasan, 1987). Single electrical impulses on RA-I afferents from the human hand often result in the detectable sensation of a light tap at a location corresponding to the receptive field. Low-frequency stimulation produces a sensation of a series of taps; at higher frequencies the taps merge into a fluttering sensation. No increase in the magnitude of the sensation follows increases in stimulation rate. These observations suggest that RA-I units are especially important in discriminations of textures moved across the skin, and of course in the sensation of flutter. Because RA-I afferents are frequently located near a joint on the back of the hand, and they respond to skin deformation during finger movements, they may also have a role in kinaesthesia (Edin and Abbs, 1991).

The SA-II Afferent or Non-Pacinian II (NP II) Channel

A second class of slowly adapting afferents, SA-II, terminate in encapsulated endings called Ruffini corpuscles (see Darian-Smith, 1984; Miller *et al.*, 1958), which are located somewhat deeper in the skin than the Merkel disks subserving SA-I afferents. Ruffini or Ruffini-like receptors are also found in deep tissues, including ligaments and tendons. Each Ruffini corpuscle contains an elongated (500–1000 μm × 200 μm) capsule of four to five layers of lamellar cells covered with a membrane, and a core of nerve fiber branches and longitudinally aligned collagen fibrils. Movement of the skin results in stretching of the corpuscle because the corpuscle is attached to surrounding tissue. Such stretching results in deformation and activation of the innervating axon. Each Ruffini corpuscle is innervated by one A-beta myelinated fiber, which may also innervate several other adjacent corpuscles. In the human hand, the SA-II class of afferents constitutes about one fifth of the tactile units (Johansson and Vallbo, 1979). SA-II fibers have large, poorly defined receptive fields (Fig. 28.3), often located near the nail bed or near skin folds on the digits or palm. These afferents are extremely sensitive to skin stretch, and often they are sensitive to direction of skin stretch. Normal movements of digits and limbs are very effective in activating these neurons. Electrical stimulation of single SA-II afferents may not be felt, or is reported as producing a buzzing sensation (Bolanowski *et al.*, 1994), so uncertainty remains about the role of SA-II afferents in tactile perception. However, there is psychophysical evidence that SA-II channels participate in the sense of touch (Bolanowski *et al.*, 1988). In addition, inputs from these skin stretch receptors may combine with sensory inputs from muscles and joints to provide limb and digit position and movement signals (e.g., McCloskey, 1978). These cutaneous mechanoreceptors

appear to contribute to a movement sense but not to an awareness of the static-position of a joint (see Clark *et al.*, 1986). Also, SA-II units are sensitive to skin shearing, and thus they might provide information about the weight of objects (McCloskey, 1974). Overall, SA-II afferents seem well suited for a role in motor guidance and control (Westling and Johansson, 1987).

The RA-II Afferent or Pacinian (P) Channel

The PC (Pacinian) or rapidly adapting RA-II afferents terminate in Pacinian corpuscles. These corpuscles are much less common than other receptor endings in the skin of the hand (10–15%), and they are also found in deeper tissues (see Darian-Smith, 1984; Johansson and Vallbo, 1979). Only about 200 corpuscles may be found in the human finger, where they are distributed within deeper skin, subcutaneous fat, and tendonous attachments of the ventral but not the dorsal finger. The PC corpuscles are large (0.3–1.5 mm $\times$ 0.2–0.7 mm) ovoids consisting of a central nerve fiber surrounded by an inner core of 60 or so layers of concentrically wrapped lamellar cells, a space filled with fluid, and an outer capsule of up to 30 less densely packed lamellae. The corpuscle acts as a mechanical filter, relaying high- frequency and attenuating low-frequency components of skin compression to the axon terminal. The PC afferents allow the detection of distant events via the transmission of high-frequency vibrations through objects and surfaces. PC afferents are extremely sensitive to transient indentations of the skin over large areas such as a complete digit and part of the palm. Thus, information is transmitted in the tissue to the region of the receptor. Sensitivity gradually decreases with distance from the receptor, and receptive field boundaries are not sharp (Fig. 28.3). PC units typically can be activated by gently blowing on the skin, and they respond to vibrations produced by tapping the table surface on which a skin surface rests. PC afferents, like RA-I fibers, respond to the indentation and release of the skin produced by a probe (Fig. 28.2), but fail to respond during steady indentation. The responses of Pacinian afferents follow the cycle of a sinusoidal vibratory stimulus. However, unlike RA-I afferents that respond with lowest thresholds in the 30–40 Hz range, PC afferents have lowest thresholds in the 250–350 Hz range. Thus, PC afferents appear to be the only afferents capable of subserving the sensation of high-frequency vibration. For most frequencies, PC and RA-I afferents both contribute to the perceived vibrotactile intensity (Hollins and Roy, 1996). Electrical stimulation of PC afferents in the human hand are not felt at low stimulation rates, but a sensation of vibration or tickle occurs at high stimulation rates. Often, the sensation is restricted to a part of the large, diffuse receptive field. PC afferents poorly resolve moving texture patterns (Johnson and Lamb, 1981), and they are apparently unimportant in object identification. Their major role, therefore, seems to be in detecting and roughly locating sudden skin deformations produced by ground and air vibrations, and by skin contacts.

Cutaneous Receptor Afferents of the Hairy Skin

As in the glabrous skin, the hairy skin has SA-I, SA-II, RA-I, and RA-II afferents. However, some modifications in the receptor mechanisms exist. First, Merkel cell disks of the SA-I receptor are often aggregated in small (0.25–0.5 μm) diameter touch domes that are slightly elevated from surrounding skin and can be visualized with a dissecting microscope. The Merkel touch spot or haarscheibe is innervated by a single, large (7–12 μm) myelinated fiber that branches to terminate in a number of disks associated with Merkel cells. Isolated Merkel cells are rare. Second, some RA-I and SA-I afferents relate to the shafts of hairs. The SA-I afferents seem to be activated by Merkel-type endings around hair follicles, and the RA-I afferents may have the equivalent of Meissner-type endings in glabrous skin. Third, the hairy skin does not have Pacinian corpuscles, but instead relies on a scattering of Pacinian corpuscles located in deep tissue around blood vessels and muscles (Bolanowski *et al.*, 1994). Thus, hairy skin is less sensitive to vibrations. Fourth, it is not yet clear how or if the SA-I afferents in hairy skin contribute to tactile sensation; in contrast, SA-II afferents may mediate sensations of pressure in hairy skin but not in glabrous skin (Bolanowski *et al.*, 1994). The hairy skin of humans also has C-mechanoreceptive afferents. The functional role of these afferents is uncertain, and they may not contribute to conscious percepts of touch (Vallbo *et al.*, 1999).

Deep Receptor Afferents

As noted earlier, SA-II type afferents associated with Ruffini-like endings are found not only in the skin, where they signal stretch, but also in deep tissues where they also signal stretch. The receptors are Ruffini corpuscles and Golgi tendon organs. SA-II afferents provide information about joint extension and tissue compression, but it is not clear that SA-II afferents have a role in the conscious awareness of joint position (Burgess *et al.*, 1982). Part of the evidence against a major role is that joint position sense survives joint removal and replacement (Cross and McCloskey, 1973). Nevertheless, there is psychophysical evidence

that joint afferents subserve joint position sense in fingers (Taylor and McCloskey, 1990).

Other important deep receptors are the muscle spindle receptors, which were once thought to participate only in reflexes via spinal cord pathways and motor control via a relay to the cerebellum. Muscle spindle afferents are now known to also relay to the cortex (Fig. 28.4), and to contribute to a sense of posture and movement (Burgess *et al.*, 1982; Clark *et al.*, 1986; Goodwin *et al.*, 1971; Jones, 1994; McCloskey, 1978). For static limb position, Clark *et al.* (1986), for example, argue that the nervous system computes joint angles and thus limb position from muscle spindle information about the lengths of the muscles that set the positions of joints.

Afferents Mediating Temperature and Pain

Other afferents in the skin and deeper tissues relate to the sensations of temperature, pain, itch, and crude touch. These include one or more types of specific nociceptors, afferents that respond to innocuous cooling, multimodal afferents responsive to heat, pinch, and cooling (HPC) and the wide-dynamic range (WDR) afferents (Chapter 30; Willis and Coggeshall, 1991). The specific nociceptors conduct in the A-delta range and mediate pricking pain, while the multimodal afferents conduct in the C range and mediate burning pain. Warm receptor afferents conduct in the C range while responding at body temperatures and higher, but not at noxious levels of heat.

Afferent Pathways

Afferents course from skin receptor and deep receptor locations to combine in nerve fascicles that join other fascicles to form the peripheral nerves. The peripheral nerves branch and segregate into dorsal sensory roots and ventral motor-sensory roots. The afferents that enter the dorsal roots terminate on neurons in the dorsal horn of the spinal cord or ascend to terminate on neurons in the dorsal column nuclear complex at the junction of the medulla and spinal cord (Figure 28.1; Chapter 7).

A number of investigators have attempted to determine the skin regions subserved by the nerves in each spinal root in humans and other mammals (see Chapter 30; Dykes and Terzis, 1981, for a review). Dissections have been used to reveal the gross patterns of these dermatomal distributions, but additional methods include using the zone of remaining sensibility after section of dorsal roots above and below the one studied, electrical recording or stimulation, interruptions of function produced by ruptured disks, and data from herpes zoster eruptions. For humans, the extensive dermatomal maps are those of Head (1920), based on skin regions affected by herpes zoster; Foerster (1933), from clinical cases where spinal roots were sectioned for the relief of pain; and Keegan (1943), from cases of local sensory loss subsequent to ruptures of intervertebral disks. Dykes and Terzis (1981) point out that these three maps of dermatomes differ considerably, and they suggest that none is accurate. However, the maps in humans, together with the results from other primates, allow several conclusions: (1) The field of each root is continuous, and tends to form a strip perpendicular to the spinal cord. (2) Adjacent dorsal root distributions overlap extensively. (3) There is little overlap at the ventral and dorsal body midlines. (4) There is considerable variability across individuals.

Within dorsal roots, studies in monkeys indicate that there is some crude organization of afferent fibers according to skin location, with distal receptive fields located caudal in the dorsal root, while fibers with proximal receptive fields tend to be rostral (Werner and Whitsel, 1967). These studies also indicate that ascending branches of axons entering the spinal cord in the dorsal columns (Fig. 28.4) tend to preserve their order of entry so that axons from lower spinal roots are medial to those from upper spinal roots (Whitsel *et al.*, 1972). In monkeys, inputs from muscle spindles branch and join the cuneate fasciculus for the upper limb, but terminate in the spinal cord for the lower limb.

Some afferent fibers with cell bodies in the dorsal root ganglia turn and enter the ventral root and then turn and retrace a path back to the dorsal root, as if correcting an error (see Willis, 1985; Chapter 8 for a review). These sensory fibers in the ventral root are largely unmyelinated axons, and many are nociceptors.

Terminations of Peripheral Nerve Afferents in the Spinal Cord and Brainstem

Afferent fibers entering the spinal cord either simply terminate on neurons in the dorsal horn of the spinal cord or also branch and send a collateral toward the brainstem to either terminate in the dorsal horn at higher levels or in the dorsal column-trigeminal nuclear complex of the lower brainstem. Figure 28.4 depicts sensory terminations in the spinal cord and relays to the medulla–spinal cord junction. Termination patterns of peripheral afferents have been investigated in monkeys and other mammals (see Chapter 8), and some rather consistent features can be assumed to apply to humans. Three general conclusions seem justified. First, the axons of specific types of afferents have characteristic termination patterns in the spinal

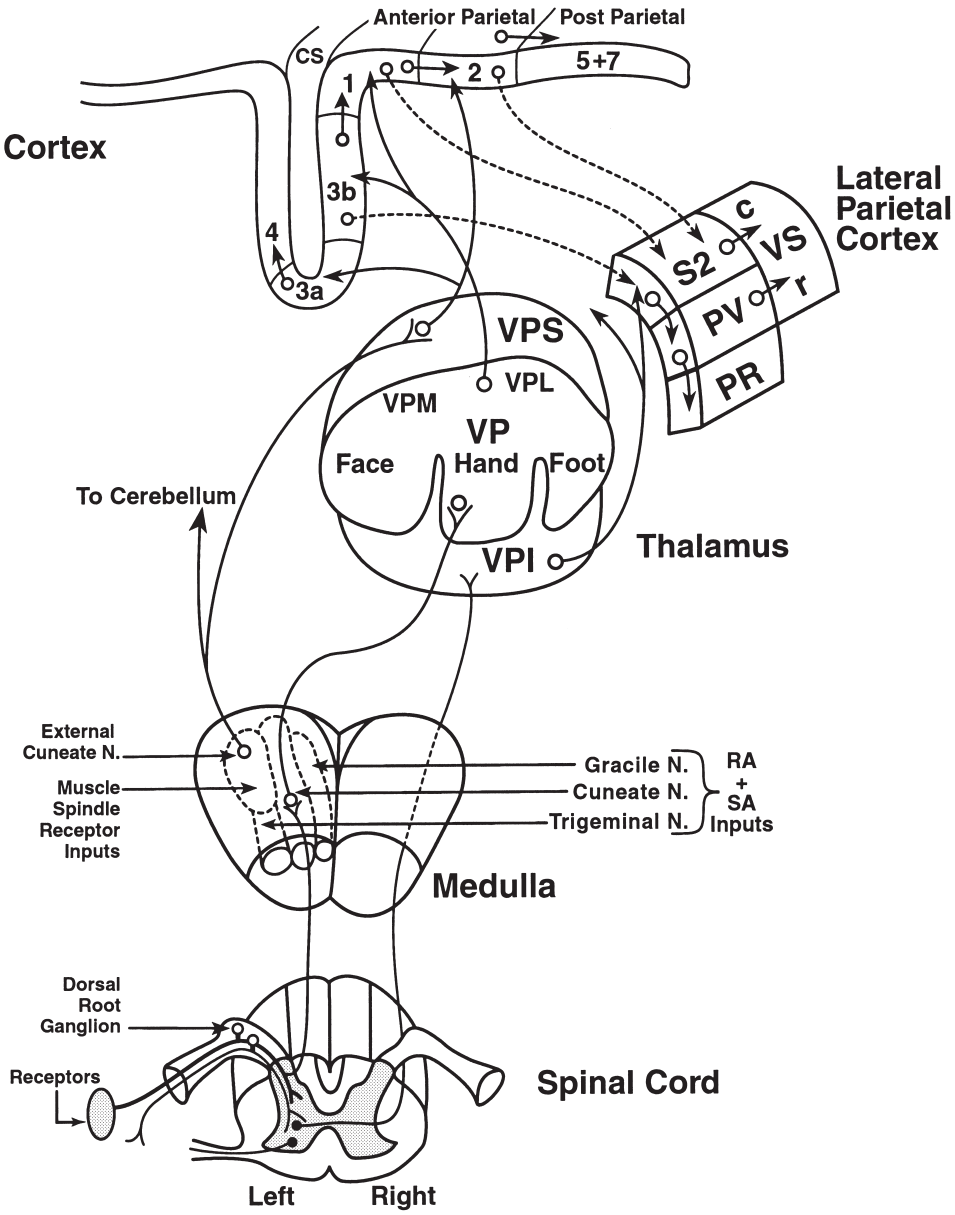

FIGURE 28.4 A more detailed overview of the basic components of the human somatosensory system. Inputs form the four main classes of cutaneous receptors (see Fig. 28.2) enter the spinal cord branch and terminate as neurons in the dorsal horn of the spinal cord and in the ipsilateral dorsal column nuclei of the lower brainstem. Muscle spindle afferents branch in a similar manner with the ascending branch covering the dorsal columns or more laterally to terminate in the gracile and cuneate subnuclei as well as the external cuneate nucleus. Other more slowly conducting afferents related to pain, touch, and temperature terminate on dorsal horn neurons that project contralaterally to form the spinothalamic pathway. Afferents from the face enter the brainstem to terminate in the main trigeminal nuclei for cutaneous and muscle spindle afferents and the spinal trigeminal nucleus for pain, temperature, and touch afferents. The gracile nucleus represents the hindlimb and lower body; the cuneate nucleus, the forelimb; and the principal trigeminal nucleus, the face for cutaneous inputs. These inputs activate second-order neurons that project to the contralateral thalamus by forming the medial lemniscus. Nuclei in the thalamus include the ventroposterior (VP) nucleus with ventroposterior medial (VPM) and ventroposterior lateral (VPL) subnuclei for the face and body representations, respectively. The foot, hand, and face are represented in a lateromedial sequence in VP. The ventroposterior superior (VPS) nucleus receives muscle spinal inputs (2nd or 3rd order), while the ventroposterior inferior nucleus receives spinothalamic axons. These nuclei project to subdividions of anterior parietal and lateral parietal cortex (see text). The second somatosensory area (S2), the parietal ventral area (PV), the parietal rostal area (PR) and caudal and rostral divisions of the ventral somatosensory (VS) complex are indicated. Brodmann's areas are numbered.

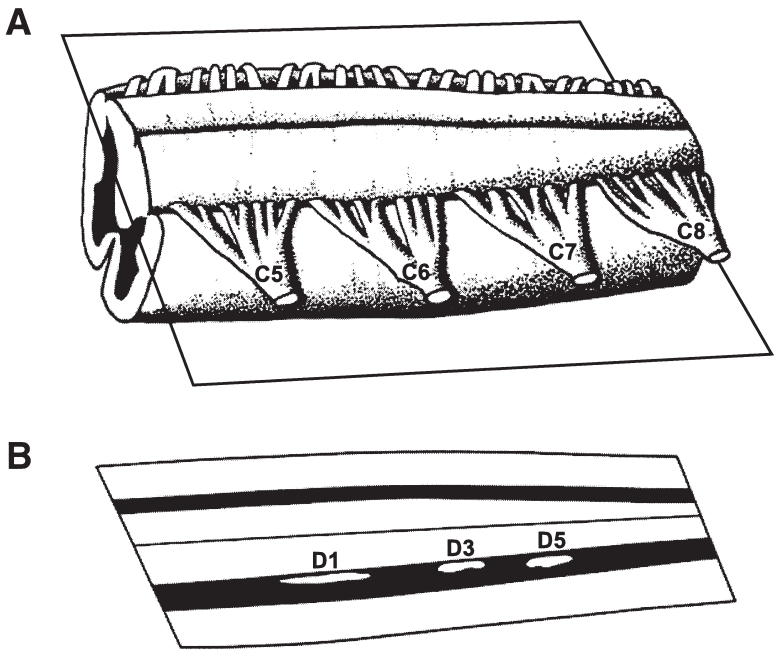

FIGURE 28.5 The rapidly conducting cutaneous afferents of peripheral nerves terminate in a somatotopic paterns in the dorsal horn of the spinal cord. In a macaque monkey, tracers were injected into the glabrus skin of digits 1, 3, and 5 (D1, D3, D5). Although afferents from each digit typically enter the spinal cord over more than one cervical dorsal root (C5, 6, 7, and 8), the inputs terminate in an orderly pattern. Inputs from D1, D3, and D5 terminate in a rostrocaudal pattern in the medial dorsal horn (white) with other digit inputs in between. The dorsal hand and palm are represented more laterally, and the forearm, in rostral and caudal bands. Based on Florence *et al.* (1988, 1989). The box in **(A)** indicates the plane illustrated in **(B).**

cord. Second, afferents from different skin regions terminate separately in the spinal cord to form a somatotopic map. Third, afferents ascending to the dorsal column nuclei terminate somatotopically.

The termination patterns of individual axons that have been physiologically identified and labeled with horseradish peroxidase are known from studies on cats (see Brown, 1981). All the four types of cutaneous afferents bifurcate as they enter the cord to send rostral and caudal branches that further branch to form a sagittally arranged series of terminal arbors. Individual RA-I collaterals form a separate arbor of about 500 μm in the sagittal plane and 50–300 μm in the transverse plane in layers III and IV. Collaterals of PC or RA-II axons terminate in several sagittally elongated arbors (400–750 μm) that extend vertically from layers III and IV to layers V and VI. SA-I axon collaterals give rise to spherical arbors (250–700 μm) that distribute in layers II, III, IV, and the dorsal margin of V. SA-II axon collaterals terminate over layers III, IV, V, and part of VI in rostrocaudally thin sheets (100–300 μm). While all types differ in the details of distribution, the results indicate that inputs from single receptive fields on the skin relate to rostrocaudal rows of cells in the dorsal horn. How axons from specific skin regions terminate in the spinal cord is known for a range of mammals, including monkeys. Similarities across species suggest that the termination pattern in humans is similar. Figure 28.5 shows that the terminations from the skin of the digits of the hand are arranged in a rostrocaudal row in the medial dorsal horn of the cervical spinal cord of macaque monkeys (see Florence *et al.*, 1988, 1989). More proximal parts of the limb are represented more laterally in the dorsal horn, and inputs from the foot demonstrate a similar orderly arrangement. As for the single axons, groups of axons from a limited skin region terminate in rostrocaudally elongated zones. Thus, body parts are represented in rostrocaudal slabs of cells. While different classes of afferents activate different groups of spinal cord cells, the single zones of label for each digit indicate that the dorsal horn cells activated from a given skin region are grouped together.

Ascending Spinal Cord Pathways

Traditionally, the ascending somatosensory pathways from the spinal cord include the dorsal column pathway and a ventrolateral pathway (Fig. 28.4). The dorsal column pathway comprises the axons of first-

order dorsal root ganglion neurons coursing ipsilaterally to the dorsal column nuclei. The ventrolateral pathway (see below) originates from second-order neurons of the dorsal horn, crosses to the opposite ventrolateral white matter of the spinal cord, and ascends to brainstem and thalamic targets, including the ventroposterior inferior nucleus of the thalamus. The ipsilateral dorsal column system was thought to deal with epicritic functions such as position sense and light touch, while the crossed spinothalamic system was thought to mediate protopathic sensibilities of crude touch, pain, and temperature. More recent research (see Chapter 8) has complicated this story by indicating that (1) second-order neurons also contribute to the ipsilateral dorsal columns; (2) additional ipsilateral pathways from second-order neurons exist, including a spinocervical system that is reduced in primates; (3) pathways from the upper and lower limbs differ; (4) crossed spinothalamic pathways vary in location; and (5) descending axons are mixed with ascending axons. Of course, these refinements are based on anatomical studies in nonhuman primates and other mammals, but findings are general enough that they are likely to apply to humans.

The Dorsal (Posterior) Column System

The extremely large dorsal column afferent pathway in humans occupies over a third of the spinal cord at high cervical levels (Wall, 1970). The two major divisions are the more medial gracile tract subserving the trunk and lower limb and the cuneate tract for the upper limb and associated trunk and neck. Inputs from the face and head via the trigeminal system form an analogous tract in the brainstem (see Chapter 29). The axons in the dorsal columns are largely myelinated dorsal root fibers that branch to ascend to the dorsal column nuclei, send descending collaterals for several segments in the dorsal columns, and emit a number of local collaterals to terminate on neurons in the dorsal horn. Other axons originate from spinal cord neurons and ascend over several segments to terminate in the spinal cord on local circuit neurons or on neurons that project to the brainstem. Some of these secondary sensory neurons project via the dorsal columns to the dorsal column nuclei. Thus, both first- and higher-order axons are found in the dorsal column pathway. A few descending fibers may also travel in the dorsal columns. Entering fibers from each dorsal root form a narrow layer at the lateral margin of fibers from lower levels, but some mixing of levels occurs as the axons ascend.

Most of what is known about the types of information conveyed by the dorsal columns comes from microelectrode recordings in monkeys (Whitsel *et al.*, 1969), although limited recordings in humans revealed nerve fibers activated by pressure and limb movement (Puletti and Blomquist, 1967). The gracile and cuneate tracts differ at high spinal cord levels in the classes of axons they contain. The gracile tract at lower levels contains a mixture of cutaneous afferents, largely rapidly adapting afferents (probably RA-I), and muscle afferents that leave to terminate in Clarke's nucleus, which projects in turn to the cerebellum and other structures via the dorsal spinocerebellar tract. At higher levels, the remaining axons that travel to nucleus gracilis are almost completely RA cutaneous afferents. The cuneate tract contains a mixture of RA cutaneous and muscle afferents, but the cutaneous inputs terminate in the cuneate nucleus, and the muscle afferents separate to innervate the external cuneate nucleus. Thus, lesions of the dorsal columns deactivate RA neurons, regardless of level, but muscle afferents from the lower body terminate on neurons that relay outside of the gracile tract. Presumably, the dorsal columns of monkeys and humans also contain SA-I, SA-II, and PC afferents, as in other mammals (see Willis and Coggeshall, 1978), but evidence is presently lacking. Lesions of the dorsal columns in humans have little effect on many simple tactile abilities, but major defects occur in the abilities to detect the speed and direction of moving stimuli and to identify figures drawn on the skin (Nathan *et al.*, 1986; see Mountcastle, 1975, and Wall and Noordenhos, 1977, for reveiws). These changes obviously can be attributed to the loss of inputs from RA cutaneous afferents. Other defects in the control of forelimb movements (Beck, 1976) may relate to disruption of muscle afferents. The sensory changes following dorsal column lesions in monkeys are similar, where they have been extensively studied (see Vierck and Cooper, 1998, for review).

The dorsal columns apparently carry all of the inputs from the upper body that activate anterior parietal cortex. After complete lesions of the dorsal columns at a high cervical level in monkeys, neurons throughout the forelimb and adjacent trunk representations in areas 3a, 3b, l, and 2 totally fail to respond to somatosensory stimuli (Jain *et al.*, 1997). Given the distribution of information from anterior parietal cortex to areas of posterior parietal and lateral parietal cortex (Fig. 28.4), the impact on somatosensory processing at the cortical level is major. However, the effects of dorsal column lesions on behavior has been difficult to study because the somatosensory system of adult primates has great plasticity, and the survival of only a few dorsal column axons can have great impact on cortical neurons (Jain *et al.*, 1997). As expected, humans (Nathan *et al.*, 1986) and monkeys (e.g., Vierck and Cooper, 1998) with dorsal column lesions are greatly impaired in somatosensory abilities and sensory

guidance of motor behavior, especially when lesions are cervical and affect forelimb and hand use rather than thoracic and affect leg and foot use. This may be partly because some of the relevant afferents from the leg travel outside the dorsal columns (see earlier discussion). The abilities that remain demonstrate the importance of the spinal cord connections and other ascending pathways, especially the spinothalamic pathway, although its mode of action in touch is uncertain.

Primary afferents from oral and facial structures travel in the trigeminal or fifth nerve and enter the brainstem to branch and terminate in the principal trigeminal nucleus and subdivisions of the spinal trigeminal complex (May and Porter, 1998; see Chapter 29). The axon branches terminating in the principal nucleus are largely of the low-threshold SA and RA classes, and they constitute the equivalent of the dorsal column pathway. Terminations in the subdivisions of the spinal trigeminal complex correspond to those from the body that terminate in the dorsal horn of the spinal cord.

Second-Order Axons of the Dorsolateral Spinal Cord (The Spinomedullothalamic System)

In monkeys, all the muscle afferents for the lower body apparently leave the gracile column and synapse on neurons that send axons in the dorsolateral (posterolateral) spinal cord to the dorsal column nuclear complex (Whitsel *et al.*, 1972). In humans, lesions of both the dorsal columns and the dorsolateral spinal cord result in severe defects in proprioception, but it is not certain that all proprioceptive axons from the lower limbs are in the dorsolateral pathway rather than the dorsal column pathway (Nathan *et al.*, 1986).

Many or all mammals have other inputs to the dorsolateral pathway, including a spinocervical pathway from second-order neurons in the dorsal horn that project ipsilaterally to the lateral cervical nucleus. A comparatively reduced lateral cervical nucleus has been described for humans (Truex *et al.*, 1970), but the types of inputs activating this nucleus are known only from studies on other mammals, especially cats (see Willis and Coggeshall, 1991, for review). Neurons projecting into the spinocervical tract have receptive fields on both the hairy and glabrous skin in monkeys (Bryan *et al.*, 1974). Peripheral inputs activating these neurons are cutaneous rapidly adapting afferents, and there is an apparent lack of slowly adapting cutaneous and deep receptor influences.

The Spinothalamic Pathways

Many second-order somatosensory neurons in the dorsal horn of the spinal cord have axons that cross in the spinal cord to ascend in the ventrolateral or dorsolateral white matter. Many axons in these pathways terminate before reaching the thalamus, but others branch to reach several thalamic nuclei. In Old World monkeys, a dorsolateral spinothalamic tract consists of locally crossing axons of lamina I cells of the dorsal horn, while the ventrolateral spinothalamic tract contains locally crossing axons of laminae I-X cells (Apkarian and Hodge, 1989a). In monkeys, spinothalamic tract neurons have been found to respond to tactile stimuli and movement of hairs, stimuli ranging from tactile to noxious (wide dynamic range neurons), noxious stimuli, and temperature (see Willis and Coggeshall, 1991; Craig *et al.*, 1999). In humans, some capacity for mechanoreceptive sensibility remains after large lesions of other ascending pathways, but electrical stimulation of the ventral quadrants of the spinal cord has produced sensations of only pain and temperature (Sweet *et al.*, 1950; Tasker *et al.*, 1976).

RELAY NUCLEI OF THE MEDULLA AND UPPER SPINAL CORD

Several groups of neurons in the spinal cord and medulla are important in relaying information to higher brain centers. These include the dorsal column nuclear complex, the dorsal nucleus of the spinal cord (Clarke's nucleus or column), and the lateral cervical nucleus. The trigeminal nuclear complex adds analogous pathways for information from the head.

Dorsal Column-Trigeminal Nuclear Complex

The dorsal column-trigeminal nuclear complex consists of groups of cells in the lower brainstem and upper spinal cord that receive inputs from ipsilateral low-threshold mechanoreceptors and project to the ventroposterior complex of the thalamus (Fig. 28.4). The part of the system originating in dorsal root ganglia and coursing in the dorsal columns terminates in the gracile nucleus for the lower body and the cuneate nucleus for the upper body. The trigeminal complex receives inputs from cutaneous mechanoreceptors in the face and mouth. The gracile, cuneate, and trigeminal "nuclei" form a somatotopic map from hindlimb to head in a mediolateral sequence in the lower medulla (Xu and Wall, 1996, 1999).

The gracile and cuneate nuclei are elongated in the rostrocaudal dimension (Fig. 28.4). The overall appearance of the nuclei in humans (see Chapter 10) is quite similar to that observed in macaque monkeys (Florence *et al.*, 1988, 1989). In both, the middle regions contain discrete clusters of neurons outlined by bands of myelinated fibers. Stains for the mitochondrial

enzyme cytochrome oxidase (CO) show that the cell clusters have more of the enzyme and, presumably, higher metabolic activity than the surrounding fiber regions. The details of the parcellation pattern of this nucleus in humans and monkeys are quite comparable (Florence *et al.*, 1989), suggesting the significance of the parcellation is the same. In monkeys, specific cell clusters in the central cuneate nucleus correspond to inputs from specific digits of the hand. Thus, the parcellation reflects the somatotopic organization of the nucleus. The rostral and caudal poles of the cuneate nucleus have more convergent terminations from afferents of the digits. Thus, the nucleus appears to segregate inputs into a discrete somatotopic map in the central part of the nucleus and into less precise maps in the rostral and the caudal poles of the nucleus in monkeys, and probably in humans, judging from the close match in appearance. There is evidence from studies in cats (Dykes, 1983) that RA-I and SA classes of cutaneous afferents activate neurons in the central zones of the dorsal column nuclei, while SA, joint, and muscle receptor afferents relate to the rostral parts of these nuclei, and Pacinian receptor afferents are concentrated caudally.

The projection neurons of the dorsal column nuclei send axons into the contralateral medial lemniscus, where they course to the ventroposterior complex (Rasmussen and Peyton, 1948). In humans, as in other mammals, some axons probably send collaterals to the inferior olive, which, in turn, projects to the cerebellum (see Schroeder and Jane, 1976; Molinari *et al.*, 1996). In monkeys and other mammals, the dorsal column nuclei, especially the rostral poles, receive inputs from the contralateral somatosensory and motor cortex (areas 4, 3a, 3b, l, and 2) that may modulate the relay of sensory information (e.g., Bentivoglio and Rustioni, 1986; Cheema *et al.*, 1985; Marino *et al.*, 1999, for a review).

The trigeminal complex includes the principal (Pr 5) or main sensory nucleus and the spinal trigeminal nucleus. The principal nucleus is thought to be analogous to the cuneate and gracile nuclei, and the three together form one or more systematic representations of cutaneous receptors of the body. The principal nucleus projects via the medial lemniscus to the medial subnucleus of the contralateral ventroposterior complex (VPM). The spinal trigeminal nucleus (Sp 5) is analogous to part of the dorsal horn of the spinal cord. As in the spinal cord, a marginal zone receives pain and temperature afferents (Craig *et al.*, 1999) and deeper neurons are activated by cutaneous and muscle receptors (e.g., Price *et al.*, 1976). Second-order neurons in the spinal trigeminal nucleus form a relay that joins the contralateral spinothalamic tract to terminate in the ventroposterior nuclear complex and the more medial thalamus (see Burton and Craig, 1979).

Lateral Cervical Nucleus, Nuclei X and Z, External Cuneate Nucleus, and Clarke's Column

Second- and third-order relay neurons are found in several structures (for the human brainstem, see Huang and Paxinos, 1995; Chapter 10) in addition to the dorsal column-trigeminal complex and the dorsal horn of the spinal cord.

Lateral Cervical Nucleus

A long column of neurons outside the gray matter proper of the dorsal horn of the spinal cord that extends from C4 to the caudal part of the medulla composes the lateral cervical nucleus. Rapidly adapting afferent fibers serving hairs and other tactile afferents enter the dorsal horn to relay on neurons forming the spinocervical tract in the dorsolateral white matter. These second-order neurons terminate on neurons in the ipsilateral lateral cervical nucleus. A subset of multimodal neurons with a convergence of nociceptive afferent inputs has been reported in the lateral cervical nucleus as well (see Boivie, 1978, for a review). The lateral cervical nucleus appears to relay touch, pressure, and vibration information, largely from the hairy skin, to the contralateral thalamus, inferior olive, and midbrain. In humans, the lateral cervical nucleus may be a rudimentary structure because it is only well defined in some individuals (Truex *et al.*, 1970). In such humans, the nucleus contains up to 4000 neurons, while nearly double that number may exist in cats (Boivie, 1983).

Nuclei X and Z

Other second-order axons of the dorsolateral fasciculus, possibly collaterals of spinocerebellar axons, terminate in two small medullary nuclei, termed X and Z by Pompeiano and Brodal (1957). Muscle spindle afferents for the hindlimb relay via the dorsolateral funiculus to nucleus Z, located just rostral to the gracile nucleus. Nucleus Z, which has been identified in the human brainstem (Sadjadpour and Brodal, 1968; see Chapter 10), projects to the contralateral ventroposterior complex in the thalamus. In monkeys, muscle spindle receptor afferents related to the forelimb relay over neurons projecting within the dorsal columns (Dreyer *et al.*, 1974). This probably also occurs in humans, since lesions of the dorsal columns impair motor control for the upper limbs (Nathan *et al.*, 1986). A separate nucleus X, not clearly present in humans, forms a second group of neurons receiving mostly

second-order muscle spindle afferents related to the lower limbs.

External Cuneate Nucleus

The muscle spindle afferents of the upper limbs and body course in the cuneate fasciculus to terminate in the external cuneate nucleus. Like nucleus X, the external cuneate nucleus relays to the contralateral ventroposterior complex of the thalamus, and to the cerebellum.

Clarke's Nucleus or Column

A long column of cells called Clarke's column is located just dorsolateral to the central canal in the medial part of the spinal cord of T1-L4 levels. Inputs are largely from muscle spindles. Clarke's column projects to nucleus Z and, via the dorsal spinocerebellar tract, to the cerebellum (for reviews, see Mann, 1973; Willis and Coggeshall, 1991; Chapter 11).

SOMATOSENSORY REGIONS OF THE MIDBRAIN

Studies in nonhuman mammals implicate several midbrain structures in somatosensory functions, but evidence for similar roles in humans is presently lacking. (1) Neurons in the external nucleus of the inferior colliculus respond to somatosensory stimuli and receive inputs from the dorsal column nuclei. The pericentral nucleus may have spinal cord inputs as well. Schroeder and Jane (1976) speculate that auditory and somatosensory systems interrelate in these structures in the detection of low-frequency vibratory stimuli. (2) The deeper layers of the superior colliculus contain neurons activated by somatosensory stimuli via inputs from the spinal trigeminal nucleus, the spinal cord, the lateral cervical nucleus, and the dorsal column nuclei (see Huerta and Harting, 1984, for a review). The somatosensory inputs form a representation that is matched in general spatial location with visual and auditory maps, and the presumed role of the matched maps is to function together in directing eye and head movements toward objects (sounds, touches, and images) of interest (see Meredith and Stein, 1985).

SOMATOSENSORY THALAMUS

Various proposals have been made for how to subdivide the human thalamus (see Chapter 20), but the thalamic structures related to somatosensory abilities have not been identified with complete certainty. In macaques and several families of New World monkeys, where considerable experimental evidence is available (see Kaas and Pons, 1988; Krubitzer and Kaas, 1992), we subdivided the somatosensory thalamus into a large ventroposterior nucleus, a ventroposterior superior nucleus (VPS), and a ventroposterior inferior nucleus (Fig. 28.4). The VP is the principal relay of information from rapidly adapting and slowly adapting cutaneous receptors to anterior parietal cortex, the VPS relays information from deep receptors in muscle and joints, while the significance of the VPI with spinothalamic inputs is less certain. Just caudal to VPI, a ventromedial posterior nucleus, VMpo appears to receive spinothalamic inputs mediating pain and temperature (Craig *et al.*, 1994). In addition, related nuclei of the posterior complex (Po) appear to have somatosensory functions. Other nuclei, notably the medial and anterior divisions of the pulvinar complex and the lateral posterior nucleus, are known to have connections with parietal cortex and thereby are implicated in somatosensory functions. However, these nuclei do not appear to have a role in relaying sensory information. The somatosensory nuclei are discussed and related to proposed subdivisions of the human thalamus later.

Ventroposterior Nucleus

The VP is a basic subdivision of the mammalian thalamus (Jones, 1985; Welker, 1974) that is characterized by (1) densely packed and darkly stained neurons; (2) a systematic representation of cutaneous receptors; (3) inputs from the dorsal column nuclei, the spinothalamic tract, and the trigeminal system; and (4) projections to "primary" somatosensory cortex. The nucleus has subnuclei of dense aggregates of neurons partially separated by cell-poor fiber bands, the most conspicuous of which is the arcuate lamina that separates the part of VP representing the face, the ventroposterior medial "nucleus" (VPM), from the portion representing the rest of the body, the ventroposterior lateral "nucleus" (VPL). Another notable fiber band separates the representations of the hand and foot in VPL.

In macaque monkeys, the dorsal boundaries of VP are not very distinct from the region we now identify as VPS (see Paxinos *et al.*, 2000). The VP of some investigators includes VPS, although this region has also been distinguished as the VP "shell." Another problem is that Olszewski's (1952) popular atlas of the thalamus of macaque monkeys includes additional parts of the thalamus related to motor cortex within an oral division of VPL (VPLo). This use of terminology is not consistent with that used in other mammals.

In the human thalamus, the region identified as the "ventrocaudalis group" or Vc (see Chapter 20)

corresponds closely to our VP in monkeys. Using the terminology of Hässler (1982), VPL is Vce (the external segment) and VPM is Vci (the internal segment of Vc). VP is composed of a range of neuron sizes that generally stain densely for Nissl substance. The dorsal border of the nucleus is described as indistinct, but medial borders with the anterior pulvinar and ventral borders with the VPI are distinct. Recent atlases of the human brain use the terms VPL and VPM (Mai *et al.*, 1997; Morel *et al.*, 1997).

The VP contains a single systematic representation of cutaneous receptors. Each location on the body surface activates a small volume of tissue or cluster of neurons in VP, and these clusters of neurons are arranged according to body part. The general form of the somatotopic organization in mammals has been reviewed by Welker (1974), and described in detail for squirrel monkeys by Kaas *et al.* 1984 (Fig. 28.6; see Rausell and Jones, 1991, for VPM of macaque monkeys). In all primates, including humans, we expect the tactile receptors of the tongue, teeth, and oral cavity to be represented medial to the lips and upper face for VPM. Because some of the inputs from the principal trigeminal nucleus are ipsilateral as well as contralateral, the ipsilateral and contralateral teeth and tongue are both represented in each VPM. More medially, a gustatory nucleus, the so-called VPM parvocellular part (VPMpc), is part of the system for taste (see Chapter 31). The medial portion of VPL contains a mediolateral sequential representation of the digits of the hand from thumb to little finger. The lateral portion of VPL is devoted to the foot, while dorsal portions of the nucleus relate to the proximal leg, the trunk, and the proximal arm in a lateromedial sequence. This arrangement, found in monkeys and in other mammals, is basically the order described for the human VP. Recordings and electrical stimulation with microelectrodes in VP of the human thalamus (Emmers and Tasker, 1975; Lenz *et al.*, 1988) indicate that the mouth and tongue relate to ventromedial portions of VPM, that the hand and foot are in ventrorostral VPL, and the back and neck are in dorsocaudal VPL. Furthermore, the fingers activate a large portion of medial VPL and the lips and tongue relate to a large part of VPM. Finally, often groups of neurons extending in the parasagittal plane are activated by the same restricted skin surface, indicating that lines of isorepresentation are largely in the parasagittal direction.

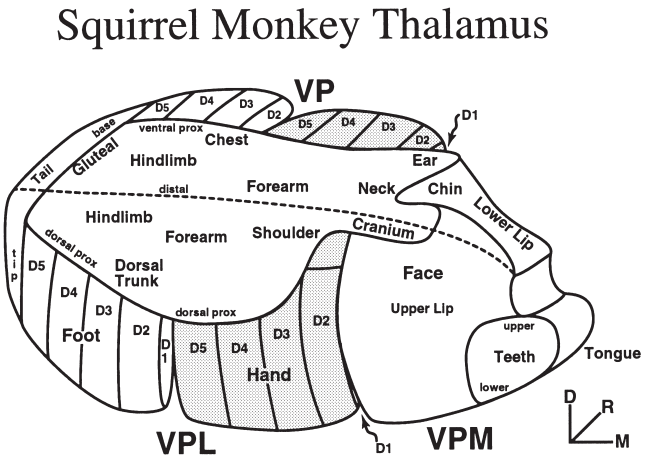

FIGURE 28.6 The somatotopic organization of the ventroposterior (VP) nucleus of squirrel monkeys. A similar organization, except for a lateral representation of the tail, exists in VP of humans (Lenz *et al.*, 1988). VP is subdivided into ventroposterior lateral (VPL) for the body and ventroposterior medial (VPM) for the face. VPL has further subnuclei for the hand and foot. Digits of the hand and foot are represented in mediolateral sequences with the tips ventral. Neurons in VP are activated by slowly and rapidly adapting afferents. Neurons activated by each class form small clusters with VP. Adapted from Kaas *et al.* (1984).

As in monkeys (e.g., Dykes *et al.*, 1981), most neurons in VP of humans are activated by RA-I or SA inputs, with local clusters of cells related to one or the other class of inputs (Lenz *et al.*, 1988). Thus, there is a double representation of the skin in VP, one for fragmented representation of RA-I afferents and one for SA afferents. The SA inputs could be SA-I or both SA-I and SA-II. There is little evidence for Pacinian (RA-II) inputs, but they may add to the complexity of the nucleus. A few neurons respond with an increasing frequency as light tactile stimuli become more intense and extend into the painful range (the wide-dynamic-range neurons); these neurons may have a role in pain perception (see Kenshalo *et al.*, 1980) or in signaling the intensity of stimuli. In humans, electrical stimulation of peripheral nerves results in evoked potentials in the contralateral VP with a latency of 14–17 ms (Celesia, 1979; Fukushima *et al.*, 1976). Electrical stimulation in sites in the nucleus or of input fibers in the medial lemniscus generally results in sharply localized sensations of numbness or tingling rather than light touch (Emmers and Tasker, 1975; Ervin and Mark, 1964; Tasker *et al.*, 1972; Davis *et al.*, 1996; Lenz *et al.*, 1998, 1988). Localized lesions of VP are followed by a persistent numbness in a restricted skin region corresponding to the body surface map in VP (Domino *et al.*, 1965; Garcin and LaPresle, 1960; Van Buren *et al.*, 1976).

The sources of ascending inputs to VP (Fig. 28.4) have been studied in many mammals, including macaque monkeys. The dense inputs are from the dorsal column nuclei via the medial lemniscus and the main sensory trigeminal nucleus via the trigeminal lemniscus. In humans, evoked potentials have been

recorded in VP after electrical stimulation of the dorsal columns (Gildenberg and Murthy, 1980). Less-dense, unevenly distributed inputs are from the spinothalamic tract and the lateral cervical nucleus (Berkley, 1980; Apkarian and Hodge, 1989b). In humans, degenerating spinothalamic terminations have been reported in VP after spinal cord damage (Mehler, 1966; see Bowsher, 1957, for a review of classical reports). The spinothalamic inputs appear to relate to small-cell regions of VP (possibly an extension of VPI) that project to superficial layers of areas 3b and 1 (Rausell and Jones, 1991). Thus, this relay likely has a modulatory role in somatosensory cortex.

The outputs of the ventroposterior nucleus have been studied extensively in primates and other mammals (see Kaas, 1983; Kaas and Pons, 1988; Darian-Smith *et al.*, 1990; Krubitzer and Kaas, 1992). In all mammals studied, VP projects to area 3b or its nonprimate homologue S1. In most mammals, other projections are to the second somatosensory area (S2) and possibly other fields, but in monkeys, and probably humans, projections to S2 are a trivial component of the output. In monkeys, VP also projects over thinner axons and in a less-dense manner to area 1, and, in macaque monkeys, a sparse input exists to part of area 2 related to the hand and even a specialized part of area 5 (Pons and Kaas, 1986). In humans, lesions of anterior parietal cortex including areas 3b and 1 cause retrograde degeneration and cell loss in VP (Van Buren and Borke, 1972), supporting the conclusion that the output patterns in humans and monkeys are similar. Furthermore, recordings from the surface of somatosensory cortex indicate that potentials evoked by median nerve stimulation are reduced or abolished by lesions of VP (Domino *et al.*, 1965).

Ventroposterior Superior Nucleus

There has been long-standing recognition that inputs from receptors in deep tissues are at least partially segregated from inputs from cutaneous receptors in the ventroposterior thalamus of primates (see Poggio and Mountcastle, 1963) and perhaps other mammals. The zone of activation by deep receptors is dorsal to that related to cutaneous receptors in monkeys, and the deep receptor zone is further distinguished by its pattern of cortical connections and architecture. We have termed the deep receptor zone the ventroposterior superior nucleus (VPS; see Kaas and Pons, 1988). Early investigators included the zone of activation by deep receptors in VP, and several recent researchers simply designate the deep receptor zone as the VP "shell." Others conclude that the deep receptor zone includes two nuclei, a VPS and a "ventroposterior oral" nucleus (see Dykes, 1983), but the evidence for such a subdivision in primates is inconclusive. Some term the VPS region VPO (see Chapter 20) as it is as much oral (anterior) as superior in some primates. Finally, the medial posterior nucleus of some investigators (see Krubitzer and Kaas, 1987, for a review) may be a nonprimate homologue of VPS.

In monkeys, VPS contains a representation of deep receptors, principally muscle spindle receptors (see Kaas and Pons, 1988; Wiesendanger and Miles, 1982). The representation parallels that in VP so that the face, hand, and foot activate the medial, middle, and lateral portions of VPS in sequence (Kaas *et al.*, 1984). The major input appears to be from the external cuneate nucleus (Boivie and Boman, 1981), and the output is largely or exclusively to area 3a and area 2. Many of the same neurons in VPS appear to project to both area 3a and area 2 via collaterals (Cusick *et al.*, 1985).

Evidence is less complete for VPS of humans. Deep receptors are represented in an orderly manner in part of the thalamus just rostrodorsal to the cutaneous representation in VP (Lenz *et al.*, 1990; Ohye *et al.*, 1993; Seike, 1993). The mediolateral progression in the representation corresponds to that in VPS with the jaw medial to fingers, followed by wrist, elbow, shoulder, and leg. VPS is probably within VP or a VL-VP "transition" zone identified as Vc.a.e. by Hässler (1959) and VPLa in more recent sudies (Hirai and Jones, 1989; Morel *et al.*, 1997).

Ventroposterior Inferior Nucleus

In all primates, including humans (e.g., Morel *et al.*, 1997), VPI is recognized as a narrow region just ventral to VP that is composed of small, pale-staining neurons. VPI is densely myelinated and reacts lightly for cytochrome oxidase. VPI extends dorsally into the cell-poor regions that separate face, hand, and foot subnuclei of VP (Krubitzer and Kaas, 1992). Because of this dorsal finger-like extension of parts of VPI, and its caudal extension into thalamic regions of similar appearance and perhaps function (see following discussion), some of the boundaries of VPI have been uncertain. As a result, the major inputs to VPI from the spinothalamic and caudal trigeminothalamic afferents have been variously described as including not only VPI but also VP as well as more caudal nuclei (see Apkarian and Hodge, 1989b). The inputs to VPI reveal a somatotopic pattern with the hindlimb inputs most lateral and the forelimb and face inputs more medial (Gingold *et al.*, 1991). Outputs to cortex also indicate this overall somatotopic pattern of organization (Cusick and Gould, 1990). Neurons in the VPI region of both monkeys (Apkarian and Shi, 1994) and

humans (Lenz *et al.*, 1993) are responsive to noxious stimulation. In monkeys, VPI projects densely to areas S2 and PV of lateral parietal cortex and less densely and more superficially to areas of anterior parietal cortex (Friedman and Murray, 1986; Cusick and Gould, 1990; Krubitzer and Kaas, 1992). Although VPI relays spinothalamic tract information, and VPI includes neurons responsive to noxious stimuli, it seems likely that the role of VPI projections to cortex are largely modulatory. They may have a role in experience-related plasticity of somatosensory cortex (see Kaas and Florence, 2000).

The Posterior Group and the Posterior Ventromedial Nucleus

A poorly defined group of nuclei with somatosensory, auditory, and multimodal functions, located just caudal to the ventroposterior complex, has been referred to as the posterior group or complex (Jones, 1985). The complex is commonly divided into separate limitans, suprageniculate, and posterior nuclei. The posterior "nucleus" is often subdivided into medial, lateral, and even intermediate nuclei. The medial posterior nucleus (Pom) is composed of small cells that seem to merge with caudal VPI. There is some evidence that neurons with large cutaneous receptive fields and multimodal responses in the lateral cervical nucleus relay to Pom (see Metherate *et al.*, 1987, for a review). Cortical projections of the posterior complex appear to be to cortex of the lateral fissure near S2.

Recently, a part of the posterior group has been distinguished in monkeys and humans as posterior ventromedial nucleus (Craig *et al.*, 1994; Davis *et al.*, 1999; Blomquist *et al.*, 2000). The nucleus receives somatotopically organized nociceptive and thermoreceptive inputs from layer I of the contralateral dorsal horn of the spinal cord via the spinothalamic tract. VMpo relays to part of lateral parietal cortex in the lateral fissure. This pathway appears to be important in mediating pain and temperature sensations (see Perl, 1998). VMpo projects to cortex in the lateral fissure in the region of the insula (Craig *et al.*, 1996).

Anterior Pulvinar, Medial Pulvinar, and Lateral Posterior Nucleus

Other thalamic structures without direct inputs from second-order somatic afferents can be considered part of the somatosensory system on the basis of connections with somatosensory cortex. These include the anterior (oral) pulvinar with widespread projections to anterior parietal cortex, posterior parietal cortex, and somatosensory cortex of the lateral fissure (Cusick and Gould, 1990; Krubitzer and Kaas, 1992); the medial pulvinar with connections with posterior parietal cortex and the temporal lobe (see Mesulam, 1981); and the lateral posterior nucleus with projections to posterior parietal cortex (see Kaas and Pons, 1988). In humans, degeneration has been noted in the anterior pulvinar after damage to parietal cortex of the lateral fissure, while LP degenerates after lesions of posterior parietal cortex (Van Buren and Borke, 1972). The roles of these nuclei in the processing of somatosensory information are unknown, but the lack of direct sensory input and the widespread cortical connections suggest modulatory and integrative functions.

ANTERIOR PARIETAL CORTEX

The anterior parietal cortex was first considered as several separate fields in early architectonic studies (e.g., Brodmann, 1909), then as a single primary somatosensory field or S-I on the basis of electrophysiological studies in monkeys (see Marshall *et al.*, 1937), and more recently as several fields again, as the validity of early subdivisions has been experimentally supported (see Kaas, 1983).

Early attempts to subdivide anterior parietal cortex resulted in the differing conclusions of Campbell (1905), Smith (1907), Brodmann (1909), Vogt and Vogt (1919), and von Economo and Koskinas (1925). The subdivisions made by Campbell and Smith fell into disuse, but the proposals of Brodmann, Vogt and Vogt, and von Economo are in use today (see Chapter 27). In brief, Brodmann distinguished a mediolateral strip of cortex in the caudal bank of the central (rolandic) fissure as area 3, an immediately superficial and caudal strip on the caudal lip of the sulcus as area 1, and a more caudal strip on the surface of the postcentral gyrus as area 2. Area 3 was described as a field with densely packed small granular cells in layer IV, as is characteristic of sensory fields, while area 1 and 2 had less dominant sensory features. Brodmann further described a "transitional" field in anterior (deep in the central fissure) area 3 with both prominent sensory (layer IV granule cells) and motor (layer V pyramidal cells) features. Vogt and Vogt (1919) added to this proposal by stressing the distinctiveness of anterior area 3, and subdivided area 3 into two fields, area 3a and area 3b (see Jones and Porter, 1980, for a review). These four architectonically defined subdivisions of postcentral somatosensory cortex are in common use today. However, some investigators use the terms of von Economo (1929) for these subdivisions.

Rather than number cortical fields, von Economo used two letters to denote fields, with the first letter

indicating the lobe of the brain for the field, and the second letter indicating the order in which fields were described in the lobe, typically starting with fields of obvious sensory nature. In general, Brodmann (1909) and von Economo (1929) divided the human brain in different ways, but the proposed subdivisions of anterior parietal cortex are quite similar, the agreement suggesting the validity of the divisions. Von Economo's most anterior field, deep in the central sulcus, is area PA, equivalent to area 3a. The adjacent field, area PB, was noted as sensory "koniocortex" as a result of the powder-like appearance of the small granule cells in layer IV of what clearly corresponds to area 3b. Area PC, characterized by a less distinct laminar structure, is equivalent to area 1. A more caudal strip of cortex with a more distinct layer IV and layer VI, is area PD, closely corresponding to area 2.

Anterior Parietal Cortex in Monkeys

Over the last few years, research on monkeys has greatly clarified the significance of the four architectonic strips. Conclusions based on an extensive number of anatomical and electrophysiological studies are briefly summarized next.

Area 3b

We have termed area 3b S-I proper because it appears to be the homologue of the primary somatosensory area, S-I, in nonprimates (Kaas, 1983). Area 3b contains a separate, complete map of the cutaneous receptors of the body. The representation proceeds from the foot in medial cortex to the face and tongue in lateral cortex, with the digits of the foot and hand pointing "rostrally" (or more precisely, deep in the central sulcus), and the pads of the palm and sole of the foot caudal in 3b near the area 1 border. Subdivisions of area 3b related to body parts can be seen as myelin-dense ovals separated by myelin-light septa (Jain *et al.,* 1998, 2001). The most conspicuous septum transects lateral area 3b where it separates the more medial hand representation from the more lateral face representation. In the hand representation, a narrow strip of cortex for each digit is bounded on each side by septa. The hand representation is bordered laterally by a caudorostral series of three myelin-dense ovals, first for the upper face, next for the upper lip, and then for the lower lip and chin. Next, a succession of four ovals represent the contralateral teeth, the contralateral tongue, the ipsilateral teeth, and the ipsilateral tongue. Except for the rostrolateral representation of ipsilateral tongue and teeth (also see Manger *et al.,* 1996), the area 3b representation, like other representations in anterior parietal cortex, is almost exclusively of the contralateral body surface. The septa-distinguishing body parts in area 3b usefully serve as an anatomical guide for other types of experiments. They have not been described in area 3b of humans, but they may be present.

The activation of area 3b neurons is from RA-I and SA (I and possibly II) afferents relayed from the ventroposterior nucleus. RA-I and SA inputs appear to be segregated into bands (columns) in layer IV (Sur *et al.,* 1984). Most of the large relay neurons in VP project to layer 4 of area 3b via thick rapidly conducting afferents. Smaller neurons in the septa of VP and in VPI project to the superficial layers (Rausell and Jones, 1991). Major outputs in area 3b are to area 1, area 2, and S2, and these fields provide feedback inputs. Area 3b is callosally interconnected with areas 3b, 1, and 2, and S2 of the opposite hemisphere. The callosal connections are unevenly distributed, with the large representation of the glabrous hand and foot having less dense connections (Killackey *et al.,* 1983). The excitatory receptive fields do not reflect the callosal connections, which may contribute to surround suppression or enhancement, but instead are confined to locations on the contralateral body surface. In monkeys, inactivation or lesions of area 3b or area 3b together with areas 1 and 2, result in impairments in all but the crudest of tactile discriminations involving texture and shape (Hikosaka *et al.,* 1985; Randolph and Semmes, 1974; Zanios *et al.,* 1997; Brochier *et al.,* 1999). Small objects are unrecognized by touch and are ignored, and coordination during grasping is impaired.

Area 1

Like area 3b, area 1 contains a systematic representation of the body surface. The representation parallels and also roughly mirrors that in area 3b. Thus, the foot, leg, trunk, forelimb, and face are represented in a mediolateral cortical sequence (as in area 3b), but the digit tips are represented caudally near the area 2 border rather than rostrally near the area 3b border. Most neurons in area 1 are rapidly adapting and respond as if they were related to RA-I cutaneous receptors. A small portion of neurons, perhaps 5%, respond as if activated by RA-II (Pacinian) afferents. Neurons in area 1 tend to have larger and more complex receptive fields (Iwamura *et al.,* 1993), including stronger suppressive or inhibitory surrounds, than area 3b neurons (Sur, 1980; Sur *et al.,* 1985). Some neurons code for the direction of movement on the skin (Hyvarinen and Poranen, 1978). The activity patterns of most area 1 neurons, but not area 3b neurons, are modified according to what motor behavior will follow the stimulus (Nelson, 1984). Area 1 receives strong activating inputs from both area 3b and the

ventroposterior nucleus. The VP inputs are partly from collaterals of neurons projecting to area 3b, and the terminations are largely of thinner axons than those of area 3b. Feedforward cortical outputs are predominantly to area 2 and S2, and feedback inputs are from these fields. Callosal connections are more evenly distributed than for area 3b, but connections in the hand, foot, and parts of the face regions remain sparse (Killackey *et al.*, 1983). The callosal connections largely modulate neurons with receptive fields on the contralateral body surface, but some neurons with ipsilateral or bilateral body midline receptive fields occur (Taoka *et al.*, 1998). In monkeys, lesions of area 1 impair discriminations of texture rather than shape (Carlson, 1981; Randolph and Semmes, 1974).

Area 2

Area 2 contains a complex representation of both cutaneous and noncutaneous receptors. Neurons appear to be influenced by cutaneous receptors, deep receptors, or both. The portions of area 2 related to the hand and face are most responsive to cutaneous stimulation. The representation is in parallel with those in areas 3b and 1 so that the foot, trunk, hand, and face form a mediolateral cortical sequence. A mirror reversal organization of that in area 1 is apparent for parts of area 2 near the area 1 border. However, the overall organization is more complex than in areas 3b and 1, and some body parts are represented more than once in area 2 (Pons *et al.*, 1985b). Receptive fields for neurons in area 2 are typically, but not always, larger than those for neurons in areas 3b and 1, and receptive field properties appear to be complex (Iwamura *et al.*, 1993). Many neurons are best activated by stimuli of certain shapes or directions of movement. The inputs from deep receptors are largely those related to muscle spindles, suggesting that area 2 combines information about limb and digit position with tactile information during active touch. The major thalamic input to area 2 is from VPS (Fig. 28.4), but a sparse input to the hand region of area 2 originates in VP. Major cortical inputs are from areas 1, 3b, and 3a. There also appear to be sparse inputs from the motor cortex and to S2. Callosal connections are fairly evenly distributed and include the hand representation (Killackey *et al.*, 1983). Neurons, however, have excitatory receptive fields mainly on the contralateral body. Lesions of area 2 in monkeys impair finger coordination (Hikosaka *et al.*, 1985) and discriminations of shape and size (Carlson, 1981).

Area 3a

Area 3a, in the depth of the central sulcus, forms the fourth systematic representation of the body in anterior parietal cortex. Area 3a is largely activated by muscle spindle and other deep receptors, but some cutaneous activation is also apparent, especially in the portion devoted to the hand. The representation parallels that in area 3b, but few details are known. Neurons in area 3a are responsive during movements and are influenced by behavioral intentions ("motor-set," see Nelson, 1984). The major input is from VPS and roughly half of the VPS relay neurons project to both area 3a and area 2, thus providing the same information. Area 3a projects to area 2, motor cortex, S2, and other fields (Huerta and Pons, 1990; Huffman and Krubitzer, 2001). Callosal connections are uneven, but the hand region has somewhat more dense callosal connections than the hand representation in area 3b.

Subcortical Projections

All four fields project to a number of subcortical fields including feedback to the thalamic relay nuclei, the basal ganglia, the anterior pulvinar, the pons, the dorsal column nuclei, and the spinal cord (see Kaas and Pons, 1988). These projections presumably function in modifying motor behavior and sensory afferent flow. The projections to the pons are to neurons that relay to the cerebellum (Vallbo *et al.*, 1999) where they may modify motor responses.

Anterior Parietal Cortex in Humans

Several types of evidence support the conclusion that the organization and functions of anterior parietal cortex in humans are similar to those in monkeys.

Architectonic Fields

As in monkeys, four architectonic fields can be identified in the anterior parietal cortex of humans—areas 3a, 3b, 1 and 2 (see Chapter 27). In early studies, the presumed boundaries of these fields varied somewhat, and other terminologies were sometimes used. Recently, a number of studies have reconsidered the issue of how anterior parietal cortex is divided into fields with the benefit of new chemoarchitectonic methods (Zilles, *et al.*, 1995; White *et al.*, 1997; Qi *et al.*, 1998). Area 3b is the most obvious field, and investigators closely agree on boundaries. Area 3a is also easily recognized as distinct from 3b and area 4 (motor cortex), although area 3a appears to have rostral and caudal subdivisions. The area 1 border with area 2 is also reasonably distinct, while the area 2 border with posterior parietal cortex (area 5) is the least obvious, as in monkeys. Detailed comparison of the architecture of these fields in monkeys (where somatotopy and connections have been studied), chimpanzees, and humans (Qi *et al.*, 1998) perhaps provide the most compelling evidence for functionally

significant boundaries. Overall, as in monkeys, areas 3a and 3b have chemoarchitectonic features that are characteristic of primary sensory areas, while areas 1, and 2 resemble secondary areas (see Eskenasy and Clarke, 2000), supporting the conclusion that areas 3b, 1, and 2 constitute a processing hierarchy in humans as in monkeys.

As in macaque monkeys, area 3a of humans occupies the depths of the central sulcus, where it extends somewhat from the posterior to the anterior bank. In area 3a, layers IV and VI are less pronounced than in area 3b, and layer V pyramidal cells are more obvious. Area 3b occupies roughly the middle half or more of the posterior bank of the central sulcus. The field appears on the surface as the central sulcus ends near the medial wall, and the field extends into the medial wall. Area 3b is easily distinguished over most of its extent by the dense packing of small cells in layer IV, and the relatively dense packing of cells in layer VI. The small cells have led to the terms "koniocellular cortex" and "parvicellular core" (see Chapter 27). Most investigators show area 3b as ending with the lateral extent of the central sulcus, but area 3b extends anteriorly past the end of the sulcus in monkeys, where it represents the mouth and tongue. However, these body parts may be represented more medially in humans (see following discussion). Area 1 occupies the anterior lip of the postcentral gyrus where it borders area 3b on the posterior bank of the central sulcus and extends over the anterior third of the postcentral gyrus. Layers IV and VI are less densely packed with cells in area 1 than in area 3b, so the overall appearance is of less conspicuous lamination. Area 1 would roughly correspond to the posterior half of the postcentral area of Campbell (1905), and the full extent (allowing for a protrusion onto the upper bank of the central sulcus that is not shown) of area 1 of Brodmann. Area 1 is unlikely to be as wide as area PC of von Economo and Koskinas (1925), area 1 of Sarkossov and co-workers (see Braak, 1980), or the medial half of the paragranulous belt of Braak (1980). Area 2 is characterized by a denser layer IV than is found in area 1. The caudal border is difficult to delimit in monkeys even with the aid of electrophysiological data, and the precise location of this border remains uncertain in humans. However, the expected width of area 2 would approximate that of area 1.

Maps in 3a, 3b, 1, and 2: Evidence from Scalp and Brain Surface Recordings

As part of efforts to localize abnormal tissue and for other clinical reasons, recordings have been made from the scalp, from the surface of anterior parietal cortex, and from depth probes in the cortex of 3b of patients. In addition, neuromagnetic recordings and scalp-evoked potentials have been recorded from healthy volunteers. Such recordings support the conclusion that separate representations with different functions exist in areas 3a, 3b, 1, and 2. The hand representation in area 3b appears to correspond to a bulge in the central sulcus (Sastre-Janer *et al.*, 1998).

1. Electrical stimulation of cutaneous afferents in the median nerve of the hand results in a focus of evoked potentials after 20–30 ms in area 3b of the caudal bank of the central sulcus and a second focus after 25–30 ms in area 1 of the dorsolateral surface of postcentral cortex (see Allison *et al.*, 1988; Ploner *et al.*, 2000). The two foci support the view that area 3b and area 1 have separate maps of the body surface. The area 1 potentials are caudal to the area 3b potentials, indicating parallel maps, although a slight medial shift of the area 1 focus suggests a small displacement of one map relative to the other. As in monkeys, activity was generated only from stimulating contralaterally.

2. Stimulation of muscle afferents from the human hand results in a focus of activity that is caudal to that for cutaneous afferents (Gandevia *et al.*, 1984). A reasonable interpretation of this result is that the muscle afferents activate area 2, which is caudal to the activity produced in areas 1 and 3b by cutaneous afferents. More recently, evoked potentials to joint movement in the fingers has been attributed to area 2 activation (Desmedt and Ozaki, 1991), suggesting that joint receptor afferents as well as muscle spindle afferents activate area 2.

3. Another focus of activity produced by deep receptor or muscle spindle afferents is deep to foci related to cutaneous stimulation. Using neuromagnetic recordings, Kaukoranta *et al.* (1986) found that mixed nerve stimulation resulted in a deeper focus of activity in the central sulcus than cutaneous nerve stimulation. The results were interpreted as evidence for muscle spindle receptor input to area 3a and cutaneous receptor input to area 3b. Similar results have been obtained with fMRI (Moore *et al.*, 2000; also see Mima *et al.*, 1996, 1997).

4. More recently, noninvasive imaging techniques have been used to explore the organization of anterior parietal cortex in awake humans. While positron emission tomography (PET) has been useful for gross localization of sites of induced activity (see Burton *et al.*, 1993, 1999), functional magnetic resonance imaging (fMRI) has provided more resolution. Most notably, vibratory and other stimuli applied to different finger tips provided evidence for separate representations in areas 3a, 3b, 1, and 2 (Francis *et al.*, 2000; Gelnar *et al.*, 1998; Lin *et al.*, 1996).

5. Recordings of scalp-recorded evoked potentials in humans also support the conclusion that the maps of receptor surfaces in anterior parietal cortex are organized much as they are in monkeys. Thus, electrical stimulation of the little finger activates cortex 1–2 cm medial to that activated by stimulating the thumb (see Hari and Kaukoranta, 1985), and activity evoked in cortex by tapping the tongue is lateral to that produced by tapping the finger (Ishiko *et al.*, 1980). Measurements of magnetic fields, thought to be generated in the depths of the central sulcus in area 3b, indicated that the thumb, index finger, and ankle are represented at successively more medial position (Okada *et al.*, 1984). These methods have now been used to show that the tongue, lower lip, upper lip, thumb through little finger, palm, forearm, elbow, upper arm, chest, thigh, ankle, and toes are represented in a lateromedial order (Nakamura *et al.*, 1998; Fig. 28.7).

6. Recently, functional magnetic resonance imaging has been used to demonstrate the representation of thumb to little finger in a lateromedial sequence in area 3b, area 1, and area 2 (Kurth *et al.*, 1998, 2000; Francis *et al.*, 2000), and show that the tongue, fingers, and toes are represented in a lateromedial sequence (Sakai *et al.*, 1995). Hoshiyama *et al.*, (1996) located the representation of the lower lip lateral (inferior) to that of the upper lip, as in monkeys (Jain *et al.*, 2001).

7. Finally, extensive observations on the somatotopy of postcentral cortex in humans come from recordings of evoked slow waves from the brain surface during neurosurgery (Woolsey *et al.*, 1979). In a sequence of recording sites along the posterior lip of the central sulcus, from near the medial wall to over two thirds of the distance to the lateral (Sylvian) sulcus, potentials were evoked from foot, leg, thigh, trunk, and hand. In individual patients, there was some notable variability in organization so that the leg representation extended from the medial wall onto the dorsolateral surface in some but not other cases. By electrically stimulating the dorsal nerve of the penis and recording evoked potentials from anterior parietal cortex of humans during surgery, Bradley *et al.* (1998) provided evidence that the penis is represented in cortex lateral to that of the foot (also see Rothemund *et al.*, 2002).

8. More details about the sequence of representation of body parts in postcentral cortex have been obtained by electrically stimulating the brain in patients. Using higher levels of stimulating current than used for motor cortex, Foerster (1931, 1936a) was able to produce a postcentral motor map that roughly matched the precentral motor map in the mediolateral cortical order of leg, hand, and face (Fig. 28.8). Penfield and Rasmussen (1950) also reported evoked movements for postcentral stimulation sites, with the postcentral

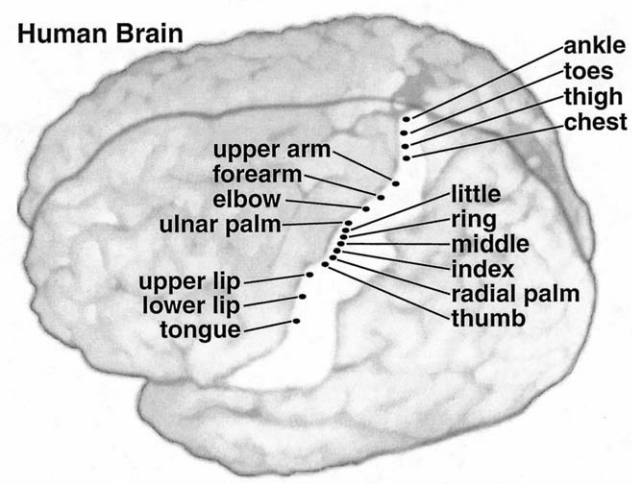

FIGURE 28.7 The organization of the anterior somatosensory cortex according to results obtained from the noninvasive recording of sensory-evoked magnetic fields (Nakamura *et al.* 1998). The center of activity for the different body parts are shown on the lip of the central sulcus, but the regions generating the magnetic fields were judged to be along the posterior bank o the central sulcus, most likely reflecting activity in area 3b and part of area 1. This map does not address the issue of separate representations, in each of area 3a, 3b, 1 and 2. In addition, center of activity for ankle and toes were likely generated from cortex on the melial wall.

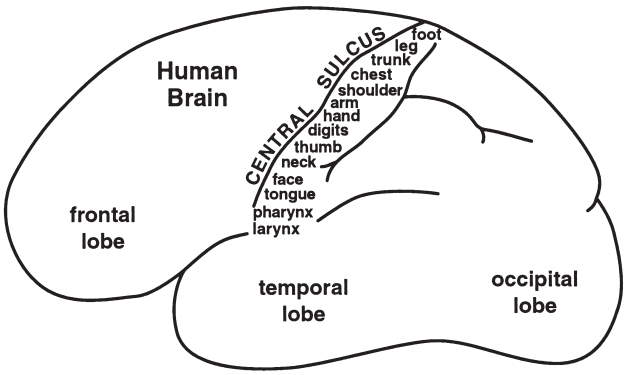

FIGURE 28.8 The order of representation in human postcentral cortex according to Foerster (1931). The summary was based on sensations reported when the surface of cortex was electrically stimulated. Most stimulation sites were in area 1 or area 2, as area 3b is largely in the central sulcus. No distinctions between the separate representations in areas 3a, 3b, 1, and 2 were made. Similar but more detailed maps were later produced by Penfield and Jasper (1954). Their maps placed the foot in the cortex of the medial wall and included the back of the head in center medial to the arm representation.

motor map roughly paralleling the precentral motor map in mediolateral organization. More precise information about the somatotopic organization of postcentral cortex has been obtained by noting where sensations are located during electrical stimulation of cortical sites. As one might expect, sensations evoked from stimulating the cortex match in somatotopic location the source of afferents related to the stimulation sites. Thus, stimulating cortex where evoked responses were obtained to ulnar nerve stimulation resulted in sensations largely confined to the ulnar hand (Jasper *et al.,* 1960). The extensive report of Penfield and Boldrey (1937) summarizes the results from stimulating precentral and postcentral cortex in 163 patients. Stimulation sites resulting in sensations were scattered over the precentral and postcentral gyri, and even a few more posterior or more anterior sites were effective. However, the vast majority of sites were along the posterior lip of the central sulcus and were probably evoking sensations by activating neurons in area 1 and perhaps even deeper to the electrode site in the superficial segment of area 3b. Surprisingly, the evoked sensations were not of light touch but were described as a localized numbness, tingling, or, infrequently, the feeling of movement. Sensations were evoked from the cortex extending from the medial wall, where the foot is represented, to the lateral fissure, where the mouth is represented. In general, the sensory order corresponds to the detailed maps compiled for monkeys (e.g., Nelson *et al.,* 1980). Cortex devoted to the foot and toes was most ventral on the medial wall. The back of the head and the neck were in medial cortex with the trunk representation, while the face was in lateral cortex separated from the head by the cortex devoted to the arm and hand. The digits were represented from little finger to thumb in a mediolateral sequence. As for the area 1 representation in macaque monkeys, the orbital skin and the nose were represented just lateral to the thumb in humans. In monkeys and humans, the tongue and mouth are most lateral in the responsive cortex. Thus, the mediolateral sequence of representation in the region of anterior area 1 appears to be quite similar in humans (Penfield and Boldrey, 1937; note more detail and some differences compared to summaries in Figs. 28.7 and 28.8) and monkeys (Nelson *et al.,* 1980). Little can be said about sequences of change in the rostrocaudal direction, however, because only microelectrode maps provide much detail about this direction in monkeys, and the surface stimulation and recordings in humans may involve amounts of tissue that are large relative to the narrow widths of the representations in areas 3b, 1, and 2.

9. Some aspects of somatosensory organization have long been known from the order of progressions of sensations or movements ("the Jacksonian march") during epileptic seizures. Because the seizure starts from a focus and spreads to more distant tissue, the order of sensations reflects the order of representation. Typical cases are described by Foerster (1936b) and Penfield and Jasper (1954). The orders of these sensory marches correspond to the evoked sensation map (Fig. 28.8). For example, a sensation of tingling or numbness in the thumb may be followed by tingling in the face, or a tingling that passes from thumb to fingers, to arm. Sensations are contralateral to the postcentral focus, and they seldom spread over many body parts (Mauguiere and Courjon, 1978).

Sensory and Perceptual Impairments Following Lesions

Damage to postcentral cortex, if extensive, causes severe and lasting impairments in pressure sensitivity, two-point discrimination, point localization, and discrimination of object shape, size, and texture (Corkin *et al.,* 1970; Head and Holmes, 1911; Roland, 1987a; Semmes *et al.,* 1960; Taylor and Jones, 1997). The spatial accuracy of motor movements is also impaired by the reduced sensory control (Aglioti *et al.,* 1996). However, the detection and crude localization of tactile stimuli remains intact. Roland (1987a) reported that lesions of the deep and anterior part of the hand region of postcentral cortex, presumably including much but not all of the area 3b representation and probably the area 1 representation, abolished the ability to discriminate edges from rounded surfaces, while lesions of the surface, apparently involving areas 1 and 2, left the ability to distinguish edges from rounded surfaces, but removed the ability to discriminate shapes and curvatures. This difference is similar to that reported for monkeys where lesions of areas 3b, 1, and 2 permanently abolished the ability to distinguish the speed of moving tactile stimuli (Zainos *et al.,* 1997) where lesions of area 1 impaired texture discriminations, while area 2 lesions altered discrimination of shape (Carlson, 1981; Randolph and Semmes, 1974; also see Lamotte and Mountcastle, 1979). Inactivations of the finger representations in area 2 of monkeys led to a major deficit in finger coordination while small food pieces were often ignored after contact with inactivation of area 3b (Hikosaka *et al.,* 1985). Remarkably, small lesions of part of the hand representation result in no obvious impairment in humans (Evans, 1935; Roland, 1987a, b). Roland (1987a) estimated that a notable impairment resulted only after lesions involving three fourths or more of the hand region of anterior parietal cortex. Furthermore, the larger the lesion of the region, the greater the impairment (Roland, 1987b). The preservation of abilities after

lesions to parts of somatotopically organized representations could be the result of cortical reorganizations that result in the recovery of lost parts of representations. Removing part of a representation or deactivating part of a representation in monkeys can be followed by cortical reorganization, even in adults, so that remaining cortex is activated by skin formerly related to the damaged area, and deactivated cortex becomes responsive to alternative inputs (see Kaas and Florence, 2000, for a review).

POSTERIOR PARIETAL CORTEX

The posterior parietal region is an arbitrary subdivision of the brain that includes most of the parietal lobe caudal to area 2 but excludes the cortex of the lateral (Sylvian) fissure and the supplementary sensory area of the medial wall. Current investigators commonly refer to the architectonic subdivisions of Brodmann (1909) or von Economo (1929), and both systems are in use. However, research on monkeys suggests that the proposed fields (areas 5a, 5b, 7a, and 7b or areas PD, PE, PF, and PG) have little validity other than denoting general regions of the lobe. Other subdivisions have been suggested by patterns of connections and the response characteristics of neuronal populations, but the organization of posterior parietal cortex is not well understood. Electrical stimulation in humans seldom produces any sensations or motor responses (Penfield and Rasmussen, 1950), although Foerster (1931, 1936a) was able to produce hand movements and leg movements on occasion with high levels of stimulating current. Posterior parietal cortex has been implicated in both somatosensory and visual functions as well as in premotor planning, but lesions do not produce simple sensory impairments. Rather, large lesions produce a variety of complex symptoms, many included within the general category of contralateral sensory neglect or inattention. In monkeys, impairments are basically the same regardless of the hemisphere of the lesion, but in humans, lesions of the right or "minor" hemisphere produce a much more profound defect. Major reviews of posterior parietal cortex organization and function in monkeys and humans include those of Mountcastle (1975), Lynch (1980), Hyvarinen (1982), Yin and Medjbeur (1988), Andersen *et al.* (1997), and Colby and Goldberg (1999). AAlso, see Chapter 26 for connections of subdivisions of posterior parietal cortex with motor areas of the frontal lobe.

Posterior Parietal Cortex in Monkeys

Since posterior parietal cortex in macaque monkeys may have many features or functional organization in common with posterior parietal cortex in humans, a brief review of current views of connections, neuron properties, and functional subdivisions in monkeys serves as a guide. As a point of caution, data in monkeys are still limited, and a consensus of opinions has not yet occurred.

One currently acceptable scheme for subdividing posterior parietal cortex in macaque monkeys is

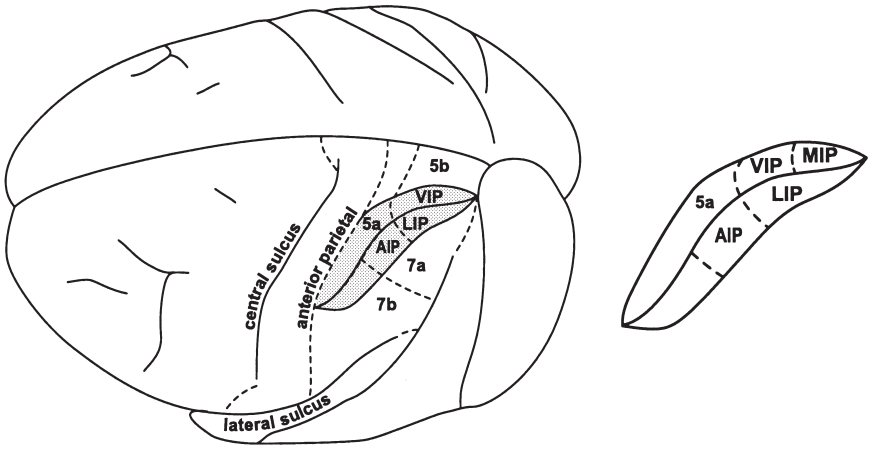

FIGURE 28.9 A dorsolateral view of the brain showing proposed subdivisions of posterior parietal cortex in macaque monkeys. Areas 5a, 5b, 7a, and 7b are traditional subdividions from Brodmann (1909) and Vogt and Vogt (1919). The ventral intraparietal region (VIP) and the lateral intraparietal region (LIP) are subdivisions that have been distinguished by visual and visuomotor connections (Anderson *et al.*, 1985; Maunsell and Van Essen, 1983). Other recently proposed fields include the medial (MIP) and the anterior (AIP) intraparietal region. The MIP region is also known as the parietal reach region (PRR).

shown in Figure 28.9 (also see Preuss and Goldman-Rakic, 1991; for an alternative proposal see Pandya and Seltzer, 1982; Seltzer and Pandya, 1980). The present proposal follows the traditional subdivision into areas 5a, 5b, 7a, and 7b introduced by Brodmann and the Vogts (Fig. 28.9), with the addition of the ventral intraparietal area (VIP) of Maunsell and Van Essen (1983) and the lateral intraparietal area (LIP) of Andersen *et al.* (1985). Both VIP and LIP overlap a region distinguished by Seltzer and Pandya as POa. Additional medial intraparietal (MIP), posterior intraparietal (PIP) and anterior intraparietal (AIP) areas have also been proposed. The most obvious flaw with the scheme summarized in Figure 28.9 is that considerable evidence suggests that anterior 7b is similar to area 5a in having predominantly somatosensory connections and functions, and that the distinction between 7b and 5a is poorly justified. Also, areas 5a, 5b, 7a, and 7b occupy large regions that are likely to be subdivided by future investigators (see Lewis and Van Essen, 2000a).

Area 5a

Area 5a is not uniform in histological structure, connections, and neuron types, but clear subdivisions have not yet been established. Subdivisions of anterior parietal cortex, especially area 2, provide direct somatosensory inputs from both deep and cutaneous receptors (Pons and Kaas, 1986). Major thalamic inputs are from the anterior pulvinar and the lateral posterior nucleus (see Yeterian and Pandya, 1985), nuclei without significant sensory inputs from the brainstem or spinal cord. However, a specialized portion of area 5 (Pons *et al.,* 1985a), receives some input from the ventroposterior nucleus (Pons and Kaas, 1986). Feedforward cortical projections are to area 7, S2, motor and premotor cortex, limbic cortex, and parts of the superior temporal gyrus; callosal connections are largely between matched regions of area 5 (see Hyvarinen, 1982). Subcortical projections include thalamic nuclei, the basal ganglia, the pontine nuclei, and the spinal cord through the pyramidal tract. Neuron properties include those related to both cutaneous and deep receptors and to passive and especially active limb movement (Iwamura and Tanaka, 1996). Receptive fields are generally much larger than those in areas 1 and 2. Specific combinations of positions in several joints may be the most effective stimulus for many neurons (Hyvarinen, 1982). Many neurons in area 5a respond to ipsilateral as well as contralateral stimulation, with receptive fields including the digits of both hands, and sometimes extending up onto the arm and even the trunk (Taoka *et al.,* 1998). Some neurons have both somatosensory and visual receptive fields (Iriki *et al.,* 1996), and visual stimuli may modulate proprioceptive activity. Thus, neurons in area 5a that were responsive to arm position when the arm was covered from view responded better to seeing the arm or even a fake arm in the correct position, but not better to a fake arm in the wrong position (Graziano *et al.,* 2000). Finally, ablation of cortex of the intraparietal sulcus including area 5a interferes with the ability to orient the hand correctly in grasping (Denny-Brown and Chambers, 1956). Overall, the results suggest that area 5a is involved in providing a mental model of what the body is doing, and thereby guiding relevant behavior such as reaching for objects.

Area 5b

Area 5b appears to be largely somatosensory in function, despite its position near the visual cortex. Major cortical inputs are from area 5a, while outputs include adjoining parietal cortex of the medial wall and parts of 7b as well as cortex caudal to S2 in the lateral fissure, and dorsal premotor cortex (Pandya and Seltzer, 1982; Marconi *et al.,* 2001).

Area 7b

Area 7b also appears to be involved in the higher-order processing of somatosensory information. Inputs to the anterior part include those from the anterior parietal cortex (Pons and Kaas, 1986). Thalamic connections include the ventral lateral nucleus and the anterior pulvinar. Cortical projections include premotor and prefrontal areas of the frontal lobe, more caudal regions in posterior parietal cortex, and the superior temporal sulcus (Cavada and Goldman-Rakic, 1989; Lewis and Van Essen, 2000a). Neurons respond to touching the skin, particularly on the head and face in anterior 7b and the hand and arm in posterior 7b (Krubitzer *et al.,* 1995; Leinonen, 1984).

Area 7a

Area 7a is related to visual and visuomotor activities. The visual functions are reflected in both connection patterns and neuron properties. Visual inputs include those from superior temporal cortex involved in processing visual motion information (see Maunsell and Van Essen, 1983). Other visual inputs are from adjacent dorsal portions of the prelunate gyrus (May and Andersen, 1986). Connections also include the cortex of the intraparietal sulcus, cortex of the medial wall, prefrontal cortex, multimodal and visual areas of the superior temporal sulcus, and cortex of the lateral sulcus (Cavada and Goldman-Rakic, 1989). Other connections are with the medial pulvinar. Several classes of visual and visuomotor neurons have been described (see Hyvarinen, 1982). Visual tracking

neurons respond during the visual pursuit of targets. Another class of neurons is activated during fixation on a moving or stationary visual target. Some neurons seem to be important to the visual guidance of reaching movements with the hand. Many neurons respond to visual stimuli, but these neurons respond poorly to visual stimuli when monkeys are not attending and visual responses are suppressed when gaze and attention is directed to the stimulus (Steinmetz *et al.,* 1994). The presence of neurons responding both to visual stimuli and to visuomotor and reaching behavior implicates areas 7a in guiding eye and hand movements.

LIP, VIP, PIP, and MIP

The cortex of the intraparietal sulcus has been subdivided into several proposed areas including the lateral intraparietal area (Andersen *et al.,* 1985), the ventral intraparietal area (Maunsell and Van Essen (1983), and sometimes the medial intraparietal area, and the posterior intraparietal area (Colby and Goldberg, 1999). Near the anterior end of the sulcus, the anterior intraparietal area has been distinguished (Preuss and Goldman-Rakic, 1991). There is evidence for functional and structural distinctions between these proposed fields, but even this number of proposed fields may not capture the architectonic complexity of the region (Lewis and Van Essen, 2000a). Seltzer and Pandya (1980) include VIP and LIP in their larger POa. LIP appears to be largely involved in attentional and oculomotor functions (Kusanoki *et al.,* 2000; Andersen *et al.,* 1997). Most neurons in LIP respond strongly before saccadic eye movements to targets in the neuron's movement field (Shandlen and Newsome, 1996), and to visual stimuli–evoking eye movements. With training with auditory signals for eye movement, some neurons come to respond to auditory signals (Grunewald *et al.,* 1999). LIP receives visual inputs from extrastriate visual areas (Blatt *et al.,* 1990), is interconnected with nearby posterior parietal fields, and projects to the frontal eye fields and the superior colliculus (Lewis and Van Essen, 2000b; May and Andersen, 1986). Eye movements can be induced by electrical stimulation of LIP (Thier and Andersen, 1998).

VIP has both visual and somatosensory functions. Most neurons respond to either visual stimuli or light touch (Duhamel *et al.,* 1998). The area seems to contain matched representations of the body surface and visual space. Small foveal visual receptive fields related to neurons with small tactile receptive fields on the muzzle and larger peripheral visual receptive fields were determined for neurons with larger receptive fields on the side of the head. VIP may have a crude somatotopic organization with nearly all of the area devoted to the head. Somatosensory inputs arise from areas 1 and 2, 5 and 7b, and S2 and nearby areas of the lateral sulcus (Lewis and Van Essen, 2000b). There also may be inputs from vestibular cortex and auditory areas. Visual inputs are from visual areas of the dorsal stream (especially the middle temporal visual area) and LIP. Outputs include projections to the frontal eye field and adjoining portions of the frontal lobe, as well as the ventral premotor area.

MIP occupies intraparietal cortex just medial and caudal to LIP. A proposed parietal reach region (PRR) overlaps MIP, but is larger. MIP is thought to function in the planning of reaching to targets with the arm (Snyder *et al.,* 2000). This cortex receives inputs from somatosensory and dorsal stream visual areas and projects especially to dorsal premotor cortex (Caminiti *et al.,* 1996).

AIP or the anterior intraparietal area may be included in area 5a or 7b of many reports. AIP occupies cortex on the anterior bank and borders of the intraparietal sulcus just anterior to LIP and VIP. AIP has somatosensory connections with S2 and adjoining areas, area 5 and area 7, as well as with VIP and LIP (Lewis and Van Essen, 2000b). A major target is an anterior division of ventral premotor cortex. Area AIP is thought to be important in the organization of grasping movements with the hand (Rizzolatti *et al.,* 1997). The term "PIP" is sometimes applied to the posterior portion of the intraparietal sulcus.

Posterior Parietal Lobe Function in Humans

Concepts of posterior parietal lobe function in humans are largely derived from the much discussed behavioral changes that typically follow large lesions (for reviews, see Critchley, 1949; Denney-Brown and Chambers, 1958; DeRenzi, 1982: Hyvarinen, 1982; Mesulam, 1981, 1983; see Chapter 27 for architecture). In brief, patients with posterior parietal lobe injury tend to neglect visual and tactile information coming from visual space or the body surface opposite the lesion (see Moscovitch and Behrman, 1994; Pouget and Driver, 2000). The defect is most severe after lesions of the right hemisphere that is nondominant for language. The defect may be profound, leading to bizarre symptoms, or it may be quite mild, resulting in little notable change in spontaneous behavior. Mild defects are typically revealed by bilateral stimulation. The expected result is that the ipsilateral stimulus is preferentially attended, either immediately or after a series of trials. In more dramatic cases, there is a denial of the existence of the contralateral (typically left) side of the body and of objects in the left side of the visual space. Patients may fail to shave or dress the neglected

side, and food on the contralateral side of the plate may be uneaten. The defect can be characterized as a change in attention, because it is clearly not a result of a sensory impairment. More specifically, a unique aspect of the impairment seems to be a difficulty in the ability to disengage attention from a current focus and move that attention to a new focus in the contralateral world (Posner *et al.*, 1984). Right-hemisphere damage produces a reluctance or inability to redirect attention from the right visual field to the left visual field, as well as a reluctance to shift attention within the left visual field (Baynes *et al.*, 1986). Other defects also occur (see Sirigu *et al.*, 1996).

1. Errors may exist in localizing objects so that accurate pointing does not occur. Right and left may be confused, and the patient may have difficulty in moving from place to place.
2. Eye movement patterns are altered, and a reduction in spontaneous eye movements and tracking movements may occur.
3. Errors in reaching into the contralateral hemifield are common. Targets may be missed by several inches. In addition, corrections of reach to displaced targets during reach are impaired during posterior parietal cortex inactivation with transcranial magnetic stimulation (Desmarget *et al.*, 1999).
4. Lesions of the right or minor hemisphere may produce a defect in drawing even simple objects such as a house and in constructing simple models. Furthermore, during constructional tasks, blood flow is increased in posterior parietal cortex (Roland *et al.*, 1980). Blood flow also increases in the superior parietal cortex and intraparietal sulcus of humans performing mental rotations of the hand (Bonda *et al.*, 1995, 1996).
5. Lesions, especially those involving the anterior half of posterior parietal cortex, may produce somatosensory deficits. Reported changes include impairment in length discrimination, weight judgment, shape discrimination, and limb position sense (see Hyvarinen, 1982).
6. Difficulties may exist in performing symbolic gestures and pantomimes. This is attributed to an inability to access or store representations of movements adequately.

Even though posterior parietal cortex is not uniform in function, much of the region appears to relate to premotor planning in relation to eye movements and reach. Clearly, the anterior part of posterior parietal cortex is more related to the somatosensory system, and the posterior part is more related to the visual system. The connections of posterior parietal cortex suggest that a motivational component depends on relationships with limbic cortex of the medial wall and perhaps the ventral temporal lobe (see Mesulam, 1981). Connections with the frontal lobe and connections with subcortical motor structures such as the superior colliculus and basal ganglia undoubtedly are important in initiating behavior. More specifically, Mountcastle (1975) hypothesized that posterior parietal cortex functions as a "command" center for movements in immediate extrapersonal space. Finally, the functional asymmetry of posterior parietal cortex in humans can be explained if the right hemisphere contains the neural substrate for attending to both sides of space, though predominantly contralateral space, while the left hemisphere is almost exclusively concerned with contralateral space (Mesulam, 1981). Thus, unilateral lesions of the left hemisphere are partially compensated by the functions of the right hemisphere, but the reverse does not hold. This difference may relate to the specialization of the left hemisphere for language.

SOMATOSENSORY CORTEX OF THE MEDIAL WALL: THE SUPPLEMENTARY SENSORY AREA AND CINGULATE CORTEX

The organization of the medial parietal cortex is not well understood. Penfield and Jasper (1954) postulated the existence of a supplementary sensory area, as an analogy to the supplementary motor area, on the medial wall of the cerebral hemisphere where electrical stimulation evoked sensations from the contralateral leg, arm, and face. Later, Woolsey *et al.* (1979) reported in a single patient that sensations were obtained from the arm or leg after electrical stimulation of sites on the medial wall. There have been only a few experimental studies in monkeys that relate to the existence or organization of a supplementary sensory area (see Murray and Coulter, 1982, for a review). In macaque monkeys, neurons on the medial wall respond to somatosensory stimuli, and there is some suggestion of anterior sites relating to the lower body and posterior sites relating to the upper body. These neurons have large receptive fields and appear to have inputs related to both skin and deep receptors. Major inputs are from dorsolateral posterior parietal cortex, especially the anterior half. Other connections of medial parietal cortex are with premotor and supplementary motor cortex and the lateral posterior nucleus of the thalamus. More recently, there is evidence for projections to the spinal cord and even sparse projections to primary motor cortex (see Wu *et al.*, 2000). The connections of posterior parietal cortex of the medial wall to

a presumptive supplementary motor area and adjoining sensory regions of cingulate cortex (see Mesulam, 1981; Chapter 26) may function to mediate motivational and attentional aspects to perception and behavioral plans (also see Chapter 24).

SOMATOSENSORY CORTEX OF THE LATERAL (SYLVIAN) SULCUS

Much of the cortex of the upper bank of the lateral sulcus and some of the cortex of the insula are somatosensory in function. Because of the general inaccessibility of this region in humans, there have been only a few attempts to reveal aspects of functional organization by stimulation or recording. However, there is clear evidence for the existence of several areas from fMRI. The lateral somatosensory cortex may be part of a critical corticolimbic pathway for touch (see Friedman *et al.*, 1986), as monkeys have severe deficits in tactile memory after combined removal of the amygdala and hippocampus (Murray and Mishkin, 1984a). The pathways for input to these limbic structures involve convergent inputs from areas 3a, 3b, 1, and 2 of the anterior parietal cortex and a relay from S2 over more rostral subdivisions of the somatosensory cortex in the lateral sulcus (Fig. 28.10). Because this lateral pathway is best understood in macaque monkeys, the organization of lateral somatosensory cortex in these primates is briefly reviewed next.

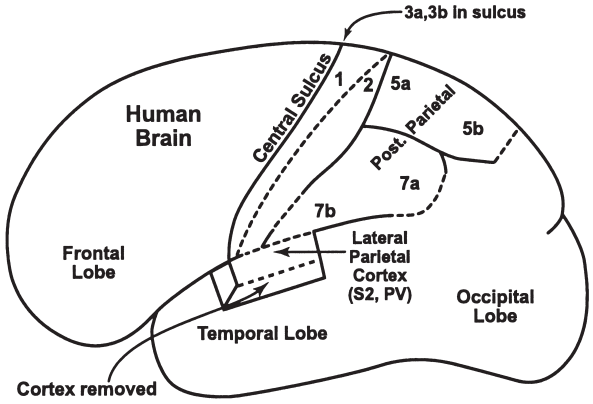

FIGURE 28.10 Posterior parietal and lateral cortex of humans The posterior parietal cortex has been variously subdivided by early investigators (for example, see Campbell, 1905; Smith, 1907; Brodmann, 1909; Economo and Koskinas, 1925; Vogt and Vogt, 1919, 1926). the subdivisions shown here reflect those of Vogt and Vogt, with the second somatosensory area (S2) and the parietal ventral area (PV) of the lateral sulcus added. Much of the region denoted here as 7b would be in Brodmann's area 40.

Organization of Cortex of the Lateral Sulcus in Monkeys

Much progress has been made in recent years in understanding the S2 functional organization of lateral somatosensory cortex in monkeys. One subdivision that has been repeatedly described is the second somatosensory area (S2), named because it was the second representation after S1 discovered in cats and later in other mammals. S2 appears to border the lateral extension of areas 3b and (or) areas 1 and 2 in monkeys, according to species (see Cusick *et al.*, 1989; Krubitzer and Kaas, 1990; Pons *et al.*, 1987; Krubitzer *et al.*, 1995; Burton *et al.*, 1995; Disbrow *et al.*, 2000). S2 forms a systematic representation of the contralateral body surface on the upper bank of the lateral sulcus with the face along the outer lip, the hand deeper in the sulcus, and the foot near the fundus. A parietal ventral area (PV) forms a second representation of the contralateral body surface just rostral to S2 (see Disbrow *et al.*, 2000, for review). S2 and PV adjoin along representations of the hand, and they form mirror-image representations of each other. PV and S2 are bordered in the fundus of the lateral sulcus by a ventral somatosensory area (VS), which extends somewhat onto the lower bank of the central sulcus and insula to border secondary auditory fields (Cusick *et al.*, 1989; Krubitzer *et al.*, 1995). More recent evidence suggests that VS actually includes separate rostral and caudal representations, one bordering PV and the other S2 (see Qi *et al.*, 2002). A caudomedial secondary auditory area (CM), that is very close and perhaps overlapping PV is responsive to both auditory and somatosensory stimuli (Schroeder *et al.*, 2000).

Cortex caudal to S2 includes part of 7b that extends into the lateral sulcus, and the retroinsular area (Ri). Neurons in both lateral 7b and Ri are responsive to cutaneous stimuli (Krubitzer *et al.*, 1995). Cortex caudal to VS on the lower bank of the lateral sulcus has neurons responsive to visual and somatosensory stimuli (Krubitzer *et al.*, 1995). Cortex rostral to PV receives inputs from PV and S2 and has been called the parietal rostral area (PR) (Krubitzer *et al.*, 1995; Krubitzer and Kaas, 1990). This somatosensory area may be part of the larger granular insular region described by Jones and Burton (1976).

S2 and PV receive feedforward inputs from all four areas of anterior parietal cortex (Burton *et al.*, 1995; Krubitzer and Kaas, 1990; Friedman *et al.*, 1986; Qi *et al.*, 2002), and removing these areas deactivates S2 and PV (Pons *et al.*, 1987; Burton *et al.*, 1990; Garraghty *et al.*, 1990). The inputs from the ventroposterior inferior nucleus do not seem to be capable of independently activating these neurons. Neurons in both S2 and PV respond to cutaneous stimulation within receptive

fields that are generally larger than those in area 3b or area 1. Inputs to S2 and PV from areas 3a and 2 undoubtedly provide some activation from deep receptors. Inputs from S2 and PV of the opposite hemisphere are particularly dense, and some bilateral receptive fields have been reported, although ipsilateral stimuli largely modulate activity based on contralateral receptive fields. Neurons in S2 may code for stimulus features such as roughness (Pruett *et al.*, 2000), but the response properties of PV and S2 neurons have not been extensively studied. Lesions of the PV-S2 region greatly impair the abilities of monkeys to make tactile discriminations and identifications (Murray and Mishkin, 1984b). Projections of PV and S2 include PR and perirhinal and entorhinal cortex (Friedman *et al.*, 1986). The processing series from anterior parietal to lateral parietal to perirhinal cortex and then to the hippocampus constitutes a proposed lateral hierarchy of areas involved in the recognition and memory of objects by touch (Mishkin, 1979; Murray and Mishkin, 1984a). The insula of lateral parietal cortex also contains a region of terminations of pain and temperature afferents from the VMpo nucleus of the thalamus (Craig *et al.*, 1994, 2000). The relationship of this termination zone to other fields of lateral parietal cortex is not yet clear. In addition, there is evidence of a thalamic relay of vestibular information to cortex of the insula (see Guldin *et al.*, 1992) called the parietoinsular vestibular cortex (PIVC). This vestibular region may overlap much of PV or Ri.

Lateral and Insular Parietal Cortex in Humans

There is increasing evidence that at least some of the cortex in the lateral fissure of humans is organized much as in monkeys. Most notably, a recent fMRI study using tactile stimuli applied to various body parts provided evidence for both S2 and PV, organized as mirror-reversal images of each other, both proceeding from face to forelimb to hindlimb from near the lip of the upper bank to the depths of the lateral fissure (Disbrow *et al.*, 2000; also see Burton *et al.*, 1993; Maeda *et al.*, 1999). Both S2 and PV demonstrate some increased activity with ipsilateral stimulation and more activity with bilateral stimulation (Disbrow *et al.*, 2001; Maldjian *et al.*, 1999). Much earlier Penfield and Rasmussen (1950) had electrically stimulated cortex in S2/PV region and produced sensations of numbness and tingling in contralateral skin locations, with sensations from the face, from the lip of the lateral fissure, and from the hand and leg from successively deeper locations on the upper bank. Recordings of evoked potentials with surface electrodes also support the view that the leg is represented deep to the hand and face in the fissure (Woolsey *et al.*, 1979). When subjects were instructed to attend to the roughness or duration of somatosensory stimuli, a greater increase in blood flow was found in the S2/PV region than in anterior parietal cortex (Burton *et al.*, 1999). As for monkeys, the lateral parietal and insular region in humans likely subserves tactile discriminations and recognition. Significantly more activity was found in the posteroventral insula in PET studies during tasks requiring tactual memories (Bundo *et al.*, 1996). While S2 and PV damage may not alter simple tactile abilities (see Roland, 1987a), disturbances in the ability to make tactile discriminations have been reported after lesions of the region (Caselli, 1993; also see Reed *et al.*, 1996, for a case of tactile agnosia after a lesion of the inferior parietal cortex). There is evidence for a relay of thalamic pain and temperature information to the insular region in humans (see Craig *et al.*, 1994).

SUMMARY

This chapter describes the organization of the parts of the somatosensory system thought to be concerned with object identification and tactile discriminations. The relevant sensory information depends on receptors in skin, muscles, and joints and is relayed over parallel afferent pathways to reach the ventroposterior complex of the thalamus. The ventroposterior complex includes a ventroposterior "proper" nucleus composed of ventroposterior lateral and ventroposterior medial subdivisions. The ventroposterior nucleus processes and relays information from rapidly and slowly adapting cutaneous receptors to area 3b of the cortex and information from rapidly adapting cutaneous receptors to area 1. Sparse projections exist to parts of area 2. The ventroposterior superior nucleus relays largely muscle spindle receptor information to areas 3a and 2. The ventroposterior inferior nucleus projects to the second somatosensory area (S2), but the significance of this projection is uncertain. The lateral posterior nucleus, the anterior pulvinar, and the medial pulvinar, without obvious sensory inputs, interconnect with subdivisions of somatosensory cortex, perhaps to modulate neural activity.

The somatosensory cortex includes anterior parietal cortex with four functional subdivisions (areas 3a, 3b, 1, and 2); posterior parietal cortex with at least five or six fields; the supplementary sensory area of the medial wall of the cerebral cortex; and the second somatosensory area and other fields in cortex of the upper bank and insula of the lateral fissure. Areas 3a, 3b, 1, and 2 all contain somatotopic representations of body receptors, with area 3b corresponding to the

primary field (S1) of nonprimates, though it is common and traditional to include all four fields of anterior parietal cortex in S-I. Basic processing of tactile information occurs in area 3b, higher-order processing of tactile information occurs in area 1, and tactile information is combined with limb and digit position information in area 2 for the recognition of shapes and objects during active touch. Muscle spindle receptor information in area 3a, combined with inputs from area 2, may relate to motor control mechanisms.

Information from anterior parietal cortex is relayed laterally to S2 and adjoining fields as part of a processing sequence related to object identification and memory, and to posterior parietal cortex for computations relating to intention, attention, motor behavior, and multimodal motor control. In particular, much of the posterior parietal cortex relates to the visual control of eye, hand, and arm movements via outputs to frontal cortex and to brainstem centers. Posterior parietal cortex is asymmetrical in humans, with the right (nondominant) hemisphere having a more dramatic role in mediating attention and motor behavior for the contralateral body and visual space. The significance of the supplementary sensory area is uncertain, but a role in motivation and other limbic cortex functions seems likely.

CHAPTER

29

Trigeminal Sensory System

PHIL M. E. WAITE and KEN W. S. ASHWELL
Department of Anatomy, School of Medical Science
The University of New South Wales
Sydney, Australia

Although generally considered part of the somatosensory system, the trigeminal sensory system has been assigned its own chapter for this second edition of the *Human Nervous System*. This chapter will address the unique anatomy of the pathway for facial sensations, involving the trigeminal ganglion and its associated nuclei within the brainstem. We will also comment on the innervation of specialized cranial structures such as the teeth, tongue, meninges, cornea, conjunctiva, and oral and nasal mucosa. Recent studies on the involvement of the trigeminal system in clinically relevant conditions such as toothache, headache, and trigeminal neuralgia are considered.

In outline, the trigeminal or fifth cranial nerve is a general sensory nerve carrying touch, temperature, nociception, and proprioception from the superficial and deep structures of the face. Trigeminal means literally "three twins" and refers to the three peripheral nerves that take origin together (i.e., are born) from each ganglion, the ophthalmic (V_1), maxillary (V_2), and mandibular (V_3) divisions. The central processes of the trigeminal ganglion cells form the trigeminal sensory root (or portio major), which enters the brainstem at midpontine level. Most fibers bifurcate to terminate in both the main sensory nucleus (Pr5, principal trigeminal nucleus) and the nuclei of the spinal trigeminal tract (Sp5, spinal trigeminal nuclei). A unique feature of the pathway is the location of proprioceptive neurons in the mesencephalic nucleus (Me5) in the brainstem, rather than in the trigeminal ganglion. From the trigeminal nuclei, second-order fibers concerned with sensation project via the dorsal and ventral trigeminothalamic tracts to several regions of the somatosensory thalamus, adjacent to projections from spinal inputs. Facial inputs then run parallel to the spinal thalamocortical projections to supply somatosensory regions of the cortex. The trigeminal motor nucleus and nerve, innervating the muscles of mastication, the mylohyoid

and anterior digastric, and the tensor tympani and tensor veli palatini muscles, will not be considered here. For the development of the receptors, trigeminal nerves and ganglion, see Chapter 4.

RECEPTORS AND THEIR INNERVATION

Receptors for the facial skin and scalp (reviewed Darian-Smith, 1973; Iggo, 1974) are similar to those in hairy skin of other body regions and are fully discussed in Chapter 28. For the glabrous skin of the lips, a comparative study reported a variety of encapsulated receptors, with the most complex structures seen in primates including man (Kadanoff *et al.*, 1980). Muscle spindles in facial and jaw muscles are similar in structure to those elsewhere in the body and are only discussed with reference to the location of their afferent somata and central connections. While innervation of the temporomandibular joint also corresponds to that for other synovial joints, it has attracted considerable recent clinical interest and so is briefly reviewed here.

Skin of the face is remarkable for its high tactile sensitivity, with pressure thresholds lower than any other body regions, in both men and women (Weinstein, 1968). The upper lip, nose, and tip of the tongue have the lowest detection thresholds reported (Rath and Essick, 1990). Regional differences in sensitivity to different stimuli have been reported, with the glabrous lip skin (vermilion) being especially sensitive to vibration and motion, compared with adjacent perioral hairy skin (Rath and Essick, 1990). For two-point discrimination, fingers have rather lower values (2.1 mm) than facial skin (3.3 mm, nose; 5–6 mm, upper perioral skin), although the tip of the tongue was lowest at 0.99 mm (McNutt, 1975; Rath and Essick, 1990).

Recordings from the human infraorbital nerve by microneurography, showed a high proportion of receptive fields at the angle of the mouth, indicating particularly dense innervation of perioral skin (Johansson *et al.*, 1988). Both slowly and rapidly adapting responses were recorded, similar to those reported for the hand (Vallbo *et al.*, 1979). Receptive fields for rapidly adapting units ranged from 2 to 118 mm^2 (median 17 mm^2) compared with 2 to 88 mm^2 (median 7 mm^2) for slowly adapting responses. Rapidly adapting thresholds were lower (median 0.5 mN) than for slowly adapting responses (cutaneous units, median 1 mN; mucosal, median 1.5 mN). A recent study on the tongue, also using microneurography to record from single nerve fibers, indicates that receptive fields (1–20 mm^2, mean 2.4 mm^2) and detection thresholds (0.03–2 mN, mean 0.15 mN) may be lower there than for any other body region (Trulsson and Essick, 1997).

Innervation of Specialized Cranial Structures: Teeth and Periodontal Ligament

Human permanent incisors and canines each receive about 360 myelinated fibers and some 1500–2000 unmyelinated afferents in adults (Johnsen and Johns, 1978). Small myelinated fibers include cholinergic afferents, while many unmyelinated fibers contain substance P and CGRP (Byers, 1984; Silverman and Kruger, 1987). Galanin-immunoreactive fibers have also been reported in several species including human (Wakisaka *et al.*, 1996). These fibers terminate mainly in free nerve endings, especially within the dental pulp (Fig. 29.1). Endings can extend for up to 200 μm into the dentinal tubules in both monkey and human teeth, particularly near the cusps of the crown (Byers and Dong, 1983; Frank, 1968). Besides these afferent fibers, unmyelinated sympathetic fibers supply blood vessels within the tooth pulp (Anneroth and Norberg, 1968). Although innervation is mainly ipsilateral, Byers and Dong (1983) used autoradiography to show that some contralateral innervation occurs in monkey mandibular incisors and canines. After tooth loss and reimplantation, reinnervation of human teeth can occur, although the number and caliber of regenerating fibers is reduced (Ohman, 1965).

Electrical, chemical, mechanical, and thermal stimuli can activate tooth receptors and usually give rise to the sensation of pain (reviewed Schults, 1992). Pain can be associated with dentinal, pulpal, gingival, or periodontal receptors, each with particular but overlapping characteristics (Sharav *et al.*, 1984). For dentinal receptors, pain is generally not spontaneous but evoked by heat, cold, and sweet stimuli. The transduction mechanism may involve odontoblasts, though this matter is not resolved. Dull ache is thought to arise from activity in unmyelinated axons, common within the tooth pulp. Pulpal pain is associated with inflammation, can be spontaneous, is generally poorly localized, and may outlast the stimulus (Hensel and Mann, 1956). The response of pulpal nerves to tooth injury and inflammation has been reviewed by Fristad (1997). In rodents, inflammation of the pulp and periodontium results in up-regulation of substance P and CGRP, as in other tissues.

Besides receptors within the tooth, the human periodontal ligament is rich in free nerve endings and a variety of coiled and Ruffini-type endings (Fig. 29.1; Maeda *et al.*, 1990; Lambrichts *et al.*, 1992). Fibers containing substance P have been demonstrated here and are likely to be associated with periodontal pain

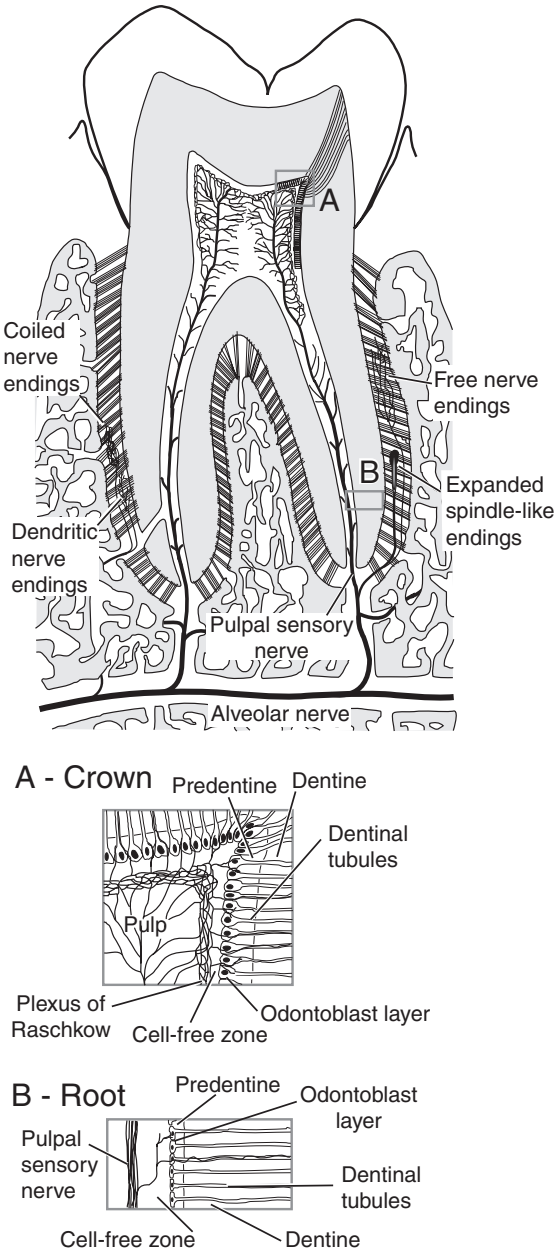

FIGURE 29.1 Diagram showing the distribution of nerve endings associated with the teeth. Free nerve endings are found within the pulp cavity and periodontium, and nerve fibers extend into the dentinal tubules. Coiled and expanded terminals also occur in the periodontium. (A) Details of pulpal and tubular innervation in the crown. (B) Innervation of dentinal tubules in the root.

(Fristad, 1997). Such pain is usually well localized and exacerbated by pressure.

In addition to nociceptors, microneurography of the inferior alveolar nerve in humans during applications of forces to the teeth has confirmed the presence of low-threshold, slowly adapting mechanoresponses from the periodontium (Trulsson and Johansson, 1996). These receptors encode food contact during biting and continuously discharge when food is held between the incisors. These response properties indicate that periodontal receptors are likely to contribute to the sensation of "dental touch" and the control of mastication, particularly on initial contact with food and its manipulation. Somata from periodontal afferents are found in both Me5 and the trigeminal ganglion (reviewed Capra and Dessem, 1992).

Temporomandibular Joint

The innervation of the temporomandibular joint (TMJ) has attracted interest in recent years, at least in part because of the involvement of the joint in a variety of painful conditions (see later). Immunostaining with neurospecific markers has shown that the human joint capsule and peripheral disc is richly innervated (Morani *et al.*, 1994). Most studies in humans have reported encapsulated receptors and free nerve endings in the joint capsule (Griffin and Harris, 1975; reviewed Zinny, 1988) and only free endings in the disc (Fig. 29.2A). However, Morani *et al.* (1994) found only free nerve endings in both locations. Reports on corpuscular endings in animals are also inconsistent with Ruffini-type and Paciniform endings described in cat and sheep, but only with free nerve endings in the mouse and rat (Dreessen *et al.*, 1990; Ichikawa *et al.*, 1990; Tahmasabi-Sarvestani *et al.*, 1996).

An interesting study on the fetal development of innervation in the human TMJ showed that nerves were present from around 9–10 weeks (Ramieri *et al.*, 1996). Innervation of the disc was particularly dense by 20 weeks and included encapsulated endings; however, this regressed during the third trimester. In adults, disc innervation was restricted to the periphery and only free nerve endings were present.

Oral Mucosa and Tongue

The oral mucosa in several primates, including humans, contains Merkel cells and free nerve endings (Fortman and Winkelmann, 1977; Luzardo-Baptista, 1973), although Ruffini endings were reportedly absent (Halata and Munger, 1983). In the human gingiva, fibers containing CGRP and substance P were seen in the lamina propria, as well as fibers containing NPY, tyrosine hydroxylase, and VIP in association with blood vessels (Luthman *et al.*, 1988). It was considered likely that the CGRP and Substance P fibers were sensory, probably associated with nociception.

In primate tongue, Meissner's corpuscles are found in the dermis close to the epidermal border, Ruffini-type endings occur in deeper dermal regions, and free

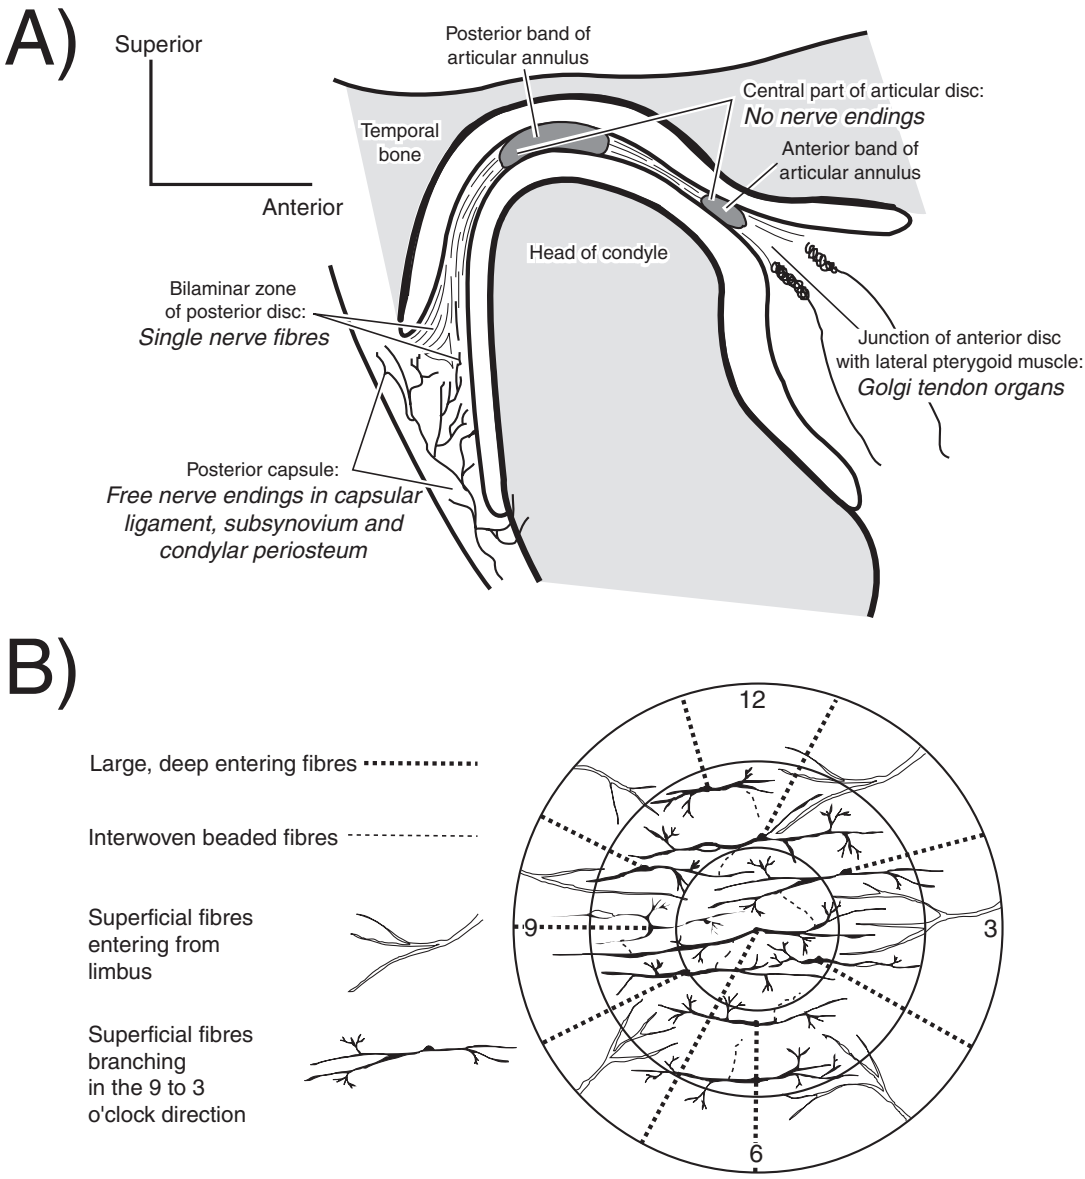

FIGURE 29.2 **(A)** Diagram showing a sagittal section through the temporomandibular joint. Encapsulated and free nerve endings are present in the posterior capsule and tendon of lateral pterygoid muscle. Free nerve endings are distributed to the periphery of the disc but are absent from the central region. **(B)** Diagram to show the distribution of nerves within the cornea. Fibers initially enter radially and then assume a predominantly temporonasal orientation within the stroma (from Figure 7, Müller *et al.*, 1997, Architecture of human corneal nerves. Invest. Ophthalmol. Vis. Sci. 38: 984–994, with permission from the copyright holder, the Association for Research in Vision and Ophthalmology, and the author).

nerve endings terminate within the epidermis (Zahm and Munger, 1985). Merkel cell complexes were not seen, confirming results from a previous study (Munger, 1973). Trigeminal afferents also innervate tongue papillae in primates and occasionally enter taste buds where they have been suggested to serve a trophic function (Zahm and Munger, 1985). Knock out studies in mice indicate that the development of gustatory and somatosensory afferents to the tongue require different trophic factors, namely BDNF for gustatory nerves and NT3 for trigeminal afferents (Nosrat, 1998).

The lingual nerve, a branch of the mandibular division, supplies tactile sensation for the anterior two-thirds of the tongue. A study of electrical activity recorded from the human lingual nerve showed some nerve fibers with low mechanical thresholds (mean force 0.15 mN) and small receptive fields (mean area 2.4 mm^2) considered to terminate near the tongue

surface (Trulsson and Essick, 1997). As noted earlier, these are lower than for any other site on the body. Both rapidly adapting responses and two types of slowly adapting units (SA I and SA II) were recorded, similar to those reported from the glabrous skin of the human hand. Generally, slowly adapting responses have been considered to be associated with Merkel cells (SA I) and Ruffini endings (SA II), so the lack of anatomically identified Merkel cells in the tongue requires reassessment. Besides these responses, lingual nerve responses to mechanical and thermal (cold) stimuli have been described (Kosar and Schwartz, 1990).

Two-point discrimination studies on the sides and tip of the tongue showed the tip had the lowest values (Ringel and Ewanowski, 1965; McNutt, 1975). However, there was an interesting difference in two point-discrimination values for the two sides in approximately half of the adults, which was not present in the children (McNutt, 1975). Either side could be more sensitive, with equal frequency. Because laterality differences were only noted in adults, they were attributed to central neural changes rather than peripheral mechanisms.

Cranial Vessels and Meninges

Major cranial blood vessels such as the middle cerebral and scalp arteries are richly innervated by trigeminal afferents, with fibers containing substance P found in the media and adventitia (Helme and Fletcher 1983; Chapter 37). A study of human temporal arteries showed both CGRP and substance P in nerve fibers in the adventitia and around the adventitia–media border (Jansen *et al.*, 1986). Two neuronal ganglia have been described on the human internal carotid artery (Suzuki and Hardebo, 1991). Although the majority of cells within these ganglia were considered to be parasympathetic, some contained CGRP and substance P, and it was suggesting a sensory function.

The dura of the anterior and middle cranial fossae receives trigeminal innervation. Animal studies have shown that the dural afferents contain substance P and CGRP (Andres *et al.*, 1987; Keller and Marfurt, 1991). Most end simply as free nerve endings within the connective tissue or adjacent blood vessels (rat, Knyihár-Csillik *et al.*, 1997). Release of peptides from these endings has been implicated in migraine (see later).

Cornea, Conjunctiva, and Nasal Mucosa

Human cornea and conjunctiva, like those of other mammals, are innervated by ophthalmic trigeminal afferents as well as sympathetic and parasympathetic efferents (Ruskell, 1985; Elsås *et al.*, 1994). Fibers containing CGRP, substance P, acetylcholine and catecholamines have all been confirmed in human cornea (Toivanen *et al.*, 1987; Ueda *et al.*, 1989; Uusitalo *et al.*, 1989). Radially oriented fiber bundles enter the cornea from the sclera and then travel, mainly with a temporonasal orientation (Fig. 29.2B), within the stroma (Müller *et al.*, 1997). Fibers penetrate Bowman's membrane and terminate between epithelial cells, mainly in the deeper layers (Müller *et al.*, 1996). Both myelinated Aδ and unmyelinated C fibers have been described in the peripheral cornea, although central cornea contains only unmyelinated fibers (Müller *et al.*, 1996). In the living human, cornea innervation can be studied with slit-scanning confocal microscopy (Auran *et al.*, 1995). This technique has been used to study regeneration of corneal innervation after operative procedures (Heinz *et al.*, 1996; Ritcher *et al.*, 1997).

The corneal innervation lacks any encapsulated receptors, being innervated by free nerve endings only (Weddell and Zander, 1950). Recordings in animals indicate that both mechanosensitive and thermosensitive afferents are present (Belmonte and Giraldez, 1981). The corneal responses are similar to those from Aδ and C skin afferents, except that mechanical thresholds are lower. In humans, most studies suggest that the only sensation evoked by corneal stimulation is pain (Beuerman and Tanelian, 1979). Lele and Weddell (1956) showed subjects could distinguish touch, cold, warmth and pain from the cornea; however, the stimulus used was air streams, and it is difficult to prevent the spread of air to adjacent conjunctiva or eyelids (Schults, 1992). The dense innervation of eyelid skin and eyelashes is well known, with Ruffini-type endings, lanceolate terminals, and Merkel cell complexes (monkey, Halata and Munger, 1980).

Trigeminal afferents also provide general somatic afferents to the nasal mucosa, again with free nerve endings only. Sensory fibers containing substance P and CGRP have been described in nasal epithelium (Hauser-Kronberger *et al.*, 1997). For the nasal vasculature, CGRP and neurokinin A fibers innervate arterial vessel walls, along with parasympathetic and sympathetic efferents (Baraniuk, 1992; Riederer *et al.*, 1995). Receptors for substance P (neurokinin 1) are present in human airway epithelium and submucosal glands (Shirasaki *et al.*, 1998), and substance P has been implicated in reflexes such as sneezing and allergic reactions (Nieber *et al.*, 1991; Baraniuk, 1992). Stimulation of nasal mucosa commonly results in a tingling sensation, which may outlast the duration of stimulation (Melzack and Eisenberg, 1968). Besides mechanical activation, many odorants stimulate trigeminal as well as olfactory afferents, although trigeminal thresholds

are generally higher (Doty, 1995). Such trigeminal sensations are described as irritant or pungent and have been shown to modify olfactory sensations.

TRIGEMINAL NERVES, GANGLION, AND ROOT

Peripheral Nerves

The three main trigeminal nerve divisions—ophthalmic, maxillary, and mandibular—together constitute the largest of the cranial nerves (reviewed Shankland, 2000). The mandibular division is the largest with some 78,000 myelinated fibers, compared with 50,000 fibers in the maxillary and only 26,000 in the ophthalmic divisions (Pennisi *et al.,* 1991). Myelinated fiber diameters range from 0.8 to 16 μm, with a similar bimodal distribution in each division (although the motor component of the mandibular division contains fibers with a larger diameter spectrum, 4–20 μm). Each division supplies a distinct dermatome on the head and face and the adjacent mucosal and meningeal tissues (Brodal, 1965; reviewed Usunoff *et al.*, 1997). Unlike spinal dermatomes, trigeminal nerve distributions show relatively little overlap. There is, however, considerable overlap with inputs from second and third cervical roots and vagal nerves (monkey, Denny-Brown and Yanagisawa, 1973). Communicating nerves between branches of the facial and trigeminal nerves are common. The best known of these is the chorda tympani, but others, such as the auriculotemporal, have been described (Namking *et al.*, 1994).

Fibres from the autonomic nervous system frequently join trigeminal nerves to reach peripheral tissues. Thus sympathetic fibers from the superior cervical ganglion travel with the external carotid artery then join the peripheral trigeminal nerves to reach sweat and mucosal glands in the facial skin and oral and nasal cavities. Sympathetic fibers also supply blood vessels in the connective tissue around the ganglion and nerves, as recently described by Smolier *et al.* (1998, 1999). Each trigeminal branch also receives parasympathetic fibers: the ophthalmic nerve from the ciliary ganglion, the maxillary from the pterygopalatine ganglion, the mandibular nerve from submandibular and otic ganglia. In addition, fibers from the facial nerve (chorda tympani) join the lingual nerve to provide the gustatory afferents for the anterior tongue.

Each trigeminal nerve branch exits the skull independently: the ophthalmic nerve through the superior orbital fissure, the maxillary nerve via the foramen rotundum and across the pterygopalatine fossa, and the mandibular nerve through the foramen ovale and the infratemporal fossa. Proprioceptive inputs from muscle spindles in the jaw muscles and some from the periodontal ligament travel with the motor nerve branch and have somata located in Me5 in the brainstem, rather than in the trigeminal ganglion. While the presence of muscle spindles is well established for jaw-closing muscles (temporalis, medial pterygoid, masseter; monkey, Kubota *et al.*, 1973; human, Voss, 1935; Freimann, 1954), their existence in jaw opening muscles (lateral pterygoid, digastric) was initially debated. They have been confirmed in the human lateral pterygoid (Gill, 1971; Rakhawy *et al.*, 1971) and the anterior belly of the digastic muscle in monkey and human (Voss, 1956). Recordings from mesencephalic tract axons in monkeys indicate that masseter muscle spindles are active during muscle contraction, rather than preceding it (therefore they are not gamma activated, Matsunami and Kubota, 1972). Animal studies indicate that other proprioceptive endings (e.g., Golgi tendon organs in jaw muscles and extraocular muscle spindles) have somata mainly in the ganglion; the location of any extraocular muscle proprioceptors in Me5 is controversial (reviewed Donaldson, 2000). For muscles of facial expression, propriceptive fibers may travel to the ganglion in the communicating nerves described between the facial and trigeminal paths (Namking *et al.*, 1994).

Trigeminal Ganglion

The trigeminal (semilunar, Gasserian ganglion) is crescent shaped and lies in Meckel's cave adjacent to the petrosal bone (Ferner, 1940). The gross morphology of the human ganglion in relation to the dura and the surrounding structures has been described in detail elsewhere (Soeira *et al.*, 1994; Kehrli *et al.*, 1997). In a study of ganglia from 64 subjects from 2 months to 81 years old, the mean neuronal count was 80,600 with no significant age or sex difference (Ball *et al.*, 1982). However, there was a marked variation in individual samples (range 20,000–157,000), which is surprising and worth investigation. Ganglion cells are pseudounipolar and invested by satellite cells, with some showing complex interdigitations with the neuronal membrane (Beaver *et al.*, 1965). There is an approximate somatotopy with ophthalmic somata lying anteromedially, mandibular cells posterolaterally, and maxillary in between (cat; Marfurt *et al.*, 1989).

As in the dorsal root ganglia, trigeminal ganglion cells can be classed as large, light (type A) cells and smaller, dark (type B) cells (Lieberman, 1976). On the

basis of ultrastructure, immunohistochemistry, and cytochemistry, Kai-Kai (1989) included a third group of small type C cells. A variety of peptides are known to be present in the ganglion, particularly in the smaller cells (see Chapter 30). For the human these include CGRP, substance P, somatostatin, galanin, and enkephalins (Del Fiacco and Quartu, 1994; Quartu and Del Fiacco, 1994; Quartu *et al.,* 1996). In the human ganglion, nearly half of the cells contain CGRP, with about 15% containing substance P, and some showing colocalization (Helme and Fletcher, 1983; Quartu *et al.,* 1992). Such cells are thought to be associated with nociceptive transmission (see later). CGRP fibers also form pericellular baskets around some ganglion cells, particularly in the fetal and newborn ganglion (Quartu *et al.,* 1992). In the rat, these fibers were shown to make synaptic contacts with trigeminal ganglion cells (Yamamoto and Kondo, 1989), but these were not seen in the monkey and are not known for humans. As in animals, discrete populations of human ganglion cells have been shown to express trkA, trkB, and trkC, receptors for the neurotrophins, often coexpressed on substance P and/or CGRP immunoreactive cells (Quartu *et al.,* 1996). The percentage of neurotrophin positive cells was lower in adults than in perinatal ganglia.

Besides the peptides, another transmitter for the trigeminal ganglion, like dorsal root ganglia, is likely to be glutamate. Wanaka *et al.* (1987) reported that about 45% of the rat trigeminal ganglion cells contain glutamate, particularly the larger cells. However, Kai-Kai and Howe (1991), also working in rat, found a lower percentage with glutamate (32%), predominantly localized in smaller cells, and this is in agreement with Cangro *et al.* (1985). Glutamatergic terminals are found throughout the trigeminal sensory complex (rat, Clements and Beitz, 1991) and there is evidence for involvement of glutamate in low-threshold mechanoresponses as well as in nociceptive responses from the tooth pulp and cornea (rat, Clements *et al.,* 1991; Bereiter and Bereiter, 1996). The percentage of glutamatergic cells in the human ganglion is unknown.

Kai-Kai and Keen (1985) confirmed the presence of serotonin in type B neurons, and mast cells in the rat trigeminal and spinal ganglia. The location of serotonin in afferent termination zones in the dorsal horn has led to its suggested role as a putative transmitter in primary afferents (Kai-Kai, 1989).

Trigeminal Root and Tract

Central processes of trigeminal ganglion cells travel posteriorly in the large sensory root (portio major, radix sensoria) to enter the brainstem at midpontine level. The smaller "motor" root (portio minor, radix motoria) arises as two or more rootlets, which join together and pass inferiorly to the sensory root and ganglion, to travel with the mandibular nerve. The total number of sensory root fibers has been estimated as 140,000 (Young, 1977) and 170,000 (Pennisi *et al.,* 1991), similar to the number of peripheral nerve fibers (154,000, Pennisi *et al.,* 1991) but considerably higher than the number of ganglion cells (80,000; Ball *et al.,* 1982). Whether this represents branching of fibers or errors in counting is not known; the puzzlingly large range of values reported for ganglion cells from different individuals has already been noted. Approximately 50% of the root fibers are unmyelinated (Young, 1977), less than the commonly quoted figure for dorsal roots (70–80%); possible reasons for this, such as the importance of discriminative sensations from the face, are discussed by Young (1977). Myelinated fibers are smaller (0.3–11 μm) than in the peripheral nerve (Kerr, 1967).

Within the sensory root, both electrophysiological recordings in monkeys and results of lesions in humans suggest that there is an approximate somatotopy, with each division maintaining individual, but overlapping, territories (Pelletier *et al.,* 1974). However there is no separation of modalities, with mechanical, thermal, and nociceptive afferents being intermingled. Similarly, in the motor root, responses from jaw muscle spindles are intermingled with motor fibers. Inputs are ipsilateral except for 2–3 mm of contralateral skin at the tip of the nose (Cushing, 1904).

From the root, most fibers pass caudally to form the spinal trigeminal tract in the dorsal and lateral brainstem. The spinal tract lies adjacent to the spinal trigeminal nucleus and extends from midpons to the second cervical level, where it becomes continuous with Lissauer's tract (Fig. 29.3). Some, but not all, root fibers bifurcate to give a short ascending branch to the principal sensory trigeminal nucleus, which they enter from the lateral, ventrolateral, and ventral aspects. Within the spinal tract there is an approximate topography, with ophthalmic fibers lying ventrally; maxillary, intermediate; and mandibular, dorsally (reviewed Capra and Dessem, 1992; Usunoff *et al.,* 1997) with all three divisions represented at all levels (Kerr, 1963).

Tract axons are relatively small, with 90% having a diameter of less than 4 μm in man (Sjoqvist, 1938). Comparison of rostral and caudal regions of the tract shows fewer myelinated fibers caudally (Usunoff *et al.,* 1997). Golgi impregnation in humans and animal studies in rat and cat (Cajal and Ramon, 1909; Hayashi, 1985 a, b; reviewed Capra and Dessem, 1992) show

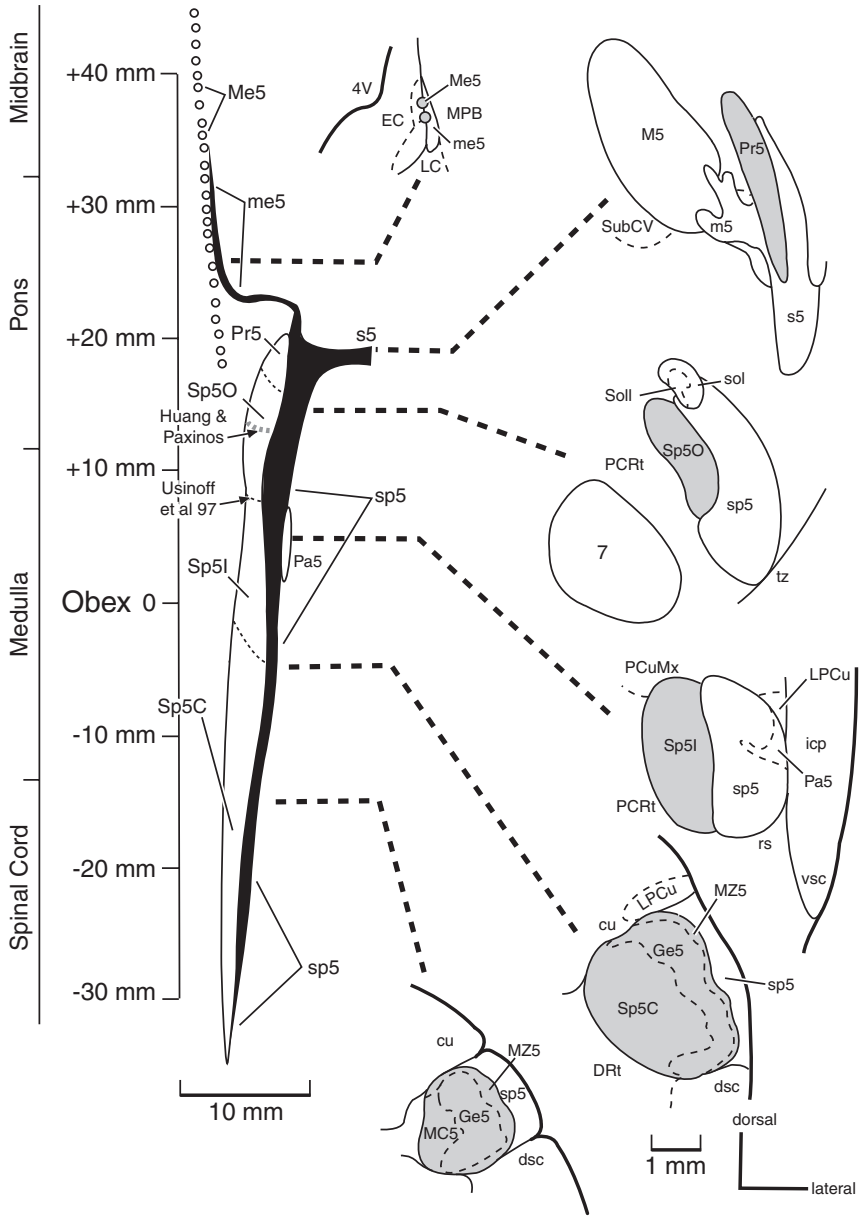

FIGURE 29.3 The left-hand side shows a diagrammatic representation of the brainstem trigeminal complex, drawn to scale from a dorsal view. The entering trigeminal root, s5, and tract Sp5 are shown in black. The mesencephalic (Me5), principal (Pr5), and spinal nuclei (Sp5I, SP50, Sp5C) are shown as well as the paratrigeminal nucleus (Pa5). Subnuclear borders are indicated; the border between Sp50 and Sp5I is shown at two locations, as described by Paxinos and Huang (1995) and Usunoff *et al.* (1997). The right-hand side of the figure shows the cross-sectional appearance of each of the nuclei (gray shading) and adjacent structures at the levels indicated, as taken from the atlas of Paxinos and Huang (1995, copyright Academic Press, reprinted with permission).

that individual axons in the tract give off a series of collateral branches that enter the nucleus at different levels. Collateral terminations in Sp5C show an arrangement that has been likened to an onion-skin, with midline and perioral face represented rostrally and more lateral facial skin represented caudally.

Mandibular and ophthalmic trigeminal primary afferents also cross the midline at caudal levels and project to the contralateral spinal nucleus caudalis (rat, Jacquin *et al.*, 1990; Marfurt and Rajchert, 1991; cat, Westrum and Henry, 1993), but this has not been confirmed in primates.

The trigeminal tract is joined by afferents from other nerves, such as the nervus intermedius, glossopharyngeal, vagal, and upper cervical nerves. Trigeminal afferents project to other brainstem regions, such as the nucleus of the solitary tract, and this has been confirmed in humans (Usunoff *et al.*, 1997). Projections to the solitary tract encompass both the rostral (gustatory) areas and caudal (cardiovascular, respiratory, and gastrointestinal) regions (rat, Marfurt and Rajchert, 1991). These inputs have been suggested to play a role in the integration of sensory activity from the mouth, pharynx, and oesophagus during mastication and swallowing.

Trigeminal afferents also project to the reticular formation, particularly alongside spinal nucleus interpolaris (reviewed Usunoff *et al.*, 1997). Direct projections to dorsal column nuclei have been reported, particularly to the cuneate nucleus and the external cuneate nucleus (monkey, Porter, 1986; Rhoton *et al.*, 1966). Such inputs have been suggested to be important in the integration of sensory inputs from neck muscles and cutaneous cranial afferents and for the coordination of head, neck, and eye movements (Porter, 1986). Finally, trigeminal projections to the paratrigeminal nucleus have been described in animals and it has been suggested that this nucleus plays a role in processing of nociceptive inputs (reviewed, Usunoff *et al.*, 1997). Trigeminal afferent inputs to regions such as the supratrigeminal nucleus and the motor trigeminal nucleus, as well as to vestibular nuclei, have been reported in animal studies but have not been substantiated in humans (reviewed by Usunoff *et al.*, 1997).

BRAINSTEM TRIGEMINAL SENSORY NUCLEI

The brainstem trigeminal sensory nuclei consist of the trigeminal sensory nuclear complex (the principal and spinal trigeminal nuclei), the mesencephalic nucleus, and a number of smaller collections of cells (paratrigeminal and peritrigeminal nuclei) thought to be predominantly sensory in function (see Chapter 10). These are all discussed later. Other trigeminal brainstem areas such as the motor trigeminal and intertrigeminal nuclei are associated with the motor control of jaw muscles (Lund and Olsson, 1983) and are not considered here. The supratrigeminal nucleus described in the mouse and cat is not seen in the human (Paxinos and Huang, 1995; Usunoff *et al.*, 1997), although Paxinos and Huang delineate a peritrigeminal zone around the motor nucleus.

Trigeminal Sensory Nuclear Complex, an Overview

The trigeminal nuclear complex is a long column of cells in the dorsolateral brainstem that extends from the rostral pons to the C_2 level, a distance of approximately 6 cm (Usunoff *et al.*, 1997). The complex is subdivided into four subnuclei (Fig. 29.3), the principal or main sensory trigeminal nucleus (Pr5), and three spinal trigeminal nuclei—oralis (Sp5O), interpolaris (Sp5I), and caudalis (Sp5C) (Olszewski, 1950; reviewed Capra and Dessem, 1992).

Animal studies using anatomical labeling (Marfurt, 1981; Shigenaga *et al.*, 1986), electrophysiological recordings (Eisenman *et al.*, 1963), and results of lesions in humans indicate a somatotopic organization throughout the complex, with the mandibular division lying dorsally; maxillary, centrally; and the ophthalmic, ventrally. Different facial regions are represented as long rostrocaudal columns of cells extending through the complex, with more midline regions (e.g., the nose) represented medially and more lateral skin represented laterally. However, particular facial regions have relative differences in central representation at the different levels, as noted later.

A major transmitter throughout the sensory complex is glutamate, with NMDA and non-NMDA receptors reported at all levels (rat, Petralia *et al.*, 1994; Tallaksen-Greene *et al.*, 1992). In addition, peptides such as substance P and CGRP are important transmitters, particularly for small diameter afferents, and may be colocalized with glutamate (Sessle, 2000). Ultrastructurally, a feature of synaptic organization at all trigeminal levels is the presence of synaptic glomeruli, in which a primary axon is surrounded by other terminals with axoaxonic synapses, with somewhat different structure at different levels (rat, Clements and Beitz, 1991).

Principal Sensory Trigeminal Nucleus

The principal sensory trigeminal nucleus is located in the lateral pontine tegmentum and extends for about 4 mm (from 17 to 20 mm rostral to the obex; Paxinos and Huang, 1995), approximately level with the motor trigeminal nucleus. In cross section, the nucleus is narrow and elongated dorsoventrally (Fig. 29.3). Most neurones are small and generally oval with some scattered medium-sized somata also present. Large neurones (more than 35 μm in diameter) are seen along the lateral border. Usunoff *et al.* (1997) describe a hint of dorsal and ventral subdivisions, with ventral cells somewhat larger and in clusters, while dorsal cells are smaller and more diffuse. However,

these subdivisions are less marked than in the cat (Shigenaga *et al.*, 1986b), and the dorsoventral subdivisions were not noted by Paxinos and Huang (1995). Ultrastructurally, Pr5 in both the rat and cat contains synaptic glomeruli (Gobel and Dubner, 1969; Gobel, 1971; Ide and Killackey, 1985).

Sections reacted for the enzyme acetylcholinesterase (AChE) show a striking organization of densely stained patches surrounded by paler regions. These patches are also seen with histochemical techniques for mitochondrial enzymes such as cytochrome oxidase (Goyal *et al.*, 1992). Animal studies indicate a similar parcellated organization. The patches of intense staining are particularly clear in rodents where they have a distinctive pattern and are known to be associated with the vibrissae (reviewed Waite and Tracey, 1995). However, they are also seen in the dorsal column nuclei in relation to the digits (Florence *et al.*, 1989). These patches have been considered to reflect regions of high innervation density (Goyal *et al.*, 1992). In rodents, similar patches also occur in spinal trigeminal nuclei Sp5I and Sp5C, but this has not been seen in primates (Noriega and Wall, 1991).

Animal studies have shown that cells in Pr5 are mechanoreceptive with low thresholds and small receptive fields (Jacquin *et al.*, 1988). Thus, Pr5 is thought to be analogous to the dorsal column nuclei in providing for discriminative tactile sensations for the face. It contains many projection cells, with its predominant projection being to the ventroposterior medial nucleus (VPM) of the thalamus. In the cat and rat, there is also a lesser projection to the posterior complex, Po (Jones, 1985) renamed as part of regio basalis (see Chapter 20), though this is unconfirmed in humans. In rodents, 60–70% of the projection cells in Pr5 contain glutamate (Magnusson *et al.*, 1987), though again this is not known for humans.

Pr5 also contains interneurones, many of which are immunoreactive for GABA (rat, Haring *et al.*, 1990). Somatostatin immunoreactive cells have also been described in the ferret (Boissonade *et al.*, 1993). In humans, somatostatin immunoreactive cells, fibers, and receptors are only seen in low levels in Pr5 (Bouras *et al.*, 1987; Carpentier *et al.*, 1996) and enkephalin-containing cells are present in the newborn (Yew *et al.*, 1991).

Spinal Trigeminal Nucleus Oralis

While all investigators agree that Sp5O extends caudally from Pr5 (level with the caudal pole of the motor trigeminal nucleus), its caudal boundary has been placed at different levels. Paxinos and Huang (1995) delineate an oblique caudal border level with the caudal pole of the facial motor nucleus (13 mm rostral to the obex), giving Sp5O a rostrocaudal extent of some 4 mm (Fig. 29.3). However, Usunoff *et al.* (1997) continue Sp5O to the level of the rostral pole of nucleus ambiguus (~7 mm rostral to the obex), a rostrocaudal distance of 10 mm. Sp5O is somewhat peanut-shaped in cross section. Usunoff *et al.* (1997) describe small (12–17 μm) oval cells and medium-sized oval, multipolar or fusiform cells (25–30 μm long and 10 μm or less wide).

AChE staining shows a few dark patches within the nucleus, especially within the central core (Paxinos and Huang, 1995). Studies in the rat, cat, and ferret have described subdivisions within the nucleus (e.g., dorsomedial and ventrolateral), but these were not noted by Usunoff *et al.* (1997) or Paxinos and Huang (1995). Many neurons in rodent Sp5O contain glutamate, likely to be the excitatory transmitter (Magnusson *et al.*, 1986). In the ferret, both somatostatin and enkephalin immunoreactive somata have been described (Boissonade *et al.*, 1993), and rodent Sp5O contains dispersed GABAergic cells (Haring *et al.*, 1990). Human Sp5O and Sp5I are high in receptors for somatostatin, although the functional significance of this in sensory processing is not yet clear (Carpentier *et al.*, 1996). Like Pr5, Sp5O contains synaptic glomeruli, often with glutamate immunoreactive profiles (rat, Clements and Beitz, 1991).

Sp5O has been shown to receive extensive intraoral projections (cat, Arvidsson and Gobel, 1981; Azerad *et al.*, 1982; rat, Marfurt and Turner, 1984; Takemura *et al.*, 1991) and this is consistent with loss of oral sensation after vascular lesions in humans (Graham *et al.*, 1988). Responses generally have very widespread receptive fields and can show modality convergence, for instance from both cutaneous and tooth receptors (rat, Jacquin and Rhoades, 1990). Indeed Sp5O has been implicated in intraoral pain, as discussed later. In the rat, Sp5O has extensive projections to the facial motor nuclei and spinal cord with less dense projections to the trigeminal motor nucleus, thalamus, and cerebellum (rat, Ruggiero *et al.*, 1981; Jacquin and Rhodes, 1990).

Spinal Trigeminal Nucleus Interpolaris

Located in the medulla, Sp5I extends between Sp5O and Sp5C. As noted earlier under Sp5O, there is some discrepancy about the rostral border of Sp5I; Paxinos and Huang (1995) delineate it as level with the caudal pole of the facial nucleus, whereas Usunoff *et al.* (1997) put the Sp5O/I border just rostral to nucleus ambiguus. Thus the rostrocaudal extent varies from 6 mm (Usunoff *et al.*, 1997) to about 13 mm (Paxinos and Huang, 1995).

With AChE staining, the nucleus stands out as an area of moderate to high reactivity. Usunoff *et al.* (1997)

describe a heterogeneous population of cells in human brain; many are small to medium-sized (15–20 μm) and oval or spindle-shaped. There are also some large scattered neurones (30–40 μm). Paxinos and Huang (1995) recognize a dorsomedial extension of Sp5I at caudal levels. Like Sp5O, the nucleus is crossed by prominent fiber bundles, for example from the glossopharyngeal nerve.

Sp5I has extensive inputs from intraoral structures, including tooth pulp, though these are generally less dense than for Sp5O (cat, Azerad *et al.,* 1982; rat, Marfurt and Turner, 1984; Takemura *et al.,* 1991). Cells responsive to both low-threshold mechanoceptors and nociceptors in the skin and periodontium have been described in rats (Jacquin *et al.,* 1989a). Glutamatergic and GABAergic neurones are present in the rat (Phelan and Falls, 1989; Usunoff *et al.,* 1997; Magnusson *et al.,* 1986, 1987; Haring *et al.,* 1990) as well as somatostatin and enkephalin neurones in ferrets (Boissonade *et al.,* 1993). In the rat, Petralia *et al.* (1994) described large multipolar neurons densely stained for NMDA R1 receptor.

Intracellular recording and staining has provided useful data on the detailed morphology of Sp5I cells in the rat. The responses and structure of projection cells (defined as cells that send axons outside the trigeminal complex), as well as "local circuit" neurons (with axons restricted to the trigeminal nucleus), were analyzed (Jacquin *et al.,* 1989a, b). The local circuit neurons often had widespread intranuclear axonal connections encompassing Pr5 and Sp5C, thus providing a mechanism for integration between subnuclei.

Sp5I projects to the thalamus, cerebellum, superior colliculus and spinal cord (rat, Kemplay and Webster, 1989; Huerta *et al.,* 1983; Jacquin *et al.,* 1989b; Phelan and Falls, 1991), with single cells often having very widespread connections (rat, Jacquin *et al.,* 1986; Patrick and Robinson, 1987; Bruce *et al.,* 1987; Phelan and Falls, 1991). In the rat, the thalamic projection is to both VPM and the medial part of Po (Chiaia *et al.,* 1991), with many of these projection cells containing glutamate (Magnusson *et al.,* 1987). The projection of Sp5I to the cerebellum has not been confirmed in the human (Usunoff *et al.,* 1997). Similarly, trigeminal inputs to the human superior colliculus have not been confirmed (for discussion see Chapter 28). Although localized receptive fields were noted for local circuit neurons, fields were generally widespread for projection cells, particularly those projecting to the thalamus (rat, Jacquin *et al.,* 1989b).

Spinal Trigeminal Nucleus Caudalis

The spinal trigeminal nucleus caudalis extends from the obex for approximately 15 mm to the C_2 level (Fig. 29.3), where it becomes continuous with the dorsal horn. Its similar laminar organization to the spinal dorsal horn (Chapter 7) has led to its alternative name, the medullary dorsal horn (Gobel *et al.,* 1981). Thus Sp5C contains a marginal zone (subnucleus zonalis, lamina 1), a substantia gelatinosa resembling Rexed's lamina 2, and a magnocellular layer, equivalent to nucleus proprius (lamina 3 and 4) of the dorsal horn (Fig. 29.3). In addition, some authors recognize a deeper zone corresponding to laminae 5 and 6.

The marginal zone in human tissue consists of a thin sheet of cells containing large multipolar neurones, some over 60 μm in diameter (Usunoff *et al.,* 1997) with small and medium-sized neurones also present. In rat, cat, and monkey, fusiform, pyramidal, and multipolar cells are described (Gobel, 1978; Zhang *et al.,* 1996; Yu *et al.,* 1999), with different functional properties for each (see later). Inputs to the marginal zone arise mainly from small-diameter myelinated fibers as well as unmyelinated afferents from all cranial tissues (reviewed Craig, 1996).

The human substantia gelatinosa was rather aptly described by Olszewski (1950) as horseshoe-shaped in cross section (Fig. 29.3) and consists of relatively densely packed small, oval, or fusiform cells (10–20 μm in diameter). This layer reacts strongly for AChE and is rich in neuropeptides such as substance P, CGRP, cholecystokinin, and somatostatin (Inagaki *et al.,* 1986; Clements and Beitz, 1987; Carpentier *et al.,* 1996). This region also contains the NGF receptor, trkA, which is especially dense in pre and perinatal human tissue, but is also present in adults (Quartu *et al.,* 1996). The region is rich in GABAergic somata and fibers (rat, Haring *et al.,* 1990; Ginestal and Matute, 1993). It receives predominantly small-diameter myelinated and unmyelinated afferents. Synaptic glomeruli, in which glutamatergic primary afferents are both pre- and postsynaptic to GABAergic terminals, have been described (rat, Clements and Beitz, 1987; cat, Iliakis *et al.,* 1996).

The magnocellular zone has medium-sized diameter (25 μm) oval or fusiform cells with scattered small and large neurones. In the rat, many cells here contain glutamate, and some of these project to VPM (Magnussen *et al.,* 1986, 1987). Synaptic glomeruli are present, often with scalloped glutamatergic profiles (Clements and Beitz, 1991). The magnocellular zone has a moderate level of AChE reactivity.

Low-threshold mechanical responses, high threshold nociceptive specific responses, thermosensitive specific (COLD) responses, HPC (heat, pinch, cold) cells, and wide dynamic range (WDR) neurones are all present in Sp5C (cat, Hu, 1990; monkey, Dostrovsky and Craig, 1996; reviewed Sessle, 2000). Low-threshold mechanical responses are found predominantly in the

magnocellular zone along with some thermal specific units (monkey, Price *et al.*, 1976). In contrast, the marginal zone contains nociceptive specific, COLD, HPC, and WDR responses (monkey, Price *et al.*, 1976; Bushell *et al.*, 1984; reviewed Sessle, 2000, and see later section on trigeminal nociception). Intracellular recordings from lamina 1 cells in cat spinal cord suggest that there is a structure/function correlation: fusiform and pyramidal cells correspond to nociceptive specific and COLD responses, respectively, whereas most multipolar cells showed HPC responsiveness (Han *et al.*, 1998). In monkey spinal cord, the fusiform and multipolar cells express the substance P receptor (neurokinin-1) supporting their role in nociception (Yu *et al.*, 1999). The role of trigeminal marginal zone neurons in nociception and thermal discrimination has been indicated by recordings in awake monkeys (Dubner *et al.*, 1981; Hayes *et al.*, 1981; Bushnell *et al.*, 1984). The responses of COLD cells depended on the behavioral significance of the stimuli, suggesting the involvement of these cells in sensory discrimination, rather than merely reflex activation.

Projections of Sp5C are extensive. Lamina 1 cells project to several thalamic regions including VPM, Po, and the midline and intralaminar nuclei (primate, Ganchrow, 1978; cat and monkey, Burton and Craig, 1979; cat, Shigenaga *et al.*, 1983; rat, Shigenaga *et al.*, 1979; Yoshida *et al.*, 1991; Iwata *et al.*, 1992; and see Chapter 30, Fig. 30.8B) as well as a new nucleus described by Blomqvist *et al.* (2000) as the posterior part of the ventral medial nucleus (VMpo, referred to as basalis nodalis in Chapter 20). Laminar 1 also gives both direct hypothalamic projections (rats, Malick and Burstein, 1998) and indirect projections through the parabrachial area (Slugg and Light, 1994; Jasmin *et al.*, 1997). The substantia gelatinosa projections are predominantly local, to the adjacent magnocellular zone and reticular formation (primate, Tiwari and King, 1974). The magnocellular zone projects to VPM, zona incerta, the facial nucleus, trigeminal motor nucleus, and adjacent reticular formation as well as ipsilateral spinal cord (Iwata *et al.*, 1992; Carpentier *et al.*, 1981). Magnocellular cells also project to more rostral trigeminal nuclei, Sp5O and Sp5I (primate, Tiwari and King, 1974; Price *et al.*, 1976; cat, Hu and Sessle, 1979; rat, Hallas and Jacquin, 1990). These intranuclear connections are likely to modulate activity in these rostral regions.

An interesting recent study has reported a discrete thermospecific region in lamina 1 in the owl monkey (Craig *et al.*, 1999). Cells here responded to cold stimuli (COLD cells) with small receptive fields on nasal and labial regions and had a pyramidal morphology similar to thermal cells in cats and rats. These cells project to the posterior ventromedial nucleus (VMpo), identified as a thermal and nociceptive region in monkey and human thalamus (Craig *et al.*, 1994, and referred to as basalis nodalis, in Chapter 20 and see later). This region of lamina 1 and the associated pathway was suggested to provide specialized thermosensitivity, likely to be relevant the nocturnal navigation and foraging behavior of the owl monkey Craig *et al.* (1999).

Mesencephalic trigeminal nucleus

The mesencephalic trigeminal nucleus comprises a band of scattered cells that extends from the level of rostral Pr5 through the pons and midbrain, a distance of some 22–24 mm (Olszewski and Baxter, 1954; Paxinos and Huang, 1995). The cells lie at the outer border of the periaqueductal gray in the midbrain and the central gray of the pons (Fig. 29.3). Me5 cells have a distinctive morphology, being mainly pseudounipolar with large, regular, oval or round somata, like that of other primary afferents. However, multipolar cells have also been seen in the human (Olszewski and Baxter, 1954) and identified in animal studies after peripheral labeling (reviewed Capra and Dessem, 1992). Cells of Me5 are the somata of proprioceptive afferents from the jaw muscles and periodontium.

Clustering of Me5 neurons with maculae adherens, gap junctions and electrotonic coupling between cells within a group have been described in the rat (Baker and Llinas, 1971; Liem *et al.*, 1991). Synapses on Me5 cells have been seen in rodents and cats, with a variety of transmitters identified including serotonin and dopamine (Liem *et al.*, 1992; reviewed Capra and Dessem, 1992), but the existence of synapses in humans is unconfirmed. Somatostatin positive fibers have been described around human Me5 cells (Bouras *et al.*, 1987). Besides these inputs, studies in rats show bilateral projections to Me5 from parvocellular reticular formation (Rokx *et al.*, 1988).

Me5 cells project to the motor trigeminal nucleus forming a monosynaptic reflex arc. In animals, Me5 also projects to the intertrigeminal and supratrigeminal nuclei probably involved in masticatory control (rat, Luo *et al.*, 1991) although, as noted previously, a human homologue of the supratrigeminal nucleus has not been confirmed. There are also projections to Pr5, which may provide a relay to the thalamus for proprioceptive sensation (Luo *et al.*, 1991, 1995) although direct projections to the ventral thalamus have been described (squirrel monkey, Pearson and Garfunkel, 1983). Thalamic projections were bilateral, but predominantly ipsilateral and may have included VPO (see later). Projections to other brainstem nuclei (the hypoglossal nucleus, nucleus of

the solitary tract, extraocular motor nuclei, and brainstem parvocellular reticular nucleus) as well as the cerebellum and spinal cord have been identified in animals (rat, Rokx *et al.*, 1986; Raappana and Arvidsson, 1993; cat, Matsushita *et al.*, 1982; Shigenaga *et al.*, 1989, 1990).

Other Sensory Trigeminal Nuclei

Besides the trigeminal sensory complex of four nuclei, the trigeminal sensory system also contains a group of cells within the spinal tract, at the level of caudal Sp5I and the Sp5I/C boundary (Fig. 29.3). There is considerable confusion about the nomenclature of this cell group (for discussion of this see Usunoff *et al.*, 1997). Originally described as interstitial cells by Cajal and Ramon (1909), this cell group was later considered part of the paratrigeminal nucleus of Chan-Palay (1978). Paxinos and Huang (1995) used the term "paratrigeminal" (Pa5), while Usunoff *et al.* (1997) reintroduced the use of "interstitial nucleus." In the human these cells are small and chromophobic (Usunoff *et al.*, 1997). Animal studies have shown that the interstitial/paratrigeminal nucleus receives a projection from the tooth pulp and cornea, with responses similar to those of the marginal zone of Sp5C (cat, Shigenaga *et al.*, 1986).

Other more scattered groups of cells, named by Paxinos and Huang (1995) as the peritrigeminal nucleus, lie lateral and ventral to the trigeminal tract at the level of Sp5I. The connections and functions of this group are unknown. A third group of large cells extends between the inferior cerebellar peduncle and the spinal and cuneate tracts, at the level of caudal Sp5I and rostral Sp5C (Fig. 29.3). This latter group of cells was named by Paxinos and Huang (1995) as the lateral pericuneate nucleus (LPCu). The cells are similar in appearance to those of the lateral cuneate nucleus and may well be related to cuneate inputs rather than the trigeminal system.

Brainstem Mechanisms in Trigeminal Nociception

Pain from the trigeminal distribution (including pain from the face, nasal sinuses, oral cavity and teeth, TMJ, and meninges) is one of the most common and distressing clinical symptoms known. In a study performed in the United States (Lipton *et al.*, 1993), it was found that 12% of adults had experienced toothache in the last six months, 5% had felt TMJ pain, while 1.4% had noticed face or cheek pain over the same period. Interestingly, there is a clear gender difference in some of these craniofacial pain syndromes, with women reporting a 28% higher incidence of pain from the TMJ than men.

Despite this major clinical significance, much of what we know about the nociceptive components of the trigeminal system is derived from animal studies, predominantly in rodents, although cat and primate studies have also contributed (see Chapters 12 and 30). Nevertheless, investigations in humans have usually been in agreement with animal-based findings, although some minor species differences in trigeminal nociceptive pathways cannot be excluded.

Nuclear Localization of Nociceptive Responses

Clinical findings involving transection of the trigeminal tract are consistent with findings in experimental animals indicating that Sp5C is the most important component of the trigeminal nuclear complex for perception of noxious stimuli applied to the craniofacial region (for review see Sessle, 2000). Cells in lamina 1 respond to noxious mechanical, thermal and chemical stimulation of structures such as the cornea, cerebral vasculature, oral and nasal mucosa, teeth, and TMJ. There is also evidence of the involvement of the trigeminal complex, in particular Sp5C, in the mediation of reflex responses to noxious craniofacial stimuli, such as changes in sweating, respiration, blood pressure, heart rate, and excitatory reflex effects in jaw-opening muscles and inhibitory effects in jaw-closing muscles. On the basis of c-fos immunoreactivity in the rat after noxious stimulation, Strassman and Vos (1993) have suggested the Sp5I/Sp5c border may be involved in these autonomic effects.

Besides the obvious involvement of Sp5C in trigeminal nociceptive activity, recordings from Sp5O and Sp5I indicate nociceptive responses are present in more rostral levels of the spinal trigeminal complex. Lesions or injections of analgesic chemicals into these rostral levels can also interfere with nociceptive behavior, particularly when the noxious stimulus is applied to intra- or perioral regions (Dallel *et al.*, 1998; Takemura *et al.*, 1993). Studies in awake monkeys indicate that Sp5O responses to dental stimulation are dependent on the behavioral state of the animal (Soja *et al.*, 1999). This indicates a role for the rostral, as well as caudal, spinal nuclei in trigeminal nociceptive mechanisms (Raboisson *et al.*, 1989; Panneton and Yavari, 1995). When the jaw-opening reflex is elicited by tooth pulp or perioral stimuli, lesion studies indicate that rostral subnuclei, such as Sp5O and Sp5I, are more crucial to the reflex than Sp5C (Dallel *et al.*, 1989; Hannam and Sessle, 1994). Involvement of rostral areas is also supported by clinical findings in patients with brainstem lesions in the caudal pons (Graham *et al.*, 1988).

It has recently been suggested, on the basis of the distinctive responses of Sp5O nociceptive neurons to noxious chemicals like formalin, that Sp5O is particularly important for processing information about short duration nociceptive stimuli, whereas Sp5C is more important for processing tonic nociceptive information (Raboisson *et al.*, 1995). Studies involving morphine administration in the superficial laminae of Sp5C indicate that these analgesics may exert their effect on Sp5O indirectly, by blocking C fiber inputs that relay in the Sp5C (Dallel *et al.*, 1998).

Nociceptive Transmitters, Response Characteristics, and Projections

As indicated previously, small-diameter afferents terminate mainly in the marginal zone and deep laminae (5 and 6) of Sp5C. These afferents contain neuropeptides and amino acids that have been implicated as excitatory neurotransmitters or neuromodulators (e.g., substance P, glutamate, nitric oxide) in central nociceptive transmission (see Sessle, 1996, 2000, for reviews). Antagonism of the substance P receptor mechanisms (NK1) blocks c-fos expression induced by noxious chemical stimulation of dural afferents (Shepheard *et al.*, 1995). In addition to substance P, studies indicate central involvement of excitatory amino acids in trigeminal nociception (Parada *et al.*, 1997). Jaw-muscle activity associated with TMJ nociception can be elicited by glutamate injection into the TMJ and blocked by glutamate receptor antagonists (Cairns *et al.*, 1998).

As noted earlier in "Spinal Trigeminal caudalis," responses to nociceptive input include nociceptive specific neurons, HPC cells and WDR neurons, all of which can be recorded from the marginal zone and deep laminae of Sp5C. The involvement of the marginal zone in nociception is supported by functional recordings as well as c-fos studies. However, comparable neurons have been reported to be present in rostral parts of the trigeminal spinal nucleus in both Sp5O and Sp5I (see Sessle, 2000, for review). Electrophysiological studies in all these regions often show a pattern of convergence of inputs from different regions, with cells responding to cutaneous nociceptive stimulation as well as stimulation of afferents supplying cranial blood vessels, dura, cornea, TMJ, or tooth pulp (Boissonade and Matthews, 1993; Meng *et al.*, 1997; also reviewed in Sessle, 2000).

There are substantial projections from the parts of the trigeminal nuclear complex involved in nociception to the thalamus (Craig and Dostrovsky, 1997; Sessle, 2000). There is also electrophysiological evidence for projections from nociceptive Sp5C neurons to the periaqueductal gray and parabrachial region (from which projections to the amygdala and hypothalamus follow), as well as direct projections to the hypothalamus (Malick and Burstein, 1998). These ascending non-thalamic projections are likely to be responsible for the affective aspects of nociception as seen clinically.

Modulation of Nociceptive Responses, Inflammation and Chronic Pain

As in the spinal cord (see Chapter 30), an important aspect of nociception is that the activity can be modulated by descending and afferent inhibitory mechanisms that are known to suppress pain in both humans and experimental animals. Projections from the nucleus raphe magnus, periaqueductal gray, sensorimotor cortex, pretectal area, and parabrachial area are capable of influencing nociceptive responses (for review see Sessle, 2000). Afferent induced modulation also appears to be an important mechanism in trigeminal nociception, studied, for instance, for responses from cat tooth pulp (reviewed Soja *et al.*, 1999). The responses of neurons to inputs evoked by deep and superficial noxious stimuli can be suppressed by low-threshold stimuli that excite large afferent fibers. Furthermore, noxious stimuli applied to other parts of the body may inhibit trigeminal responses to small fiber craniofacial nociceptive stimulation (i.e., "pain inhibits pain," Sessle, 2000).

There is also a large body of literature concerning the long-term effects of craniofacial injury and inflammation on nociception in the trigeminal complex. Deafferentation in the trigeminal system of experimental animals (e.g., by transection of the infraorbital nerve) is well known to lead to significant morphological, neurochemical, and physiological changes in the brainstem, thalamus, and somatosensory cortex (Woolsey, 1990; Weinberger, 1995). Endodontic removal of tooth pulps in adult animals also induces morphological and physiological changes in the trigeminal nuclear group, particularly in Sp5O and Sp5C (Hu and Sessle, 1989). The sensitivity of many nociceptive endings may increase after mild forms of injury, such as when the threshold of nociceptors is lowered as a result of repeated exposure to noxious stimuli—a phenomenon known as "peripheral sensitization" (see Levine and Taiwo, 1994, for review). Some of this sensitization may also be the result of central factors.

Relatively little attention has been given to models of chronic pain in the craniofacies. Chronic constrictive infraorbital nerve injury has been applied in a behavioral model of trigeminal neuropathic pain (Vos *et al.*, 1994) and has been shown to be associated with some of the features of neuropathic pain behavior, but

central effects of this model have not been fully investigated as yet. However, neuroplasticity of trigeminal nociceptive neurons has been found to be induced by dermal or deep tissue injection of mustard oil, which induces pain and other nociceptive behaviors in humans and experimental animals (see Sessle, 2000, for review). Accumulating evidence concerning the role of NMDA receptor mechanisms in these nociceptive processes has prompted the suggestion that NMDA antagonists may be beneficial in the treatment of chronic trigeminal injury and pain (Dubner and Basbaum, 1994).

The Trigeminovascular System: Implications for the Pathogenesis of Headache

The term "trigeminovascular system" refers to the cranial vessels and their trigeminal innervation, implying a functional network that may play an important role both in normal cerebrovascular function and in the aetiology of several types of headache. Sensory fibers innervating the pial and dural vessels of the anterior and middle cranial fossae arise from the trigeminal nerve, mostly within the ophthalmic division (Mayberg *et al.*, 1981; Liu-Chen *et al.*, 1984; Moskowitz *et al.*, 1983). On the other hand, the cell bodies of sensory afferents innervating the posterior cranial fossa and basilar arteries are located in the C1-C3 dorsal root ganglia (Keller *et al.*, 1985; Saito and Moskowitz, 1989). Electrical stimulation studies of the superior sagittal sinus have shown cells in Sp5C, the cervical dorsal horn, and in the dorsolateral spinal cord at the C2 level, which are responsive to dural stimulation and may be involved in vascular headache (Goadsby and Zagami, 1991; Angus-Leppan *et al.*, 1994). Convergence of inputs from facial skin and intracranial vessels could explain the pattern of referred pain seen in vascular headaches (Dostrovsky *et al.*, 1991).

For most of the 20th century, the prevailing theory of pathogenesis of migraine held that the pain was the result of abnormal dilation of intracranial dural and pial blood vessels. This dilation was believed to result in mechanical excitation of the sensory fibers associated with the vessel adventitia (Graham and Wolff, 1983). Recent studies have shown that vessel dilation does not always coincide with the onset of pain and that vessel constriction does not necessarily coincide with pain relief. Alternative theories have proposed a chemical mode of activation of meningeal perivascular sensory fibers, one that also implicates neurotransmitter release from the sensory fibers themselves in the pathogenesis of the condition (so-called neurogenic inflammation model of vascular headaches; Moskowitz, 1992).

It is now clear that meningeal blood vessels share some of the anatomical and physiological properties seen in other body tissues (e.g., joints) where pain commonly arises as a result of local sterile inflammatory processes. Importantly for the neurogenic inflammation model of vascular headaches, activation of trigeminovascular fibers can lead to release of vasoactive neuropeptides into the vessel wall (Goadsby *et al.*, 1988; Moskowitz *et al.*, 1989; Sicuteri *et al.*, 1990), thereby promoting neurogenic inflammation. Orthodromic and antidromic conduction along trigeminovascular fibers is believed to facilitate the spread of the inflammatory response to adjacent tissues, as well as to transmit the nociceptive information to Sp5C. Collaterals and higher order connections of these central fibers of the trigeminovascular system also terminate in centers associated with the generation of other symptoms of vascular headaches (e.g., nausea, emesis, autonomic activation, affective alterations; Allen and Pronych, 1997).

The triggering factor may involve temporary exposure to an unknown endogenous chemical agent that alters the sensitivity of trigeminovascular fibers to mechanical stimuli and leads to the sensation of head pain. Strassman and co-workers have shown that application of acidic and inflammatory agents to the dura causes sensitization of dural trigeminovascular fibers to mechanical stimuli that previously evoked minimal or no response (intracranial sensitization; Strassman *et al.*, 1996). This sensitization can also lead to enhanced responses of central neurons to stimuli applied at extracranial sites, thereby explaining the extracranial tenderness (mechanical and thermal allodynia) experienced by migraineurs in the absence of extracranial vascular pathology (Burstein *et al.*, 1998).

Agents that have been shown to be effective in the therapy of either migraines or cluster headaches (sumatriptan, ergotamine, somatostatin) may exert their influence by receptor-mediated effects on fibers of the trigeminovascular system. Both sumatriptan and dihydroergotamine have been shown to reduce the release of CGRP and inhibit increases in cranial blood flow resulting from trigeminal ganglion stimulation (Goadsby and Edvinsson, 1993). Somatostatin, which inhibits the effects of release of substance P from nerve terminals, is also effective in reducing the pain of cluster headaches (Sicuteri *et al.*, 1984). Similarly, repeated application of capsaicin to nasal mucosa leads to its desensitization, with a concomitant decrease in intensity and duration of cluster headaches. Experimental data support the idea that sumatriptan activates an inhibitory receptor resembling 5-HT1D on perivascular fibers and by so doing blocks

neuropeptide release and impulse conduction in the trigeminovascular system (Moskowitz, 1992).

Pathophysiology of Trigeminal Neuralgia

Recent work concerning the debilitating condition trigeminal neuralgia is worth commenting on here. Trigeminal neuralgia (TN) is characterized by severe unilateral paroxysmal pain of short duration and restricted to the trigeminal distribution (Türp and Gobetti, 2000). The symptoms are often triggered by nonnociceptive stimuli to the face (e.g., chewing or touching the face) applied to a trigger zone within the trigeminal distribution. The paroxysms last only seconds but may occur with varying frequency. Often there is a remission of weeks to months, but this only serves to heighten the patient's anxiety, sometimes to the point of suicide, as they wait for the next painful paroxysm (Choi and Fisher, 1994). TN has an increased prevalence among patients with multiple sclerosis, consistent with the presumed importance of demyelination in the pathophysiology.

The pathophysiology of TN remains controversial. One postulated cause is demyelination within the posterior trigeminal root entry zone and brainstem, leading to repetitive firing of the nerve and its central connection. A large proportion of patients with TN show evidence of external vascular compression (Hamlyn, 1997), with focal demyelination near the compression site.

Two physiological mechanisms have been postulated to explain how nerve compression may lead to painful paroxysms (Choi and Fisher, 1994). In the first, compression is believed to lead to selective demyelination of large sensory fibers with relative sparing of smaller nociceptive fibers. The segmental inhibitory effect of larger fibers is lost while transmission of painful impulses through the smaller undamaged nociceptive afferents continues uninhibited. In the other proposed mechanism, extra axon potentials are believed to be initiated at the site of injury. Such ectopic activity may arise by injury-induced repetitive firing of nociceptive afferents. Alternatively, ephaptic "cross-talk" between fiber classes has been proposed, with action potential currents in low-threshold afferents causing impulse generation in adjacent nociceptive fibers.

Studies of the ultrastructure of trigeminal roots removed during microvascular decompression surgery for TN have shown zones of de- and dysmyelination, juxtaposition of denuded axons, apparent axon loss and degeneration, and collagen deposition (Rappaport *et al.*, 1997). Those authors' observations of the proximity of denuded axons support the hypotheses of ectopic generation of impulses, ephaptic contacts, and crossed after-discharge. They have proposed that a small cluster of trigeminal ganglion cells (the ignition focus) develops autorhythmicity as a result of trigeminal root damage. Activity then spreads from this focus to other parts of the ganglion by release of neurotransmitter and potassium ions through the extracellular space (Rappaport and Devor, 1994). The effectiveness of phenytoin and carbamazepine in the treatment of TN is consistent with the importance of excitable membrane instability in the pathophysiology of the condition (Choi and Fisher, 1994).

The effectiveness of surgical microvascular decompression of the trigeminal root has long been taken as an indication of the importance of compressive nerve damage in the aetiology of TN. More recently, Tenser (1998) has questioned this presumption, pointing to the effectiveness of many other therapies for TN (e.g., glycerol or thermal rhizolysis, balloon compression, blunt trauma to the trigeminal root, alcohol injury, and radiation therapy), which probably produce controlled injury to the ganglion. Tenser maintains that similar effectiveness of a wide range of treatments for TN suggest that these therapies act through a common pathway (i.e., the induction of damage to trigeminal ganglion cells with alteration in ganglion cell transcription). He argues that altered ganglion cell function (as reflected in the high frequency of herpes simplex virus activation after these treatments), rather than reduction in ephaptic transmission or the elimination of ectopic signal generation, is responsible for bringing relief. Nevertheless, it remains to be explained how a general increase in ganglion cell transcription diminishes pain—an issue not adequately addressed by Tenser.

Correlation of with Clinical Features

Although much of the preceding discussion has been derived from studies in experimental animals, it is possible to correlate many of the results from animal studies with clinical experience. For example, many patients experiencing or anticipating craniofacial pain (e.g., dental patients) undergo or experience diverse effects including reflex changes in blood pressure, heart rate, respiration, and sweating, as well as coactivation of jaw-opening and -closing muscles. These phenomena have been shown in experimental animals to involve Sp5C. Effects on masticatory muscle tone may serve an adaptive function by "splinting" the TMJ, as often seen clinically after painful injury.

The poor localization of pain in most toothaches and headaches, and the common feature of pain referral in these conditions, probably reflects the extensive convergence of nociceptive afferents from diverse sources (tooth pulp, cranial vessels, and dura), as noted earlier

in findings from experimental animals (Sessle and Hu, 1991; Strassman *et al.*, 1994). Acute toothaches and headaches are often associated with intense pain and tenderness, often with radiation or referral to neighboring craniofacial regions. These aspects are considered to reflect convergence and peripheral sensitization phenomena (see Sessle, 2000, for review).

Studies of trigeminal nociception in experimental animals will continue to be an important area of research. Nevertheless, more correlation of findings from experimental animals with clinical experience is necessary to realize the full benefits of animal studies.

Trigeminothalamic Projections

As noted previously, there is an extensive thalamic projection from Pr5 to VPM. Both Sp5O and Sp5I also project to VPM, but to a lesser extent than Pr5, while Sp5I also gives projections to Po, at least in animal studies. For Sp5C, there are projections to VPM, Po, VMpo, and VPI as well as to the mediodorsal nucleus and the intralaminar nuclei. Some cells in the marginal zone also provide projections to VPI (Craig, 1996). There are also thalamic projections from Me5 in the squirrel monkey (Pearson and Garfunkel, 1983), possibly to a region anterior to VPM designated VPO by Percheron (Chapter 20) and VPS by Kaas and Pons (1988; Chapter 28). This region receives inputs from deep receptors (e.g. muscle spindles) mainly via the external cuneate nucleus and is topographically organized (Chapter 28).

Trigeminothalamic pathways have long been recognized for their ability to show species differences (Verhaart and Busch, 1960). Humans have both dorsal and ventral trigeminothalamic tracts (reviewed Usunoff *et al.*, 1997). The ventral pathway, also called the trigeminal lemniscus, arises from all levels of the trigeminal nuclear complex. Fibers run through the ventral pontine tegmentum and decussate to join the dorsomedial side of the contralateral medial lemniscus. They then travel with the medial lemniscus to terminate in various thalamic sites (see later). Lesions in the brainstem involving the trigeminal lemniscus lead to contralateral sensory loss of both touch and pain, supporting its crossed projection and its involvement in both low- and high-threshold responses (Kim, 1993).

The dorsal tract arises primarily from the dorsomedial (intraoral) part of Pr5 (cat, Azerad *et al.*, 1982; cat and monkey, Burton and Craig, 1979). Fibers pass dorsomedially in the dorsal pontine tegmentum, run ventral and lateral to the periaqueductal gray in the midbrain, and then pass laterally to enter the dorsomedial part of the ipsilateral VPM.

THALAMIC SITES FOR TRIGEMINAL SOMATIC SENSATIONS

Subdivisions of the thalamus are discussed by Percheron (Chapter 20) and the somatosensory thalamus is considered in detail by Kaas (Chapter 28). Rather than repeat this information, we consider here only those nuclei that are associated with cranial somatic sensations.

Brainstem trigeminal nuclei provide a major input to VPM, and also project to VPO and the midline and intralaminar nuclei. In addition, there are inputs to a region posterior and inferior to VPM and VPL, which Percheron (Chapter 20) has called regio basalis. This region includes, from medial to lateral, the suprageniculate, the Po and VMpo areas described by Blomqvist *et al.* (2000), and VPI. Regio basalis receives inputs from laminar 1 cells of Sp5C and the spinal cord (Hassler, 1959). For humans, information on trigeminal responses is available only for VPM, VMpo, and Po, and the following sections consider these. For trigeminal inputs to VPO and VPI, the only details available in the human, relate to somatotopy and are considered by Kaas in Chapter 28. Somatic inputs to the midline nuclei, such as the ventrocaudal part of the mediodorsal nucleus (MDvc), with its projections to the anterior cingulate cortex, are thought to be involved in the affective-motivational aspects of nociception (Rainville *et al.*, 1997; Craig, 1996; Peyron *et al.*, 2000). Responses in these areas show widespread receptive fields and modality convergence, which are not specific to facial sensations, and consequently are not considered further.

Ventroposterior Medial Nucleus

The (VPM) nucleus (also called Vci) lies medial to VPL and is separated from it by a narrow band of fibers sometimes referred to the arcuate lamina though is really only an accumulation of lemniscal fibers. VPM is characterized by relatively densely packed, small to medium-sized cells and shows a high level of parvalbumen immunoreactivity and, conversely, low calbindin levels (Morel *et al.*, 1997).

VPM is somatotopically organized, with the intraoral surface, including the tongue, lying medially. VPM is adjacent to, but excludes, the relatively parvocellular area (VPMpc), which receives gustatory inputs, also referred to as VMb or Varc. The most medial cells of VPM have ipsilateral intraoral receptive fields. This region receives input from dorsal (mandibular) Pr5 via the ipsilateral dorsal trigeminothalamic tract (Smith, 1975). The remainder of VPM receives contralateral inputs via the ventral trigeminothalamic tract, with

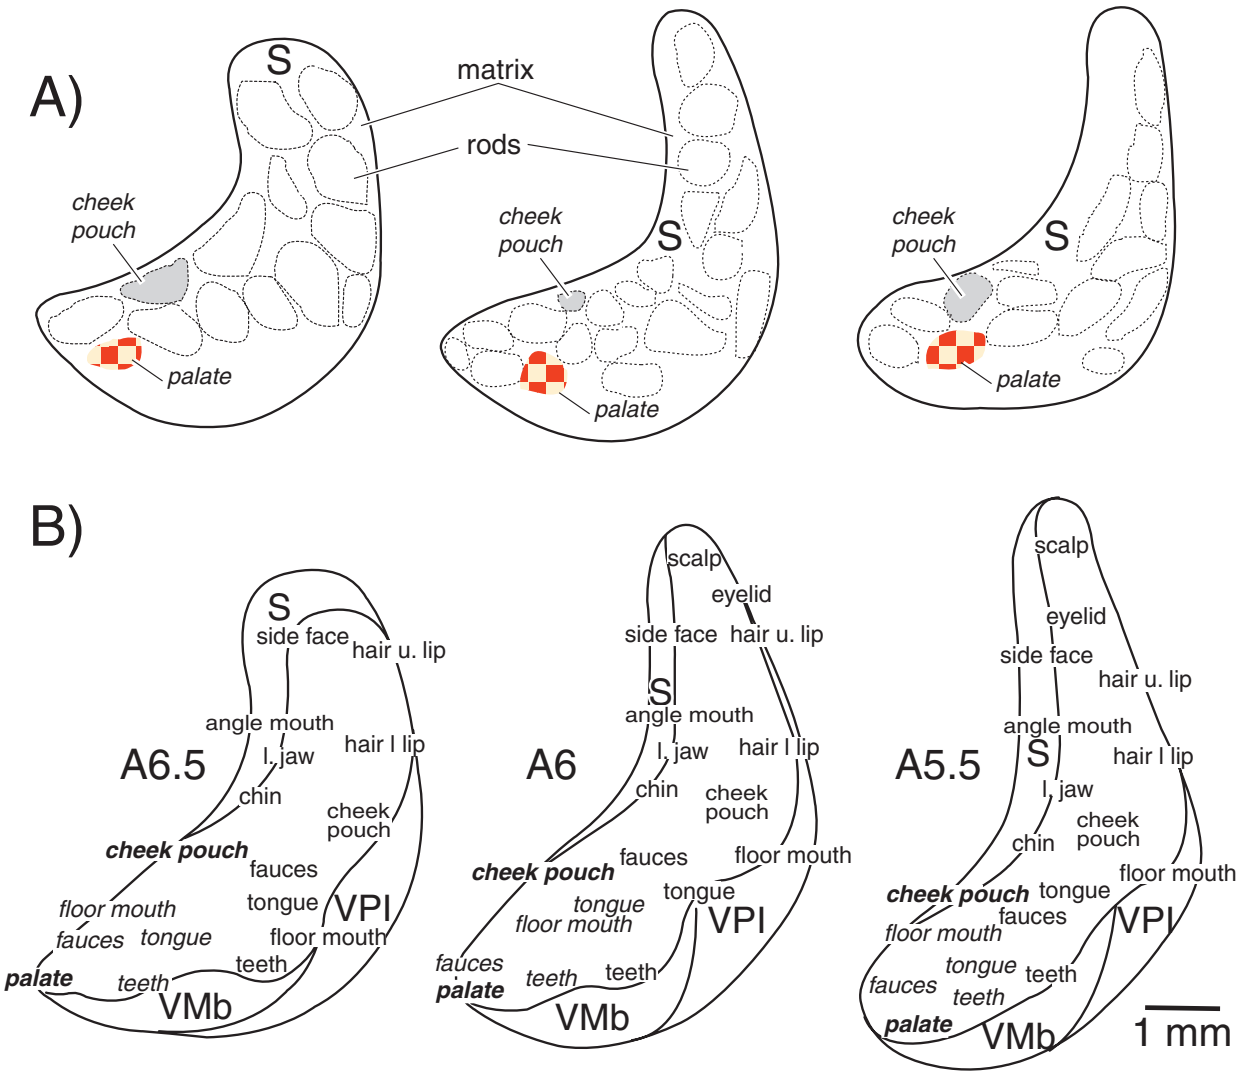

FIGURE 29.4 **(A)** Coronal cross sections through monkey VPM at three successive rostrocaudal levels (rostral to left) to show cytochrome oxidase (CO)-dense rods surrounded by a CO-pale matrix, S (after Fig. 4, Raussell and Jones 1991a, J. Neuroscience 11: 210–225, with permission, Copyright 1991, Society for Neuroscience). **(B)** Cross sections of VPM at similar levels to those shown in A with the peripheral receptive fields for cells at each site reconstructed from stereotaxic coordinates (Russell and Jones, 1991a, Fig 8, with permission, as in A). Receptive fields shown in italics are ipsilateral; those in roman type are contralateral. Some receptive fields such as the cheek pouch and palate (bold) can be localized to specific CO-rich rods (denoted in A) and identified at corresponding sites at each level. S indicates part of the small-celled matrix region; VPI, ventral posterior inferior nucleus; VMb, ventral medial basal nucleus receiving gustatory inputs.

intraoral and mandibular skin represented ventrally and ophthalmic regions dorsally (Fig. 29.4). Adjacent regions in VPL are responsive to finger and hand stimulation. The close proximity of these regions is indicated by the clinical finding that localized vascular lesions in this boundary region can lead to the cheiro-oral syndrome, in which there is a sensory disturbance of the contralateral face and hand (Fisher, 1982; Shintani *et al.*, 2000).

Raussel and Jones (1991a) described monkey VPM as consisting of cytochrome oxidase (CO)-rich rods surrounded by a CO pale matrix (see Fig. 29.4 and Table 29.1). The rods contain large and medium cells, which are parvalbumen positive, as well as smaller GABAergic cells. These areas also stain richly for AChE and tachykinin immunoreactive fibers (e.g., substance P, neurokinin A and B, Liu *et al.*, 1989). The rods extend as anterior–posterior columns within the nucleus, with all cells in a column having similar receptive fields. They receive their major input from Pr5 and project to cortical layer 4 of the primary somatosensory cortex (Raussel and Jones, 1991b). In contrast, the matrix lies around the rods and forms a shell at the edges of VPM, which can extend into adjacent nuclei (Jones, 1998). It contains small calbindin positive cells and some GABAergic neurones.

TABLE 29.1 Thalamic Sites concerned with Cranial Somatic and Gustatory Sensations

Nucleus	Parvalbumen	Calbindin	Substance P *(B)*	CGRP *(B)*	Input	Output	Functional Group

P&N, Norgren and Pritchard, Chapter 31.

The predominant input to the matrix of VPM arises from Sp5C, mainly the deeper laminae. The calbindin positive matrix cells have widespread projections to superficial cortical layers.

Response properties of human VPM cells have been reported by a number of authors (Jasper and Bertrand, 1966; McComas *et al.*, 1970; Ohye *et al.*, 1972; Donaldson 1973; Lenz *et al.*, 1988). Most have reported low-threshold, mechanoreceptive responses to hair or skin stimulation. Besides cutaneous cells, responses to deep pressure and/or joint movement have been noted (Ohye *et al.*, 1972; Lenz *et al.*, 1988; Seike, 1993) though these may have been located in VPO (see Chapter 28, where it is referred to as VPS). In the rat, VPM receives inputs from the TMJ and jaw muscles and may be involved in proprioceptive sensations (Luo *et al.*, 1991; Ohya *et al.*, 1993) via Pr5 and Sp5I though this is not confirmed in humans.

All studies in humans agree that receptive fields are contralateral and generally small, similar in size to those on the fingers. There is a predominance of responses from the lips and perioral area (Donaldson, 1973; Lenz *et al.*, 1988). Many cells in VPM are activated by speech movements; for instance, cells with receptive fields on the lips may be activated when the subject makes the sound "p" (McClean *et al.*, 1990). Two-thirds of the responses are slowly adapting (Lenz *et al.*, 1988) and spontaneous activity, at up to 40–50 impulses/s, is present in some cells (Jasper and Bertrand, 1966). These results are similar to those in the alert monkey where Bushnell and Duncan (1987) found 90% of VPM cells had low-threshold cutaneous receptive fields, usually within one trigeminal division. Cells were activated by hair or skin stimulation, and both rapidly and slowly adapting responses were noted.

In most studies in primate VPM and VPL, responses to noxious stimulation have been rare or absent. In monkey VPM a small population of cells (10%) gave nociceptive, WDR responses (Bushnell and Duncan, 1987). Similarly, a study by Lenz *et al.* (1993a) in humans reported 6% of neurons in the ventrocaudal thalamus responded to noxious heat as well as innocuous thermal and mechanical stimuli, as for WDR responses. Moreover microstimulation of this region in humans evoked thermal and pain sensations (Lenz *et al.*, 1993b). Such sensations were more common (30% of sites) from the posteroinferior region, which may have corresponded to VPI, than from the "core" region (5%). An extensive study by Dostrovsky *et al.* (2000) found only 8% of sites evoked pain in normal subjects though this was markedly increased in patients with poststroke pain. Animal studies have also reported innocuous thermal responses in VPM to cooling of the tongue, but not other facial regions (monkey, Poulos and Benjamin, 1968). Cells were either cold-specific or responded to cooling and mechanical stimuli; no responses to warming were found. The paucity of thermal and nociceptive responses in VPM suggests that these modalities may activate additional thalamic sites and a major relay is probably the adjacent region VMpo (see later).

Ventromedial Nucleus, Posterior Part and Surrounding Po (Basalis Nodalis and Halo)

A relatively recently identified nucleus, thought to be a relay for pain and temperature sensations, has been described in monkey and human (Craig *et al.*, 1994; Blomqvist *et al.*, 2000). VMpo lies posterior and medial to VPM and VPL, ventral to the anterior pulvinar and center median nuclei and dorsal to the medial geniculate nucleus. It was designated the posterior ventromedial nucleus by Paxinos and Huang (1995), although Percheron (Chapter 20) considers it a discrete nucleus "Nodalis" within the regio basalis. VMpo contains small to medium-sized cells, loosely aggregated in clusters (Blomqvist *et al.*, 2000). In both monkey and human, it stains richly for calbindin with a dense plexus of immunopositive fibers (Craig *et al.*, 1994). Lamina 1 cells of Sp5C and the spinal dorsal horn have been shown to project to this region in monkeys (Craig *et al.*, 1994). Double labeling has been used to establish that the calbindin immunoreactivity in these terminals colocalized with anterogradely transported tracer from lamina 1 cells (Craig *et al.*, 1994). In human tissue, calbindin immunoreactive fibers of the spinal lemniscus form dense patches of terminals over VMpo neurons (Blomqvist *et al.*, 2000). Immunocytochemistry was used to show that fibers containing substance P or CGRP terminated in VMpo. Substance P staining frequently overlapped with that of calbindin, but was less dense, suggesting that substance P was present only in a subset of the calbindin-positive fibers. In contrast, CGRP immunoreactivity never overlapped with calbindin but lay between calbindin-rich areas.

Recordings from this region in monkeys show responses to innocuous thermal (cooling) or noxious stimuli. Cells had small receptive fields on the contralateral body surface, with clusters of adjacent cells sharing similar response properties (Craig *et al.*, 1994). Both recording experiments and tracing studies in monkeys indicate a topographic organization. Trigeminal inputs are represented anteromedially, posterior and ventromedial to VPM, whereas the limbs are represented more posterolaterally, posterior and ventromedial to VPL.

As in monkeys, recordings from this site in humans indicate that cold-specific (COLD) responses are present (Dostrovsky and Craig, 1996). Stimulation of this site in awake humans evoked cold sensations on localized parts of the contralateral body surface, including the face (Davis *et al.*, 1999). Moreover, imaging of the region shows activation with noxious and thermal stimuli (Craig *et al.*, 1996). Thus VMpo has been suggested to be a specific thalamic relay site for nociceptive and cold-specific responses from the whole body surface, with the possible exception of the tongue. Infarcts in this region are associated with analgesia and loss of thermal sensibility (Leijon *et al.*, 1989). VMpo projects to a localized region of the insula, which shows activation in PET studies with noxious or cooling stimuli (Craig *et al.*, 1996).

Blomqvist *et al.* (2000) have also identified a region around VMpo that they call Po, though this should not be confused with Po as described by Jones (1985). Percheron (Chapter 20) describes it as a "halo" around VMpo within the regio basalis (i.e., basalis halo, BH). Po (BH) is a curved region forming the anterior, lateral, and ventral aspects of VMpo. It contains patches of CGRP positive fibers known to be associated with visceral inputs (Blomqvist *et al.*, 2000; de Lacalle and Saper, 2000). Po (BH) has therefore been suggested to act a general visceral afferent for inputs from the glossopharyngeal, vagal and pelvic nerves (Blomqvist *et al.*, 2000).

Overview of Thalamic Relay Nuclei for Cranial Sensations

The sites associated with somatic and gustatory sensations in the human are summarized in Table 29.1. Staining for the Ca-binding proteins parvalbumen and calbinin has been included, although calretinin has been omitted as it is generally low or absent in these areas (Fortin *et al.*, 1998; Cicchetti *et al.*, 1998). In this schema, the rod component of VPM (and VPL, though not included here) forms the general somatic relay nuclei for tactile information, with its main output to area 3b the primary somatosensory cortex (Darian-Smith *et al.*, 1990; Chapter 28). In contrast, the matrix has more diffuse projections to superficial cortical layers and is suggested to have a modulatory role (Jones, 1998). VPO is likely to provide for proprioceptive sensation, although the extent of trigeminal involvement in this is unclear. VPMpc acts as a special visceral relay for taste, receiving inputs primarily from the nucleus of the solitary tract (Beckstead *et al.*, 1980; Chapter 31). Po (BH), with its dense plexus of CGRP fibers, may correspond to the relay for visceral afferents (glossopharyngeal, vagal, and pelvic inputs; Chapter 31), while VMpo, with its input of substance P positive fibers, comprises the relay for general somatic afferents for pain and temperature. VPI receives input from both superficial and deep laminae and, like the matrix of VPM and VPL, may have a more diffuse modulatory role (Chapter 28). VMpo, Po, and VPI have been considered part of the regio basalis by Percheron (Chapter 20).

CRANIAL SOMATOSENSORY CORTEX

As for the thalamus, we will not attempt to repeat here the organization and function of the whole somatosensory cortex and associated areas involved with somatosensory processing. These have been well covered in Chapter 28. Rather we focus on recent data addressing those aspects that are unique for cranial somatic sensations.

Organization of Orofacial Somatosensory Cortex

The overall organization of the primary somatosensory cortex, with face located laterally adjacent to the hand, has long been established. A recent report of the facial representation in owl and squirrel monkeys (Jain *et al.*, 2001) shows a remarkable pattern of myelin-dense patches within area 3b (Fig. 29.5). They are separated from each other by myelin-light septa, which mainly receive callosal inputs (Krubitzer and Kaas, 1990). Jain *et al.* (2001) used electrophysiological recordings to show that each patch represented a specific region: upper face, upper lip, chin and lower lip, contralateral teeth and tongue, and ipsilateral teeth and tongue. These representations extended in an orderly sequence from caudal to rostral in the cortex. In addition, within each patch, receptive fields were somatotopic; for example, for the upper face, the upper forehead was caudal to the lower forehead. Similar representations were also found in parallel strips of cortex medial and lateral to area 3b and were presumed to correspond to areas 3a and 1. A similar organization is found in the macaque monkey (Manger *et al.*, 1995, 1996), although macaques have a larger representation of the intraoral cheek pouches, likely to reflect their use of these for food storage.

Like other body regions (Woolsey *et al.*, 1979; Wood *et al.*, 1988), recordings of somatosensory-evoked potentials after stimulation of trigeminal nerves have been used to assess localization and topography of orofacial responses in humans (Stöhr and Petruch, 1979; Bennett and Jannetta, 1980; Findler and Feinsod,

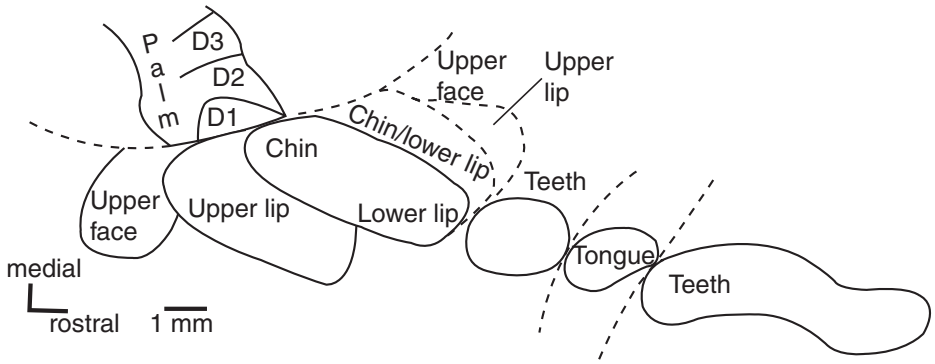

FIGURE 29.5 Trigeminal representation of the primary somatosensory cortex of the owl monkey. Myelin-rich regions in area 3b of the hand, face, and oral cavity representations are outlined (solid lines). Somatic positions for receptive fields for cells obtained from electrophysiological mapping experiments are superimposed for each region. Boundaries between regions, corresponding to myelin-light septa, are shown (dashed lines). Adapted from Figure 3, Jain *et al.* 2001, Anatomic correlates of the face and oral cavity representations in the somatosensory cortical area 3b of monkeys. *J. Comp. Neurol.* **429:** 455–468. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley and Sons, Inc.

1982; Badr *et al.*, 1983). Response latencies for somatosensory-evoked potentials from the orofacial region are generally shorter than for the hand region but otherwise show a similar series of waves (Ishiko *et al.*, 1980; Seyal and Browne, 1989). As found in animal studies, face representation is lateral to the hand, with an orderly progression of upper face, upper lip, lower lip, and tongue, from medial to lateral (Penfield and Rasmussen, 1950; McCarthy *et al.*, 1993). In contrast to most studies on the limbs, orofacial inputs have generally been found to give bilateral responses (Hashimoto, 1988).

Over the past decade or so, imaging techniques of positron emission tomography (PET; Fox *et al.*, 1987; Bittar *et al.*, 1999), magnetoencephalography (MEG; Nakamura *et al.*, 1988; Yang *et al.*, 1993; Hoshiyama *et al.*, 1996) and functional magnetic resonance imaging (fMRI; Sakai *et al.*, 1995; Moore *et al.*, 2000) have been used to address the organization of the human somatosensory cortex. These studies confirm the overall topography reported from somatosensory evoked potentials, with the orofacial representation lying lateral to that of the hand (see Chapter 28, Fig 28.7). As for evoked responses, PET has demonstrated the bilateral nature of the tongue representation (Pardo *et al.*, 1997).

Disbrow *et al.*, (2000) have recently used fMRI to show that besides SI, human cortex has both SII and parietal ventral (PV) representations within the lateral sulcus. Both regions are mirror-symmetrical and topographically organised with face most lateral on the lip of the upper bank of the lateral sulcus, similar to the macaque (Krubitzer *et al.*, 1995; Disbrow *et al.*, 2000; Chapter 28). They found that unlike areas 3b and 1, localized stimuli were less effective in SII and PV. Stimuli over larger skin areas and stimuli moving across the skin were particularly effective in SII and PV, suggesting, indirectly, that cells in these areas may have larger receptive fields. This was also supported by the finding that unilateral stimuli caused bilateral activation in both areas.

For intraoral representations, a recent PET study has considered the issue of somatosensory versus gustatory areas by using water as the stimulus (Zald and Pardo, 2000). Intraoral water caused activation of a large area of the pre- and post-central gyrus, insula, and operculum. Voluntary swallowing was used to eliminate areas thought to be associated with somatosensory and motor processing, as compared with gustation. Subtraction of activity associated with voluntary swallowing reduced activation in all these regions. Not surprisingly, the peak focus of somatosensory activation occurred in the post-central gyrus, in an area consistent with the representation of the tongue and oral cavity.

Orofacial Response Characteristics

Responses of cells in areas 3b, 1, and 2 in orofacial regions are similar to those from the limbs. Thus 3b gives primarily cutaneous responses with small receptive fields, while area 1 has larger, more complex responses and area 2 contains both cutaneous and deep receptors. These are discussed in Chapter 28. Nociceptive responses have also been reported in SI from trigeminal activation (Kenshalo and Isensee,

1983; Kenshalo *et al.*, 1988; Chudler *et al.*, 1990). Such responses are found within SI as well as in SII and adjacent regions (Dong *et al.*, 1989).

A series of experiments in awake macaque monkeys has provided the best information to date on responses of cells within orofacial regions of the primate SI cortex. Cells were located in areas 3b, 1, and 2. The most frequently recorded responses were from cells sensitive to stimulation of the lips, tongue and periodontium (Lin *et al.*, 1994a). Most cells were activated by low-threshold stimulation and gave rapidly adapting responses. Seventy-eight percent of the units responded to contralateral stimuli; the others being bilateral. The activity of many units was modified by a protrusion of the tongue, and in some cases activity could change significantly prior to the onset of EMG activity associated with the movement. However, biting movements did not change the firing pattern in most of the cells. Modification of somatosensory responses during facial movements would relate in part to movement-activated stimulation within the receptive field of the neuron. In addition, Lin *et al.* suggested that these sensory cells may provide an important input for controlling the movement or even initiating it. The role of these cells in regulating tongue movements was further supported by a study (Lin *et al.*, 1994b) in which monkeys were trained to protrude the tongue in different directions. Over half of the responses from areas 3b and 1 showed a difference in response in relation to the direction of tongue protrusion. Moreover it was shown that the response of cells to stimulation of their receptive fields on the lips or tongue were suppressed during a tongue protrusion movement. This suppression was not generalized across all the somatosensory cortex but rather was dependent on the location of a particular receptive field in relation to the movement being undertaken (Lin and Sessle, 1994). The importance of responses in SI for undertaking learned movements was shown by Lin *et al.* (1993) by cooling of SI during a tongue protrusion or biting task. During cooling, monkeys had difficulty in maintaining the steady tongue protrusive force during the holding period.

Plasticity of Trigeminal Responses

There is increasing evidence to support reorganization of somatosensory responses following deafferentation, for instance after nerve section or amputation. This is widely reported from animal studies (Wall, 1988; Garraghty *et al.*, 1994; Jain *et al.*, 1998; Waite, 2000) where representation of a body part adjacent to a denervated area expands into the deafferented representation. There is now considerable evidence that similar reorganization can occur in humans (Mogilner *et al.*, 1993; Ramachandran, 1993). Some of the most extensive changes involve cortical regions originally responsive to stimulation of the hand, becoming reorganized to respond to facial stimuli. For example, MEG imaging has shown an anatomical shift of the cortical area activated by facial stimuli after amputation (Elbert *et al.*, 1994). The facial area was shifted medially into the region normally associated with responses from the hand. Such changes may explain the finding that stimulation of the face evokes sensations on the "phantom" hand (Ramachandran *et al.*, 1992; Halligan *et al.*, 1993). Correspondingly, referral to the hand occurred after the removal of the maxillary and mandibular regions of the trigeminal ganglion (Clarke *et al.*, 1996). Some cortical reorganization occurs immediately after deafferentation, although it is clear that reorganization continues to become more extensive for years after the injury (Pons *et al.*, 1991).

The cortical reorganization reported in monkeys can extend for 10 to 14 mm (Pons *et al.*, 1991), well beyond the known overlap in thalamocortical projections (about 1.5 mm, Rausell and Jones, 1995). Similarly in humans shifts of approximately 2 cm have been demonstrated (Elbert *et al.*, 1994). One possible mechanism for such widespread remapping was suggested to involve changes in horizontal intracortical connections. However, Manger *et al.* (1997) showed that there were few such horizontal connections crossing the border between the hand and trigeminal areas in macaques. In contrast, the hand representation had extensive intracortical connections with lower jaw and neck regions innervated by C2 and C3 cervical nerves. These extended for some 3 mm and may, at least in part, explain the remapping after amputations or deafferentation. However, the limited extent of intracortical connections indicates that they are probably not sufficient to explain the total reorganization seen.

Another mechanism likely to contribute to the remapping that is seen at cortical level is the degree of subcortical change that can occur. Plasticity at both brainstem and thalamic levels have been documented in animal studies (reviewed Kaas *et al.*, 1999). For example, in the brainstem, trigeminal inputs grow into the cuneate nucleus after amputations or lesions of the dorsal columns (monkey, Jain *et al.*, 2000). There is now evidence for plasticity in the human thalamus, both immediately after a cold block of the receptive field of a neuron (Dostrovsky, 1999) and chronically after amputation (Kiss *et al.*, 1994). Similarly after spinal transections or surgery for chronic pain, expansions of border zone responses into anaesthetic areas were found (Lenz *et al.*, 1994). These changes suggest that

expansions from adjacent central representations can occur at any level of a sensory path. Thus besides cortical reorganization, changes in brainstem and thalamus may underlie trigeminal expansions into other central somatic territories. Similarly, limb inputs can invade trigeminal territories at all central levels after damage to trigeminal nerves or ganglion (rat, Waite, 2000; human, Clarke *et al.*, 1996).

CHAPTER

30

Pain System

WILLIAM D. WILLIS, JR. and KARIN N. WESTLUND
Department of Anatomy and Neurosciences
University of Texas Medical Branch
Galveston, Texas, USA

The somatovisceral sensory system is responsible for signaling a variety of types of sensory information. Of particular interest in medicine is pain, since pain is the most common reason for a patient to confer with a physician. Pain signals are processed in humans and other mammals by the pain system (Willis, 1985), which is composed of primary afferent nociceptors, ascending spinal cord (and trigeminal) nociceptive pathways, descending modulatory pathways, and a number of brain structures that process information related to pain signals. There are a variety of reactions to painful stimuli (Hardy *et al.*, 1967), including not only sensory discrimination of pain but also motivational–affective responses to painful stimuli (Melzack and Casey, 1968; Price and Dubner, 1977), as well as somatic and autonomic reflexes, endocrine changes, and memories of pain. Transmission of pain signals to the brain also activates feedback circuits that can inhibit the effects of sensory input at the spinal cord or brain stem level or, alternatively, accentuate pain responses. The negative-feedback pathways are often referred to as the "endogenous analgesia system."

Evidence about the pain system has been reviewed previously, based on work utilizing a variety of laboratory mammals, especially rats (Willis, 1985; Besson and Chaouch, 1987; Willis *et al.*, 1995; Willis and Westlund, 1997; Millan, 1999; Willis and Coggeshall, 2003). This chapter emphasizes work concerning the pain system that is based primarily on experiments that used primates and on observations in human subjects. Although most of the studies described here refer to pathways that involve the spinal cord, there will be some reference to the comparable pain system that signals information conveyed by the trigeminal and other cranial nerves and their central connections (see also Chapters 28 and Chapter 29).

NOCICEPTORS

Cutaneous, Muscle, Joint, and Visceral Nociceptors

Painful stimuli are transduced by nociceptors, which are specialized peripheral nerve endings in the skin, muscle, joints, viscera, teeth and dura (Sherrington, 1906; Belmonte and Cervero, 1996; Kumazawa *et al.*,

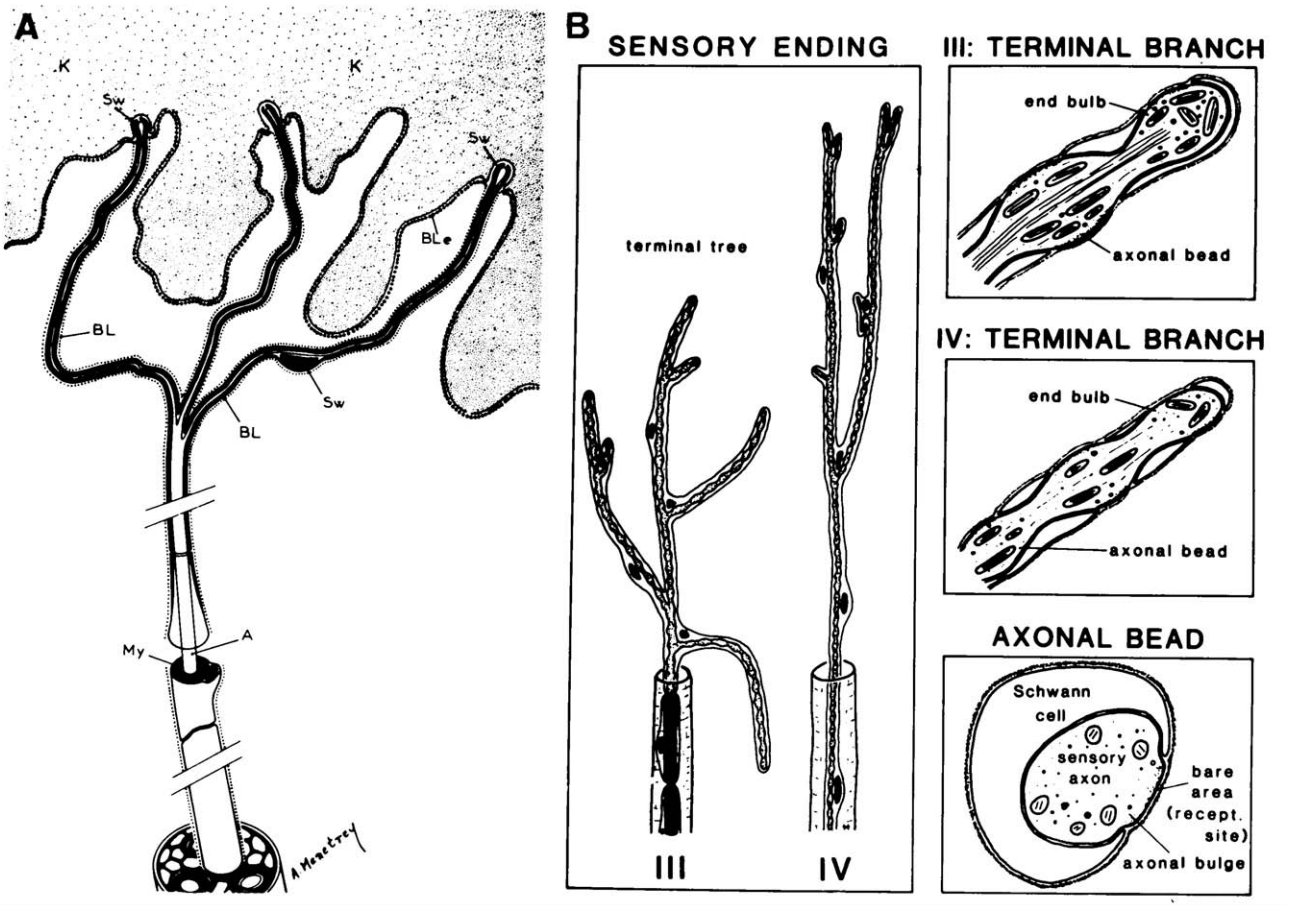

FIGURE 30.1 Structure of nociceptive terminals in the skin and the knee joint. In **A** are shown the terminals of an Aδ mechanical nociceptor in the skin of a cat. The reconstruction was based on electron microscopic observations. Note that the afferent fiber has several different endings that penetrate the basal lamina (BLe) and then extend into the epidermis. The myelin sheath (My) ends within the dermis. Most of the terminal membrane of the endings is covered by Schwann cell (Sw) processes. Other abbreviations: A, axon; K, keratinocytes. (From Perl, 1984.) In **B** are drawings of low- and high-magnification views of the endings of group III and IV joint afferents, as reconstructed from electron micrographs. The "free endings" are covered in large part by Schwann cell membrane. However, there are areas where the axonal membrane is exposed to the extracellular fluid. Such areas may be the sites of transduction or membrane regions that contain receptor molecules for bioactive substances. (From Schaible and Schmidt, 1996.)

1996). Nociceptors respond maximally to overtly damaging stimuli, although they generally also respond, but less vigorously, to stimuli that are merely threatening (Burgess and Perl, 1973). Axons that relay information about noxious input to the central nervous system (CNS) include small Aδ fibers, which are wrapped in a thin layer of myelin and which conduct at 4–35 m/s, and C fibers, which are very small, unmyelinated fibers with conduction velocities under 2.5 m/s (Boivie and Perl, 1975). In addition, more rapidly conducting nociceptive A fibers (up to 51 m/s) have been described in monkeys (Georgopoulos, 1976; Treede *et al.*, 1995).

Experiments on cats provide evidence that noxious cutaneous and joint stimuli are transduced by unencapsulated free nerve endings ensheathed by Schwann cells (Fig. 30.1) (Perl, 1984; Heppelmann *et al.*, 1990; Schaible and Schmidt, 1996). Areas of axon membrane bare of a Schwann cell covering may be sites of nociceptive transduction (Schaible and Schmidt, 1996) or the locations of surface membrane receptors for agents that modulate nociceptive transduction (Coggeshall and Carlton, 1997). Presumably, similar morphological arrangements would be found in human nociceptors.

The two main types of cutaneous nociceptors found in human skin are Aδ mechanical and C polymodal nociceptors, although other types of nociceptors have also been described (e.g., Davis *et al.*, 1993). Mechanical nociceptors respond to strong mechanical stimuli,

whereas several different types of noxious stimuli, such as noxious mechanical, thermal, and chemical stimuli, can activate polymodal receptors. Human nociceptors have been studied extensively in experiments utilizing the microneurography technique (Van Hees and Gybels, 1972; 1981; Torebjörk, 1974; Torebjörk and Hallin, 1974; Ochoa and Torebjörk, 1989; Torebjörk and Ochoa, 1990; Hallin *et al.*, 1981; Konietzny *et al.*, 1981; Adriaensen *et al.*, 1983; Bromm *et al.*, 1984; LaMotte *et al.*, 1992; Yarnitsky *et al.*, 1992; Koltzenburg and Handwerker, 1994; Schmetz *et al.*, 1994; Schmidt *et al.*, 1995; Treede *et al.*, 1998; Weidner *et al.*, 1999).

The sudden application of a painful stimulus, such as noxious heat, can elicit two distinct forms of pain in human skin: an initial sharp pain, followed by a burning pain. These sequential pain sensations are often termed "first" and "second" pain. Aδ nociceptors are responsible for first pain and C fibers for second pain (Lewis, 1942; Torebjörk and Hallin, 1973; Handwerker and Kobal, 1993; Treede *et al.*, 1995). Consistent with this, intraneural stimulation of Aδ nociceptors through a microneurography electrode evokes a sensation of stinging or sharp pain (Konietzny *et al.*, 1981; Schady *et al.*, 1983; Marchettini *et al.*, 1990), whereas stimulation of individual or small groups of C fibers evokes a sensation of burning or dull pain (Ochoa and Torebjörk, 1989; Torebjörk and Ochoa, 1990).

Pain arising from tissue that is deep to the skin is typically aching or cramping in quality (Lewis, 1942). For example, intraneural microstimulation experiments have shown that electrical or chemical stimulation of either group III or IV nociceptors in muscle nerves of human subjects causes a deep, aching, or cramping pain (Torebjörk *et al.*, 1984; Simone *et al.*, 1994; Marchettini *et al.*, 1996; Graven-Nielsen *et al.*, 1997a, b, 1998).

As in humans, the skin of monkeys is supplied by Aδ mechanical nociceptors and C polymodal nociceptors (Perl, 1968; Beitel and Dubner, 1976; Georgopoulos, 1976; Kumazawa and Perl, 1977; Meyer and Campbell, 1981; LaMotte *et al.*, 1982; 1983). Two different types of mechanoheat nociceptors with Aδ-size afferent fibers (types I and II) have been described in monkey skin (Treede *et al.*, 1995). Only the type II receptors have characteristics (strong heat responsiveness, sufficiently rapid conduction velocity) that can account for first pain.

C nociceptors in monkeys can generally be activated by mechanical, thermal, and chemical stimuli, leading to their designation as C polymodal nociceptors (Beitel and Dubner, 1976; Kumazawa and Perl, 1977). Similar receptors are found in humans (Torebjörk, 1974). However, mechanical and thermal stimuli are often the only noxious stimuli tested, in which case the fibers may be termed C mechanoheat receptors (LaMotte *et al.*, 1983; Treede *et al.*, 1990). C nociceptors that respond to noxious heat appear to end in both the epidermis and dermis of the skin of monkeys (Tillman *et al.*, 1995).

A large proportion of the cutaneous A and C nociceptors in monkeys are insensitive to mechanical stimulation when initially tested under normal conditions (Meyer *et al.*, 1991). These nociceptors, as well as many nociceptors that are initially sensitive to mechanical stimuli, have been shown to respond to chemical agents, including inflammatory mediators and capsaicin (Baumann *et al.*, 1991; Davis *et al.*, 1993). Such nociceptors often become sensitized to mechanical stimuli after tissue is damaged or becomes inflamed (Meyer and Campbell, 1981; LaMotte *et al.*, 1982; Thalhammer and LaMotte, 1982; Campbell and Meyer, 1983; Campbell *et al.*, 1988a; Davis *et al.*, 1993; Handwerker and Kobal, 1993; cf., Schmeltz *et al.*, 1994).

Most studies of nociceptors in tissues other than the skin have been performed on nonprimate laboratory animals. Free endings of finely myelinated and unmyelinated nociceptive afferents are located in the cornea (Belmonte and Gallar, 1996; see also Chapter 29), the fascia and the adventitia of blood vessels in muscle (Stacey, 1969; Mense, 1993, 1996), in joints (Fig. 30.1B) (Schaible and Grubb, 1993; Heppelmann *et al.*, 1996), dura (Messlinger, 1996; Hanesch, 1996), gastrointestinal tract (Gebhart, 1996), testis (Mizumura and Kumazawa, 1996), and many other organs (see reviews of the older literature by Willis, 1985, and Willis and Coggeshall, 2003).

Dorsal Root Ganglion Cells

Nociceptors, like other somatovisceral sensory receptors, have their cell bodies in dorsal root (or cranial nerve) ganglia (Willis and Coggeshall, 2003; see also Chapter 29). The cell body gives off a single process. At a short distance from the soma, this process divides into a peripheral and a central branch. The peripheral branch of each nociceptive dorsal root ganglion (DRG) cell follows the distribution of a peripheral nerve. The terminals of nociceptors innervate a target organ (Fig. 30.1). On the other hand, the central branch passes into the spinal cord and transmits sensory information from the target organ to the CNS. Most studies of DRG cells have been done on rodents.

DRG neurons may have large or small cell bodies ("large, light cells" and "small, dark cells"; reviewed in Willis and Coggeshall, 2003; see also Chapter 8). Large, light DRG cells give rise to myelinated axons, whereas small, dark DRG cells generally have unmyelinated axons.

Specific types of DRG cells can be labeled by antibodies against particular marker molecules. For example, large, light DRG cells are rich in neurofilaments, whereas small, dark DRG cells are poor in neurofilaments. Large, light DRG cells can be distinguished from small, dark ones by immunostaining the cells for neurofilament protein, using the RT97 antibody (Lawson and Waddell, 1991). DRG cells that can be immunostained for RT97 comprise about one-third of lumbar DRG cells (Bergman *et al.,* 1999; Perry and Lawson, 1998). Most lumbar dorsal root ganglion cells fail to immunostain for RT97 and are small, dark cells. Most of the latter are nociceptors.

Other markers include cell surface carbohydrates, which can be recognized by immunocytochemistry using monoclonal antibodies (Dodd and Jessell, 1985; Chou *et al.,* 1988; Alvarez *et al.,* 1989a, b). Antibodies against globoseries carbohydrates recognize DRG cells and primary afferents that project to laminae III and IV, whereas antibodies to lactoseries oligosaccarides recognize primary afferent neurons that terminate in laminae I and II.

Furthermore, primary afferent neurons that supply skin, muscle, or viscera have different phenotypes that can be distinguished based on their profiles of expression of different markers (Perry and Lawson, 1998). For example, an antibody for peanut agglutinin labels many more cutaneous and visceral afferents than muscle afferents, whereas the antibody 2C5 labels more cutaneous than muscle afferents, but very few visceral afferents. Antibodies to the antigens SSEA-3 and SSEA-4 label all sizes of somatic afferents but no visceral afferents.

Nociceptors are included in the subset of DRG neurons that have small, dark cell bodies (Lawson *et al.,* 1985, 1996, 1997) and therefore that do not immunostain for neurofilament protein (Lawson and Waddell, 1991). Small, dark DRG cells, most of which are nociceptors, can be further subdivided into peptidergic and nonpeptidergic primary afferent neurons. Small, dark peptidergic DRG cells contain substance P, calcitonin gene–related peptide (Lawson *et al.,* 1997), or other neuropeptides (Willis and Coggeshall, 2003). Two or more peptides may be co-localized in the same ganglion cell. The proportions of peptidergic DRG cells that contain a particular peptide may differ depending on the type of peripheral nerve. For example, calcitonin gene–related peptide is found in 50% of skin afferents, in 70% of muscle afferents, but in almost all visceral afferents. Similarly, substance P is found in 25% of skin afferents, in 50% of muscle afferents, but in more than 80% of visceral afferents. Somatostatin, on the other hand, is not found in visceral afferents, although it is present in a small number of somatic afferents. A large fraction of substance P–containing dorsal root ganglion cells have been shown to be nociceptors in electrophysiological experiments on guinea pigs (Lawson *et al.,* 1997).

Small, dark nonpeptidergic DRG cells usually have binding sites for the isolectin B4 (Wang *et al.,* 1994; Guo *et al.,* 1999). These small DRG cells presumably give rise to unmyelinated afferent fibers. This idea is reinforced by the observation that very few DRG cells that bind IB4 can be stained with RT97, a marker for myelinated primary afferent fibers (Lawson and Weddell, 1991).

Most IB4-positive DRG cells (85%) colocalize fluoride-resistant acid phosphatase and almost all of those that contain fluoride resistance acid phosphatase are IB4 positive (Wang *et al.,* 1994). Interestingly, human DRG cells appear to lack fluoride-resistant acid phosphatase (see Chapter 7). A clear distinction can generally be made between IB4-positive and peptidergic DRG cells (Guo *et al.,* 1999), although there is evidence for some overlap between IB4-positive and peptidergic DRG cells (Wang *et al.,* 1994). IB4-positive DRG cells usually contain $P2X_3$ purinoceptors, whereas peptidergic DRG cells generally do not. In fact, of DRG cells with $P2X_3$ receptors, more than 95% have IB4 binding sites (Bradbury *et al.,* 1998).

Additional chemical markers for nociceptors include a number of neurotransmitter receptor molecules. For example, glutamate has been identified by immunohistochemistry in primary afferent neurons, including rat dorsal root axons (Westlund *et al.,* 1989) and primate joint afferents (Westlund *et al.,* 1992b), as well as in DRG cells (Battaglia and Rustioni, 1988). Glutamate is believed to be a fast-acting central excitatory neurotransmitter substance that is released by many primary afferent nerve fibers, including nociceptors (De Biasi and Rustioni, 1988). Its central synaptic action is modulated by peptides, such as calcitonin gene–related peptide (CGRP) and substance P (Murase *et al.,* 1989; Dougherty and Willis, 1991). However, there also appears to be a role for glutamate released from the peripheral terminals of primary afferent nociceptors in the skin and in joints during sensory transduction as an initiating event in neurogenic inflammation (Ault and Hildebrand, 1993; Jackson *et al.,* 1995; Zhou *et al.,* 1996; Davidson *et al.,* 1997; Lawand *et al.,* 1997; 2000; Carlton and Coggeshall, 1999). This action depends on the presence of glutamate receptors on the peripheral nerve endings of primary afferent fibers (Carlton *et al.,* 1995, 2001b) and on other peripheral cell types.

Primary afferent terminals presumed to be nociceptors may also contain neuropeptide receptors, such as μ- and δ-opiate receptors (Coggeshall and Carlton,

1997; Coggeshall *et al.*, 1997; see Willis and Coggeshall, 2003), somatostatin receptors (Carlton *et al.*, 2001a), or substance P receptors (Carlton *et al.*, 1996). CGRP receptors are found on primary afferent endings in the dorsal horn and on DRG cells (Ye *et al.*, 1999), and so they may also be present on the peripheral terminals of nociceptors.

Other markers of nociceptors include vanilloid (VR-1) receptors, which are on the terminals of many unmyelinated and some finely myelinated nociceptors and respond to capsaicin, heat, or low pH (Holzer, 1991; Caterina *et al.*, 1997, 2000; Helliwell *et al.*, 1998; Tominaga *et al.*, 1998). By contrast, vanilloid-like-1 (VRL-1) receptors are on primary afferents with myelinated axons, have a high heat threshold, but do not respond to capsaicin or low pH (Caterina *et al.*, 1999). A very large fraction of DRG cells express these markers. For example, capsaicin sensitivity is observed in 88% of a sample of small- to medium-sized DRG cells in rats (Helliwell *et al.*, 1998). IB4 binds to 51% of rat DRG cells of all sizes (Wang *et al.*, 1994). Recently, mRNA for VR-1 has been shown to be widely distributed in the brains of both rats and humans, and so the role of these receptors in response to painful stimuli may be much more complex than previously thought (Mezey *et al.*, 2000).

Additional ligand-gated receptors that are found on the terminals of nociceptors include receptors for bradykinin, prostaglandin, serotonin, catecholamines, ATP, and histamine (Willis and Coggeshall, 2003). These contribute to the activation and/or sensitization of nociceptor endings, especially following tissue damage and inflammation. They are regarded as inflammatory mediators.

Additional molecules are beginning to be examined in studies of the mechanisms by which sensory transduction occurs in nociceptors. For example, a protein belonging to a family of non-voltage-gated sodium channels (DEG/ENaC) that has been characterized in *Caenorrhabditis elegans* has been proposed as the mechanical transducer in Aδ mechanical nociceptors (García-Añoveros *et al.*, 2001). The VR-1 and VRL-1 receptors are thought to transduce noxious heat signals, and VR-1 receptors are activated by lowered pH. However, pH changes during inflammation are also thought to be signaled by other acid-sensing (ASIC) channels (Habelt *et al.*, 2000; Immke and McCleskey., 2001).

Nociceptors are also influenced by the actions of growth factors. For example, peptidergic nociceptors, such as those containing substance P or CGRP, are regulated by nerve growth factor through an action on tyrosine kinase A (TrkA) receptors (McMahon *et al.*, 1994; Averill *et al.*, 1995). On the other hand, IB4-immunoreactive primary afferent neurons are regulated, at least in adult animals, by glial cell line–derived neurotrophic factor (GDNF) (Bennett *et al.*, 1996; Molliver *et al.*, 1997).

Nociceptive Input to Spinal Cord Dorsal Horn

In general, large primary afferent fibers enter the spinal cord medially in the dorsal roots, and many of these give rise to collaterals that ascend in the dorsal column (see Willis and Coggeshall, 2003). The small fibers enter more laterally and many end in the gray matter of the same or neighboring segments (Ranson and Billingsley, 1916). A similar arrangement is found in humans (Fig. 30.7B) (Sindou *et al.*, 1974, 1987; see also Chapter 8). However, it should be noted that peptidergic (CGRP and substance P containing) unmyelinated primary afferent axons can be found to ascend in the dorsal column to upper cervical levels and some appear to end in the dorsal column nuclei, at least in rats and cats (Patterson *et al.*, 1989, 1990; Tamatani *et al.*, 1989; Conti *et al.*, 1990; Fabri and Conti, 1990).

Nociceptive afferent fibers give rise to branches that may ascend or descend in Lissauer's tract before they send off collaterals that synapse in the gray matter of the spinal cord (Willis and Coggeshall, 2003). Lissauer's tract in monkeys is notable for its large content of unmyelinated axons, which are often arranged in bundles of 2,000 to 10,000 axons (Fig. 30.2) (Coggeshall *et al.*, 1981). Most of these unmyelinated axons in the primate Lissauer's tract are collaterals of primary afferent fibers, since 80% of them degenerate following transection of three successive dorsal roots (at, above, and below the particular segmental level that was examined). The majority of the unmyelinated primary afferent axons in Lissauer's tract of primates can be presumed to originate from nociceptors, but some must originate from other types of primary afferent neurons, and about 20% are probably the axons of interneurons.

Clinical Application

Lissauer's tract is important in pain transmission in humans, since surgical interruption of Lissauer's tract has been used successfully to improve the results of anterolateral cordotomy in relieving pain (Hyndman, 1942).

Rexed (1952) subdivided the gray matter of the spinal cord of cats into 10 laminae, based on its cytoarchitecture. A similar arrangement is also seen in the spinal cords of a variety of other animals and also in humans (for a detailed analysis of the cytoarchitecture and myeloarchitecture of the human spinal cord, see Chapter 7).

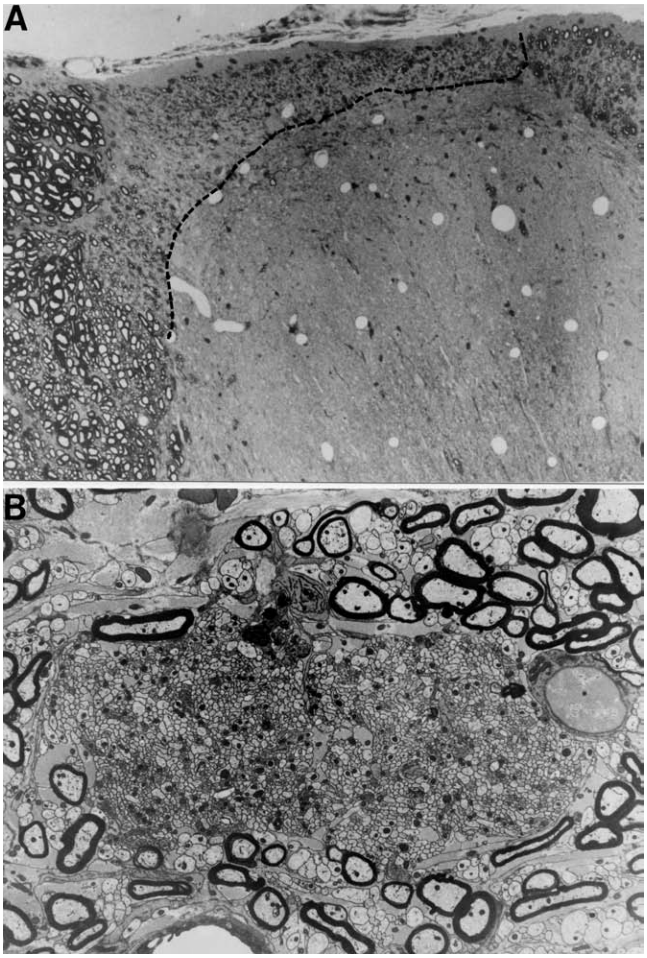

FIGURE 30.2 Unmyelinated axon bundles in monkey Lissauer tract. The light micrograph in **A** shows some of the dorsal white matter and the superficial dorsal horn in the S2 segment of a monkey spinal cord. The dashed line shows the boundary between Lissauer's tract and the dorsal horn. The dorsal column is to the left of the dorsal horn, and the dorsolateral fasciculus is to the right. The electron micrograph in **B** illustrates an axonal bundle in the medial part of Lissauer's tract in a monkey. The bundle contained 2038 unmyelinated axons. (From Coggeshall *et al.,* 1981.)

In cats and monkeys, cutaneous Aδ mechanical nociceptors have been shown by intracellular labeling of functionally identified axons to terminate chiefly in laminae I, V, and X (Fig. 30.3A, B) (Light and Perl, 1979). Most of the endings are ipsilateral, but some collaterals cross the midline to end in the gray matter on the contralateral side of the spinal cord (Fig. 30.3B). It is, of course, much more difficult to label C nociceptors by intracellular injection of a tracer into the axon. However, in guinea pigs, Sugiura *et al.* (1986, 1989) were able to inject *Phaseolus vulgaris* leucoagglutinin into cervical DRG cells belonging to cutaneous C polymodal nociceptors and to trace the axons into the spinal cord. Terminals were found in laminae I and II (Fig. 30.3C). Sugiura *et al.* (1989) also traced the axons of visceral C afferent fibers in guinea pigs in the same manner and found that these were distributed over more than five segments, in contrast to somatic afferents, which traveled only a short distance rostrocaudally from the dorsal root through which they entered the spinal cord. The terminals of visceral afferents were much more abundant than those of somatic afferents (cf. Fig. 30.3C, D). They were found not only in laminae I and II but also in laminae IV, V, and X (Fig. 30.3D), and some collaterals extended into the contralateral laminae V and X (Fig. 30.3D). In cats, anterograde labeling studies have demonstrated that fine muscle afferent fibers terminate in laminae I and V (Craig and Mense, 1983) and that joint afferent fibers end in laminae I, V–VII (Craig *et al.,* 1988). A similar distribution of primary afferent terminals would presumably be found in monkeys and humans, although this has not been demonstrated.

Typical of the superficial layers of the dorsal horn are large glomerular synaptic complexes, often referred to as scalloped primary afferent endings or "central terminals" (see reviews by Csillik and Knyihár-Csillik, 1986, and Willis and Coggeshall, 2003). There are several types of glomeruli. In monkeys, most of the glomeruli in lamina I are classified as large dense-core vesicle terminals, most in lamina II as dense sinusoid terminals, and most in lamina III as regular synaptic vesicle–containing terminals (Coimbra *et al.,* 1984; Csillik and Knyihár-Csillik *et al.,* 1986). All of these types of glomeruli degenerate following dorsal rhizotomy, indicating that they arise from primary afferent fibers (Csillik and Knyihár-Csillik *et al.,* 1986). Csillik and Knyihár-Csillik (1986) have proposed that the dense sinusoid terminals are supplied by unmyelinated fibers (see also Coimbra *et al.,* 1984) and that they are equivalent to the terminals in rodents that stain for fluoride-resistant acid phosphatase. Thus, these would be the endings of IB4-positive primary afferent neurons. The large dense-core vesicle glomeruli are thought to be the endings of peptidergic primary afferent neurons and the regular synaptic vesicle glomeruli are probably the endings of large, myelinated primary afferent fibers (Csillik and Knyihár-Csillik, 1986).

Evidence that large, dense core vesicles contain peptides comes from experiments that employ immunocytochemical staining at the ultrastructural level. For instance, electron microscopic studies of the superficial dorsal horn in monkeys show that many large, dense-cored vesicles contain substance P (Fig. 30.4A) or CGRP (Fig. 30.4B) (Csillik and Knyihár-Csillik, 1986; Carlton *et al.,* 1988; Hayes and Carlton, 1992; Alvarez *et al.,* 1993). In the human spinal cord, peptides

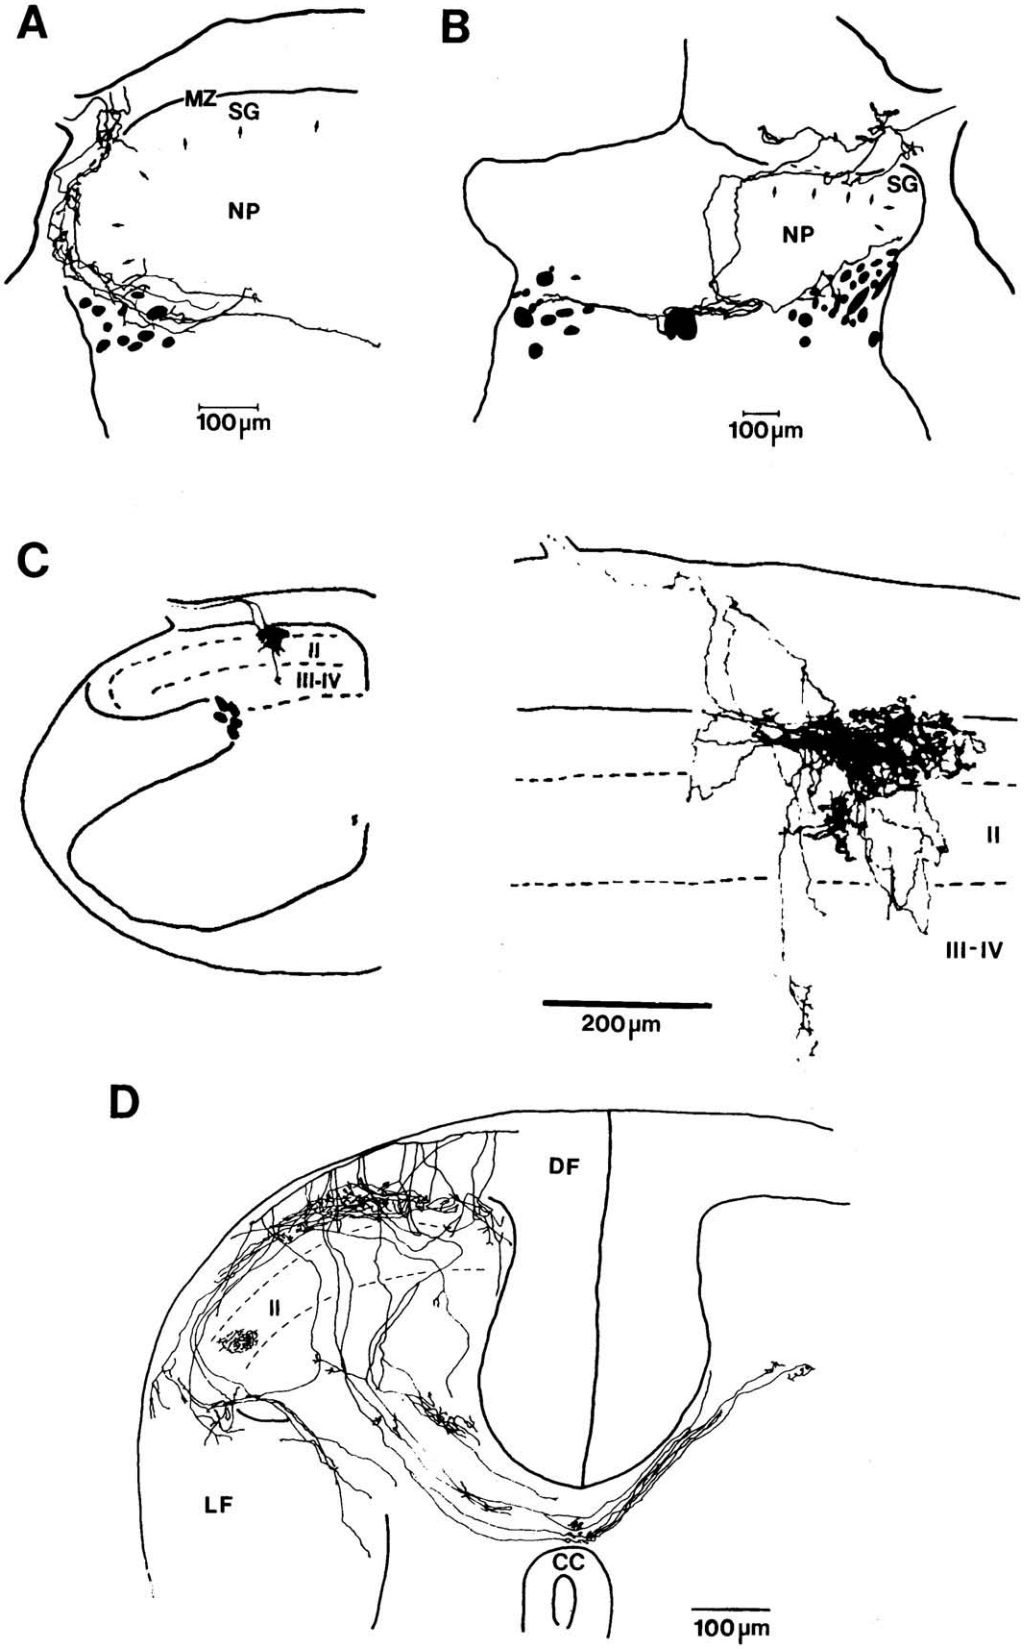

FIGURE 30.3 Projection of myelinated and unmyelinated primary afferent nociceptive axons into the spinal cord. The drawings in **A** and **B** show the distribution of the terminal branches of cutaneous Aδ mechanical nociceptors within the spinal cord of a cat **(A)** and a monkey **(B).** The axons were injected with horseradish peroxidase after the fibers were functionally identified. Laterally placed dark areas of the spinal cord represent bundles of longitudinally oriented myelinated axons. The shaded region at the midline in **B** is an area near the central canal in which some of the terminals could be found. The labeled afferent in **B** projected bilaterally. Abbreviations: MZ, marginal zone; NP, nucleus proprius; SG, substantia gelatinosa. (From Light and Perl, 1979.) The drawings in **C** show that the terminals of a somatic C-fiber in a guinea pig were chiefly in laminae I and II (with a slight extension into deeper layers). The axon was labeled anterogradely following injection of *Phaseolus vulgaris* leucoagglutinin into a dorsal root ganglion cell at an upper cervical level. The scale bar = 200 mm. (From Sugiura *et al.,* 1986). **D** illustrates the profuse spinal cord terminations of a visceral C-afferent fiber identified by stimulation of the celiac ganglion in a guinea pig. Abbreviations: CC, central canal; DF, dorsal funiculus; LF, lateral funiculus. (From Sugiura *et al.,* 1989.)

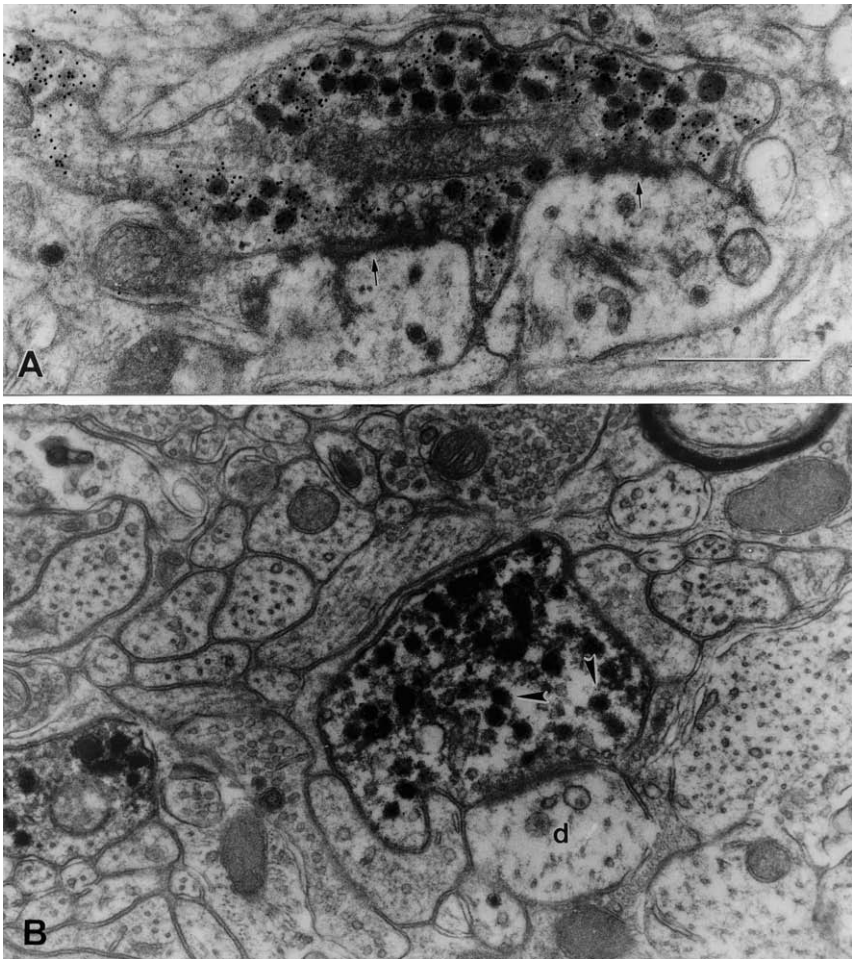

FIGURE 30.4 Peptide content of dense core vesicles in primary afferent synaptic terminals in the superficial dorsal horn of a monkey spinal cord. The electron micrograph in **A** illustrates a synaptic ending that was shown to be immunoreactive for substance P, using the immunogold staining technique. The gold particles are in close relationship to dense core vesicles. The arrows indicate synaptic contacts made by this ending on dendrites in the neuropil of the superficial dorsal horn. The scale is 1 μm. (From Alvarez *et al.,* 1993.) The electron micrograph in **B** shows an axodendritic synapse in the dorsal horn of a monkey. In this case the dense core vesicles in the terminal were stained for calcitonin gene–related peptide using the immunoperoxidase technique. (From Carlton *et al.,* 1988.)

that have been found in the superficial dorsal horn include CGRP (Fig. 30.5A, B) (Harmann *et al.,* 1988), bombesin, substance P, cholecystokinin, somatostatin, met-enkephalin, and vasoactive intestinal polypeptide (Fig. 30.5C) (Chung *et al.,* 1989; see also Chapter 7). The immunostaining of CGRP-containing terminals at the light microscopic level presumably reflects the distribution of primary afferent terminals, since CGRP staining in the dorsal horn is eliminated in rats following an extensive dorsal rhizotomy (Chung *et al.,* 1988). However, other peptides are often localized not only in primary afferent terminals but may also be contained in the terminals of pathways that descend from the brain or in the cell bodies or the processes of neurons intrinsic to the spinal cord.

The synapses made by primary afferent nociceptors in the spinal cord gray matter result in the activation of second-order postsynaptic neurons (reviewed in Willis and Coggeshall, 2003). Some of these neurons project to the brain and therefore convey nociceptive signals to higher levels of the nervous system (see **"Pain Transmission Neurons and Pathways"**). Other second-order neurons are excitatory or inhibitory interneurons. The excitatory interneurons may also activate projection neurons, or they may excite inhibitory interneurons or elicit reflex responses by exciting somatic

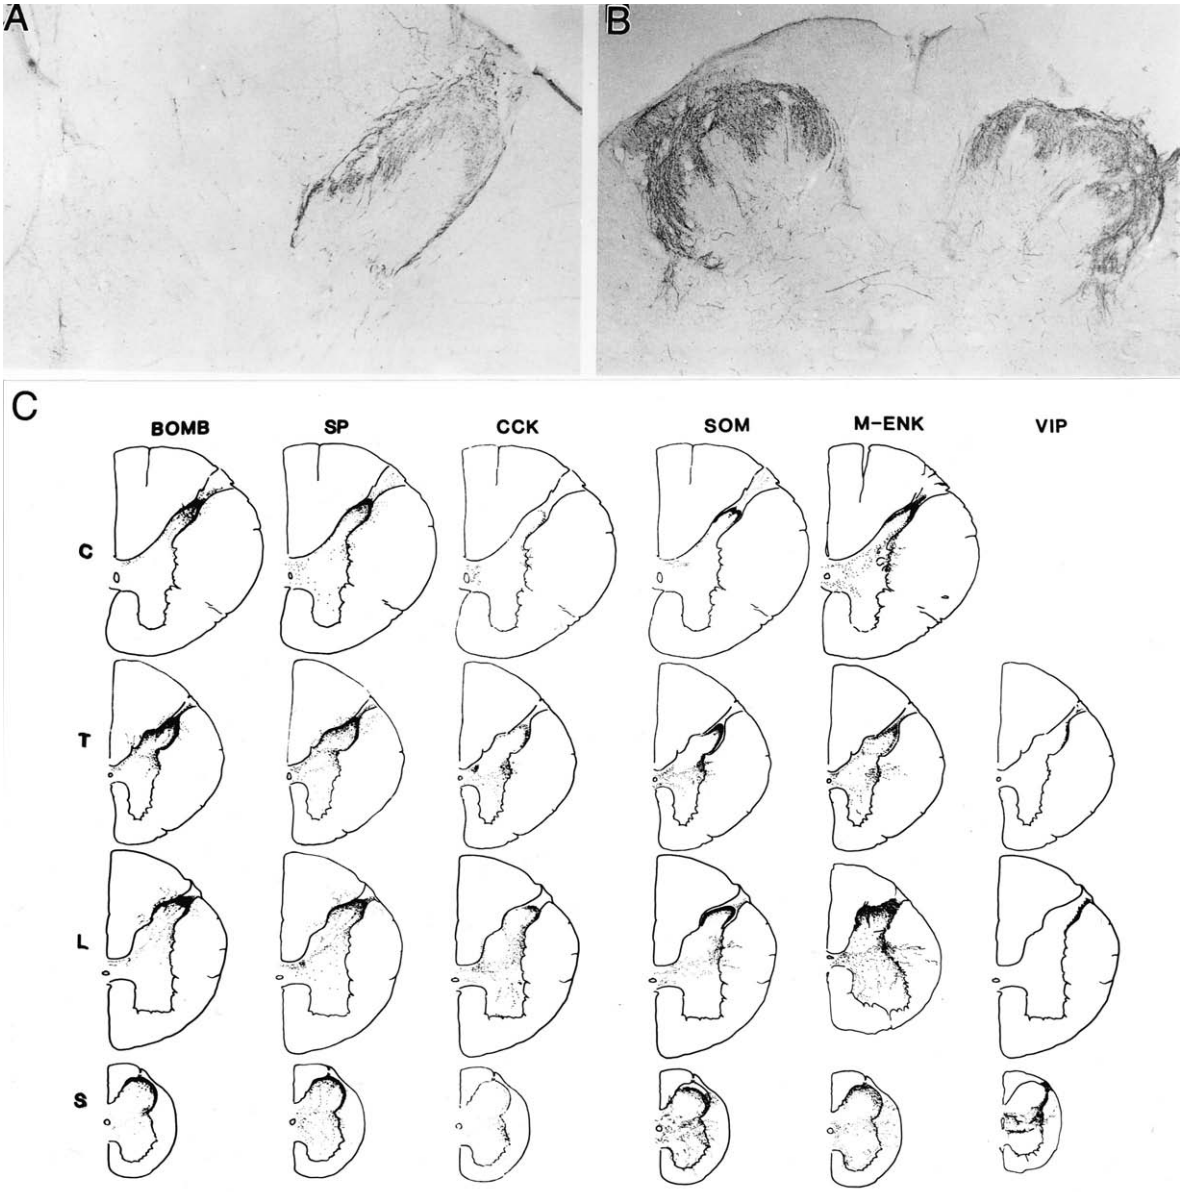

FIGURE 30.5 Peptides in the dorsal horn of the human spinal cord. **A** and **B** show the distribution of calcitonin gene-related peptide immunoreactivity in transverse sections of the lumbar and sacral dorsal horn of a human spinal cord. (From Harmann *et al.*, 1988.) **C** shows the distribution of several peptides (BOMB, bombesin; SP, substance P; CCK, cholecystokinin; SOM, somatostatin; M-ENK, met-enkephalin; VIP, vasoactive intestinal polypeptide) in drawings of transverse sections of the human cervical (C), thoracic (T), lumbar (L), and sacral (S) spinal cord. (From Chung *et al.*, 1989.)

or autonomic motor neurons. The projection neurons can activate not only brain mechanisms that lead to sensory experience and other pain responses, such as endocrine changes or memory, but also feedback systems that modulate nociceptive transmission in the spinal cord by way of descending projections. The circuits involved in such actions are complex and still incompletely known.

Inhibition of spinal nociceptive transmission following stimulation of the skin can occur through activation of segmental or supraspinal circuits or both. In the circuit proposed for the gate theory of pain by Melzack and Wall (1965), large, presumably mechanosensitive primary afferents activate inhibitory interneurons that in turn cause presynaptic inhibition of the actions of fine, nociceptive primary afferent fibers.

Thus, activation of large afferent fibers "closes the dorsal horn gate," reducing pain. Soon after the proposal of the gate theory, Wall and Sweet (1967) reported that pain can be diminished in human patients by stimulation of large primary afferent fibers in peripheral nerves. The anatomical substrate for this inhibitory interaction, which can reduce neurotransmitter release, is likely to be GABAergic interneurons in the superficial dorsal horn that are excited by synaptic release of glutamate from primary afferent terminals. These GABAergic interneurons in turn cause presynaptic inhibition by releasing GABA, which acts on $GABA_A$ receptors to depolarize the terminals of primary afferent fibers (Rudomin and Schmidt, 1999; Willis, 1999). GABAergic inhibition can also occur by means of a postsynaptic action of GABA on interneurons. Another mechanism of GABA action is the activation of $GABA_B$ receptors on primary afferent endings. Activation of $GABA_B$ receptors results in another form of presynaptic inhibition in which there is no primary afferent depolarization but rather a blockade of calcium channels and a reduction in transmitter release (see Willis and Coggeshall, 2003).

Evidence for the presence of GABAergic synapses on the synaptic endings of Aδ nociceptors is shown in Fig. 30.6A (Alvarez *et al.,* 1992). These synapses are presumably responsible for presynaptic inhibition of the actions of the Aδ axon endings on dorsal horn interneurons. In the same study, GABAergic inhibitory interneurons were also found to make synaptic connections with the dendrites of other spinal cord neurons. This is consistent with the well-known prominence of GABAergic postsynaptic inhibition in the dorsal horn (Willis and Coggeshall, 1991).

An effort has been made by several groups to determine if there are GABAergic terminals presynaptic to peptidergic synaptic endings, presumably of C fibers, in the superficial dorsal horn of monkeys. These synapses often contain both glutamate and peptides, such as substance P and/or CGRP (Hökfelt *et al.,* 1975; De Biasi and Rustioni, 1988; Hayes and Carlton, 1992). CGRP-labeled afferent fibers commonly synapse with GABAergic dendritic profiles (presumably of islet cells). However, the terminals of GABA-containing interneurons only occasionally make synaptic contacts back onto primary afferent endings, although they do form many synapses onto other dorsal horn neurons (Fig. 30.6B, C) (Hayes and Carlton, 1992).

Alvarez *et al.* (1993) were unable to demonstrate any GABAergic contacts onto the terminals of two intracellularly labeled C fibers in monkeys (including one that had been identified as a nociceptor prior to the injection of horseradish peroxidase into the axon). The C fiber endings contained CGRP, and so they were the endings of peptidergic primary afferent C fibers. However, Alvarez *et al.* (1993) frequently observed GABAergic endings that were presynaptic to nonpeptidergic glomerular terminals. It is conceivable that these were the endings of unmyelinated afferents that bind IB4. Interestingly, the densest staining for $GABA_A$ receptors in the dorsal horn is in the region of the densest terminations of IB4-labeled afferents (Alvarez *et al.,* 1996).

$GABA_A$ receptors might also be activated in a paracrine manner by volume conduction of GABA. However, no positive immunocytochemical evidence was found for the localization of $GABA_A$ receptors on glomerular primary afferent terminals at the light and ultrastructural levels, although this possibility could not be ruled out, especially since $GABA_A$ receptors were found on most of the DRG cells examined (Alvarez *et al.,* 1996).

Recently, it has been shown in rats that both Aδ and C primary afferent axons can be depolarized sufficiently following a strong noxious stimulus (capsaicin injection into the skin or adjuvant into a joint) to result in dorsal root reflex discharges. This action is mediated through glutamate receptors that are presumably on inhibitory interneurons and through $GABA_A$ receptors on the terminals of fine primary afferent fibers (Sluka *et al.,* 1993; Rees *et al.,* 1994; 1995; Lin *et al.,* 1999; 2000; see also Willis, 1999). Dorsal root reflexes are action potentials that originate near the primary afferent terminals in the spinal cord and then propagate antidromically out to the periphery. Dorsal root reflexes in nociceptors are thought to release neurotransmitters, such as glutamate, substance P, and CGRP, from their sensory nerve terminals in the periphery. These agents would then trigger neurogenic inflammation (Sluka *et al.,* 1994, 1995; Willis, 1999). For instance, released substance P would be expected to produce plasma extravasation and CGRP would result in vasodilation (Geppetti and Holzer, 1996).

The inhibitory circuit proposed in the gate theory is contained in the spinal cord dorsal horn, although inhibitory actions were suggested to be triggered or influenced by supraspinal loops (Melzack and Wall, 1965). On the other hand, the diffuse noxious inhibitory control (DNIC) system for inhibition of wide-dynamic-range neurons in the spinal cord by nociceptive afferent input from widespread regions of the body is dependent on a supraspinal loop. It has been proposed that DNIC is mediated through a descending pathway that originates from the subnucleus reticularis dorsalis of the medulla (LeBars *et al.,* 1979a, b; Villanueva and Le Bars, 1995). However, Almeida *et al.* (1996, 1999) disagree with this proposal, instead suggesting that the subnucleus reticularis dorsalis is pronociceptive. A

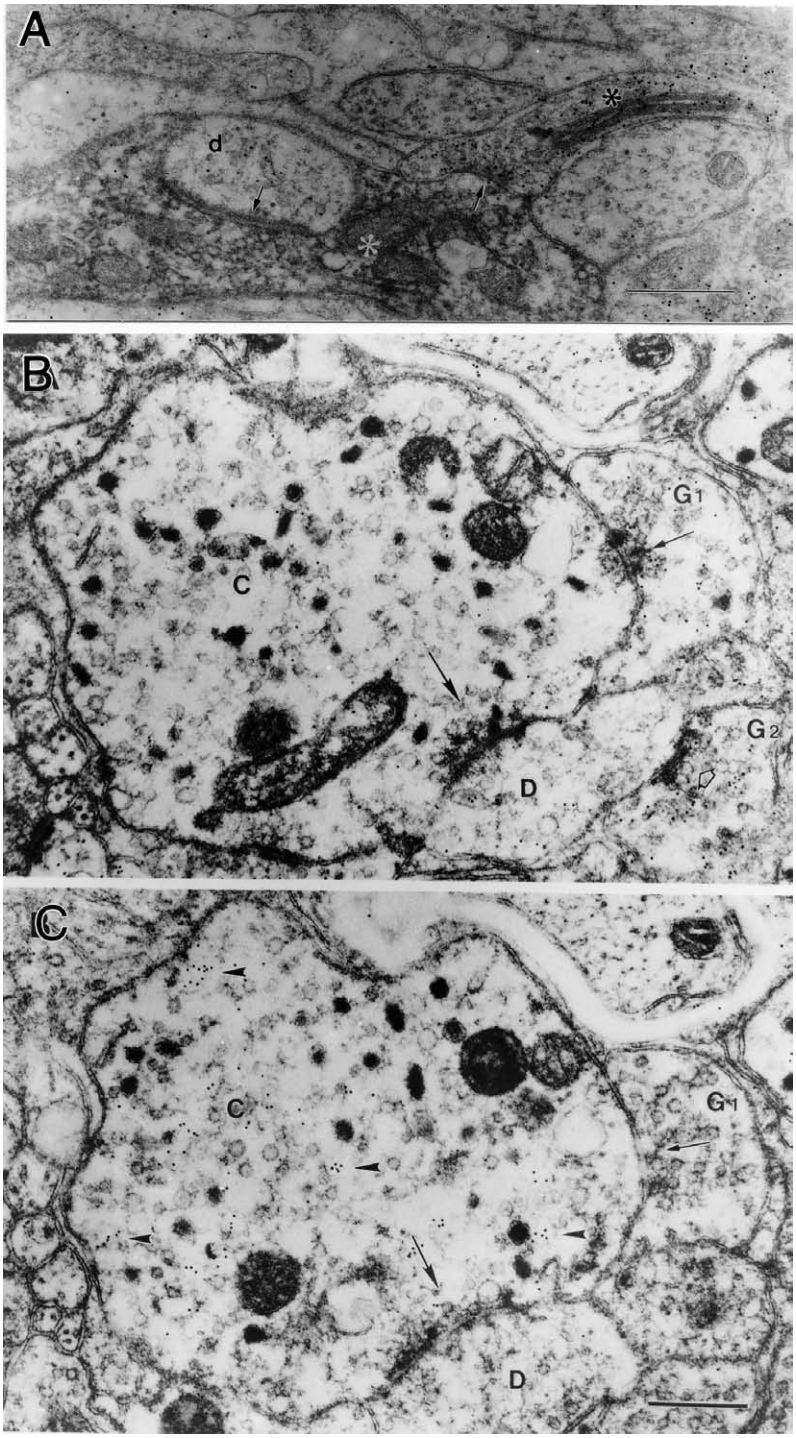

FIGURE 30.6 GABAergic synapses on the terminals of primary afferent axons in the dorsal horn. The electron micrograph in **A** is from a double labeling study. An Aδ mechanical nociceptor was identified and then injected with horseradish peroxidase. One of its terminals is indicated by the white asterisk. The section was also immunolabeled for GABA. The immunogold particles in the synaptic ending indicated by the black asterisk show that this ending was from a GABAergic inhibitory interneuron. The GABA-containing ending makes a symmetrical synapse with the nociceptor terminal. (From Alvarez *et al.,* 1992.) The electron micrographs in **B** and **C** are of serial sections of the terminal of a primary afferent axon in the dorsal horn of a monkey. The ending was labeled for calcitonin gene–related peptide (CGRP) by immunogold particles in **C.** In the adjacent section in **B,** a synapse formed by a GABAergic interneuron on the CGRP-containing terminal (G_1) is immunostained for GABA. The synapse is an asymmetrical one. Another GABAergic terminal (G_2) is seen to synapse with a dendrite (D). (From Hayes and Carlton, 1992.)

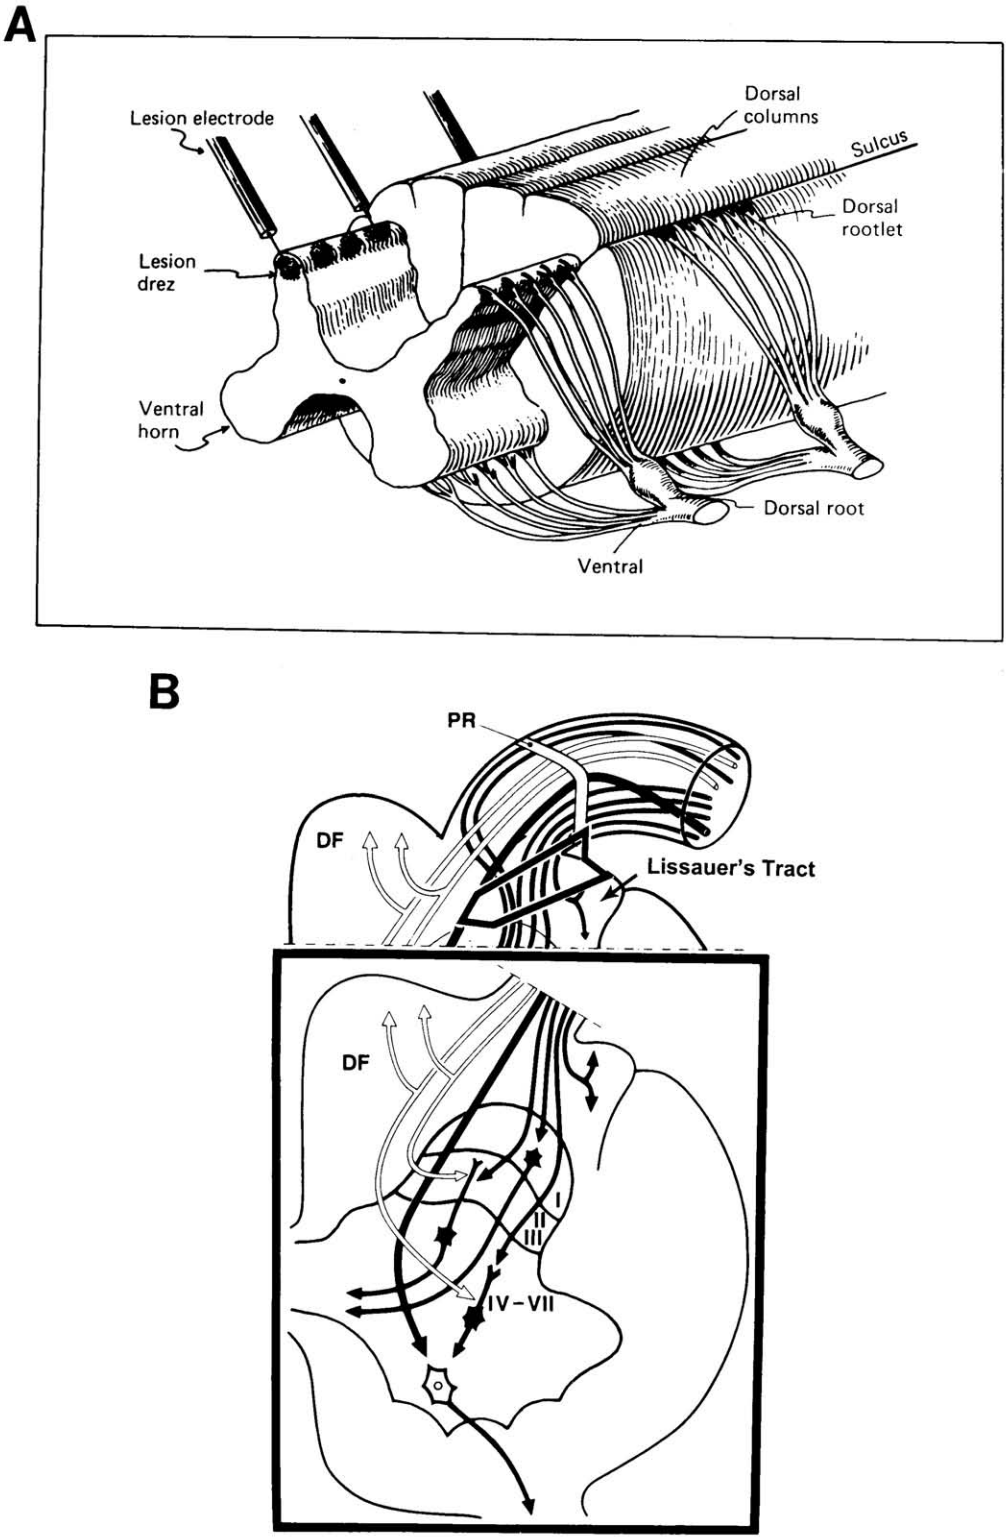

FIGURE 30.7 Dorsal root entry zone (drez) lesions. The drawing of the spinal cord in **A** shows the placement of dorsal root entry zone or "drez" lesions in the dorsal horn on one side of the spinal cord. (From Nashold and Ostdahl, 1979.) The drawing in **B** shows an alternative surgical approach in which a lesion interrupts fine nociceptive afferent fibers as they enter the spinal cord through the lateral aspect of each dorsal rootlet, travel in Lissauer's tract and penetrate into the dorsal horn. DF, dorsal funiculus. (From Jeanmonod and Sindou, 1991.)

number of investigations have shown that there is a functional DNIC system in monkeys (Villanueva *et al.*, 1990) and humans (Talbot *et al.*, 1987; Willer *et al.*, 1989; De Broucker *et al.*, 1990; Bouhassira *et al.*, 1993).

Experiments in which repetitive stimulation of peripheral nerves in monkeys at different intensities was used to determine the relative effectiveness of afferent volleys in large versus small afferent fibers in inhibiting the responses of spinothalamic tract neurons to C-fiber input showed that stimulation of fine afferents (presumably activating the DNIC mechanism) was much more effective than stimulation of large afferents (Chung *et al.*, 1984), suggesting that activation of the DNIC mechanism might be a more effective means for reducing pain than activation of the spinal cord gating mechanism.

Clinical Application

Chronic pain in humans is often associated with activity in primary afferent nociceptive neurons and the dorsal horn neurons on which the nociceptive afferents synapse. A surgical procedure that is sometimes used to relieve neuropathic pain due to avulsion of dorsal roots is the placement of a series of lesions in the "dorsal root entry zone" (drez lesions; Fig. 30.7A) (Nashold and Ostdahl, 1979; Nashold, 1984; Rawlings *et al.*, 1989; Campbell *et al.*, 1988b; Rath *et al.*, 1997). Similar lesions in monkeys destroy the region of Lissauer's tract and at least part of the dorsal horn (Singh *et al.*, 1989). Pain relief is presumably attributable to the loss of nociceptive afferent input to the dorsal horn, as well as to the destruction of many dorsal horn neurons. A different approach to drez lesions is the interruption of fine nociceptive afferents as they pass through the lateral part of the dorsal root and into Lissauer's tract (Fig. 30.7B) (Jeanmonod and Sindou, 1991). This procedure also seems to be effective for the management of neurogenic pain.

PAIN TRANSMISSION NEURONS AND PATHWAYS

A number of pathways that ascend from the spinal cord to the brain are activated by noxious stimuli. These have been reviewed previously (Willis, 1985; Willis and Westlund, 1997; Willis and Coggeshall, 2003; see also Chapters 8, 28, and 29). The emphasis here will be on the primate spinothalamic tract. The spinothalamic tract has long been regarded as the major pathway in humans that is responsible for evoking pain sensations. In addition, evidence for the recently described role of the dorsal column in conveying nociceptive signals from viscera will be described. Other pathways, such as the spinocervical, spinoreticular, spinomesencephalic, spinoparabrachial, spinohypothalamic, and spinolimbic tracts, will also be discussed briefly.

Spinothalamic Tract

Nociceptive neurons in the spinal cord include spinothalamic tract cells, most of which project directly to the contralateral thalamus. Early reports of the distribution of neurons that show chromatolysis in human patients following an anterolateral cordotomy (Foerster and Gagel, 1932; Kuru, 1949; Smith, 1976) do not permit a definitive determination of the locations of human spinothalamic tract cells, since chromatolysis would also be expected in the cells of origin of other tracts that ascend in the anterolateral spinal cord white matter (see Chapter 8). Another technique, such as retrograde labeling, is required, but this cannot be done in humans. However, retrograde labeling has been done in monkeys. It can be presumed that the organization of the spinothalamic tract is similar in humans and monkeys.

Spinothalamic tract neurons that are retrogradely labeled from the ventral posterior lateral (VPL) nucleus of the thalamus in monkeys are concentrated in lamina I and in the lateral half of the neck and base of the dorsal horn in laminae IV–VI (Fig. 30.8C, D) (Willis *et al.*, 2001; cf. Trevino and Carstens, 1975; Willis *et al.*, 1979; Hayes and Rustioni, 1980; Apkarian and Hodge, 1989a; Zhang and Craig, 1997). Other spinothalamic tract neurons are in the intermediate region and the ventral horn (laminae VII–X). Many of these send projections to the medial thalamus to end in the intralaminar complex, particularly in the central lateral nucleus (Willis *et al.*, 1979; Giesler *et al.*, 1981; Ammons *et al.*, 1985; Wang *et al.*, 1999). Other spinothalamic cells project to the ventral posterior inferior nucleus (Gingold *et al.*, 1991). (For a description of the thalamic nuclei receiving spinothalamic terminations, see Chapter 20.)

Lamina I spinothalamic tract cells have been suggested to project to a part of the posterior complex of the thalamus that was recently termed the posterior ventromedial (VMpo) nucleus by Craig *et al.* (1994) in monkeys and by Blomqvist *et al.* (2000) in humans and not to the VPL nucleus. This proposal has been critically reviewed (Willis *et al.*, 2002; see also the discussion of this nomenclature by Percheron in Chapter 20). The basis for part of the criticism was evidence from a recent retrograde tracing study (Willis *et al.*, 2001) and from antidromic mapping experiments (Zhang *et al.*, 2000a, b) showing that many primate lamina I spinothalamic tract cells do in fact project to the VPL nucleus (Fig. 30.8).

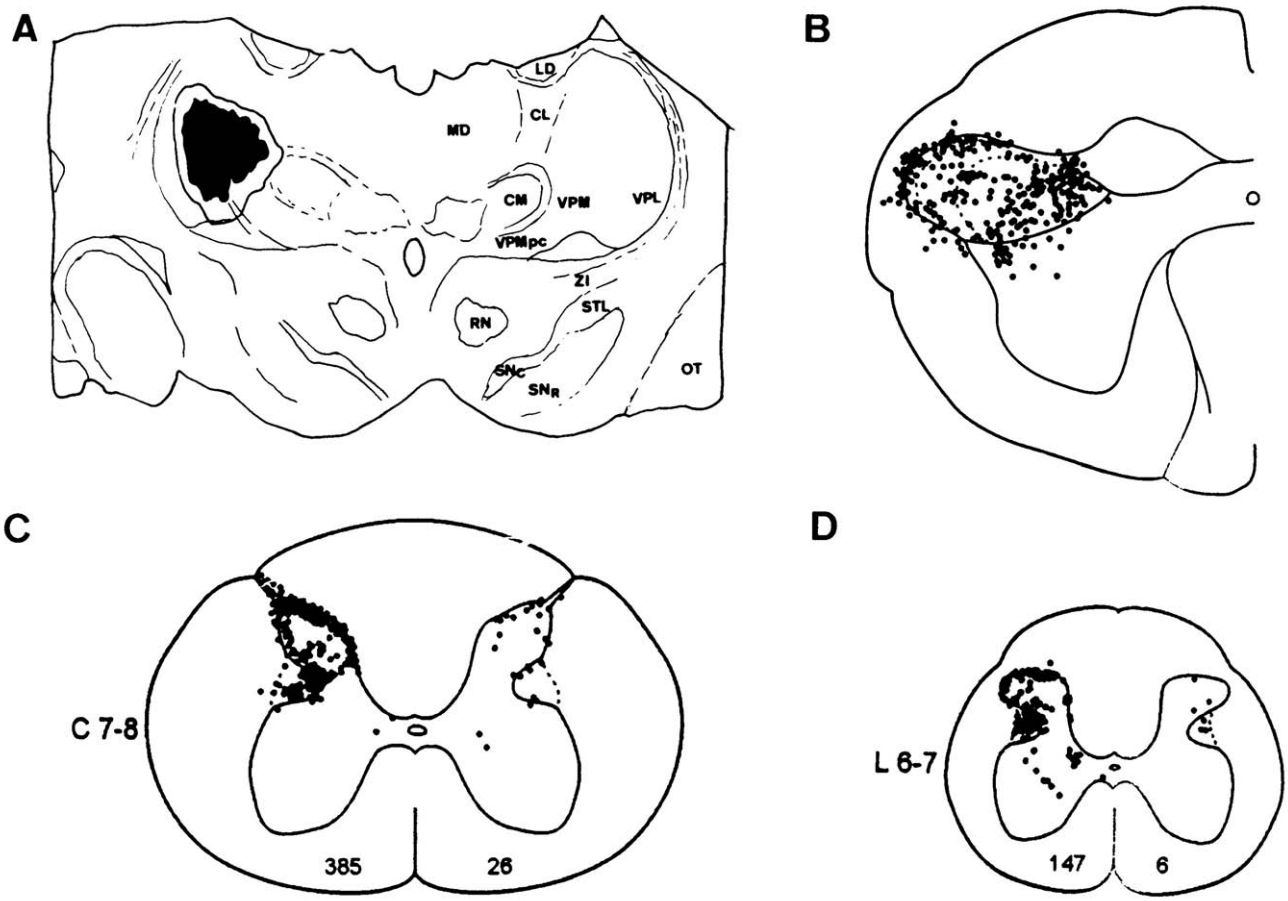

FIGURE 30.8 Projections from the marginal zone and deep dorsal horn of the spinal cord and medullary dorsal horn to the ventrobasal complex. The drawing in **A** shows the site of injection of a retrograde tracer, cholera toxin subunit B, into the ventral posterior lateral and ventral posterior medial nucleus of the thalamus in a monkey. The distribution of retrogradely labeled trigeminothalamic neurons in the spinal trigeminal nucleus, caudal part, is shown in **B** and labeled spinothalamic tract neurons in the cervical and lumbar segments of the spinal cord in **C** and **D**. (From Willis *et al.,* 2000.)

Most spinothalamic tract cells in lamina I of the monkey spinal cord are oriented rostrocaudally (Fig. 30.9A) (Zhang and Craig, 1997), whereas those in the neck of the dorsal horn are oriented in the transverse plane of the spinal cord (Fig. 30.9B–D) (Willis *et al.,* 1979; Apkarian and Hodge, 1989a; Carlton *et al.,* 1989; Westlund *et al.,* 1992a; cf. Chapter 7). These dendritic arrangements are presumably responsible for the finding that lamina I STT cells tend to have a more distinctly somatotopic organization than do STT cells in deeper layers of the dorsal horn (Willis *et al.,* 1974; see Willis and Coggeshall, 2003).

Functional studies have shown that a large fraction of primate spinothalamic tract cells are nociceptive, since they respond preferentially to noxious stimulation of skin, muscle, joints, and/or viscera (Willis *et al.,* 1974; Price *et al.,* 1978; Chung *et al.,* 1979; Foreman *et al.,* 1979; Kenshalo *et al.,* 1979; Milne *et al.,* 1981; Ferrington *et al.,* 1987; Ammons, 1989; Foreman, 1989; Dougherty *et al.,* 1992; Chandler *et al.,* 1998; Al-Chaer *et al.,* 1999). Spinothalamic tract cells are often classified according to their responses to graded intensities of cutaneous stimuli as low threshold (LT), wide dynamic range (WDR), and high threshold (HT; or nociceptive specific, NS) (Mendell, 1966; Chung *et al.,* 1979). The most effective stimuli for LT neurons are tactile ones, although these neurons may also respond to noxious stimuli. WDR neurons respond to some extent to innocuous cutaneous stimuli, but they are most powerfully activated by noxious stimuli. HT spinothalamic tract cells have no or only weak responses to tactile stimuli, and they respond chiefly or sometimes exclusively to noxious stimuli.

Cluster analysis has been utilized to provide an objective basis for classifying the responses of spinothalamic tract cells to mechanical stimulation of the

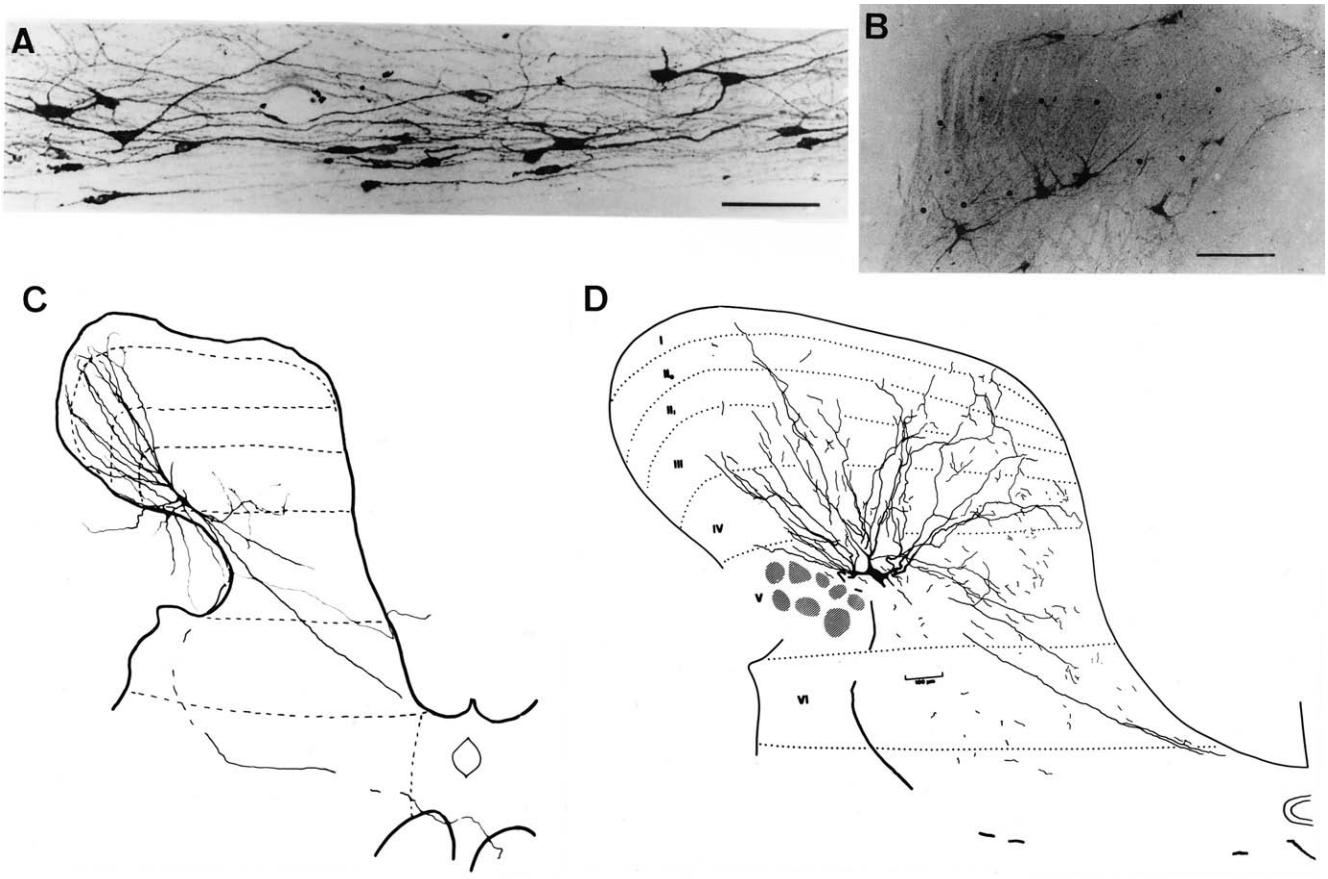

FIGURE 30.9 Cells of origin of the primate spinothalamic tract. In **A** is shown a horizontal section through lamina I of the spinal cord of a monkey. Numerous spinothalamic tract neurons were labeled retrogradely from the thalamus following an injection of cholera toxin subunit B. The scale is 100 µm. (From Zhang and Craig, 1997.) **B** shows a transverse section of a monkey spinal cord. Several retrogradely labeled spinothalamic tract cells are seen in lamina I, but their main dendritic trees are cut in cross-section because they are oriented at right angles to the section. Other labeled cells in the deep dorsal horn have elaborate dendritic trees in the plane of section. The retrograde label was wheat germ agglutinin conjugated to horseradish peroxidase. (From Apkarian and Hodge, 1989a.) The drawing in **C** is a reconstruction of a high-threshold spinothalamic tract cell that was injected intracellularly with horseradish peroxidase after its responses to cutaneous stimulation were recorded. (From Westlund *et al.,* 1992a.) The cell was contacted by both glutamate- and GABA-containing axonal endings. The drawing in **D** is of a similarly injected spinothalamic tract cell, but the response properties in this case were those of a wide dynamic range neuron. (From Carlton *et al.,* 1989.)

skin (Chung *et al.,* 1986b; Surmeier *et al.,* 1988; Owens *et al.,* 1992). One approach resulted in the identification in a large sample of spinothalamic tract cells of three clusters based on response profiles to graded intensities of mechanical stimulation. These clusters could be correlated with the LT, WDR, HT groups in the usual system of classification. Based on this analysis, most spinothalamic cells, whether in lamina I (69%) or V (59%), were judged to belong to the WDR class (Owens *et al.,* 1992). About 20% of the spinothalamic tract cells in lamina V were of the LT class. A substantial fraction of spinothalamic tract cells in either lamina I (29%) or V (22%) were HT cells.

The axons of most primate spinothalamic tract cells decussate near their cell bodies (Fig. 30.9C, D) and ascend to the brain in the contralateral anterolateral white matter. Spinothalamic axons can be seen in the monkey spinal cord following injection of wheat germ agglutinin–conjugated horseradish peroxidase into the thalamus (Stevens *et al.,* 1991), provided that axonal transport is blocked by ligation (Fig. 30.10A, upper panel) or by colchicine (Fig. 30.10A, lower two panels). In the thoracic spinal cord, axons of spinothalamic neurons that have a fine caliber are found in the middle of the lateral funiculus and even dorsal to the level of the dentate ligament, whereas axons with a

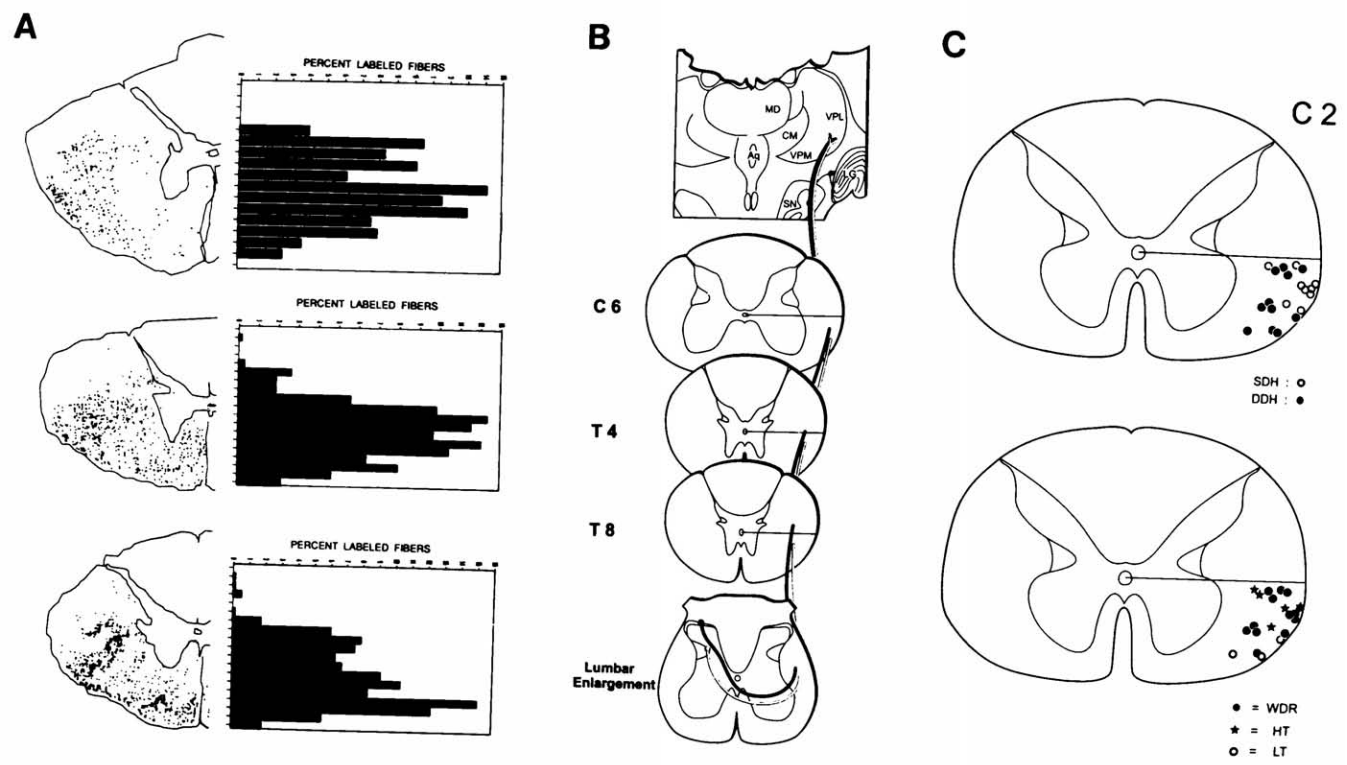

FIGURE 30.10 Location of spinothalamic tract axons in the lateral funiculus. The drawings in **A** are of transverse sections at the thoracic level of the spinal cord in three monkeys. The dots indicate the locations of individual axons that were retrogradely labeled from the thalamus. The histograms show the proportions of labeled STT axons at different dorsal-ventral levels of the cord. (From Stevens *et al.,* 1991.) The drawings in **B** are of sections of the spinal cord at different segmental levels, as well as of the posterior thalamus. The axons of spinothalamic tract cells of lamina I are represented by the black axon and those of spinothalamic tract cells in lamina V by the light axon. Both sets of axons belonged to neurons that could be activated antidromically by low current stimuli applied in the ventral posterior lateral (VPL) nucleus of the thalamus. (From Zhang *et al.,* 2000b.) The drawings of transverse sections of the C2 spinal cord in **C** show the locations of the axons of spinothalamic tract cells, as determined by antidromic mapping with low-current stimuli. The axons are identified in the top drawing by their origins from neurons in the superficial dorsal horn (SDH) or deep dorsal horn (DDH). The same axons are identified in the lower drawing by their response type as wide dynamic range (WDR), high threshold (HT), or low threshold (LT). (From Zhang *et al.,* 2000a.)

thicker diameter are seen ventrally in the lateral funiculus and also in the ventral funiculus (Stevens *et al.,* 1991). Antidromic microstimulation experiments show that, in the thoracic spinal cord, the axons of primate lamina I spinothalamic neurons are concentrated in the middle of the lateral funiculus in a region that extends dorsal to the level of the dentate ligament, whereas the axons of spinothalamic tract cells in the deep dorsal horn are located more ventrally, in the ventral part of the lateral funiculus (Fig. 30.10B) (Zhang *et al.,* 2000b; cf. Stevens *et al.,* 1991; Craig, 2000). However, axons that originate from lamina I spinothalamic cells of the lumbar enlargement shift ventrally as they ascend in the spinal cord. At the level of the upper cervical spinal cord, they become intermingled with the axons from spinothalamic cells in the deep dorsal horn of the lumbar enlargement (Fig. 30.10C) (Zhang *et al.,* 2000a).

Clinical Application

Anterolateral cordotomy is a surgical procedure that has been employed for many years to relieve pain, beginning with the pioneering operation by Spiller and Martin (1912) that was designed based on Spiller's observation that interruption of both anterolateral quadrants of the spinal cord by tuberculomas resulted in analgesia on both sides of the body (Spiller, 1905). At that time, it was already known that pain transmission depended on a pathway that ascended on the side opposite to that affected by a painful stimulus (Brown-Séquard, 1860; Gowers, 1878; Head and Thompson, 1906). Many neurosurgeons have since

performed anterolateral cordotomies with varying degrees of success (Foerster and Gagel, 1932; Hyndman and Van Epps, 1939; White *et al.*, 1950; White, 1963; see review in Gybels and Sweet, 1989). Percutaneous cordotomy is an improved approach in which a cordotomy is produced at a high cervical level without a laminectomy by making a lesion with a needle introduced into the anterolateral quadrant through the C1–C2 intervertebral foramen (Mullen *et al.*, 1963; Mullen, 1966; Rosomoff *et al.*, 1965, 1966). Cordotomies are no longer performed as frequently as in the past, in part because of the tendency for pain to recur even after an initially successful cordotomy and in part because of improvements in drug therapy for pain. Bilateral high cervical percutaneous cordotomies proved to be hazardous because of the complication of sleep-induced apnea following the interruption of descending pathways for respiratory control (Ischia *et al.*, 1984; see Gybels and Sweet, 1989). Attempts have also been made to interrupt the spinothalamic tract at medullary or midbrain levels, but such procedures have not been widely adapted (White, 1941; Walker, 1942a, b; Wycis and Spiegel, 1962).

Areas of analgesia associated with partial interruption of the anterolateral white matter on the two sides of the spinal cord at an upper thoracic segmental level in a human patient are shown in Figure 30.11A and B (Hydman and Van Epps, 1939). The lesion that was placed in the anterolateral white matter on the right side of the spinal cord was more extensive than that made on the left side of the cord (Fig. 30.11A). The lesion in the right anterolateral quadrant extended from just below the dentate ligament to the anterior funiculus. The analgesia on the left side included the left lower extremity and extended up the trunk as far rostrally as the T4 dermatome (Fig. 30.11B). The lesion on the left side of the spinal cord was restricted to an area near the dentate ligament. The corresponding analgesia was restricted to part of the right lower extremity. The explanation for the different distributions of the analgesia following these two anterolateral cordotomies is that the spinothalamic tract has a somatotopic organization in humans (Fig. 30.11C) (Hyndman and Van Epps, 1939; Walker, 1940; White *et al.*, 1956; see Gybels and Sweet, 1989). A similar somatotopic organization appears to be present in monkeys as well (Weaver and Walker, 1941; Yoss, 1953; Applebaum *et al.*, 1975). Presumably, the shift of the axons from spinothalamic tract cells in lamina I ventrally in the upper thoracic and cervical segments so that both sets of axons intermingle (Fig. 30.10B, C) permits a restricted anterolateral cordotomy to interrupt pain transmission more effectively (cf., Zhang *et al.*, 2000a, b). However, if pain transmission depended primarily on the set of axons from spinothalamic cells in lamina I, it would be difficult to explain why the anterolateral cordotomy illustrated in Figure 30.11 had to extend so far anteriorly to produce analgesia on the trunk. In fact, Gybels and Sweet (1989) stress that "total division of the spinothalamic tract by anterolateral cordotomy stops pain from cancer. This means that the section should include the medial and anterior portion of the anterior quadrant, extending 1–2 mm medial to the most medial fibers of the ventral root." This implies that the axons of spinothalamic cells of both the marginal zone and the deep dorsal horn contribute importantly to pain sensation (see also Mayer *et al.*, 1975; Ralston and Ralston, 1992). Anterolateral cordotomies in monkeys are also effective in reducing contralateral responses to noxious stimuli; as in humans, there is often substantial recovery with time (Yoss, 1953; Vierck and Luck, 1979; Greenspan *et al.*, 1986; Vierck *et al.*, 1990).

Additional evidence about the role of the anterolateral quadrant in pain comes from a case that was first reported by Noordenbos and Wall in 1976. A patient had been stabbed in the back, resulting in transection of all of the spinal cord except for one anterolateral quadrant (Fig. 30.12). The patient was examined initially and then reexamined a year later (Wall and Noordenbos, 1977). The findings in the physical examination of this patient provide positive evidence for the types of sensory experience that can be conveyed through one anterolateral quadrant. She could identify pain evoked by pinprick on the side contralateral to the intact anterolateral quadrant of the spinal cord but not on the ipsilateral side, although repeated pinpricks here could produce discomfort. Warm and cold stimuli were identified when applied to the side of the body contralateral but not ipsilateral to the side of the intact anterolateral quadrant, although application of heat to the ipsilateral side evoked an unpleasant burning sensation that continued after the stimulus was removed. Thus, axons ascending in the contralateral anterolateral quadrant are required for recognition of sharp pain and temperature sensations. However, an unpleasant, burning sensation can be conveyed by axons that ascend in the ipsilateral anterolateral quadrant.

Primate *(Macaca fascicularis)* spinothalamic neurons are believed to contain glutamate as a neurotransmitter (Westlund *et al.*, 1992a; cf. Magnusson *et al.*, 1987). Different populations of spinothalamic neurons in rats contain enkephalin, dynorphin, vasoactive intestinal polypeptide, cholecystokinin, bombesin, and/or galanin (Coffield and Miletic, 1987; Ju *et al.*, 1987; Leah *et al.*, 1988; Nahin, 1988). There is also indirect evidence that some spinothalamic cells may

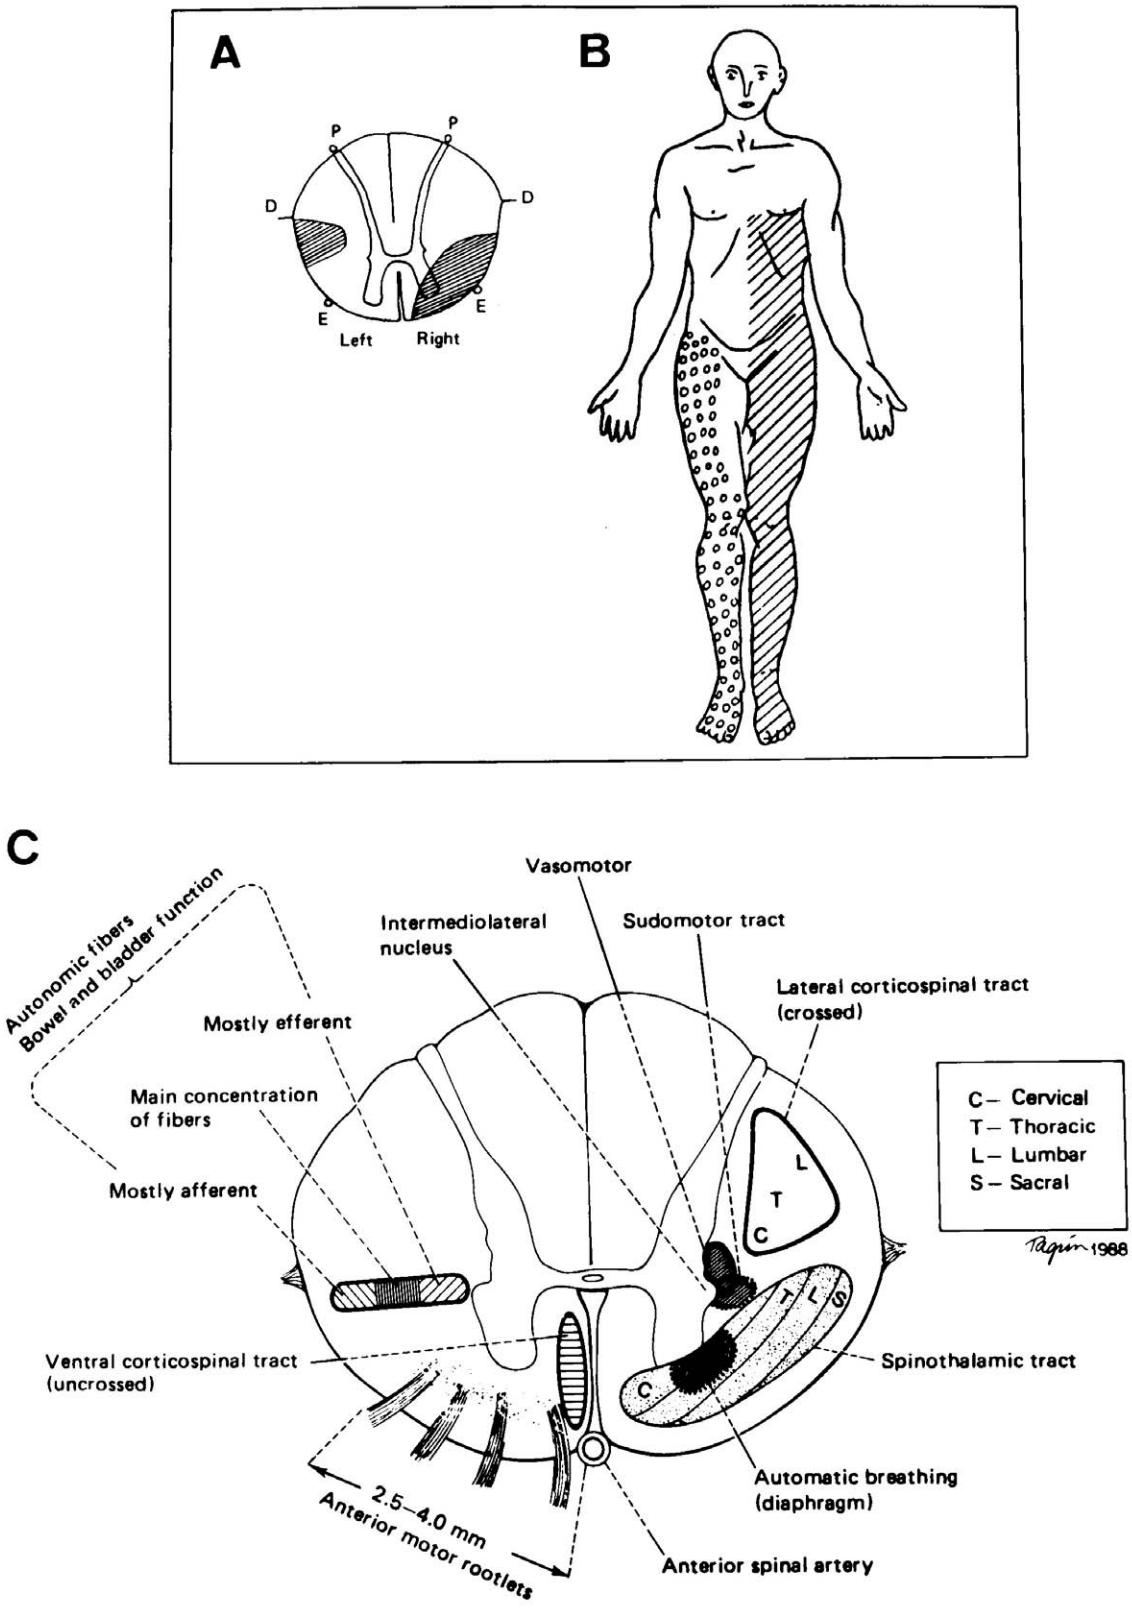

FIGURE 30.11 Differential anterolateral cordotomy in human patient based on somatotopic organization of the spinothalamic tract. **A** and **B** show the lesions made in the spinal cord to interrupt the spinothalamic tract and the distribution of the sensory changes that resulted from the cordotomy. The cancer patient had pain in the left hip and leg. There was radiographic evidence of metastases in the chest and in the fourth lumbar vertebra. After the anterolateral cordotomy shown in the illustration was performed, the patient was pain free at least until he was discharged from the hospital 4 weeks later. The drawing of the spinal cord shows how the cord was sectioned. The cross-hatched area on the diagram of the body indicates the distribution of complete loss of pain and temperature in this patient, and the open circles show where there was only a partial loss of these sensory modalities. Abbreviations: D, dentate ligament; E, exit line of anterior roots; P, entry line of posterior roots. (From Hyndman and Van Epps, 1939.) **C** shows a transverse section through the human upper thoracic spinal cord. A number of landmarks are shown. The location of the spinothalamic tract and its somatotopic organization are estimated based on a number of clinical reports. (From Gybels and Sweet, 1989.)

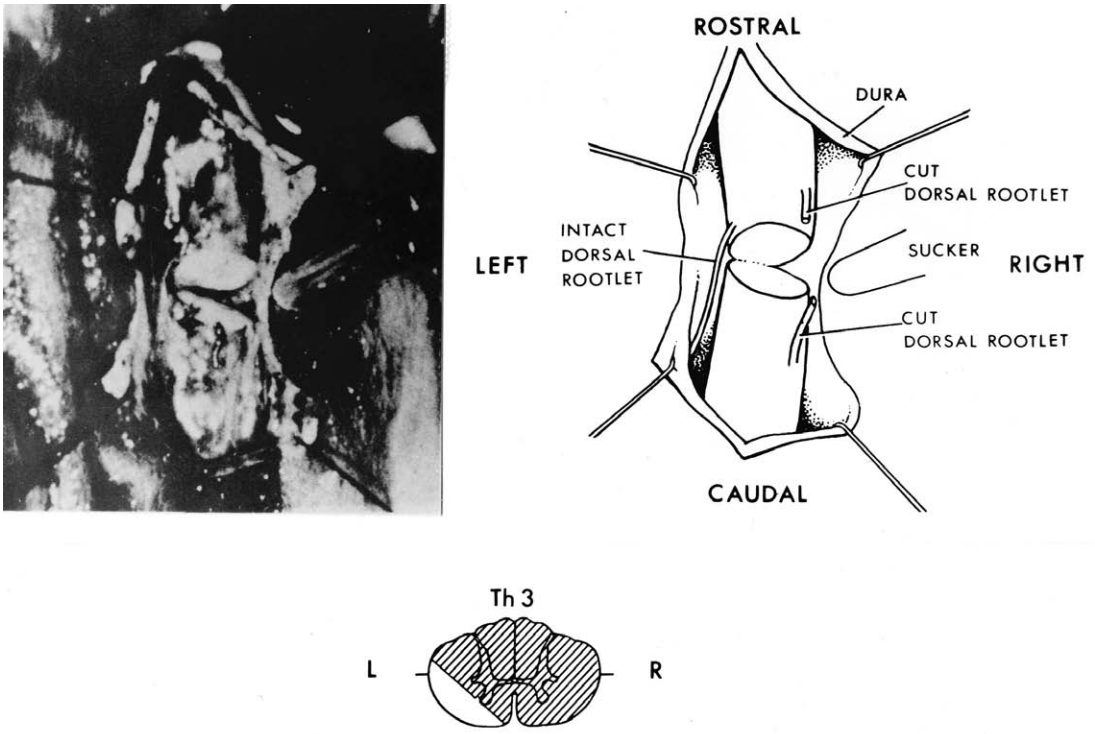

FIGURE 30.12 Interruption of all of the spinal cord except for one anterolateral quadrant in a patient following a stab wound in the back. The photograph shows the spinal cord after it was exposed by a T3–4 laminectomy. The drawing identifies the structures seen in the photograph, and the hatched area in the drawing of a transverse section of the cord is an estimate of the extent of the lesion. (From Noordenbos and Wall, 1976.)

contain substance P (Battaglia and Rustioni, 1992; Nishiyama *et al.*, 1995). Numerous terminals that label for glutamate contact primate spinothalamic cells (Westlund *et al.*, 1992a); other synaptic contacts contain GABA (Carlton *et al.*, 1992), noradrenergic markers (Westlund *et al.*, 1990), serotonin (C. C. LaMotte *et al.*, 1988), CGRP (Carlton *et al.*, 1990), or substance P (Carlton *et al.*, 1985).

Postsynaptic Dorsal Column Pathway

The dorsal column of mammals contains axons that ascend from spinal levels to synapse in the dorsal column nuclei (reviewed in Willis and Coggeshall, 2003). Many of these axons are collaterals of the central processes of DRG cells. However, others arise from projection neurons in the spinal cord gray matter. The latter are called postsynaptic dorsal column neurons. In monkeys, as in other mammals, most of the cells of origin of the postsynaptic dorsal column pathway are located in laminae III and IV of the dorsal horn, although some are near the central canal (Bennett *et al.*, 1983). In cats, postsynaptic dorsal column neurons respond to cutaneous stimuli, often including noxious stimuli (Uddenberg, 1968; Angaut-Petit, 1975; Jankowska *et al.*, 1979; Brown and Fyffe, 1981). However, interruption of the posterior column in humans does not prevent the perception of cutaneous pain (e.g., see Noordenbos and Wall, 1976; however, cf. Vierck *et al.*, 1971), and so these nociceptive projections are not necessary for this type of pain. Cutaneous pain presumably depends on information carried by the spinothalamic and associated tracts (see Al-Chaer *et al.*, 1996a; Palecek *et al.*, 2002).

Recently, a series of studies in rats and monkeys have shown that postsynaptic dorsal column neurons located in the vicinity of the central canal, where many visceral afferents have terminals (Fig. 30.3D) (Sugiura *et al.*, 1989), respond to noxious visceral stimuli (Al-Chaer *et al.*, 1996b, 1999). These postsynaptic dorsal column neurons are responsible for evoking visceral responses of neurons of the gracile nucleus. Evidence for this is that visceral nociceptive responses of gracile neurons are nearly eliminated either by a lesion of the dorsal column or by microdialysis administration of morphine or of a non-NMDA glutamate receptor antagonist into the sacral spinal cord to block synaptic transmission to postsynaptic dorsal column neurons

(Al-Chaer *et al.*, 1996b; Houghton *et al.*, 2001). These agents would not block conduction in primary afferent visceral nociceptors that might project directly to the dorsal column nuclei through the dorsal column, and so it was concluded that the visceral responses in the dorsal column nuclei depended primarily on information carried by the axons of postsynaptic dorsal column neurons. The responses of neurons of the cuneate nucleus to stimulation of cardiopulmonary afferents in monkeys are also dependent in part on activity transmitted in the dorsal column (Chandler *et al.*, 1998). Interruption of the dorsal column or placement of a lesion in the gracile nucleus profoundly reduces visceral responses of neurons in the ventral posterior lateral nucleus of the thalamus, suggesting that the thalamic responses depend largely on signals that are relayed by way of the dorsal column nuclei (Al-Chaer *et al.*, 1996a, 1997, 1998; Feng *et al.*, 1998). A lesion of the lateral column that would interrupt the spinothalamic tract has only a small effect on visceral nociceptive responses (Al-Chaer *et al.*, 1996a, 1998).

A lesion of the dorsal column in monkeys dramatically reduces the regional cerebral blood volume changes that are seen by functional magnetic resonance imaging in anesthetized animals (Willis *et al.*, 1999). This reduction persists for months after the surgery. Dorsal column lesions also reduce nociceptive behavioral responses in rats to visceral stimulation (Houghton *et al.*, 1997; Feng *et al.*, 1998; Palecek *et al.*, 2002).

An anterograde tracing study in rats has demonstrated the course of this pathway from lamina X both from sacral and from midthoracic levels of the spinal cord (Wang *et al.*, 1999). Axons from the sacral cord ascend near the midline to the gracile nucleus (Fig. 30.13D); those from the midthoracic cord ascend more laterally, near the dorsal intermediate septum, to the lateral gracile and medial cuneate nuclei.

Clinical Application

These observations in animal models of visceral nociception are consistent with clinical reports that neurosurgical interruption of the appropriate part of the posterior columns in human patients can relieve visceral pain, such as pelvic and epigastric cancer pain (Fig. 30.13A–C) (Gildenberg and Hirshberg, 1984; Hirshberg *et al.*, 1996; Nauta *et al.*, 1997; 2000; Becker *et al.*, 1999; Kim and Kwon, 2000). The clinical and research findings that visceral nociceptive input travels in the dorsal column midline may help explain why commissural myelotomies and upper cervical midline myelotomies can be highly effective in relieving pain from much more caudal parts of the body than might have been inferred from the locations of the surgical lesions (Armour, 1927; Putnam, 1934; Guillaume *et al.*, 1945; Wertheimer and Lecuire, 1953; Sourek, 1969; Hitchcock, 1970, 1974, 1977; Papo and Luongo, 1976; Schvarcz, 1976, 1978, 1984; King, 1977; see review by Gybels and Sweet, 1989). These procedures may have interrupted the visceral pain pathway that ascends in the posterior columns. Previously, the results were attributed to sectioning of a hypothetical pain pathway that was supposed to ascend in the central region of the spinal cord (however, see Karplus and Kreidl, 1914). An important issue with respect to midline myelotomy is that axons conveying nociceptive signals from the pelvis in rats, and presumably in humans as well, ascend near the midline of the dorsal columns (Wang *et al.*, 1999), and so a lesion near the midline can successfully relieve pelvic visceral pain (e.g., Fig. 30.13A, C). By contrast, nociceptive signals from abdominal or thoracic organs are carried by axons that ascend more laterally in the dorsal columns, and so the myelotomy must extend or enter more laterally on each side. For example, Figure 30.13B shows a lesion that was not optimally placed, at least on one side.

Spinocervical, Spinoreticular, and Spinomesecephalic Pathways

There are several other spinal cord projection systems that convey nociceptive information directly or indirectly to the brain stem and higher centers. These include the spinocervical, spinoreticular, and spinomesencephalic tracts.

The spinocervical tract originates from neurons that are located chiefly in the nucleus proprius of the dorsal horn (reviewed in Willis and Coggeshall, 2003). The tract ascends in the dorsal part of the ipsilateral lateral funiculus and synapses in the lateral cervical nucleus in the uppermost cervical segments. The lateral cervical nucleus is a distinctive nucleus just lateral to the dorsal horn in many species, including monkeys, but its presence in humans is controversial (however, see Truex *et al.*, 1970; see also Chapter 28). Axons from neurons in the lateral cervical nucleus decussate in the upper cervical spinal cord and then ascend to access the contralateral thalamus through the medial lemniscus. Nociceptive responses have been recorded from spinocervical tract neurons and neurons in the lateral cervical nucleus in monkeys (Downie *et al.*, 1988), as well as in cats (see Willis and Coggeshall, 2003). It is unclear if interruption of the nociceptive signals carried in the spinocervical tract has an influence on sensation or behavior. A lesion of the dorsal lateral funiculus in monkeys results in hyperresponsiveness of the animals to noxious stimuli (Vierck *et al.*, 1971), but this change presumably results from interruption of descending inhibitory pathways.

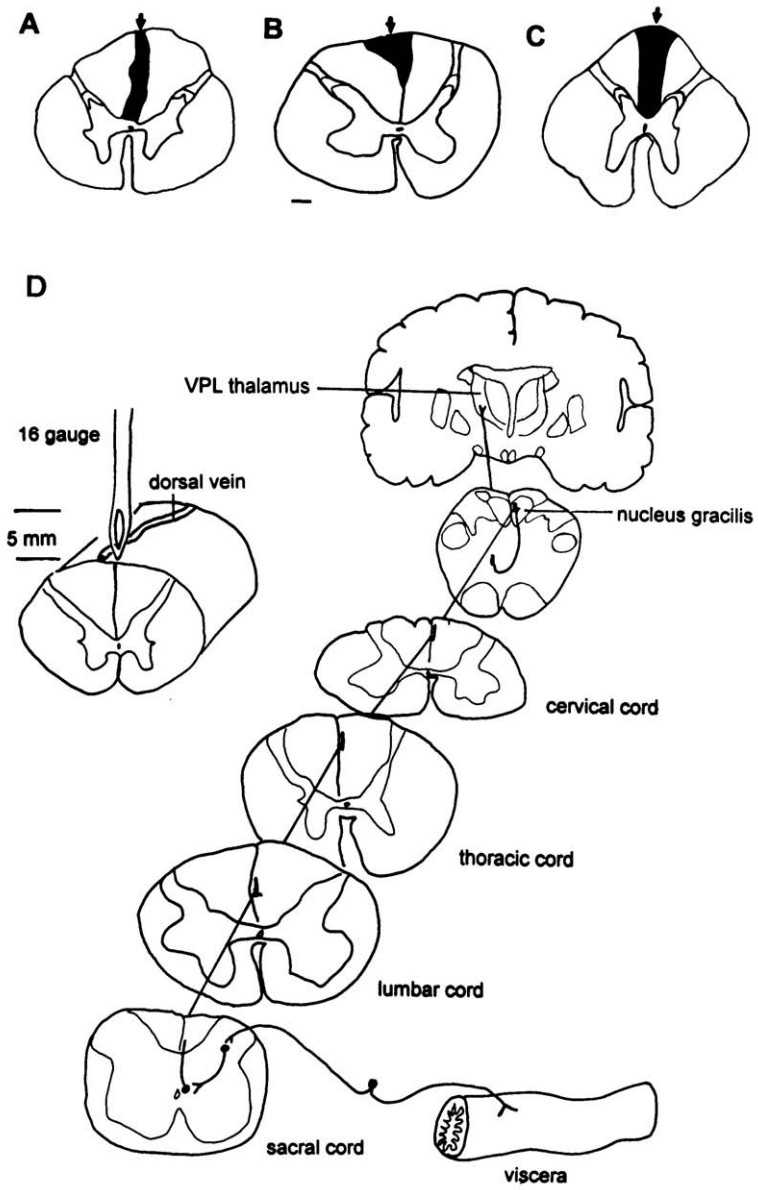

FIGURE 30.13 Interruption of the dorsal column to relieve visceral pain. The transverse sections of the spinal cord in **A–C** show the locations of midline myelotomies that were performed on three patients to relieve visceral pain. The lesion in **A** was from a successful case in which a lesion at T10 completely relieved pain due to colon cancer. The lesion shown in **B** was from a patient who had lung cancer. The lesion was made at T7, but it was not very effective, perhaps because it was not wide enough on one side to interrupt the axons of thoracic postsynaptic dorsal column neurons or because it was not placed sufficiently rostrally in the spinal cord. The lesion in **C** was in a patient whose pelvic cancer pain was successfully relieved for several years (From Willis and Westlund, 2000). **D** shows the posterior column visceral pain pathway as inferred from animal experiments. (From Willis and Westlund, 1997.)

The spinoreticular tract in monkeys arises mostly from neurons in the ventral part of the spinal cord gray matter, as shown by retrograde labeling (Kevetter *et al.*, 1982). Some spinoreticular neurons were found in laminae I, V, and X, but more than half were in laminae VII and VIII. The axons of many spinoreticular neurons decussate and ascend in the contralateral ventrolateral white matter. In monkeys, the spinoreticular tract has been shown to terminate in a number of reticular formation nuclei, including the nucleus medullae oblongatae centralis, lateral reticular nucleus, nucleus reticularis gigantocellularis, nucleus reticularis

pontis caudalis and oralis, nucleus paragigantocellularis dorsalis and lateralis, and nucleus subcoeruleus (Mehler *et al.*, 1960; see also Willis and Coggeshall, 2003). Some of these nuclei are involved in modulation of spinal cord nociceptive mechanisms (see below). Other reticular nuclei are interconnected with the cerebellum, regulate autonomic activity, participate in the control of states of consciousness, or conduct other functions of the reticular formation (Magoun, 1963). A spinoreticulothalamocortical pathway forms an indirect projection that allows painful input to influence the forebrain (however, cf. Blomqvist and Berkley, 1992). Particular functions presumably include attentional mechanisms and arousal.

The primate spinomesencephalic tract originates from the same regions of the spinal cord gray matter as the spinothalamic tract, i.e., mainly from laminae I and V, as well as from scattered neurons in other locations (Trevino, 1976; Willis *et al.*, 1979; Wiberg *et al.*, 1987). Given the similarity in location of spinothalamic and spinomesencephalic tract cells, it is not surprising that some neurons can be retrogradely labeled in monkeys from both the midbrain periaqueductal gray and the thalamus, indicating that some neurons project to both targets (Zhang *et al.*, 1990). Nociceptive responses have been recorded from neurons that project to the midbrain or to both the midbrain and the thalamus in monkeys (Yezierski *et al.*, 1987).

The spinomesencephalic tract projects to the nucleus cuneiformis of the midbrain reticular formation, the periaqueductal gray, the intercolliculus nucleus, the deep layers of the superior colliculus, the anterior and posterior pretectal nuclei, the nucleus of Darkschewitsch, the red nucleus, the Edinger–Westphal nucleus, and the interstitial nucleus of Cajal (see Fig. 12.10 in Chapter 12) (Mehler *et al.*, 1960; Wiberg *et al.*, 1987; Yezierski, 1988). The terminals of the spinomesencephalic tract have a caudal to rostral somatotopic organization (Wiberg *et al.*, 1987). The functions of many of these structures are probably unrelated to pain. However, the nucleus cuneiformis presumably contributes to attentional and alerting mechanisms, and the periaqueductal gray and the anterior pretectal nucleus are involved in the descending modulation of nociceptive transmission (see **"Descending Pain Modulatory Systems"**).

Clinical Application

Stimulation in the midbrain tegmentum in human patients can evoke paresthesias or pain on the contralateral side of the body, and stimulation in the periaqueductal gray can trigger emotional responses, such as an unpleasant feeling or even fear (Nashold *et al.*, 1969).

Spinoparabrachial, Spinohypothalamic, and Spinolimbic Pathways

Several projection systems that connect the spinal cord indirectly or directly with limbic system structures have been described during the past decade (see review by Burstein, 1996). These include spinoparabrachial, spinohypothalamic, and spinolimbic pathways.

The spinoparabrachial tract is sometimes lumped with the spinoreticular or spinomesencephalic tracts. However, it merits separate consideration, since many spinoparabrachial neurons in rats terminate in a part of the lateral parabrachial nuclear complex that projects to the amygdala (Bernard *et al.*, 1989; Bernard, 1999). This pathway and direct spinolimbic projections provide a special route for nociceptive information to access the limbic system (see review by Willis and Westlund, 1997). In addition, spinal connections to the parabrachial region, including the locus coeruleus and subcoeruleus, can activate catecholaminergic neurons that project caudally into the brain stem and spinal cord, providing a means for modulation of nociceptive transmission (see next section). The functions of spinoparabrachial tract neurons have not been investigated in monkeys, but many of these cells in cats are clearly nociceptive (Hylden *et al.*, 1986), as are neurons in the parabrachial region of rats that project to the amygdala (Bernard and Besson, 1990; Bernard *et al.*, 1994). Many parabrachial neurons respond to noxious visceral stimuli, as well as to noxious cutaneous stimuli (Bernard *et al.*, 1994). Buritova *et al.* (1998) have shown that the intraplantar injection of carrageenan into the paw in rats results in the expression of FOS protein in neurons in lamina I of the ipsilateral spinal cord dorsal horn (presumably including spinoparabrachial projection neurons) and in contralateral parabrachial subnuclei that project to the amygdala. Anterograde tracing studies have demonstrated projections of lamina I cells to the parabrachial region and locus coeruleus in monkeys (Craig, 1995; Bernard, 1999). En route through the brain stem reticular formation, the axons of these ascending tract cells contact catecholaminergic neurons throughout the medulla and pons (Westlund and Craig, 1996). In addition, parabrachial nuclei that receive spinal cord input through the spinoparabrachial pathway project to the hypothalamus, periaqueductal gray, nucleus raphe magnus, and ventrolateral medulla (Bernard, 1999).

A spinohypothalamic tract has recently been characterized functionally in monkeys (Zhang *et al.*, 1999). The spinohypothalamic neurons examined were all nociceptive, and most could also be activated antidromically from the thalamus, suggesting that at least some of these neurons project to both the hypothalamus

and the thalamus. Most of the work on the spinohypothalamic tract has been done in rats. Almost all (87%) of the spinohypothalamic neurons studied in rats, like those in monkeys (Zhang *et al.,* 1999), were nociceptive (Burstein *et al.,* 1991; Katter *et al.,* 1996). About 70% of the cells of origin of the rat spinohypothalamic tract are found contralaterally to the side of the spinal cord in which the axons ascend, and they are concentrated in the superficial and deep dorsal horn and around the central canal, although some are in the intermediate zone and ventral horn (Burstein *et al.,* 1990). The axons decussate, ascend through the brain stem, and pass ventral to the thalamus to enter the hypothalamus, where they terminate in a number of hypothalamic nuclei (Cliffer *et al.,* 1991). The axons of many of these neurons decussate a second time and then descend on the same side as the cell body to levels of the brain stem as far caudally as the medulla (Zhang *et al.,* 1995). Nociceptive neurons in this pathway could presumably affect autonomic and endocrine functions as part of the spectrum of reactions to painful stimuli.

Direct spinolimbic projections have also been described in rats (Cliffer *et al.,* 1991). These terminate in such structures as the central nucleus of the amygdala, septal nuclei, nucleus accumbens, bed nucleus of the stria terminalis, and even some areas of limbic cortex. Such pathways, along with the spinoparabrachioamygdalar pathway, could provide a means for nociceptive signals to influence parts of the brain that are likely to be involved in autonomic control, motivational–affective responses to pain, and learning and memory.

DESCENDING PAIN MODULATORY SYSTEMS

Nociceptive input is modulated at a variety of sites, but particularly in the dorsal horn of the spinal cord, by descending pathways that are parts of inhibitory and excitatory control systems. These pathways can profoundly influence the perception of pain. The concept that the brain can control sensory input was popularized in the 1950s by the discovery of the reticular formation by Moruzzi and Magoun (see Magoun, 1963). However, the notion that pain is subject to descending modulation came into focus only after the demonstration by Reynolds that abdominal surgery could be performed on awake rats during stimulation in the periaqueductal gray (Reynolds, 1969). Following this, a number of laboratories examined what came to be known as "stimulation-produced analgesia" and showed the relationship of this to opioid analgesia and "stress-induced analgesia" (see reviews by Willis, 1982; Besson and Chaouch, 1987).

The ability to inhibit nociceptive input to higher centers and thus to interfere with the perception of pain is likely to be accomplished through activation of complex supraspinal circuits. Descending inhibition of spinal nociceptive processes was initially proposed to occur through a periaqueductal gray relay to serotonergic neurons in the nucleus raphe magnus and the adjacent reticular formation (Liebeskind *et al.,* 1973; Oliveras *et al.,* 1974a, b, 1975, 1979; Proudfit and Anderson, 1975; Beall *et al.,* 1976; Willis *et al.,* 1977; Fields *et al.,* 1977; Basbaum *et al.,* 1978; Martin *et al.,* 1978; Basbaum and Fields, 1979; Chung *et al.,* 1983). However, subsequent findings suggest a more complicated circuitry that also involves descending catecholaminergic pathways (Yaksh, 1979; Hodge *et al.,* 1981; Budai *et al.,* 1998; Cui *et al.,* 1999), as well as descending opioidergic pathways (Budai and Fields, 1998). For reviews of many of the early studies, see Mayer and Price, 1976; Basbaum and Fields, 1978; Fields and Basbaum, 1978; Yaksh and Rudy, 1978; Willis, 1982; Besson and Chaouch, 1987; Fields and Besson, 1988; Willis and Coggeshall, 2003; see also Chapter 8. For evidence concerning the chemical anatomy of descending pathways in the human spinal cord, see Chapter 7.

There is an increasing appreciation that supraspinal circuitry is also responsible for descending modulation that results in enhancement or sensitization of the nociceptive responses of spinal cord dorsal horn neurons (see Haber *et al.,* 1980; Giesler *et al.,* 1981; Cervero and Wolstencroft, 1984; Urban *et al.,* 1996; Wei *et al.,* 1999). Whether this results from a decrease in descending inhibition or an enhancement of facilitatory mechanisms or both remains to be determined. For example, descending inhibitory influences on inhibitory interneurons in the dorsal horn could result in a decreased GABAergic and/or glycinergic tone. It has been proposed that the interactions between spinal and supraspinal circuits may be responsible for the decreased efficacy of morphine as tolerance develops (Heinricher *et al.,* 1994; Ossipov *et al.,* 1997).

Raphe Spinal and Reticulospinal Tracts

In primates, a large population of neurons with descending spinal projections has been identified in the raphe nuclei of the medulla and in the reticular formation of the midbrain, pons, and medulla (Kneisley *et al.,* 1978; Coulter *et al.,* 1979). Many raphe neurons have been shown to contain serotonin and are therefore the origin of descending serotonergic projections that can inhibit spinal nociceptive processing

(Bowker *et al.*, 1982a, b; see also Basbaum and Fields, 1978). However, other bulbospinal neurons do not contain serotonin, although they may contain any of several peptides (Bowker *et al.*, 1982b). Spinothalamic tract neurons in monkeys can be powerfully inhibited by stimulation in the nucleus raphe magnus or the adjacent medullary reticular formation (Beall *et al.*, 1976; Willis *et al.*, 1977; Gerhart *et al.*, 1981). However, only part of this inhibition appears to be mediated by serotonin (Yezierski *et al.*, 1982).

Nociceptive input may be relayed from the spinal cord to the reticular formation by ascending projections arising from laminae I and X (Craig, 1995; Wang *et al.*, 1999), as well as by spinoreticular projections from other parts of the spinal cord gray matter (Kevetter *et al.*, 1982). A direct spinal projection to the nucleus raphe magnus has recently been described to arise from the region around lamina X, the area from which the postsynaptic dorsal column visceral nociceptive pathway originates (Wang *et al.*, 1999; see above).

Serotonin is released in the spinal cord in animals following stimulation of either the nucleus raphe magnus (Sorkin *et al.*, 1990; 1993) or the periaqueductal gray (Cui *et al.*, 1999). Although serotonin has been identified as one of the major neurotransmitters involved in descending inhibitory mechanisms, it should be noted that serotonergic mechanisms in the spinal cord can exert either antinociceptive or pronociceptive actions through different serotonergic receptor subtypes (Alhaider *et al.*, 1991; Peng *et al.*, 1996a; Lin *et al.*, 1996a; Millan, 1997, 1999).

Clinical Application

It is known that spinal serotonin turnover is modified in chronic pain patients (Wolfe *et al.*, 1997; Weil-Fugazza, 1989; Von Knorring, 1989). Stimulation in the vicinity of the periaqueductal gray has been used to produce naloxone-reversible relief of pain in human patients (Hosobuchi *et al.*, 1977). When tolerance to such stimulation develops, the tolerance can be reversed by tryptophan administration, suggesting that serotonin release is involved in the analgesic action, as are opioids (Hosobuchi, 1978; Hosobuchi *et al.*, 1980).

Descending Catecholamine Projections

Descending noradrenergic input to the spinal cord provides an alternative mechanism for the inhibition of spinal nociceptive neurons. A large percentage of the spinally projecting neurons that have been identified in the locus coeruleus and the subcoeruleus in monkeys and rats are noradrenergic (Westlund and Coulter, 1980; Westlund *et al.*, 1983). Other catecholaminergic cell groups in the dorsolateral pons—the A5 cell group, the Kölliker–Fuse nucleus, and the parabrachial nuclei—also have projections to the spinal cord. There is no convincing evidence for descending noradrenergic input from medullary levels of the brain stem, although a small epinephrine-containing spinal projection from the ventrolateral medulla has been reported in primates (Carlton *et al.*, 1991). In monkeys and cats, the bilateral terminations of dorsal horn projections from the locus coeruleus and subcoeruleus region were found to be densest in nociceptive processing regions, including laminae I, II, V, and X, with the majority of the fibers ending contralaterally (Westlund and Coulter, 1980; Holstege and Kuypers, 1982). Noradrenergic terminals in the dorsal horn have been shown to contact identified spinothalamic neurons in laminae I and V (Westlund *et al.*, 1990).

Electrical stimulation of the dorsolateral pons produces analgesic effects (Segal and Sandberg, 1977; DeSalles *et al.*, 1985). Nociceptive responses are inhibited by norepinephrine acting on α_2 adrenoreceptors (Howe *et al.*, 1983). Iontophoretic release of norepinephrine in the dorsal horn inhibits nociceptive neurons, including primate spinothalamic neurons (Headley *et al.*, 1978; Fleetwood-Walker *et al.*, 1983; Willcockson *et al.*, 1984).

Periaqueductal Gray

The periaqueductal gray receives heavy innervation from ascending spinal pathways, including projections arising from laminae I and X (see section on the spinomesencephalic tract) (Craig, 1995, Wang *et al.*, 1999). However, no direct pathway from the periaqueductal gray to the spinal cord has been identified to account for the strong analgesia reported after stimulation of the periaqueductal gray. The periaqueductal gray, including its dorsolateral and ventrolateral regions, projects to brain stem regions containing epinephrine, norepinephrine, and serotonin cell groups with descending projections to the spinal cord in the rat (Cameron *et al.*, 1995). The ventrolateral periaqueductal gray projects preferentially to the nucleus raphe magnus (B3 serotonin group) and the dorsolateral region projects preferentially to the dorsolateral pons. The ventrolateral medulla, another site known to induce stimulation-produced analgesia, also receives projections from both of these regions of the periaqueductal gray. It has been shown that stimulation of the rostral part of the lateral paragigantocellular nucleus and the gigantocellular nucleus pars alpha produces analgesia in the rat through both serotonergic and noradrenergic mechanisms (Satoh *et al.*, 1983; Lovick, 1986). Since there are no noradrenergic spinal projections from this region, a complex circuitry

involving the noradrenergic dorsolateral pontine cells has been proposed (Holden and Proudfit, 1998).

Inhibition of primate spinothalamic cells is produced by stimulation of the midbrain periaqueductal gray (Hayes *et al.*, 1979; Gerhart *et al.*, 1984). Inhibition of nociceptive dorsal horn neurons following periaqueductal gray stimulation can be partially blocked by administration of antagonists of serotonin receptors (Yezierski *et al.*, 1982; Lin *et al.*, 1996a; Peng *et al.*, 1996a), of α_2 adrenoreceptors (Peng *et al.*, 1996b), or of inhibitory amino acid receptors (Lin *et al.*, 1994, 1996b). Electrical stimulation of the periaqueductal gray has been shown to cause the release of serotonin, norepinephrine, and glycine in the spinal cord (Sorkin *et al.*, 1990; Cui *et al.*, 1999). These same neurotransmitters can inhibit primate spinothalamic cells when released iontophoretically (Willcockson *et al.*, 1984; cf. Basbaum and Fields, 1979). Thus, it is likely that inhibition occurs following the release of serotonin and norepinephrine from the descending serotonergic and noradrenergic projections that were described above. Release of inhibitory amino acids may be either from the terminals of descending projections or from spinal cord interneurons that are activated by descending projections.

Thus, the brain stem circuitry involved in stimulation-produced analgesia involves not only the periaqueductal gray but also connections of the periaqueductal gray with the nucleus raphe magnus, the ventrolateral medulla, and the dorsolateral pons.

Anterior Pretectal Nucleus

Stimulation in the anterior pretectal nucleus produces antinociceptive actions, as detected by the tail flick, formalin, and paw pressure tests, by inhibition of nociceptive dorsal horn neurons (Rees and Roberts, 1993), including primate spinothalamic tract cells (Chen, 2000). The anterior pretectal nucleus has a minor direct input from laminae I and X of the spinal cord (Wiberg and Blomqvist, 1984; Craig, 1995; Wang *et al.*, 1999). Input from low-threshold afferent fibers to the anterior pretectal nucleus is relayed through the dorsal column nuclei (Rees and Roberts, 1989a, b). Activation of the latter pathway has been proposed as a mechanism that could explain the ability of dorsal column stimulation to inhibit pain in humans (Rees and Roberts, 1989b; cf. Shealy *et al.*, 1970; Gybels and Sweet, 1989). Projections from the anterior pretectal nucleus to the spinal cord have not been reported. Indications are that the antinociceptive actions following stimulation in the anterior pretectal nucleus are mediated through dorsolateral pontine noradrenergic descending pathways (Chen, 2000).

Thus, complex spinobulbospinal feedback loops are activated by nociceptive inputs that serve important functions associated with integration of sensory input relevant to the perception of pain. These pathways are likely to be part of an even more complex homeostatic control network involved in sensory, motor, and autonomic integration. Unfortunately, it is difficult to take practical advantage of these circuits for the purpose of producing pain relief by using electrical stimulation. For example, attempts to stimulate the nucleus raphe magnus or the dorsolateral pons in humans would probably be too dangerous.

Periventricular Gray and Ventrobasal Thalamus

Since stimulation in the periaqueductal gray has been shown to result in a powerful analgesic action in animals, comparable stimulation has been attempted in the periaqueductal gray of human pain patients. However, as mentioned earlier, this can produce emotional responses, such as fear, as well as eye movements. Richardson and Akil (1977a, b) and Hosobuchi *et al.* (1997) have reported pain relief in patients without these side effects following stimulation in the nearby periventricular gray matter (see review by Gybels and Sweet, 1989).

Stimulation in the ventrobasal complex of the thalamus has also been found to result in the inhibition of nociceptive dorsal horn neurons, including primate spinothalamic cells (Gerhart *et al.*, 1983; Dickenson, 1983). The inhibition has been attributed to the antidromic activation of collaterals of spinothalamic axons that terminate in the periaqueductal gray or nucleus raphe magnus (Gerhart *et al.*, 1983; Willis *et al.*, 1984; Tsubokawa *et al.*, 1985). Further evidence for this idea is that stimulation in the VPL nucleus of the monkey thalamus causes the release of serotonin in the spinal cord (Sorkin *et al.*, 1992). It has been found that stimulation in the VPL nucleus of the human thalamus can suppress acute pain induced experimentally (Gybels *et al.*, 1976).

Clinical Application

In general, nociceptive pain seems to respond better to stimulation in the periventricular gray matter, whereas neuropathic pain responds better to stimulation in the thalamic ventrobasal complex (Gybels and Sweet, 1989). Stimulation in both sites can be useful, especially if the pain is of both types. The duration of the analgesia that is produced often outlasts the period of stimulation by many hours (Hosobuchi *et al.*, 1977). This cannot be readily explained by the activation of brain stem neurons during the electrical

stimulation, since this activity in animal models does not greatly outlast the period of stimulation (Gybels and Sweet, 1989).

BRAIN STRUCTURES INVOLVED IN PAIN PERCEPTION AND INTEGRATION

While it is clear that the perception of pain in humans requires activity in higher centers of the brain, including parts of the thalamus and cerebral cortex, as well as in many subcortical structures, the precise regions of the brain that are involved are only now becoming clarified with the assistance of positron emission tomography (PET) and functional magnetic resonance imaging (fMRI; see also Chapter 28). Imaging studies have implicated the SI and SII somatosensory receiving areas of the cortex, as well as the anterior cingulate gyrus and the insula, as important structures for the higher processing of the pain that is evoked by acute noxious stimuli (Fig. 30.14, upper panels; Jones *et al.,* 1991; Talbot *et al.,* 1991; Casey *et al.,* 1994; Coghill *et al.,* 1994, 1999; Di Piero *et al.,* 1994; Andersson *et al.,* 1997; Rainville *et al.,* 1997; Silverman *et al.,* 1997; Davis *et al.,* 1998; Iadarola *et al.,* 1998; Bushnell *et al.,* 1999; Gelnar *et al.,* 1999; Tracey *et al.,* 2000; see also Treede *et al.,* 2000). Other areas that have been activated in at least some studies include the prefrontal, supplementary motor, and ventral premotor cortices, as well as the lentiform nucleus, cerebellum, thalamus, and several brain stem areas. Activation is generally contralateral in the SI cortex, but it is often bilateral in the SII, insula, and anterior cingulate cortices and in motor structures (Coghill *et al.,* 1999). The usual type of stimulus in these studies has been noxious heat, but in one investigation the noxious stimulus was intradermal injection of capsaicin (Iadarola *et al.,* 1998) and in another it was noxious visceral stimulation (Silverman *et al.,* 1997).

These studies support the view that the SI and SII cortices are involved in the sensory-discriminative aspects of pain, the anterior cingulate cortex in the affective component of pain, the insula in memory and learning of painful events, and parts of the motor system, such as the lentiform nucleus and cerebellum, in motor responses to painful stimuli. There is no longer any reason to adhere to the notion proposed by clinical investigators early in the 20th century that pain is perceived in the thalamus. This idea was based on evidence from patients with relatively focal lesions of the cerebral cortex that would not have affected other cortical regions involved in pain (Head and Holmes, 1911; Holmes, 1927). Hence, such lesions would have only partially interfered with pain reactions. Additional evidence came from studies in which the somatosensory cortex was stimulated electrically during surgery to remove epileptic foci (Penfield and Boldrey, 1937). Only rarely was a sensation of pain evoked. However, a sensation of pain was reported in those few cases. The current view is that painful stimuli activate multiple parallel circuits that process different aspects of the pain response (Coghill *et al.,* 1994, 1999).

Imaging studies of patients with chronic pain reveal that regional cerebral blood flow changes can occur in a different group of brain areas than those that are activated by acutely painful stimuli (Hseih *et al.,* 1994). For example, Kupers *et al.* (2000) recently reported a PET study of a patient who had chronic neuropathic pain in the right cheek following removal of an adenocarcinoma. Electrical stimulation of the left ventral posterior medial thalamic nucleus relieved the pain and also produced tingling and a sensation of warmth in the painful area (see **"Descending Pain Modulatory Systems"** above). For the PET study, the patient was imaged after the stimulation was turned off overnight, which was long enough for the pain to resume fully. After an imaging session while the patient was in pain, thalamic stimulation was initiated and the pain eliminated. Another imaging session was done during stimulation, and a third after stimulation was discontinued but while the pain was still absent. Figure 30.14 (A, lower row of panels) shows structures that had increased blood flow during chronic pain. These structures included the prefrontal cortex, the anterior insula, the hypothalamus, and the periaqueductal gray. No changes were seen in the SI or SII cortex or in the anterior cingulate gyrus. The regional blood flow produced by thalamic stimulation was also evaluated (Fig. 30.14, B in lower row of panels). Significant increases were seen in the amygdala, ventromedial frontal cortex, and anterior insula. Kupers *et al.* (2000) suggest that during the chronic pain state of this patient, the mechanisms responsible for sensory discrimination of pain did not play an important role. This is reasonable because the perception of stimulus localization or intensity would have no meaning in ongoing chronic neuropathic pain, which does not depend on peripheral stimulation. The activation of the ventromedial prefrontal cortex in this patient may have related to memory of the affective component of the pain (Rosen *et al.,* 1996). Kupers *et al.* (2000) propose that the increased blood flow in the hypothalamus and periaqueductal gray reflected activation of the descending analgesia system or of autonomic responses to the pain. Increases in blood flow in the

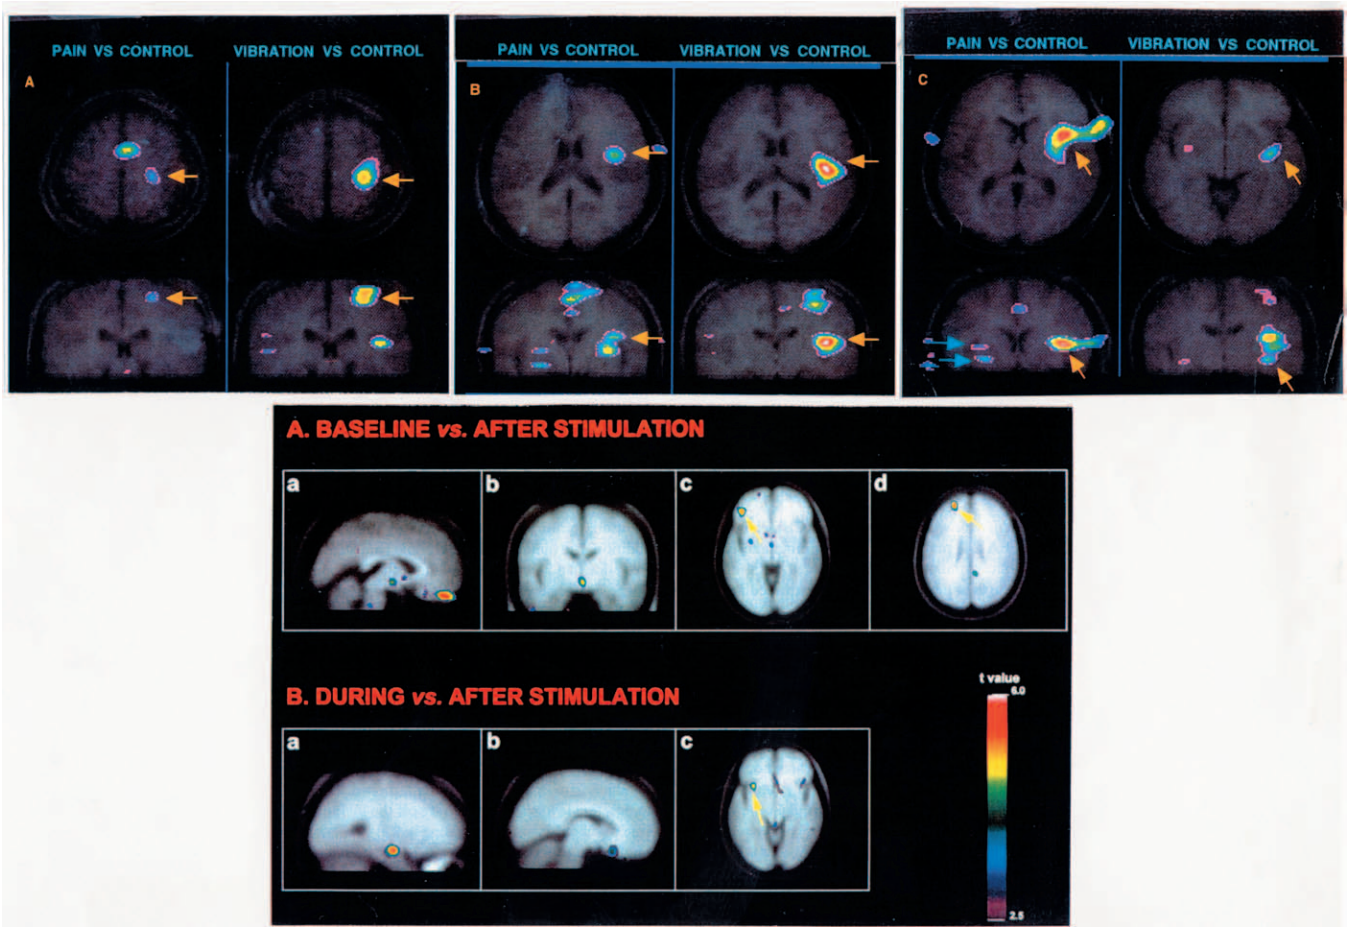

FIGURE 30.14 Imaging pain. **Upper panels.** Functional magnetic resonance images of areas of the human cerebral cortex that were activated during a painful stimulus in comparison to areas that were activated by a vibratory stimulus. The images in **A** show that both painful heat and vibrotactile stimuli activated the contralateral SI cortex *(arrows).* **B** shows that these same stimuli activated the contralateral SII cortex *(arrows)* and that the painful stimulus also activated the anterior cingulate gyrus. **C** shows that both stimuli activated the insula *(orange arrows).* Basal ganglia could also be involved following painful stimulation *(blue arrows.)* (From Coghill *et al.,* 1994.) **Lower panels.** Subtracted PET images of the brain of a patient who had chronic neuropathic pain in the cheek following removal of an adenocarcinoma. In **A** are shown the results of subtraction of images made of the regional blood flow observed in the chronic pain state during analgesic stimulation. Significant regional blood flow increases were seen in the orbitofrontal cortex (a), hypothalamus (b), inferior frontal gyrus (c), and superior frontal gyrus (d). In **B** are shown the results of subtraction of images made after analgesic stimulation was ended from the regional blood flow observed during thalamic stimulation. Stimulation in the ventral posterior medial thalamic nucleus activated the amygdala (a), ventromedial frontal cortex (b) and anterior insula (c). (From Kupers *et al.,* 2000.)

amygdala by thalamic stimulation may also have reflected the role of this structure in the descending analgesia system.

Thalamus

Most sensory input to the cerebral cortex, including that evoked by painful events, is first processed in the thalamus. The thalamus contains several nuclei that distribute sensory information to particular sensory receiving areas of the cerebral cortex by way of thalamocortical projections (Jones, 1985; see Chapter 28). Furthermore, the sensory regions of the cerebral cortex project in an orderly fashion back to the sensory nuclei of the thalamus through corticothalamic projections, and by this means the cerebral cortex regulates the flow of sensory input from the spinal cord and brain stem. Inhibitory interneurons in the thalamic reticular nucleus, as well as in the main relay nuclei at least in primates, play an important role in this

regulation of sensory transmission to the cerebral cortex (Jones, 1985, 1998).

The monkey and the human thalamus are organized in a similar fashion (Jones, 1985, 1997b, 1998; see also Chapter 20). Evidence about the areas of the thalamus that might be important for pain processing comes both from a knowledge of the parts of the thalamus that are connected with the cerebral cortical areas activated in monkeys and humans by painful stimuli and from parts of the thalamus that receive direct spinal projections. Some the pertinent regions in the monkey and the human posterior thalamus include the ventral posterior lateral (VPL) and ventral posterior medial (VPM) nuclei, the ventral posterior inferior (VPI) nucleus, the central lateral (CL) nucleus, and the medial part of the posterior complex (POm). The latter is dorsal to the magnocellular part of the medial geniculate (MGmc) nucleus and lateral to the suprageniculate (SG) nucleus (see discussion of the thalamic nuclei that receive spinothalamic input in Chapter 20).

Mehler (1962) described the terminations of spinal projections to the thalamus in a human subject by an anterograde degeneration study of a postmortem specimen from a patient who had had a bilateral anterolateral cordotomy for pain relief (Fig. 30.15B). Most of the terminals were in the VPL and CL nuclei (Fig. 30.15), but some were in the posterior complex. The endings in the VPL nucleus were in scattered patches (Fig. 30.15). Similar projections have been observed in monkeys following cordotomy (Mehler *et al.*, 1960).

The patches of STT terminals are in regions that correspond to the matrix areas of the VPL nucleus, which are rich in calbindin-immunoreactive neurons and presumably receive input from spinothalamic neurons (Jones and Hendry, 1989; Rausell *et al.*, 1992a; see also Jones, 1998). Further evidence for this comes from experiments in which cervical dorsal roots were sectioned chronically (3–20 years) and then immunostained for calcium-binding proteins after there was degeneration of parvalbumin-containing neurons in the dorsal column–medial lemniscus pathway. Figure 30.16A–C shows the area of the thalamus from which the dorsal column nuclear projection that represented the upper extremity was lost (Rausell *et al.*, 1992b; Jones and Pons, 1998). This area no longer stained for cytochrome oxidase (Fig. 30.16A), and staining for $GABA_A$ receptors (Fig. 30.16B) and for parvalbumin was markedly reduced (Fig. 30.16C) compared with that seen in normal animals. However, staining for calbindin was increased (Fig. 30.16D) compared to the normal brain (Fig. 30.16E). The animals appeared to have chronic central pain, which may have been related to a loss of GABAergic inhibition within the thalamus (cf. Ralston and Ralston, 1994) and an intact and even strengthened calbindin-staining nociceptive pathway.

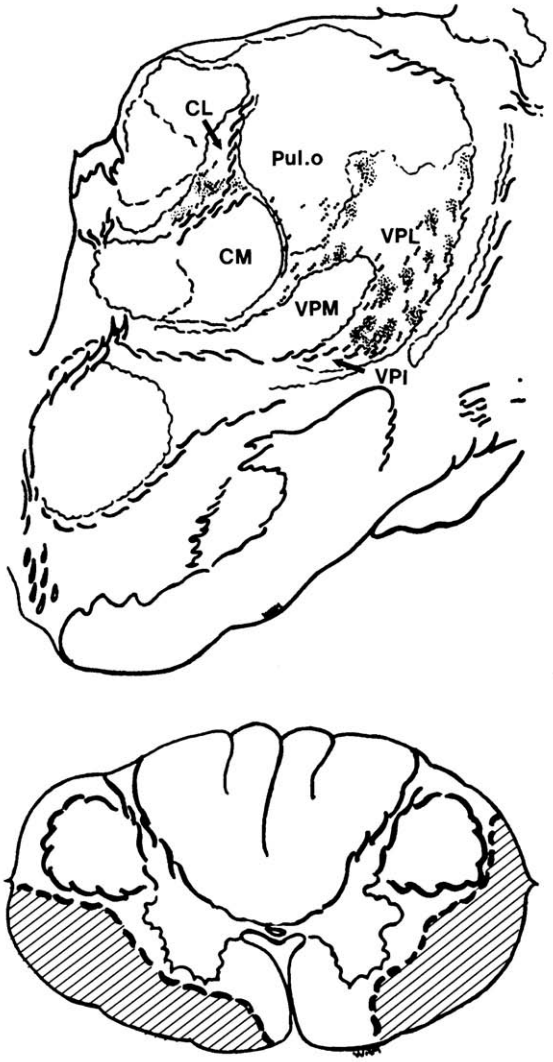

FIGURE 30.15 Terminations of the human spinothalamic tract in the thalamus. Anterograde degeneration of the spinothalamic tract was traced into the thalamus after a survival period of 12 days following a bilateral anterolateral cordotomy at a cervical level for the treatment of intractable pain. Results are shown for only one side, but the fiber degeneration was symmetrical. Terminals *(fine stipple)*, as well as fibers of passage *(large dots)*, are shown in several nuclei of the thalamus, including the ventral posterior lateral (VPL) and central lateral (CL) nuclei. The section of the spinal cord shows the extent of the anterolateral cordotomies. (From Mehler, 1962.)

Besides the VPL and CL nuclei, sites of termination of the STT include the densocellular and multiformis regions of the medial dorsal nucleus. However, Mehler regarded many of the cells in this part of the MD nucleus as belonging to the CL nucleus, although others have considered the cells in the densocellular

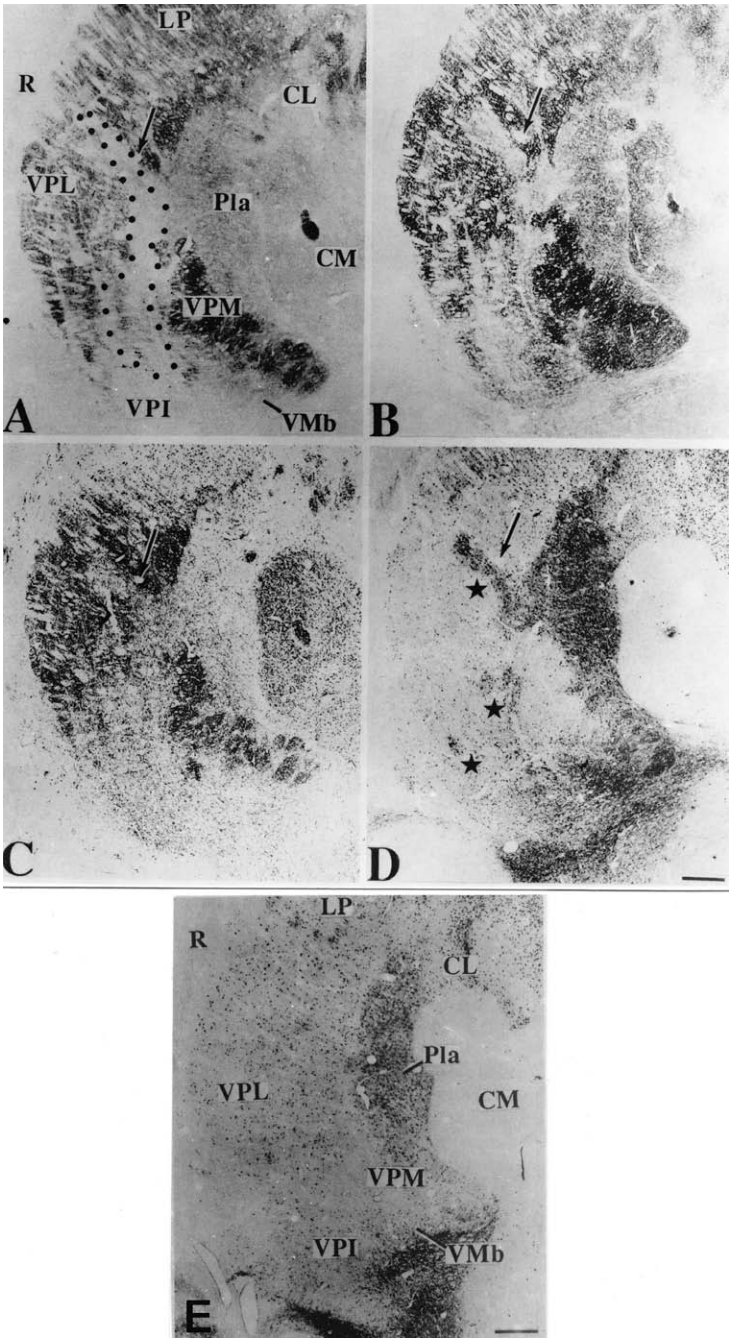

FIGURE 30.16 Loss of parvalbumin staining and increase in calbindin staining in a monkey after chronic multiple dorsal rhizotomies at a cervical level. In **A** is shown a frontal section stained for cytochrome oxidase. The section was taken through the posterior thalamus of a monkey. The monkey had had multiple cervical dorsal rhizotomies several years previously. Note the unstained area that corresponds to the expected region of termination of the part of the dorsal column–medial lemniscus pathway that represents the forelimb *(dotted zone in the VPL nucleus).* **B** and **C** show that there was decreased staining for $GABA_A$ receptors and for parvalbumin in the same area. However, **D** shows that staining for calbindin in this area was increased, as compared to the section in **E** from a normal animal. The arrows in **A–D** point to the same blood vessel. The asterisks in **D** indicate patches of enhanced calbindin staining in the affected area of the thalamus. The scale is 1 mm. Abbreviations for thalamic nuclei: CL, central lateral; CM, central median; LP, lateral posterior; Pla, anterior pulvinar; R, reticular; VMb, basal part of ventral medial; VPI, ventral posterior inferior; VPL, ventral posterior lateral; VPM, ventral posterior medial. (From Rausell *et al.*, 1992b.)

and multiformis subnuclei to be part of the MD nucleus proper (Apkarian and Hodge, 1989b). A number of morphological investigations on monkeys have demonstrated the projections to the posterior part of the VPL nucleus, CL, and the medial part of the posterior complex and have also included several other targets of the spinothalamic tract, such as the centralis medialis, the VPI nucleus, and what is now regarded as the anterior part of the VPL nucleus (Clark, 1936; Chang and Ruch, 1947; Bowsher, 1961; Boivie, 1979; Berkley, 1980; Mantyh, 1983; Apkarian and Hodge, 1989b; Gingold *et al.*, 1991; Stevens *et al.*, 1993). There may also be some spinothalamic terminations in the anterior pulvinar nucleus (Apkarian and Hodge, 1989b). Ralston and Ralston (1992) did not find a significant spinothalamic projection to the VPI nucleus, and they regard the main projections to the Po/SG region to originate from lamina I and those to the VPL and CL nucleus to come largely from the deep dorsal horn. However, the evidence shown in Fig. 30.8 indicates that both lamina I and lamina V spinothalamic cells project to the VPL nucleus (Willis *et al.*, 2000). For further discussion of the thalamic targets of the spinothalamic tract, see Chapter 20.

The VPL and VPM nuclei in monkeys contain nociceptive neurons that have properties suited for transmitting information to the SI and SII somatosensory cortex for sensory discrimination of pain signals (Perl and Whitlock, 1961; Gaze and Gordon, 1967; Pollin and Albe-Fessard, 1979; Kenshalo *et al.*, 1980; Casey and Morrow, 1983, 1987; Bushnell *et al.*, 1984, 1993; Chung *et al.*, 1986a; Bushnell and Duncan, 1987; Chandler *et al.*, 1992; Morrow and Casey, 1992; Duncan *et al.*, 1993; Apkarian and Shi, 1994; Brüggemann *et al.*, 1994; Al-Chaer *et al.*, 1998; see also review by Willis, 1997). For example, many of these nociceptive neurons have small contralateral receptive fields, they are somatotopically organized, they encode stimulus intensity, and they project to the SI cortex (as shown by antidromic activation experiments). Furthermore, a subpopulation of WDR neurons in the VPM nucleus can discriminate small changes in the intensity of noxious heat stimuli just as well as can an awake, behaving monkey (other WDR and HT neurons are not this responsive). The characteristics of these neurons in the VPL and VPM nuclei can be accounted for by input from spinothalamic and trigeminothalamic tract cells (cf. section on the *spinothalamic tract*; see also Price *et al.*, 1976; Hoffman *et al.*, 1981; Bushnell *et al.*, 1984; Dubner *et al.*, 1989; Kenshalo *et al.*, 1989; Maixner *et al.*, 1989). WDR neurons have also been recorded in the human thalamic principal somatic sensory nucleus (Lee *et al.*, 1999); however, in the absence of postmortem evidence, it is uncertain exactly in which nucleus the recordings were made (see discussion in Jones, 1998).

Nociceptive neurons have also been found in the VPI nucleus (Pollin and Albe-Fessard, 1979; Morrow and Casey, 1992; Apkarian and Shi, 1994). The receptive fields have a somatotopic organization, but they are larger than those of nociceptive neurons in the VPL nucleus, and the receptive fields of neurons in the ventral part of VPI may be complex or discontinuous. Many neurons in the VPI nucleus project to the SII cortex (Stevens *et al.*, 1993).

Neurons in the CL and other intralaminar nuclei in anesthetized animals are characterized by large, often bilateral receptive fields (Bushnell and Duncan, 1989). These neurons encode stimulus intensity. However, intensity coding is presumably important not only in sensory discrimination but also in affective responses, attentional mechanisms, and motor control (Coghill *et al.*, 1999). The responses of neurons in the CL nucleus can be accounted for by inputs from spinothalamic cells that project to the medial but not to the lateral thalamus (Giesler *et al.*, 1981; Ammons *et al.*, 1985). Some neurons of the CL nucleus project broadly to the cerebral cortex, including the SI cortex (Jones and Leavitt, 1974) and the SII cortex (Stevens *et al.*, 1993).

Craig *et al.* (1994) and Blomqvist *et al.* (2000) have proposed that there is a spinothalamic projection from lamina I to a region that is probably a part of the posterior complex, called by them the posterior part of the ventromedial thalamic nucleus (VMpo). They identified this area in both monkeys and humans. Craig *et al.* (1994) recorded thermoreceptive and nociceptive responses from neurons in this area. The significance of this nucleus is unclear (see Willis *et al.*, 2002). It was proposed that it may project to the insula. Burton and Jones (1976) used an anterograde tracing method to determine the cortical projection of neurons in the posterior thalamic region. They found that the medial part of the posterior complex projected to the retroinsular cortex, which is just posterior to SII.

Cerebral Cortex

As already discussed, imaging techniques have shown that the SI, SII, anterior cingulate, and insular cortex are generally activated following acutely painful stimulation of human volunteer subjects (Fig. 30.14, upper panels). The fact that multiple cortical areas are involved in the cerebral cortical response to pain explains why pain is not always reduced after brain injury (Head and Holmes, 1911; Holmes, 1927; Coghill *et al.*, 1994). However, it should be noted that there have been a number of reports of pain reduction

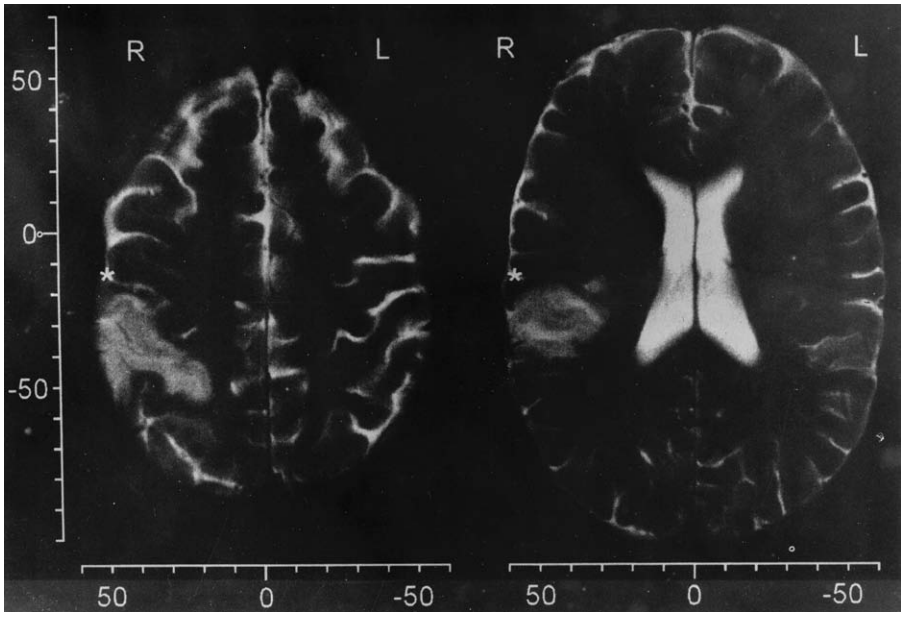

FIGURE 30.17 Images of the somatosensory cortex in a patient who had lost pain sensation in the hand without loss of the motivational–affective component of pain following a stroke that destroyed the hand area in the SI and SII somatosensory cortex. The functional magnetic resonance images were taken in transaxial planes 42 and 18 mm dorsal to the anteroposterior commissural line. The scales are in millimeters. The asterisks indicate the central sulcus. (From Ploner *et al.,* 1999a.)

following cortical damage (Russell, 1945; Marshall, 1951), and lesions of the somatosensory cerebral cortex in monkeys have been shown to reduce nociceptive behavioral responses (Peele, 1944; Brinkman *et al.*, 1985; Kenshalo *et al.,* 1989; see also reviews by Kenshalo and Willis, 1991; Treede *et al.,* 1999).

Clinical Application

Recently, a case was reported by Ploner *et al.* (1999a) of a patient who had a stroke that destroyed the hand area of the SI and SII cortices on one side of the brain (Fig. 30.17). The patient had a marked loss of sensory modalities that can be attributed to activity in the posterior column system (e.g., graphesthesia and stereognosis; see Nathan *et al.,* 1986). In addition, thermal sense was abolished, and the threshold for recognition of noxious thermal pulses applied by a laser was elevated. Suprathreshold heat stimulation was not recognized as painful and the source was poorly localized. For instance, noxious heat stimulation of the left hand of the patient produced an unpleasant feeling somewhere between the fingertips and shoulder. These findings were consistent with the interpretation that the SI and SII cortices are crucial for sensory discrimination of pain, but that other cortical areas (such as the anterior cingulate gyrus) mediate the aversive component of pain.

Imaging experiments support this interpretation. For example, hypnotic suggestion has been used to alter the perceived intensity of heat pain (Bushnell *et al.,* 1999). If attention is diverted from a painful stimulus, the degree of activation of the SI cortex is reduced. By contrast, if hypnosis is used to alter the unpleasantness of pain, activation of the anterior cingulate gyrus, but not the SI cortex, is altered (Rainville *et al.,* 1997). The particular region of SI cortex that is most closely associated with painful stimulation appears to be area 1. For example, painful stimuli produce more intense activation of area 1 than other areas of SI (Gelnar *et al.,* 1999).

The involvement of SI in acute responses to painful stimuli has been confirmed in human studies using magnetoencephalography (Arendt-Nielsen *et al.,* 1999; Ploner *et al.,* 1999b; Kanda *et al.,* 2000). This approach also confirmed the importance of area 1 in such responses (Ploner *et al.,* 2000).

Electrophysiological experiments have been done on monkeys to determine if nociceptive neurons can be found in the SI cortex (Kenshalo and Isensee, 1983; Kenshalo *et al.,* 1988; Chudler *et al.,* 1990; Kenshalo *et al.,* 2000). Both WDR and HT neurons have been identified in area 1 (Fig. 30.18). These cells are located in cortical layers III and IV among neurons that respond preferentially to tactile stimuli (Kenshalo *et al.,* 2000).

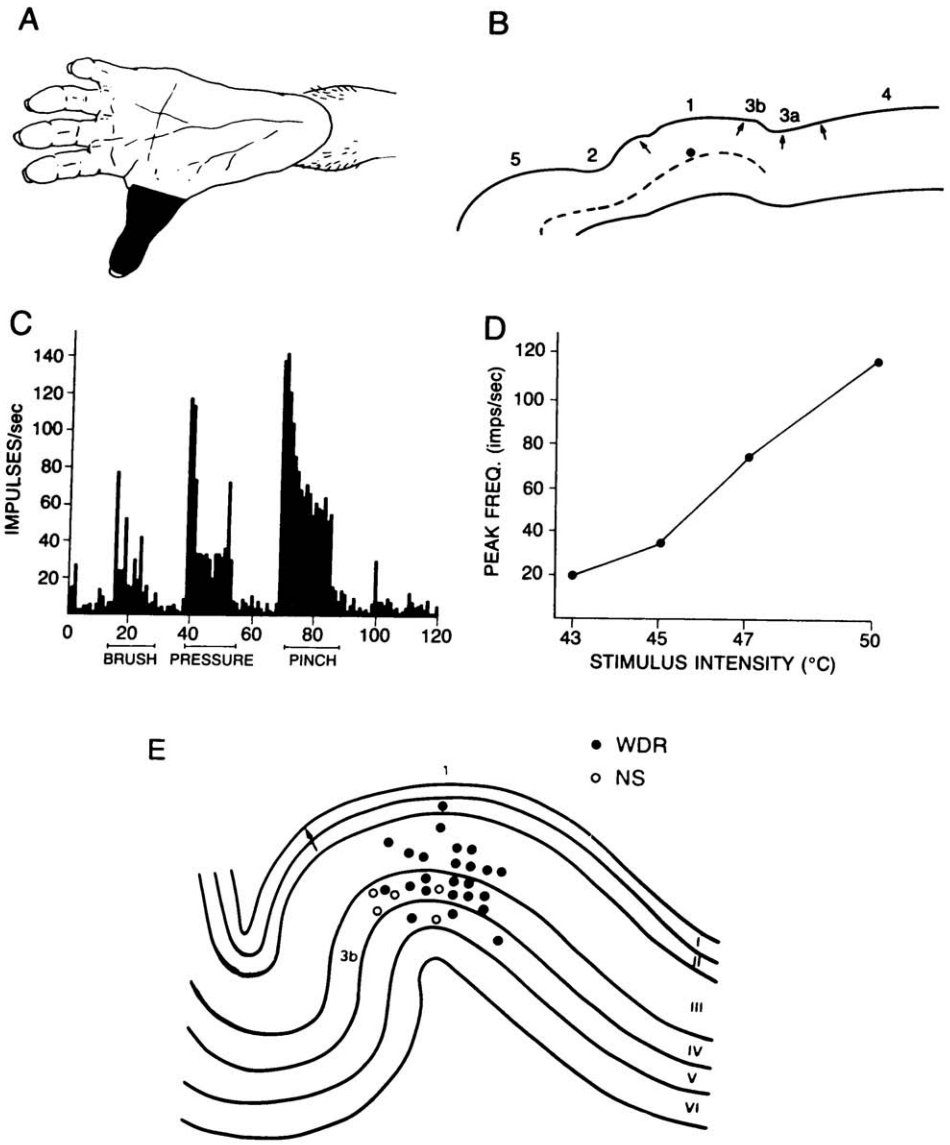

FIGURE 30.18 Nociceptive neurons in area 1 of the monkey SI somatosensory cortex. In **A** is the cutaneous receptive field of a wide dynamic range cortical neuron. Its location in area 1 is indicated in **B.** Responses to graded mechanical stimulation of the receptive field are seen in **C.** The curve in **D** shows the responses of the neuron to graded noxious heat stimuli. In **E** are plotted the locations of a population of wide dynamic range (WDR) and nociceptive-specific (NS) neurons in area 1. (From Kenshalo *et al.,* 2000.

The receptive fields are small and located contralaterally. The neurons respond in a graded manner to graded noxious heat stimuli, and they are also activated by intradermal injection of capsaicin. They do not respond to innocuous cooling or stimulation of deep tissue. Neurons in the SI cortex of monkeys have also been found that respond to visceral stimuli (Brüggemann *et al.,* 1997). Nociceptive cortical neurons in the face representation encode the intensity of noxious heat pulses applied to the face in awake, behaving monkeys (Kenshalo *et al.,* 1988; Chudler *et al.,* 1990). The responses of nociceptive neurons in the SI cortex can be accounted for by the response properties of nociceptive neurons in the VPL and VPM nuclei.

It is known that the VPL nucleus projects to all four areas of the SI cortex (including area 1) (e.g., Jones *et al.,* 1979; Friedman and Jones, 1981). However, the details of how areas of the VPL nucleus that are rich in particular calcium-binding proteins in the thalamus relate to the distribution of the terminals of nociceptive thalamic neurons in the SI cortex are still unclear. For example, neurons in the matrix area, which stain for calbindin and receive input from the STT, project preferentially to the superficial layers of the SI cortex

(see Jones, 1998); yet, as mentioned, the nociceptive neurons in area 1 of the SI cortex are located in layers 3 and 4 (Kenshalo *et al.*, 2000). Perhaps the calbindin-containing terminals end preferentially on the apical dendrites of the nociceptive neurons.

Nociceptive neurons have also been described in the anterior cingulate gyrus in rabbits (Vogt *et al.*, 1993). The receptive fields of these are large and unsuited to a role in stimulus localization. The responses resemble those of neurons in the intralaminar nuclei. In some cases, Vogt *et al*. (1993) were able to eliminate the nociceptive responses of anterior cingulate neurons by injecting lidocaine into the parafascicular nucleus.

SUMMARY AND CONCLUSIONS

Pain depends on sensory processing by the pain system. This includes (1) primary afferent nociceptors, which transduce noxious stimuli; (2) ascending nociceptive pathways, which transmit nociceptive information from the spinal cord (or brain stem) to higher centers; (3) descending modulatory pathways, which regulate pain signals; (4) forebrain structures, which process nociceptive information, leading to a variety of pain responses.

Nociceptors have small myelinated or unmyelinated axons and are found in most organs. They signal damage or potential damage. Nociceptors can respond to one or more types of noxious stimuli, and their activation may evoke a particular quality of pain, depending on the tissue innervated and the type of nociceptor. Many nociceptors are normally insensitive to mechanical stimuli but they may be sensitized by damage or inflammation, after which they may respond to very weak mechanical stimuli that now become painful. Primary afferent nociceptors in peripheral nerves originate from small DRG cells, which can be recognized by chemical markers, such as peptide content, VR-1 receptors, or IB4 binding sites. Many nociceptors release glutamate, as well as peptides, as neurotransmitters.

The central processes of nociceptive DRG cells enter the spinal cord through dorsal roots. The axons of cutaneous nociceptors travel only a short distance in Lissauer's tract; by contrast, those of visceral nociceptors may travel rostrocaudally as far as five segments. In primates, large bundles of unmyelinated afferents can be found within Lissauer's tract. Nociceptors often end in laminae I, II, V, and X, although particular types of nociceptors may have more restricted zones of termination. The synapses formed by nociceptors in the superficial dorsal horn are often glomerular endings. Some glomeruli probably belong to nociceptors with IB4 binding sites, whereas others are peptidergic. Nociceptor endings may receive synaptic contacts from GABAergic inhibitory interneurons; these connections are presumably responsible for presynaptic inhibition, such as that envisioned in the gate theory of pain. There are also inhibitory circuits (the so-called diffuse noxious inhibitory controls, DNICs) that depend on ascending input to the brain stem and a descending inhibitory pathway. The DNIC system seems to be more powerful than the gate mechanism.

There are a number of ascending pathways that transmit nociceptive information to the brain. These include the spinothalamic tract (STT), which has traditionally been regarded as the most important pain-signaling pathway. The cells of origin of this pathway are concentrated in laminae I and V of the dorsal horn, where many primary afferent nociceptors end. STT cells generally respond best to noxious stimuli. The axons of most STT cells cross at the segmental level and ascend to the thalamus in the anterolateral white matter. The axons of lamina I STT cells tend to be dorsal to those of lamina V STT cells until they reach the upper cervical spinal cord, where a ventral shift results in intermingling of axons of STT cells of both laminae. The STT has a somatotopic organization, which accounts for the distribution of the analgesia that results from anterolateral cordotomies for relief of pain in patients.

Recently, a visceral pain pathway has been described in the dorsal column. This is formed by the axons of postsynaptic dorsal column neurons, many of which are located in the vicinity of the central canal. The pathway is somatotopic, with the axons of neurons in the sacral cord ascending near the midline and those from the midthoracic cord near the dorsal intermediate septum. Higher levels of this pathway involve the dorsal column nuclei and the VPL thalamic nucleus. These observations in animal experiments help explain why midline myelotomies and commissural myelotomies in patients can relieve pelvic visceral pain even when performed at rostral levels of the spinal cord.

Other ascending nociceptive pathways include the spinocervical, spinoreticular, and spinomesecephalic pathways, as well as pathways that project to limbic structures, such as the spinoparabrachial, spinohypothalamic, and direct spinolimbic pathways.

The processing of pain signals is strongly affected by complex brain circuits that may either inhibit or facilitate nociception. Important modulatory pathways that originate in the brain stem and descend to the spinal cord include serotonergic neurons of the

medullary raphe and catecholaminergic neurons of the dorsolateral pons. Stimulation in the periventricular and periaqueductal gray or the ventrobasal thalamus in humans can be useful in producing pain relief in patients.

Imaging studies in humans have demonstrated that a number of cerebral cortical areas are activated by painful stimuli, including the SI and SII somatosensory areas, the anterior cingulate gyrus, and the insula. These different areas presumably contribute to different aspects of the reactions to painful stimuli. Evidence indicates that the SI and SII cortices are involved in sensory discrimination of pain. The anterior cingulate gyrus is likely to contribute to affective responses, and the insula may be involved in pain memories. Several motor system structures can also be activated; these may help with motor reactions to painful stimuli.

Activation of the cerebral cortex by painful stimuli engages the thalamus. The ventral posterior lateral and medial nuclei provide the main input to SI and SII. The ventral posterior inferior nucleus also projects to SII. These parts of the ventral posterior thalamus are presumably the main sources of input used for the sensory discrimination of pain by SI and SII. CL projects widely to the sensory motor cortex and may participate in arousal and attention. The large receptive fields of these neurons are not appropriate for spatial discrimination. It is unclear what the main sources of nociceptive inputs to the anterior cingulate gyrus and insula are.

Nociceptive neurons have been described in the SI cortex, in particular in area 1. This observation is consistent with the findings of imaging studies and also of magnetoencephalography in human subjects. Nociceptive neurons have also been found in the anterior cingulate cortex.

CHAPTER

31

Gustatory System

THOMAS C. PRITCHARD and RALPH NORGREN
Department of Neural and Behavioral Sciences
The Pennsylvania State University College of Medicine
Hershey, Pennsylvania, USA

The first edition of this chapter (Norgren, 1990) began with the following sentence: In humans, information about the central gustatory system is sparse at best, spread out, methodologically flawed, and inconsistent. A decade later, this statement remains substantially true despite the advent of new imaging techniques. Overall, the additional knowledge obtained from the modern imaging techniques has been vitiated by problems similar to those in the earlier literature. Thus, any discussion of the human central gustatory system must rely heavily on data from other primates, especially Old World monkeys (Pritchard, 1991). Even monkey experiments must be interpreted cautiously, however, because they remain relatively few in number and include very few species. Caution also is warranted because the central organization of intraoral sensory systems displays considerable variability across species (Bombardieri *et al.*, 1975; Jones *et al.*, 1986; Karamanlidis and Voogd, 1970).

The following description of the human gustatory system represents our best attempt to integrate the clinical and experimental literature. When the clinical reports contradict the experimental literature, we have weighed the likelihood of a species difference versus the possibility that the disagreement reflects differences in the quality of the data. In some instances, we gave more weight to the more rigorous studies; in other cases, the differences could not be reconciled. We deal primarily with the central organization of the gustatory system and emphasize its cortical organization, where most of the research over the last decade has been done. More detail about the peripheral anatomy of taste is available in the earlier version of this chapter (Norgren, 1990) and in Pritchard (1991). Functional issues such as transduction (Herness and Gilbertson, 1999), coding (Scott and Giza, 2000), and behavior (Kaplan *et al.*, 1995) are covered in recent review articles.

GUSTATORY APPARATUS AND PERIPHERAL INNERVATION

Oral Distribution of Taste Buds

Unlike its central ramifications, the human peripheral gustatory apparatus is both well described and similar to the general mammalian scheme. On the anterior tongue, taste buds occur in fungiform papillae. When present, there are from 1 to 36 taste buds per papilla, but perhaps as many as half the fungiform papillae have none (Arvidson and Freiberg, 1980). The density of taste buds on the anterior tongues

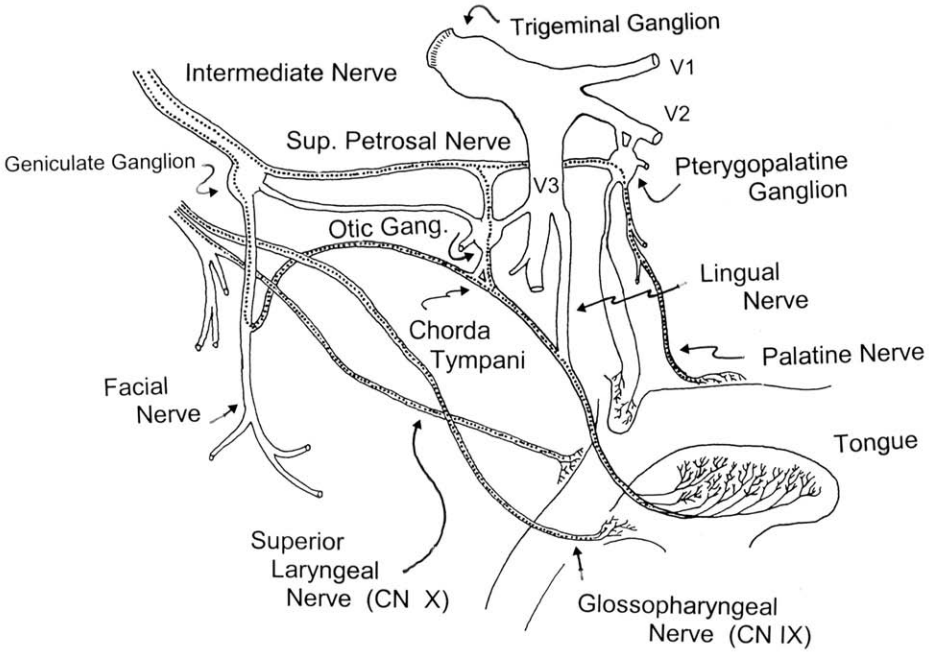

FIGURE 31.1 Diagram of taste pathways (dotted lines) from the anterior and posterior tongue, soft palate, pharynx, epiglottis, and upper esophagus. (Diagram adapted with permission from Oxford University Press.)

of adult cadavers varies by two orders of magnitude, and the differences are not attributable to age or race (see Miller, 1986, 1987). These differences in the number of taste buds per papilla are more than an anatomical curiosity. The number of fungiform papilla correlates positively with taste intensity, the inherited ability to taste bitterness, and the intensity of the "burn" produced by capsaicin, the active ingredient in chili peppers (Prutkin *et al.*, 2000).

As in other mammals, most taste buds are located in the trenches of the foliate papillae along the lateral edge of the tongue and the circumvallate papilla on the posterior third of the human tongue. In one study involving the foliate papillae of 115 cadavers, Mochizuki (1939) counted an average of 1279 taste buds per tongue, but the range varied by a factor of 22. Taste buds also are found on the soft palate, pharynx, epiglottis, and larynx of humans, but their numbers and exact distribution are subject to debate (Lalonde and Eglitis, 1961; Miller, 1977; Miller and Spangler, 1982; Wilson, 1905). Given the recent evidence from the anterior tongue, this debate may reflect methodological differences, age, or normal variation among humans. These extralingual gustatory receptors are histologically identical to those on the tongue, but are clustered in pseudostratified columnar or stratified squamous epithelium rather than in distinct papillae. Although a role in taste perception has not been ruled out (Miyaoka *et al.*, 1998; Stedman *et al.*, 1980), the extralingual taste buds most likely protect the airway from fluid aspiration.

Peripheral Innervation

By the end of the 19th century, the innervation of the lingual gustatory receptors was established to the satisfaction of most observers (Fig. 31.1). The chorda tympani branch of the facial nerve supplies both the taste buds in the fungiform papillae and a variable percentage of those in the foliates. The remaining buds in the foliates and all those in the circumvallate papillae receive axons via the lingual branch of the glossopharyngeal nerve. Although others came close earlier, Lussana (1869, 1872) first proposed this general arrangement based upon both clinical observations and experimental intervention in animals. The only other candidate proposed for conveying gustatory afferent activity was the trigeminal system. This assertion rested primarily upon clinical observations of ipsilateral loss of gustatory sensibility after intracranial section of the trigeminal roots, usually for relief of tic douloureux. Eventually, Lewis and Dandy (1930) demonstrated that, unless there was evidence of facial nerve damage, trigeminal root section alone did not interfere with taste. Based on their own surgical cases, Schwartz and Weddell (1938) suggested that, in a few

individuals, gustatory afferent axons innervating the anterior tongue passed through the greater superficial petrosal (GSP) branch of the facial nerve and the otic ganglion before rejoining the chorda tympani nerve.

Because of the lack of either human clinical or monkey experimental evidence, the innervation of the taste buds on the palate must be generalized from other species and cadaveric material. In rats, about 85% of the taste buds on the palate are innervated by the greater superficial petrosal nerve (Miller and Spangler, 1982). Based upon the pattern of nasopharyngeal innervation in human embryos described by Kanagasuntheram *et al.* (1969), Miller and Spangler (1982) suggested that the remaining buds are innervated by glossopharyngeal fibers traveling with the sympathetic plexus associated with the internal carotid artery. Another possibility for this residual palatal innervation is a tympanic branch of nerve IX that is diverted through the otic ganglion (Hamilton and Norgren, 1984). In humans, there are connections between the auricular branch of the vagus nerve (X), the tympanic branch of IX, and each of the petrosal nerves that could serve the gustatory receptors on the palate (Vidic and Young, 1969).

Based upon the electrophysiological literature and the similarity in laryngeal innervation between humans and other mammals, laryngeal gustatory sensation is carried by the superior laryngeal branch (SLN) of the vagus nerve (see Norgren, 1984, p. 1088, for a short review and Stedman *et al.*, 1980). The innervation of taste buds on adjoining surfaces, such as the epiglottis, uvula, and pharynx, might vary more among species. In addition to the anterior branches of the SLN, in human's gustatory afferent axons to these surfaces, particularly the pharynx, may travel in the tonsilar branch of IX.

The distribution of gustatory function among three cranial nerves confers at least two unusual properties upon the sense of taste. First, taste is difficult to eliminate. Very few individuals are ageusic, particularly permanently. In animals, experimental ageusia has yet to be reported. Second, taste is difficult to separate from intraoral somatosensory activity. In most nerves that contain gustatory afferent axons, the majority of sensory fibers respond to tactile or thermal stimuli. The chorda tympani nerve is the closest to a pure gustatory nerve, but even its taste fibers respond to thermal and perhaps tactile stimuli. In addition, central to the geniculate ganglion, chorda tympani axons join the intermediate nerve of Wrisberg, which has mixed chemical and somatosensory functions. These two properties of the peripheral gustatory apparatus—its resiliency and interdigitation with the somatosensory system—combine to make taste deficits resulting from central damage particularly difficult to evaluate.

THE CENTRAL NERVOUS SYSTEM

Medulla

Although the identities of the first-order gustatory nerves remained unsettled well into the 20th century, what was known in the late 1800s was sufficient to implicate the nucleus of the solitary tract (Sol) in taste function. Subsequent electrophysiological and anatomical studies conducted in a variety of species including the rat (Makous *et al.*, 1963), hamster (Travers and Smith, 1979), and monkey (Scott *et al.*, 1986a) have confirmed that early speculation. The organization of the Sol described later for the Old World monkey is similar to the other mammalian species and, by extension, is presumed to be the best approximation for humans.

Afferent Projections

The rostrocaudal organization of taste within the Sol of the monkey recapitulates the pattern of taste bud innervation within the oral cavity (Beckstead and Norgren, 1979). Axons of the intermediate nerve of Wrisberg (VII) that innervate taste buds on the anterior tongue and soft palate enter the lateral surface of the medulla, perforate the spinal tract of V, and terminate within the lateral aspect of the rostral Sol (Fig. 31.2A). Unlike the rat, in the monkey a small contingent of axons turns rostrally and ends in a narrow prefacial extension of the Sol (Beckstead and Norgren, 1979; Rhoton, 1968). The glossopharyngeal nerve enters the medulla caudally to VII and terminates within both lateral and medial divisions of the rostral Sol (Beckstead and Norgren, 1979; Satoda *et al.*, 1996; Fig. 31.2B). Although there is substantial overlap of the terminals of VII and IX in the lateral division of the Sol, the bulk of terminals from IX lie caudally to those of VII. Because IX contains both gustatory and somatosensory information, anatomical studies cannot rule out the possibility that the gustatory zone of Sol extends into the caudal half of the nucleus; if it did however, it would be a departure from the pattern seen in rodents (Travers and Norgren, 1995). Axons of the vagus nerve enter the medulla immediately caudal to the fibers of IX and terminate throughout the entire Sol. As Figure 31.2 shows, the terminal distributions of VII, IX, and X overlap considerably within the Sol, but in no place more than in the lateral division of the nucleus between the entry points for nerves VII and IX. After their entry into the Sol descending axons of

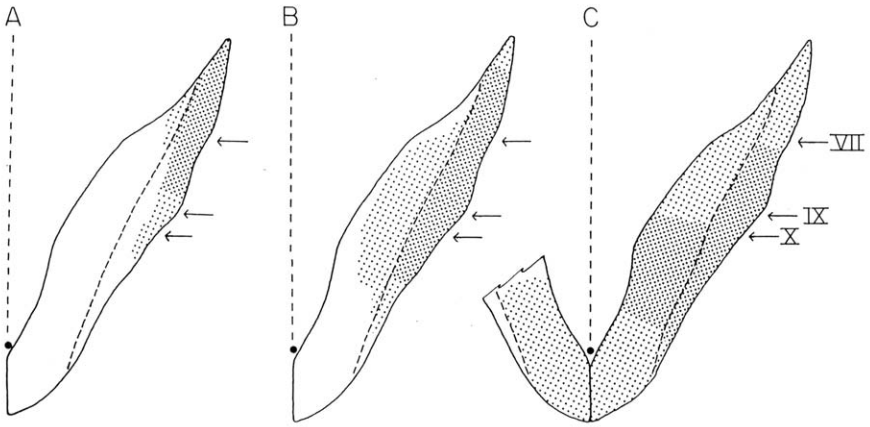

FIGURE 31.2 Terminal distributions of cranial nerves VII **(A),** IX **(B),** and X **(C)** within the Sol of the Old World monkey. Each panel shows an outline of the Sol as it appears in the horizontal plane. The vertical dotted line represents the midline, the obex is marked by a filled circle, and the level of entry of nerves VII, IX, and X into the nucleus is indicated by arrows. The medial and lateral subdivisions of the nucleus are separated from one another by a dotted line through the nucleus. Each panel is oriented with anterior to the top of the page and lateral to the right. The stippling represents the density of autoradiographic label within the Sol after injections of the respective ganglia for cranial nerves VII, IX, and X. Although there is some somatotopy within the Sol, the terminal areas of all three nerves show considerable overlap, especially within the rostral third of the nucleus. Of these three nerves, only the vagus projects to the contralateral side of the brain. (Diagram constructed with data originally summarized in Beckstead and Norgren (1979). Used with permission from Lippincott, Williams and Wilkins).

VII and IX follow an intranuclear path; vagal fibers, by comparison, descend within the solitary tract itself. In the human, it is possible that the solitary tract contains descending axons of nerves VII, IX, and X (Nageotte, 1906; Schwartz *et al.*, 1951).

In the monkey, the terminal distributions of nerves VII, IX, and X within the Sol suggest a division of the nucleus into rostral (gustatory) and caudal (visceral) segments. The Sol also has been divided into medial and lateral subdivisions in both humans (Olszewski and Baxter, 1954) and nonhuman primates (Beckstead and Norgren, 1979). In monkeys, the lateral subdivision is the terminal area of nerves VII and IX, while the vagus nerve projects mostly to the medial subdivision in the caudal half of the nucleus and the lateral subdivision in the rostral half (Beckstead and Norgren, 1979). The lateral and medial subdivisions in the monkey Sol appear to correspond, respectively, to the ventral and dorsal sensory nuclei of the vagus in human (Olszewski and Baxter, 1954). Cyto- and chemoarchitectural studies have shown that the Sol of the rat (Kalia and Sullivan, 1982), hamster (Whitehead, 1988), and cat (Loewy and Burton, 1978) can be divided into six to ten discrete subnuclei, which are relatively well-preserved across species. The human Sol has been divided into ten subnuclei, of which at least one, the interstitial nucleus, contains gustatory neurons (Tork *et al.*, 1990; Hyde and Miselis, 1992; McRitchie and Tork, 1993; see also Chapter 10).

In addition to the terminations in the Sol, cranial nerves VII, IX, and X contain axons that terminate elsewhere, primarily in the marginal subdivision of the caudal spinal trigeminal nucleus and in the dorsal horn as far caudally as the third cervical segment. Clinical evidence, with some experimental support (Nomura and Mizuno, 1984), has associated some of these projections with somatosensory innervation of the ear. Other clinical observations, together with anatomical and electrophysiological evidence from animals, suggest that these extrasolitary projections subserve somatosensory functions of the oral cavity (see Norgren, 1981 for discussion and references). Anatomic evidence indicates that the marginal zone of the caudal spinal trigeminal nucleus projects to the Sol, as well as to pontine and thalamic gustatory relays (Burton *et al.*, 1979; Fulwiler and Saper, 1984; Menetrey and Basbaum, 1987). Apparently these sensory areas have yet to be tested for gustatory responsiveness, but their anatomy suggests that, even if these neurons do not respond to pure gustatory stimuli, they might influence neurons that do.

Clinical Studies

Although the homology of the Sol between nonhuman primates and other animals is strong, few reports link the human Sol to either the animal literature or gustatory function. Lateral medullary strokes (Wallenberg syndrome) typically impair taste

perception, but have little localizing value. More precise localization has been obtained from anatomical studies that have traced terminal degeneration into the Sol after peripheral taste nerve damage. Of the human cases, by far the most informative was reported by Nageotte (1906). About a month prior to his death from stomach cancer, Nageotte's patient developed a right facial paralysis. Postmortem examination revealed that the paralysis resulted from "a metastatic nucleus as large as a grain of hempseed, situated in the aqueduct of Fallopius (facial canal) immediately *below* the geniculate ganglion" (Nageotte, 1906, p. 474, italics in original, parentheses added). Thorough postmortem histological analysis showed that the facial trunk and the axons of the chorda tympani nerve distal to the tumor were completely degenerated. Proximally, the geniculate ganglion, the extrapontine segment of the facial nerve, and the intermediate nerve all appeared intact. Within the brain, however, the radiations of the facial motor nerve were degenerated, as well as "all the fascicles of the intermediary nerve of Wrisberg" (p. 476). Because the tumor was distal to the geniculate ganglion, the degeneration observed by Nageotte in the intermediate nerve was of the transganglionic Wallerian variety that occurs when transected distal axons fail to regenerate (Csillik and Knyihar-Csillik, 1987; Whitehead *et al.*, 1995). The normal appearance of the intermediate nerve was caused by the intact greater superficial petrosal nerve, which was not damaged by the lesion.

According to Nageotte, degenerating fascicles entered the gustatory nucleus, a small, round nucleus "enclosed in a mantle of white matter" (1906, p. 477) and situated just dorsal to the spinal trigeminal nucleus. Nageotte traced degenerating axons both rostrally (1.5 mm) and caudally (4.5 mm) from their zone of entry to the Sol. Nageotte's description of the gustatory nucleus itself was based upon comparisons of the Marchi-stained sections with serial sections through three normal human brains. For present purposes, only a few additional points need to be summarized. First, the nucleus is continuous with what was then known as "the nucleus or *gelatinous substance of the solitary bundle*" (1906, p. 479, italics original). The nucleus of the gelatinous substance[1] corresponds to the nucleus ovalis of Olszewski and Baxter (1954) and the interstitial nucleus of the solitary tract in the present terminology (McRitchie and Tork, 1993). Paxinos *et al.* (1990) show serial sections of the intensely AChE-reactive interstitial nucleus of the solitary tract (see also McRitchie and Tork, 1993). Second, axons of the glossopharyngeal nerve reach the nucleus posterior to those of the intermediate nerve and both ascend and descend within the Sol. Finally, rostrally, just dorsal to the principal trigeminal nucleus, the nucleus expands to 0.8 mm in diameter, but contracts to only 0.1 mm in diameter at the level where axons of the intermediate nerve first approach it, only to expand again just rostral to the incoming fascicles of IX. Nageotte claimed that this enlargement of the Sol rostral to the entry of VII was observed previously by Wallenberg (1897a); it has since been described in the human (Pearson, 1947; McRitchie and Tork, 1993) and, by homology, in the Old World monkey (Beckstead and Norgren, 1979). Although the prefacial extension of the Sol does not exist in the rat (Rhoton, 1968; Kerr, 1962), its presence in the salamander (Herrick, 1914) suggests that it is not a recent evolutionary development.

Much of Nageotte's description can be confirmed from other examinations of the human Sol, but these studies lack the authority of Nageotte's case. They relied upon normal material, in which finely myelinated fiber tracts and preterminal ramifications are notoriously difficult to interpret, or when Marchi-stained material was available, the lesions involved several cranial nerves. Mellus (1902), using normal tissue, and Bruce (1898), using Marchi-stained material from a patient with complete destruction of the trigeminal and glossopharyngeal nerves, described nuclear areas associated with the human solitary tract that appear to be coextensive with the caudal half of Nageotte's gustatory nucleus. Unfortunately, both reports were not detailed enough to provide a confident verification of Nageotte's observations. Freeman (1927) provided a more detailed description of the entire Sol of a normal human fetal brain, including its rostral extension, but his interpretations relied too heavily upon previously published experimental material, including Nageotte's, to consider this report an independent confirmation. Olszewski and Baxter (1954) identified the prefacial extension of the Sol in normal material and renamed it nucleus ovalis. Schwartz *et al.* (1951) described the composition and course of the solitary tract based upon Marchi material from a patient who had the roots of cranial nerves V, VII, IX, X, and spinal nerves C1-C3 sectioned unilaterally to relieve intractable pain. Schwartz *et al.* (1951) confirmed Nageotte's description of the general organization of the Sol, but because of the number of degenerating nerves, they could not be specific about the contribution of each to the solitary tract or its nucleus.

The anatomical differences in the Sol between primate and nonprimate species should not overshadow

[1]Nageotte's use of the name gelatinous nucleus should not be confused with the modern term "nucleus gelatinosus," which describes a smaller nucleus located near the commissural Sol.

the significant similarities among these species. As discussed previously, the same three cranial nerves convey gustatory information to the Sol from the oral cavity. Within the Sol, electrophysiological data from nonhuman species, including the cat (Bernard and Nord, 1971), hamster (Travers, 1988), rat (Norgren, 1978), rabbit (Schwartzbaum and DiLorenzo, 1982), and monkey (Beckstead *et al.*, 1980; Scott *et al.*, 1986a) demonstrate that gustatory neurons are located within the rostral pole of the nucleus. In such a highly conserved system, the available clinical data suggest that the gustatory medullary relay in humans is located within the rostral pole of the Sol.

Gustatory/Trigeminal Overlap Within the Medulla

One possible difference between humans and other species in the organization of the Sol relates to potential contributions from primary trigeminal afferent axons. Both Astrom (1953) and Torvik (1956) recognized that trigeminal axons project to the lateral division of the Sol. In the rat, the rostral pole of the Sol actually abuts the spinal trigeminal nucleus, but trigeminal axons from the lingual nerve terminate more caudally within the terminal zone of the glossopharyngeal nerve (Hamilton and Norgren, 1984). In monkeys, axons from both the mandibular and ophthalmic divisions of the trigeminal nerve bypass the rostralmost aspect of the spinal trigeminal nucleus and terminate in the lateral Sol at glossopharyngeal levels. Based upon evidence from a case supplied by Wallenberg (1897b), Nageotte asserted that trigeminal axons terminate throughout the prefacial extension of the Sol, which places the human data at odds with the experimental evidence from other animals including primates. Nageotte's assertions, however, were not confirmed in other Marchi material from humans that involved trigeminal lesions (Schwartz *et al.*, 1951). Although this issue may seem esoteric, the organization of the remainder of the central gustatory system hinges upon it. The spatial proximity of trigeminal and chemosensory projections within the Sol raises the obvious possibility for gustatory/somatosensory integration, which has already been demonstrated in both single (Ogawa *et al.*, 1984; Travers and Norgren, 1995; Travers *et al.*, 1986) and multineuron (Halsell *et al.*, 1993) recording studies in the rat.

Pons

Afferent Projections

Chapter 10 provides detailed descriptions of the chemo- and cytoarchitecture of the pontine parabrachial (PB) nuclei. The afferent projections to the Sol in subprimate species were identified around the turn of the century, but its efferent projections were discovered only during the last 20 years. The early experiments used Marchi staining of degenerating myelinated axons to conclude that the efferent axons from the Sol of the guinea pig and rabbit ascended in the contralateral medial lemniscus and terminated in the ventrobasal thalamus (Allen, 1923; Gerebtzoff, 1939). In these studies, degeneration within the medial lemniscus and ventrobasal thalamus was probably caused by lesions of the Sol that encroached upon the dorsal column nuclei or internal arcuate fibers. Recent experiments using more sensitive and discrete neuroanatomical tract tracing techniques have shown that in both rat and cat, neurons in the rostral (gustatory) and caudal (visceral) regions of the Sol project to the PB (Loewy and Burton, 1978; Norgren and Leonard, 1973). Kinney (1978) employed the Fink-Heimer technique to trace degenerating axons in a single monkey from the rostral and intermediate Sol through the contralateral central tegmental tract to the rostral pole of the ventral posteromedial nucleus of the thalamus (VPMpc). Unfortunately, like the early degeneration studies in the guinea pig and rabbit (Allen, 1923; Gerebtzoff, 1939), the four large lesions (two dorsal pontine; two medullary) in Kinney's study almost certainly interrupted internal arcuate fibers crossing from the dorsal column nuclei to the contralateral medial lemniscus as well as crossing cerebellar and trigeminal pathways. Although the Fink-Heimer staining technique can identify both myelinated and unmyelinated degenerating axons, the survival time (14 days) in the Kinney study probably was too short to impregnate small caliber gustatory fibers.

Just as in the rabbit and guinea pig, the pathways identified by Kinney with the Fink-Heimer technique have not been confirmed with modern neuroanatomical tracing techniques. Beckstead *et al.* (1980), after making electrophysiologically-guided injections of tritiated amino acids at five different anterior–posterior levels of the Sol, concluded that projections from the rostral, primarily gustatory, part of the Sol ascend in the ipsilateral central tegmental tract, bypass the PB, and terminate within the caudal half of the parvicellular division of the ventroposteromedial nucleus (Fig. 31.3; Beckstead *et al.*, 1980). The PB of the monkey, by comparison, receives projections only from the caudal and commissural viscerosensory regions of the nucleus. These data were confirmed with injections of horseradish peroxidase into the thalamus that retrogradely labeled neurons within the rostrolateral Sol (Beckstead *et al.*, 1980; Pritchard *et al.*, 2000).

The anatomical data of Beckstead *et al.* (1980) are supported by other electrophysiological data that show gustatory information in the monkey ascends

FIGURE 31.3 Selected coronal sections through the brainstem and thalamus of a monkey, *Macaca fascicularis*, tracing the labeled axons and terminal fields that resulted from an injection of tritiated amino acid centered in the Sol, just rostral to the level at which axons of the intermediate nerve of Wrisberg reach the nucleus. Neurons at this location responded to sapid chemicals applied to the anterior tongue. Labeled fibers ascend ipsilaterally through the pontine (D) and midbrain tegmentum (C), and terminate in VPMpc (A and B). With an injection at this rostral level in the Sol, little label is evident in the pontine parabrachial nuclei (D). Injections more caudally in the Sol result in terminal label in both PB and VPMpc. Injections even further caudally in Sol, posterior to the level at which vagal axons reach the nucleus, result in terminal label in the PB, but not in the thalamus. Abbreviations: BC, brachium conjunctivum; BP, brachium pontis; cg, central gray; CL, nucleus centralis lateralis thalami; CM, central medial nucleus; CM-Pf, thalamic centromedian nucleus, thalamic parafascicular nucleus; FR, fasciculus retroflexus; H, H1, H2, fields H of Forel; HL, habenula lateralis; HM, habenula medialis; lc, locus coeruleus; LGN, lateral geniculate nucleus; MD, thalamic mediodorsal nucleus; MGN, medial geniculate nucleus; ML, medial lemniscus; MLF, medial longitudinal fasciculus; ntb, nucleus of the trapezoid body; OT, optic tract; Pf, parafascicular nucleus; pn, pontine nuclei; pp, peripeduncular nucleus; PP, pes pedunculi; rtp, nucleus reticularis tegmenti pontis; sc, superior colliculus; snc, substantia nigra, pars compacta; snr, substantia nigra, pars reticulata; so, superior olive; SPf, nucleus subparafascicularis thalami; stn, subthalamic nucleus; svn, superior vestibular nucleus; SVT, spinal trigeminal tract; TB, trapezoid body; VII, motor root of the facial nerve; VIm, abducens nucleus; Vp, principal sensory trigeminal nucleus; VPI, ventroposteroinferior nucleus; zi, zona incerta; III, oculomotor nerve. FIGURE 31.4 Dorsal view of the caudal brainstem and diencephalon of the Old World monkey showing the efferent projections of the Sol. The caudal part of the Sol that receives projections primarily from the vagus nerve projects to the PB. The efferent projections from neurons in the rostral primarily gustatory region of the Sol bypass the PB and project directly to VPMpc in the thalamus. (Used with permission from John Wiley & Sons, Inc.).

uncrossed from the tongue to the thalamus (see following discussion; Fig. 31.4). Assuming that the human nervous system resembles that of other primates more than it does other mammalian species, the best hypothesis is that most if not all axons of second-order gustatory neurons in the Sol ascend ipsilaterally within the central tegmental tract and terminate in the thalamic gustatory relay.

Efferent Projections

In the rat, the PB projects to the VPMpc as well as the ventral forebrain (central nucleus of the amygdala, bed nucleus of stria terminalis, lateral hypothalamus; Norgren and Leonard, 1973; Saper and Loewy, 1980). Although most of the projections to the ventral forebrain are presumed to be related to visceral sensation, some do convey gustatory information (Norgren, 1970, 1974, 1976; Azuma *et al.*, 1984; Schwartzbaum and Morse, 1978). The central pathways of the rodent gustatory system are described in more detail by Norgren (1995).

The efferent projections of the PB in monkey resemble those of the rat but are more consistent with those of a general visceral relay than a gustatory relay. Pritchard *et al.* (2000) used autoradiographic injections to demonstrate that the PB of the Old World monkey projects to the same ventral forebrain sites as in the rat, as well as restricted areas of the hypothalamus (dorsomedial, lateral, ventromedial) and the thalamus (VPMpc, VPM, central lateral, parafascicular/centromedian, reuniens). The projections of the PB to the extended amygdala and hypothalamus provide general visceral information entree to the entire limbic system. The projections to VPMpc are significant because they terminate in the rostral half of the nucleus that does not receive gustatory projections from the Sol (Beckstead *et al.*, 1980). Large injections of horseradish peroxidase into the caudal, gustatory half of VPMpc retrogradely labeled neurons within the rostral pole of the Sol, but not within the PB (Pritchard *et al.*, 2000). Thus, in monkeys, the PB does not appear to be an obligatory relay for ascending gustatory information as it is in rodents and lagomorphs (Norgren, 1984).

Gustatory Processing in the PB.

Numerous studies in rats (e.g., Hajnal *et al.*, 1998; Lundy and Norgren, 2001), rabbits (DiLorenzo and Schwartzbaum, 1982), and hamsters (Smith *et al.*, 1994), have recorded taste-responsive neurons within the PB. Although the PB has received much less scrutiny in the monkey than in these subprimate species, in more than a dozen preparations, we have never isolated a neuron in the monkey PB that responded to sapid stimulation of the anterior tongue (Pritchard *et al.*, 2000). In the same animals, electrically stimulating the glossopharyngeal and vagus nerves did elicit evoked potentials and drive some individual neurons and neuron clusters within the PB (Pritchard *et al.*, 2000). Could gustatory afferent activity from the anterior (facial) and posterior (glossopharyngeal) gustatory fields on the tongue ascend to the forebrain along separate brainstem pathways? Although possible, an Sol-PB-VPMpc route for taste responses of glossopharyngeal origin seems unlikely given that the PB projection to the thalamus terminates in the nongustatory part of VPMpc. Nevertheless, we cannot exclude the possibility that gustatory information passes through the PB on its way to the ventral forebrain. Taste-responsive neurons have been identified in the lateral hypothalamus (Aou *et al.*, 1984; Oomura *et al.*, 1991), in the substantia innominata (Nishijo *et al.*, 1986; Burton *et al.*, 1975), and throughout the amygdala (Karadi *et al.*, 1992; Scott *et al.*, 1993; Yan and Scott, 1996), but, as discussed below, the route by which taste information reaches these areas is uncertain.

Clinical Studies

Taste deficits may be among the presenting symptoms of pontine damage caused by hemorrhagic or embolic infarction (Goto *et al.*, 1983; Graham *et al.*, 1988; Nakajima *et al.*, 1983; Onoda and Ikeda, 1999) or multiple sclerosis (Combarros *et al.*, 2000; Uesaka *et al.*, 1998). These six reports describe eight patients whose pontine damage was accompanied by taste deficits. In each case, focal testing with sapid stimuli demonstrated either an ageusia or a hypogeusia on the side of the tongue ipsilateral to the pontine damage. The lesions varied considerably between patients, but in each case the damage within the pontine tegmentum included the central tegmental tract. In some but not all cases, the PB was damaged. Even a liberal reading of the published radiographs clearly shows that medial lemniscus was spared in most of the cases (e.g., Combarros *et al.*, 2000; Graham *et al.*, 1988; Uesaka *et al.*, 1998). Based upon the data from these eight patients, we believe that in humans, like the Old World monkey, the ascending gustatory projection from the Sol courses ipsilaterally though the pons. None of these studies provides a convincing demonstration for the PB being a taste relay.[2]

Thalamus

The only central taste relay that was known with certainty by 1940 was the Sol in the medulla. Gustatory cortex was assumed to reside near the olfactory areas in the temporal lobe, and a thalamic gustatory relay was presumed but not proven. After Le Gros Clark (1937) and Walker (1938) identified the thalamocortical projections of the somatosensory system in the monkey and Bornstein (1940a, b) published his influential reports on taste cortex in human, Blum *et al.* (1943) hypothesized that the thalamic gustatory relay would be located in VPMpc, which borders the medial aspect of the oral somatosensory nucleus, VPM. Blum *et al.* measured the rejection threshold for quinine hydrochloride in three rhesus monkeys before and after lesions were made in the vicinity of VPMpc. Two monkeys with incidental damage to VPMpc showed only a transient impairment in taste preference. A third monkey with severe damage to VPMpc showed a profound taste impairment that persisted for the duration of the experiment (57 days). Given the large size and poor placement of the lesions, these data were more suggestive than compelling, but at that time they were sufficient to establish VPMpc as the gustatory relay in the thalamus.

The thalamic gustatory nucleus, VPMpc, fills the wedge-shaped tip of the ventrobasal thalamus that lies immediately ventral to the centromedian/parafascicular nuclei. The dorsal, medial, and ventral boundaries of VPMpc are formed by the internal medullary lamina. By contrast, the anterior and posterior borders of VPMpc are vague but discernible as they blend with the cell-poor areas of the ventral lateral and posterior thalamic nuclei, respectively. The most difficult border to discern is the lateral border of VPMpc, which adjoins VPM. In Nissl stains, cell density is similar within VPM and VPMpc, but the median cell diameter is approximately 13% larger in VPM than VPMpc (20.3 μm vs. 18.0 μm; calculated from Van Buren and Borke, 1972). In myelin-stained material, VPMpc has a much paler, more gelatinous appearance than VPM whose fine myelinated fiber matrix gives it the appearance of felt. According to Jones and Hendry (1989), neurons in both VPM and VPMpc are immunoreactive for calbindin, but only VPM stains for parvalbumin. Jones *et al.* (1986) have shown that cytochrome oxidase (CO) preferentially stains VPM. In this latter study, the VPM/VPMpc boundary was defined by injecting the principal trigeminal nucleus with horseradish peroxidase. After the oral and perioral receptive fields of VPM were mapped, they plotted their electrophysiological data onto CO-stained charts of VPM/VPMpc, complete with the HRP-defined nuclear boundaries. In this manner, Jones *et al.* (1986) demonstrated that CO-staining defines VPM, but not its ventral neighbor, which they surmised was VPMpc. This ventral area did not receive ascending projections from the principal trigeminal nucleus and did not contain neurons responsive to somatosensory stimulation, but because gustatory stimuli were not included in their test battery, it was not possible to state with certainty whether this ventral area was VPMpc or the ventral posterior inferior nucleus. Staining for CO and the calcium-binding proteins calbindin and parvalbumin may provide a more decisive partition between VPM and VPMpc than traditional Nissl or myelin stains. Chapter 20 provides a comprehensive description of the entire thalamus, including VPMpc. Chapter 29 include a complete description of the connectivity and immunohistochemical properties of VPM.

Locating and describing the thalamic relay for taste has been easier than naming it. In the rhesus monkey

[2]Nine other reports were not considered because of inadequate documentation, usually in the method section, or their publication in a non-English language journal. Two of these reports described taste deficits in two patients with bilateral pontine damage. If we exclude those cases and accept at face value the results of the other seven reports, the data from six patients suggest that taste ascends ipsilaterally through the pons; the remaining two cases suggest a contralateral course for taste within the pons.

the crescent-shaped thalamic gustatory relay was originally called the arcuate or semilunar nucleus, but since Olszewski (1952) published his atlas of the rhesus monkey brain, this parvicellular region has been called VPMpc. In humans, the thalamic gustatory nucleus was called the nucleus ventrocaudalis parvocellularis internus (V.c.pc.i) by Hassler (1959), but Hirai and Jones (1989) suggested the name basal ventral medial nucleus (VMb). These differences in nomenclature and occasional shifts in nuclear boundaries typically reflect attempts to group different thalamic nuclei on the basis of cyto- or myeloarchitectural (Olszewski, 1952; Dewulf, 1971) or histochemical/immunocytochemical criteria (Hirai and Jones, 1989; Jones, 1990). A strictly functional term such as thalamic gustatory nucleus (Gus; Paxinos *et al.*, 2000), might resolve the nomenclature issue, but, in fact, it is a misnomer because this area also contains lingual thermal and tactile neurons, as well as neurons that respond to neither taste or somatosensory stimuli (Pritchard *et al.*, 1989). Based upon functional and hodological criteria, grouping the region containing gustatory neurons with the adjacent oral and facial somatosensory nucleus (VPM) appears to be the most logical solution. Accordingly, in this chapter we emphasize Olszewski's (1952) terminology for the thalamus, including VPMpc, for the thalamic gustatory relay.

In the years since Blum *et al.* (1943) first asserted that the gustatory relay for taste lies within VPMpc, numerous anatomical, electrophysiological, and clinical studies have reached the same conclusion. Anatomical studies have demonstrated that the thalamic gustatory relay occupies homologous structures in all mammals for which experimental data are available, including the *rat* (Karimnamazi and Travers, 1998; see Norgren, 1995 for a review), *rabbit* (Block and Schwartzbaum, 1983), *cat* (Ishiko *et al.*, 1967), *dog* (Ninomiya and Funakoshi, 1982), *hamster* (Halsell, 1992), and *monkey* (Beckstead *et al.*, 1980). Thus, it appears that the interspecies differences within the PB discussed earlier have little bearing on the locus of the gustatory area within the thalamus. As described previously, in nonhuman primates axons originating in the rostral, gustatory half of the Sol ascend ipsilaterally within the central tegmental tract and terminate within the caudal half of VPMpc (Beckstead *et al.*, 1980). The rostral half of VPMpc receives afferent projections from the PB (Pritchard *et al.*, 2000). This anatomical partition of VPMpc into rostral and caudal halves confirms electrophysiological data in the cat (Emmers, 1962) and squirrel monkey (Blomquist *et al.*, 1962) showing that electrical stimulation of the chorda tympani and glossopharyngeal nerves drives neurons in the posterior but not anterior half of the nucleus (see also Burton and Benjamin, 1971; Pritchard *et al.*, 2000). Given the role of the PB as a relay for ascending general visceral information, the anterior half of VPMpc and several nearby nuclei might serve as thalamic relays for general visceral information bound for the cerebral cortex (Cechetto and Saper, 1987; Craig *et al.*, 1994; Davis *et al.*, 1995; Saleh and Cechetto, 1993).

The most compelling evidence that VPMpc serves as the thalamic gustatory relay derives from electrophysiological studies. In both primate (Benjamin, 1963; Pritchard *et al.*, 1986, 1989; Reilly and Pritchard, 1995) and subprimate species (e.g., Scott and Erickson, 1971), gustatory neurons are located within VPMpc. When tested, the receptive fields for thalamic gustatory neurons in monkeys are on the ipsilateral side of the tongue (Pritchard *et al.*, 1989). Indeed, over the course of several hundred penetrations performed during the last two decades, we have never observed a taste response that originated from the contralateral side of the tongue. As in other species, gustatory neurons are not the sole tenants of VPMpc (Benjamin, 1963; Pritchard *et al.*, 1989). In addition to gustatory (36%) neurons, VPMpc contains tactile (11%) and thermal-responsive (<1%) neurons as well as other cells that are either unresponsive (18%) to the stimulus set or respond in anticipation of stimulus delivery (35%; Pritchard *et al.*, 1989). Gustatory neurons are located only within the medial half of VPMpc; the lateral half of the nucleus contains neurons responsive to oral somatosensory stimulation (Burton and Benjamin, 1971; Pritchard *et al.*, 1986). In three awake thalamotomy patients, Lenz *et al.* (1997) electrically stimulated the posterior thalamus in the vicinity of the ventroposterolateral nucleus, pars oralis and caudalis (VPLo, VPLc, respectively), and VPMpc. The patients reported tingling in various parts of the perioral cavity, and in several instances they described a sour taste and metallic sensation on the tongue as well as vinegar-like smells and nasal itching similar to that evoked by pepper. These sensations localized to the side of the tongue ipsilateral to the thalamic stimulation.

Despite the general agreement about the location of the thalamic taste relay in human and nonhuman primates, the laterality of the thalamic projection is disputed in the clinical literature. The earliest known study by Adler (1933; Walker, 1938, p. 61) describes a patient who, over a period of 2 years, lost taste function and tactile sensibility on the *contralateral* side of the face as a result of a glioblastoma that encroached upon VPMpc and the nucleus centromedianum. These findings are consistent with a report by Onoda and Ikeda (1999) who described a patient with a posterior thalamic infarction accompanied by a contralateral

hypogeusia. Taste thresholds within the chorda tympani and glossopharyngeal fields were tested with electrogustometry as well as with commercially available filter-paper disks impregnated with sucrose, sodium chloride (NaCl), tartaric acid, or quinine hydrochloride (QHCl; five concentrations each). During the electrogustometry testing there were no differences between the left and right sides of the tongue, but with the filter-disk method, the patient was unable to detect any of the four basic taste stimuli when they were applied to the contralateral side of the tongue (stimulus concentrations not reported). The conclusions of these two reports are contradicted by the data of Combarros *et al.* (1994), who describes a female patient with an ipsilateral taste deficit. This patient, diagnosed with multiple sclerosis, had demyelinating plaques in the medial part of the posterior thalamus and complained of numbness of the hand and corner of the mouth, both on the contralateral side. Her subjective reports of taste were normal, but, on testing, she was almost completely ageusic on the ipsilateral tongue. Despite perfect detection and identification when drops of 1.2*M* NaCl, 0.47*M* glucose, 0.17*M* tartaric acid, or 2.52 m*M* QHCl were applied to the contralateral side of the tongue, during ipsilateral testing, she detected only three of the eight stimuli, and for each of those, she misidentified the quality.

If the ascending taste pathway crosses, as the Adler (1933) and Onoda and Ikeda (1999) studies suggest, at what level does the crossing take place? As summarized in the previous section, the central gustatory pathways ascend ipsilaterally through the pons. After examining two patients with vascular lesions, Shikama *et al.* (1996) concluded that taste ascends ipsilaterally as far as the rostral midbrain. Crossing of the ascending taste pathway between the rostral midbrain and the posterior thalamus is possible but unlikely given the weight of evidence favoring an ipsilateral representation of taste within the cerebral cortex. Thus, the likelihood of a contralateral taste projection to the thalamus seems low, but until more cases are reported, this issue will not be resolved.

Cortex

Over the last decade, there has been more research on the cortical organization of taste than on all other levels of the gustatory neuraxis combined. Neuroanatomical and neurophysiological research in nonhuman primates has provided our first glimpse of taste processing in secondary and tertiary cortical areas. The last decade also witnessed the introduction of noninvasive imaging techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) to the field of gustation. Progress notwithstanding, significant questions remain, and just as a decade ago, the cortical organization of taste must be inferred by reconciling the experimental data derived from nonhuman primates with the clinical literature.

Clinical Studies

During the late 19th and early 20th centuries, seizure-induced auras originating in the uncus and hippocampus convinced the medical establishment that taste cortex was located near the olfactory areas within the temporal lobe. After Bornstein (1940a) reviewed the largely clinical literature that supported a temporal lobe localization for taste and found it wanting, he attempted to locate the primary gustatory cortex by testing the taste sensitivity of three head trauma patients. Based upon two experimental reports in rabbits (Gad, 1891; Schtscherbak, 1892) and a separate interpretation of data from dogs (Gorschkow, 1901) that buttressed his own clinical evaluations of his head trauma patients, Bornstein (1940b) localized gustatory cortex in humans to the base of the postcentral gyrus in Brodmann area 43. Bornstein's neurological and gustatory examinations were careful and well documented. He used graded concentrations of chemicals that humans categorize as sweet, salty, sour, and bitter, as well as thermal and tactile stimuli. In addition, Bornstein tested the tip, lateral edge, and base of the tongue independently on both sides. In each of the three cases, the lesion apparently included the base of the pre- and postcentral gyrus with varying involvement of the underlying operculum. Gustatory deficits were prominent in each case and were always more severe on the contralateral tongue. The publication of Bornstein's two reports not only effectively ended speculation about the role of the temporal lobe in taste perception but also placed taste cortex firmly in the parietal operculum.

Bornstein's (1940a, b) thorough testing methods and data presentation obscure problems inherent in those reports. For example, Bornstein (1940b, p. 144) identified gustatory cortex in his patients by projecting skull damage to the underlying cortex through a method he referred to as "neighboring signs and symptoms." Although brain injuries often result from insults to the overlying skull, this method is, at best, only an estimate of the locus of brain injury. Bornstein included taste dysfunction within the "parietal operculum syndrome," a constellation of symptoms observed in patients with damage to the foot of the postcentral gyrus. According to Bornstein, patients

with the "parietal operculum syndrome" demonstrate ageusia, furring of the contralateral tongue, hypesthesia, Broca's aphasia, or epileptic foci in the oral/perioral or digital region. Thus, he used the diagnosis of taste dysfunction to determine the locus of brain injury when a more prudent strategy would have been to make the anatomical determination independently. As a result, Bornstein gave little consideration to damage outside of Brodmann area 43, especially to cortical areas buried within the lateral sulcus.

Bornstein also demonstrated a strong bias toward the conventional contralateral sensory representation of the cerebral cortex that was already well established for the somatosensory system by the 1940s. In discussing one patient with temporal lobe damage and an ipsilateral taste loss, Bornstein (1940a) wrote, "Ipsilateral loss of taste can hardly be explained by a cortical lesion" (p. 723). Given this bias, it is not surprising that Bornstein never considered the possibility that furring of the tongue, which he observed in his patients and was more pronounced on the contralateral side, may have interfered with taste acuity. Perhaps for these reasons, Bornstein's observations are difficult to reconcile with subsequent studies that locate gustatory cortex within the anterior insula. Nevertheless, Bornstein is credited with making the first careful evaluation of gustatory deficits in humans with cortical damage.

More recently, Motta (1958, 1959) described gustatory deficits in patients who were decorticated, had brain tumors, or had suffered a cerebral vascular accident. Like Bornstein, Motta's tests were thorough, and his data address both the locus and laterality of gustatory cortex. Motta tested both the anterior and posterior tongue with concentration series of saccharin, NaCl, HCl, and QHCl. Patients with large temporal, occipital, or prefrontal lesions had normal taste function, whereas the ten patients with tumors in the parietal or rolandic region or with occlusions of the middle cerebral artery had moderate to severe gustatory deficits on the side of the tongue ipsilateral to the cortical defect. Patients whose taste deficits were caused by tumors in the parietal or rolandic area usually noticed improvement after removal of the tumor. Motta demonstrated with carotid angiograms that the initial taste deficits in these patients were likely caused by compression of the underlying insula and operculum. The patients described by Bornstein (1940b) also had space-occupying lesions (e.g., cysts, angiomas) capable of exerting pressure on the underlying brain, but it is not clear that he considered the possibility that the taste deficits he observed may have been caused by intracranial pressure transmitted to the underlying insular and opercular cortices.

Of the patients Motta tested, none reported a contralateral taste deficit, despite the fact that many had an accompanying contralateral hemiplegia. A thorough examination of three patients led Motta to conclude that gustatory deficits accompanied damage to the anterior insula. Two patients, who had hemiplegias caused by emboli lodged in the middle cerebral artery or the internal carotid artery, had normal taste perception and, as confirmed by carotid angiograms, normal circulation to the insula. The third patient, a gunshot victim, had a pellet of shot lodged in the middle cerebral artery immediately proximal to the anterior insula. Carotid angiography confirmed that the occlusion of the middle cerebral artery compromised both the insula and the precentral gyrus. This patient experienced a contralateral hemiplegia and an ipsilateral hypogeusia. Three other patients who had undergone decortication to manage intractable epilepsy were ageusic on the ipsilateral side of the tongue.

Other studies such as the classic research by Penfield and his colleagues on epileptic patients also suggests that the insula is involved in taste perception (Kahn *et al.*, 1969). Penfield and Jasper (1954) described a patient with an astrocytoma located in the insula who repeatedly experienced an unpleasant taste aura prior to the onset of a major seizure. According to the authors, "The patient has a sense of fear a few minutes before the bad taste sensation. [The patient was] unable to describe the taste (not salty, sour or bitter) which lasted about one minute" (p. 411). Occasionally the taste auras were triggered by the mere sight or the odor of food. One epileptic patient treated by Penfield and Faulk (1955) experienced taste auras that disappeared following surgical excision of the epileptic focus near the foot of the central sulcus. During a subsequent surgery to treat recurrent seizures, the taste auras could be evoked by electrical stimulation of the posterior insular cortex. In alert neurosurgical patients, Penfield and Faulk (1955) evoked distinct taste sensations by electrically stimulating the anterior insula. Because other visceral sensations from the epigastrium were evoked more often and from a more widespread area of the insula, Penfield's data were never considered definitive proof that taste cortex is located in the insula.

Additional support for an insular locus for taste cortex has been provided by Pritchard *et al.* (1999) who performed psychophysical testing on six patients with damage to the insula. In this report, four patients with damage to the rostrodorsal insula had significant deficits in taste intensity on the ipsilateral side of the tongue. No taste deficits were found in the other patients with damage to the ventral insula ($N = 1$) or the posterior insula ($N = 1$), patients in the head

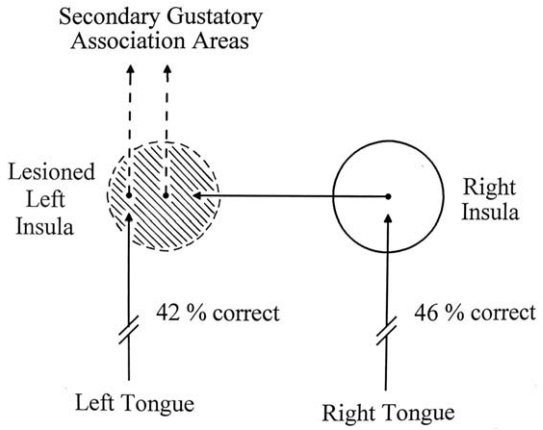

FIGURE 31.5 Taste quality identification following damage to the left insula. Subjects with left insular damage were impaired in taste quality identification for both sides of the tongue (42 and 46% correct), compared to subjects in the two control groups (62.5 and 69.3% correct). Left insular damage also impaired identification of taste quality for stimuli applied to the opposite (right) side of the tongue (46% correct). When sapid stimuli were applied to the left side of the tongue in patients with right insular damage, taste quality identification was comparable to the control subjects (63% correct). Damage to the left insula caused a bilateral impairment in taste quality identification, suggesting that the left hemisphere names taste quality for both sides of the tongue. (Used with permission from the American Psychological Association).

trauma group (N = 3), or the normal control subjects (N = 11). Damage to the left insula impaired taste *quality* identification on both sides of the tongue. These data suggest that taste quality recognition for both sides of the tongue takes place in the left hemisphere. Furthermore, these data suggest that taste information originating on the right side of the tongue reaches the language areas located in the left hemisphere by crossing in the vicinity of the insula (Fig. 31.5). Recent noninvasive imaging-based studies provide additional evidence for hemispheric specialization in the gustatory system (*vide infra*).

Two reports by Aglioti *et al.* (2000, 2001) addressed the issue of taste laterality in commissurotomy patients. The authors, after confirming that language was located in the left hemisphere of these right-handed subjects, applied sapid stimuli to either the left or right side of the tongue. The subjects were asked to point (with their right hand) to the name of the taste quality or an image representative of each taste quality (e.g., lemon = sour). One subject tested by Aglioti *et al.* (2001) had a complete section of the corpus callosum; in another subject the genu and rostrum of the corpus callosum was spared. If naming of taste quality takes place in the language areas of the left hemisphere, callosotomy patients should perform poorly on a tastes-naming task when the stimuli are applied to the right side of the tongue. As predicted, when sapid stimuli were applied to the right side of the tongue, the subjects correctly identified 56.3% of the tastants, compared to an 80.5% correct score when the tastants were applied to the left side of the tongue. Another subject, whose callosal section spared the splenium, also performed at an above chance level for sapid stimuli applied to the right side of the tongue. These data confirm a previous report from their laboratory that showed better than chance performance by a callosotomy patient who also had focal damage to the left orbital cortex and partial removal of the right frontal lobe (Aglioti *et al.*, 2000). Aglioti *et al.* (2000) also described a patient with congenital agenesis of the corpus callosum who was capable of almost perfect performance in a similar taste recognition task

The demonstration by Aglioti *et al.* (2000, 2001) that the left hemisphere of commissurized subjects has access to taste information originating from the right side of the tongue is both interesting and provocative. Before concluding that the taste pathway decussates during its ascent to cortex, however, several alternative explanations must be considered. First, Aglioti *et al.* (2000) note that the advantage for the left hemisphere decreased over trials in the verbal response sessions and suggested that this may have been caused by cross-cueing.[3] Second, the anterior commissure, which was not sectioned in these subjects, represents a potential conduit for taste information in the temporal lobe to cross from one hemisphere to the other (Small *et al.*, 1997a). Consistent with this view is the finding by Aglioti *et al.* (2001) that response latencies were longer when the right side of the tongue was stimulated. Third, Aglioti *et al.* (2001) speculated that interhemsipheric transfer of gustatory information may take place through the splenium of the corpus callosum. Although this is unlikely given the rostrocaudal correspondence between the corpus callosum and the cerebral hemispheres (Lomber *et al.*, 1994) and the fact that axons that originate in the parietal lobe form the splenium (Matsunami *et al.*, 1994), the interpretation of Aglioti *et al.* is supported by their data.

There are several reasons why it has been difficult to use the clinical literature to make a clear and compelling case for the location of gustatory cortex. First, patients with cortical injury often do not notice and thus do not report gustatory impairment. Second,

[3]In cross-cueing, the uninformed hemisphere guesses by pointing, speaking, and so on. When the informed hemisphere realizes that the answer was incorrect, an autonomic response is triggered and detected by the uninformed hemisphere, which then changes its answer.

confusion between taste and smell sensations by most patients (and some physicians) has interfered with the proper diagnosis of taste deficits. Third, when gustatory deficits are reported, they may not be observed in the clinic because of inadequate or superficial testing. Fourth, when taste deficits are reported and detected in the clinic, they typically are given less attention than the motor deficits caused by coincident damage to the perirolandic area. Fifth, this coincident damage makes identification of the core gustatory region impossible unless data are available from several similar cases.

Imaging Studies

A decade ago noninvasive imaging techniques such as computerized axial tomography (CT) and magnetic resonance imaging (MRI) scans were limited to diagnosis and localization of CNS damage. Both techniques facilitated correlation of the locus of CNS damage with gustatory deficits (e.g., Cascino and Karnes, 1990). The advent of other noninvasive imaging techniques such as fMRI, PET, and magnetoencephalography (MEG) has permitted observation of gustatory-evoked brain activity in awake, behaving human subjects. Few doubt that these techniques hold tremendous promise for gustatory research, but to date, they have raised more questions than they have answered. Small *et al.* (1999) used the Talairach coordinates of six published reports to calculate the common areas of taste-evoked activity in the cerebral cortex, as measured by PET (Frey and Petrides, 1999; Small *et al.*, 1997a, b; Kinomura *et al.*, 1994; Petrides *et al.*, 1996; Zald *et al.*, 1998). Their metaanalysis of these six studies showed increased activity in each of the regions of interest included in their analysis: the insula, the frontal and parietal opercula, and the orbitofrontal cortex, all of which have been implicated previously in taste processing by the clinical and experimental literature (Pritchard, 1991).

A closer look at the data from the individual studies shows tremendous variation within the insula and the operculum. Zald *et al.* (2002) reported that the PET activity evoked by quinine and sucrose was only marginally better than that seen during water trials. In other studies where significant responses were found in the insula, sapid stimulation of the tongue activated 15 different loci across 22 mm of the rostral insula (Zald *et al.*, 1998; Petrides *et al.*, 1996). In the dorsoventral plane, these 15 loci were scattered across 28 mm (Small *et al.*, 1997b; Petrides *et al.*, 1996). Twelve of these 15 taste-evoked loci were located in the right (nondominant) hemisphere.

Studies using fMRI and MEG also implicate the insula, the opercula, and the orbitofrontal cortex, but they introduce conflicting data as well. Barry *et al.* (2001) using fMRI reported that electric taste stimulation predominantly activates the dorsal insula in the right hemisphere. Small *et al.* (1999), in their review of the PET literature, also concluded that sapid stimulation of the tongue preferentially activates the right insula. But King *et al.* (1999), Faurion *et al.* (1999), and O'Doherty *et al.* (2001) using fMRI, and Kobayakawa *et al.* (1996, 1999) using MEG, reported that taste-evoked activity is represented bilaterally. Taste-evoked activity has been observed in the ventral insula, but there is disagreement about the laterality of the projection. Barry *et al.* (2001) using fMRI reported that taste stimulation activates the ventral insula primarily on the right (nondominant) side, while Del Parigi *et al.* (2002) found more PET activity in the left hemisphere of their right-handed subjects. Faurion *et al.* (1999), on the other hand, observed more fMRI activity in the dominant hemisphere of both right- and left-handed subjects. Laterality aside, there also is disagreement about the rostrocaudal location of primary taste cortex. King *et al.* (1999), O'Doherty *et al.* (2001), and Faurion *et al.* (1999) usually placed primary taste cortex in the rostral insula, while Francis *et al.* (1999) located it much further posteriorly, and Kobayakawa *et al.* (1999) placed it close to the caudal pole of the insula. Barry *et al.* (2001) reported significant taste-activated loci within the rostral half of the dorsal insula. Other studies have been unable to activate primary taste cortex (Small *et al.*, 1997a) or the thalamic taste relay (Barry *et al.*, 2001; King *et al.*, 1999). Similar problems attend the location of taste within orbitofrontal cortex (Small *et al.*, 1999; O'Doherty *et al.*, 2001).

The validity of these imaging techniques is unquestioned, but their application to the gustatory system may be more challenging than for other sensory systems. Noninvasive imaging techniques work best with robust systems that have large neurons concentrated in a moderately large area and, in the case of MEG, foci located close to the surface of the brain. Gustatory neurons, which account for at most 5–10% of the cells in the insula and the orbitofrontal cortex, are small, are diffusely distributed, and respond sluggishly to sapid stimulation of the tongue. Successful imaging of taste-related activity may require development of more powerful magnets and improved data analysis algorithms as well as more consistency in stimulus application and control conditions between studies. Until interstudy reliability improves, noninvasive imaging techniques are unsuitable for either confirming positive data obtained in the clinic/laboratory or for generating new findings.

Experimental Studies

Experimental attempts to locate gustatory cortex have been carried out in a variety of species (Old and

New World monkeys, cats, rabbits, hamsters, mice, and rats) using electrophysiological, anatomical, and lesion-behavioral techniques. Given the differences between lissencephalic and gyrencephalic species or even between gyrencephalic species (e.g. cats, monkeys), the most germane data must come from primates. The different techniques, each with its own strengths and weaknesses, provide a complex but still incomplete picture of how gustatory information is organized in the cerebral cortex.

Electrophysiological studies The earliest electrophysiological descriptions of gustatory cortex were obtained by mapping the evoked potentials produced by electrical stimulation of the chorda tympani nerve, lingual-tonsillar branch of the glossopharyngeal nerve, and the lingual branch of the trigeminal nerve (Benjamin and Burton, 1968; Benjamin *et al.*, 1968). This research conducted in New World monkeys showed that evoked potentials could be recorded from the insula and inner operculum after stimulation of either the ipsilateral chorda tympani or the glossopharyngeal nerve. Although stimulation of either nerve produced evoked potentials on the lateral convexity of both hemispheres, the ipsilateral responses had a shorter latency, had a larger magnitude, and were more widespread than the contralateral responses. The evoked responses within the chorda tympani and glossopharyngeal fields on the ipsilateral side overlapped each other and the rostral half of the lingual field. Benjamin and Burton concluded that the ipsilateral insula–operculum projection, unlike the field on the lateral convexity, was a "pure taste area uncontaminated by other lingual modalities" (p. 229). Ogawa *et al.* (1985), using similar techniques in the Old World monkey, recorded lingual as well as chorda tympani and glossopharyngeal evoked potentials both on the lateral convexity and in frontal opercular cortex.

Additional insight has been obtained by recording individual taste-responsive neurons located within the insula, inner operculum, and the lateral convexity of awake and anesthetized monkeys. In the first study of this kind, Sudakov *et al.* (1971) tested neurons in the insula and inner operculum of New World monkeys with gustatory, auditory, visual, and somatosensory stimuli. Almost 80% of the neurons isolated did not respond to these stimuli. Gustatory neurons, 3.2% (14 of 437) of the neurons tested, were located near the rostral pole of the insula, interspersed with tactile neurons whose receptive fields were located within the oral cavity. None of these neurons responded to both gustatory and tactile stimulation. Most of the neurons that responded to external somatosensory (8.8%; $N = 43$), auditory (10.7%; $N = 53$), and visual 0.4%; $N = 2$) stimulation were located further caudally in the insula. Within the frontal operculum, only 3.7% (19 of 509) of the driven neurons responded to gustatory stimulation.

Ogawa *et al.* (1989), using anesthetized monkeys, and Ito and Ogawa (1994), using awake, behaving monkeys, recorded from a more extensive area of the operculum. Both studies found taste-responsive neurons within the insula and Brodmann areas 3b, 1, and 2, but the distribution of taste neurons across these areas differed significantly. Ogawa *et al.* (1989) reported that the majority of gustatory neurons (13/25) were located within the granular insula adjacent to the crest of the superior circular sulcus (scir). Of the insular neurons that could be activated by sensory stimulation, 12.5% responded to sapid stimulation of the tongue; the remaining 91 neurons responded to mechanical stimulation of oral and perioral structures. Several of taste-responsive neurons also were driven by mechanical stimulation of the oral cavity. On the inner and outer opercula, taste stimulation was effective for only 3.1% (12 of 383) of the driven neurons. Ito and Ogawa (1994), by comparison, reported that most of the gustatory neurons were located within the dysgranular cortex of the inner operculum (Brodmann areas 1 and 2). It is noteworthy that the dysgranular part of the inner operculum does not receive a direct projection from the gustatory thalamus. In both studies the tactile neurons were broadly distributed across Brodmann areas 3, 1, 2, 4, 6, and SII. Ogawa *et al.* (1989) reported a concentration of tactile neurons around the inferior precentral sulcus, which Pritchard *et al.* (1986) showed receives a direct projection from VPMpc. Based upon the reports of Ogawa *et al.* (1989) and Ito and Ogawa (1994), somatosensory neurons vastly outnumber taste neurons within the insula and frontal operculum, but, more importantly, most of the neurons in these areas are unresponsive to the stimuli they tested.

Numerous electrophysiological reports, most within the last 10 years, have confirmed that gustatory neurons are located within the rostral pole of the insula and the inner operculum (Scott *et al.*, 1986b; Rolls and Baylis, 1994; Scott *et al.*, 1991). Although the actual size of the gustatory area differed slightly from experiment to experiment, in most reports it occupied approximately 50 mm^3 within the dorsal insula (Scott and Plata-Salaman, 1999). Unlike the previous reports by Ogawa *et al.* (1989) and Ito and Ogawa (1994), however, most of the taste-responsive neurons recorded by Rolls and Scott were located in the dysgranular insula (Fig. 31.6). Based on the data they collected from 12,659 neurons, Scott and Plata-Salaman (1999) report that taste-responsive neurons constitute only 6.5% of the neurons within the insula. Other neurons in the insula responded to mouth movements (23.8%), tactile

stimulation of the oral cavity (3.7%), approach of the stimulus delivery syringe (1.2%), or tongue extension (0.3%). The majority (64.6%) of the neurons they encountered did not respond to the stimulus battery employed in those experiments. Although multisensory convergence was not examined in most of these experiments, one study (Rolls and Baylis, 1994) reported that only 9 taste neurons from a sample of 2000 recorded from the insular-opercular and orbitofrontal cortices received convergent visual or olfactory information. In summary, gustatory neurons represent only a small fraction of the cells within the insular-opercular cortex, and unexpectedly, their spatial distribution covers a substantially larger area than the region that receives direct projections from the thalamic gustatory relay. As discussed later, local projections within the insula may account for the presence of taste neurons that lie within the insula but beyond the boundaries of primary taste cortex, as defined by anatomical tracing (Pritchard *et al.*, 1986).

Other gustatory neurons have been found throughout the posterior orbitofrontal cortex, but they are sparsely distributed and few in number (Rolls and Baylis, 1994; Rolls *et al.*, 1990, 1996). Estimates of the incidence of taste-responsive neurons within the OFC range from 1.6 to 7.3% ($\bar{X}$ = 3.8%; Thorpe *et al.*, 1983; Rolls *et al.*, 1990, 1996; Rolls and Baylis, 1994). These and other studies reported that some taste neurons receive convergent *visual* (0.8–32.4%; Rolls and Baylis, 1994; Critchley and Rolls, 1996), *olfactory* (Critchley and Rolls, 1996), *auditory* (1.4%; Thorpe *et al.*, 1983), or *somatosensory* (Critchley *et al.*, 1993) information. Still other neurons respond to the presentation of food (5.3%; Thorpe *et al.*, 1983) or the intraoral administration of fat (1.0%; Rolls *et al.*, 1999). Unlike gustatory neurons in the insula (Yaxley *et al.*, 1988) and inner operculum (Rolls *et al.*, 1989), the taste-evoked activity of OFC neurons can be modulated by the animal's level of hunger and satiety (Rolls *et al.*, 1989).

The studies by Rolls and colleagues have shown that taste-responsive neurons are scattered across the posterior OFC. Although the taste responsive neurons are located as far medially as the medial orbital sulcus and as far laterally as the precentral operculum (area PrCO), most of the cells are within Brodmann area 13, the lateral orbital cortex, and the agranular insular cortex that lies on the posterior orbital surface immediately rostral to primary taste cortex. The area of the caudolateral OFC designated by Rolls as secondary gustatory cortex (Rolls, 2000; Rolls *et al.*, 1990; Rolls and Baylis, 1994) lies along the lateral orbital surface, which has been designated as Brodmann area 12o (Carmichael and Price, 1994) and more recently as Brodmann area 47/12o (Paxinos *et al.*, 2000; Petrides and Pandya, 2001; Price, personal communication). The presence of multimodal neurons within the OFC has fueled speculation that flavor, the amalgam of taste, temperature, touch, and smell, first emerges here (Rolls and Baylis, 1994; Carmichael and Price, 1995a, 1996). Compared with gustatory neurons in the insula, operculum, thalamus, and medulla, those in the OFC are more narrowly tuned and have more complex response properties. It is clear that the OFC contains some higher order gustatory neurons; whether it should be considered secondary taste cortex is an issue discussed in the next section.

Anatomical studies Early anatomical experiments reported that neurons in VPMpc degenerate after combined, but not separate, lesions of the rostral insula and the lateral convexity (Roberts and Akert, 1963; Locke, 1967; Benjamin and Burton, 1968).

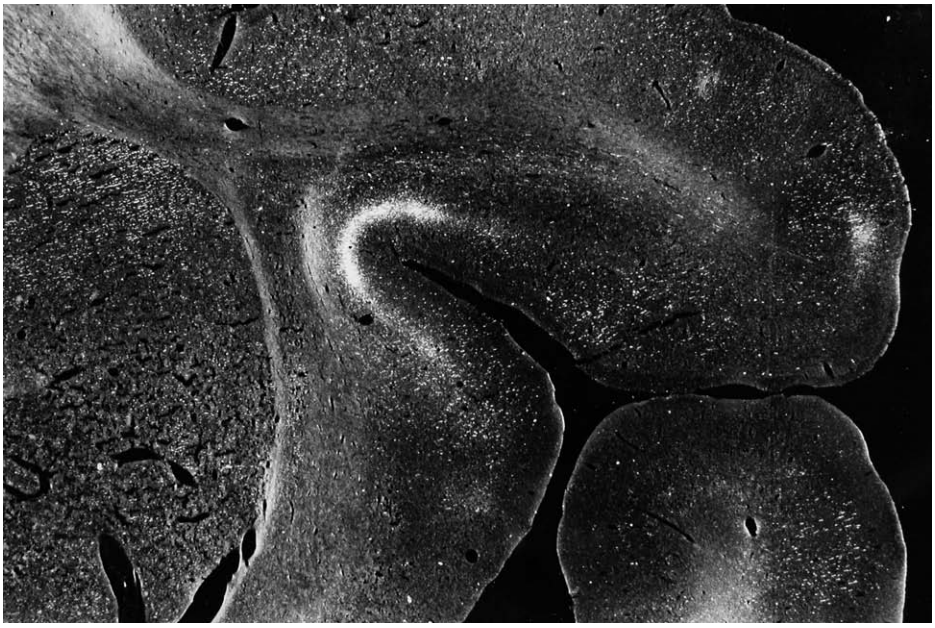

FIGURE 31.7 Darkfield photomicrograph of autoradiographic label in monkey cortex after an injection of tritiated amino acid into the VPMpc. The photomicrograph was taken at the same level as the chart in Figure 31.8B. (Adapted with permission from John Wiley and Sons, Inc.).

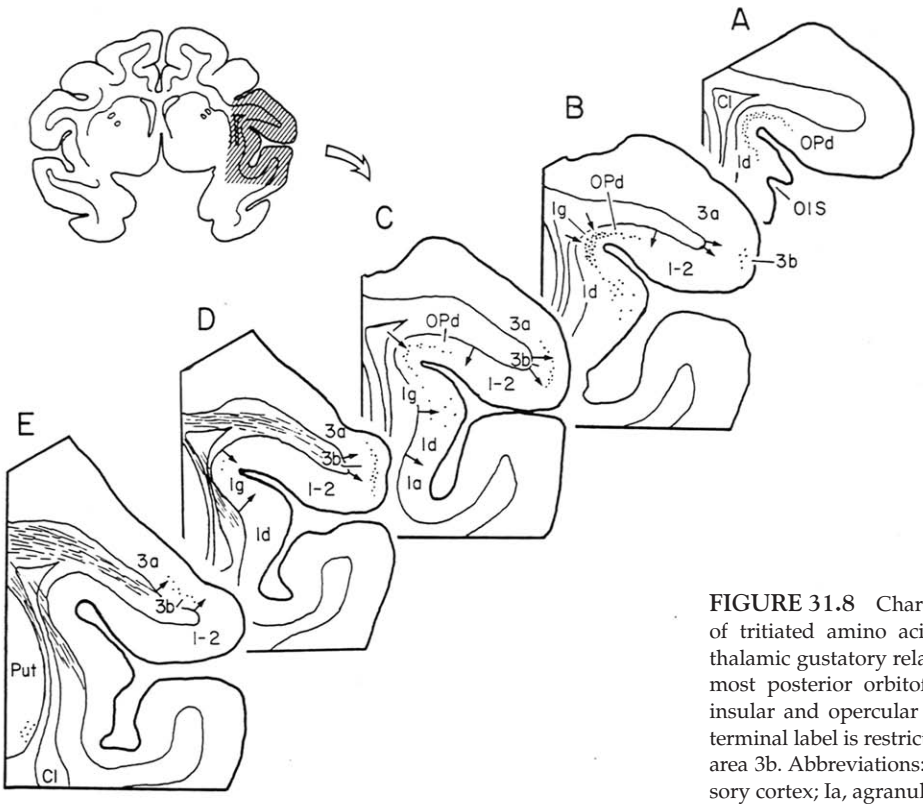
Because retrograde degeneration was observed only when both cortical projection areas were destroyed, Benjamin and Burton (1968) suggested that neurons in VPMpc have bifurcating axons that terminate in both cortical areas. Subsequently, the projections from the taste thalamus to the insula/inner operculum and lateral convexity were confirmed by injecting each cortical area with the retrograde tracer horseradish peroxidase (Pritchard *et al.*, 1986; Kusama *et al.*, 1985). Some doubt was cast upon the existence of a sustaining (bifurcating) pathway, however, when only single-labeled neurons were found in VPMpc after injections of the lateral convexity and the insula with two different fluorescent tracers (diamidino yellow and fast blue; Pritchard and Lu, unpublished observations). This issue deserves further investigation.

The clearest demonstrations of the location and extent of primary taste cortex in nonhuman primates derives from studies that have examined the efferent projections of the thalamic taste relay. Injections of anterograde tracers under electrophysiological guidance into VPMpc produced terminal label in two spatially separate cortical areas, the anterior insula/inner operculum and the outer operculum of the frontal lobe (Figs. 31.7 and 31.8; Pritchard *et al.*, 1986; Mesulam and Mufson, 1982; Carmichael and Price, 1995b). The larger of the two terminal distributions appeared as a continuum stretching from the dorsal aspect of the anterior insula around the scs and onto the adjacent inner operculum. The label was densest within the granular cortex (layers IIIb and IV) adjacent to the scs and gradually thinned out as it spread into dysgranular regions of the insula and the inner operculum. As such, the density of terminal label was proportional to the density of granule cells in cortical layers II and IV. The gustatory thalamus does not project to the agranular insula, which extends onto the orbital surface of the frontal cortex (Pritchard *et al.*, 1986; Carmichael and Price, 1995b), or include the lateral half of the inner operculum, as shown by Sanides (1968), Jones and Burton (1976) and Paxinos *et al.* (2000).

The smaller projection from VPMpc to the lateral convexity was located within Brodmann area 3b, immediately rostral to the oral and perioral somatosensory areas of S1 cortex (Figs. 31.7 and 31.8). In area 3b, the terminal label from the VPMpc injections was restricted to the deeper half of layers II, III, and IV, which fuse into a single stratum. In view of the miniscule number of taste cells and the relatively high percentage of tactile neurons located within the precentral extension of Brodmann area 3b, it is likely that this limited projection to this area reflects spread of the autoradiographic injection from VPMpc into the adjacent somatosensory relay, VPM.

In each of the electrophysiological studies cited in the previous section, it was assumed that the gustatory neurons recorded from the insula and operculum were located within primary taste cortex (Ogawa *et al.*, 1989;



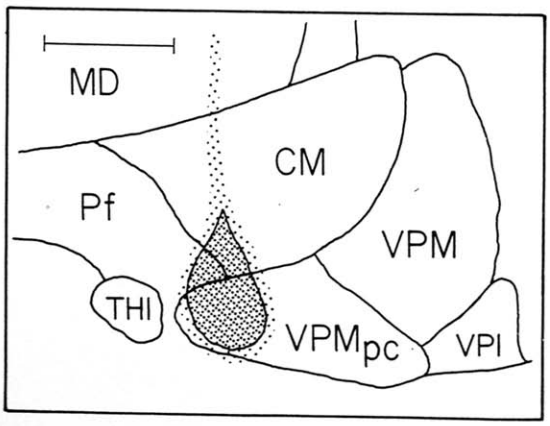


FIGURE 31.8 Charts of terminal label resulting from an injection of tritiated amino acid into the electrophysiologically identified thalamic gustatory relay, VPMpc. The buried field extends from the most posterior orbitofrontal cortex (A) caudally into the rostral insular and opercular cortices (B and C). In the precentral cortex, terminal label is restricted to the most rostral extension of Brodmann area 3b. Abbreviations: 3a, 3b, 1–2, areas of the primary somatosensory cortex; Ia, agranular insula; Id, dysgranular insula; Ig, granular insula; OIS, orbitoinsular sulcus; OPd, dysgranular operculum. (Used with permission from John Wiley and Sons, Inc.).

Ito and Ogawa, 1994; Scott *et al.*, 1986b; Yaxley *et al.*, 1988). Given this presumption, Rolls *et al.* (1990) asserted that the gustatory-responsive neurons within the caudolateral OFC constitute secondary taste cortex. The available electrophysiological and anatomical data suggest that these assertions about both primary and secondary gustatory cortex are, at best, only partly correct. The gustatory neurons recorded in these studies were scattered throughout the granular (Ig), dysgranular (Id), and agranular (Ia) subdivisions of the insula, and the dysgranular operculum (Plata-Salaman *et al.*, 1993). Although the Id receives the faintest projection from the gustatory thalamus, there is no direct projection to Ia or the dysgranular operculum (Pritchard *et al.*, 1986; Carmichael and Price, 1995b). Traditionally, the major determinant for designating an area of the cerebral cortex as primary sensory cortex has been whether that area receives a direct projection from one of the principal sensory relay nuclei in the thalamus. In addition, primary sensory areas within neocortex typically have a distinct granular appearance in layers II and IV, which Sanides (1968, 1970) has referred to as incipient koniocortex (area G). With these considerations in mind, only the Ig located at the insular/opercular junction of the frontal lobe should be considered

primary taste cortex (Pritchard *et al.*, 1986). Other anatomical evidence points to the ventral insula (areas Id and Ia) and the inner operculum (Brodmann areas 1 and 2), rather than the caudolateral OFC, as more likely candidates for secondary gustatory cortices.

If the dysgranular and agranular cortices within the rostral insula and operculum contain taste-responsive neurons but receive no direct projections from the gustatory thalamus, how does taste information reach those areas? Primary taste cortex (Ig) may account for the afferent taste projections to Id and Ia, but Ig has very few projections to the vast expanse of OFC that contains taste-responsive neurons (Rolls and Baylis, 1994; Thorpe *et al.*, 1983; Rolls *et al.*, 1996). The cortical taste areas more likely to project to the OFC are the Id and Ia. The Id receives direct afferent projections from Ig (Barbas, 1993; Mufson and Mesulam, 1982, Mesulam and Mufson, 1985) and the Ia receives projections from both Ig and Id (Barbas, 1993; Mesulam and Mufson, 1982; Carmichael and Price, 1995b; Morecraft *et al.*, 1992). According to Carmichael and Price (1994, 1995a, b), the caudolateral OFC (Brodmann area 47/12o) receives heavier projections from the Ia and Id than from the Ig (see also Mesulam and Mufson, 1982; Barbas, 1988; Morecraft *et al.*, 1992; Baylis *et al.*, 1995) (Fig. 31.9). Areas Ia and Id, but not Ig, also project to all of the other areas within the OFC where taste-responsive neurons have been found (Carmichael and Price, 1995b). For these reasons, Ia and Id are more likely candidates for secondary taste cortices. Anatomical investigations of the efferent projections of the insula suggest that taste-responsive neurons should be located within areas 13l, 13m, 13a, 13b, 47/12o, 14c, and 11l of the OFC (Carmichael and Price, 1995b). Based on the density and distribution of the insulo-orbitofrontal projections to the OFC, the highest concentration of chemosensory neurons are likely to be found in area 13l. To date, however, only a small fraction of the neurons within any part of the OFC appear to be taste-responsive (Rolls and Baylis, 1994), and an even smaller fraction respond to convergent visual, somatosensory, gustatory, and olfactory information (Rolls and Baylis, 1994). Both PET and fMRI studies have shown that gustatory stimuli activate parts of the OFC, but as in primary taste cortex, the papers often obtain different and sometimes contradictory results that are difficult to reconcile with the neurophysiological data collected in nonhuman primates (Zald *et al.*, 1998; O'Doherty *et al.*, 2001). The fact that aversive stimuli are more effective than positive stimuli and the tendency for these responses to be located in only a single hemisphere (typically the left) suggest that these OFC foci are processing the hedonic valence of the stimuli rather than their sensory characteristics. Because the OFC is the first synaptic level where gustatory, olfactory, and visual projections come into close proximity with one another, it is not surprising that even a small cohort of multimodal cells in the OFC has fueled speculation that this is the site where the perception of flavor first emerges.

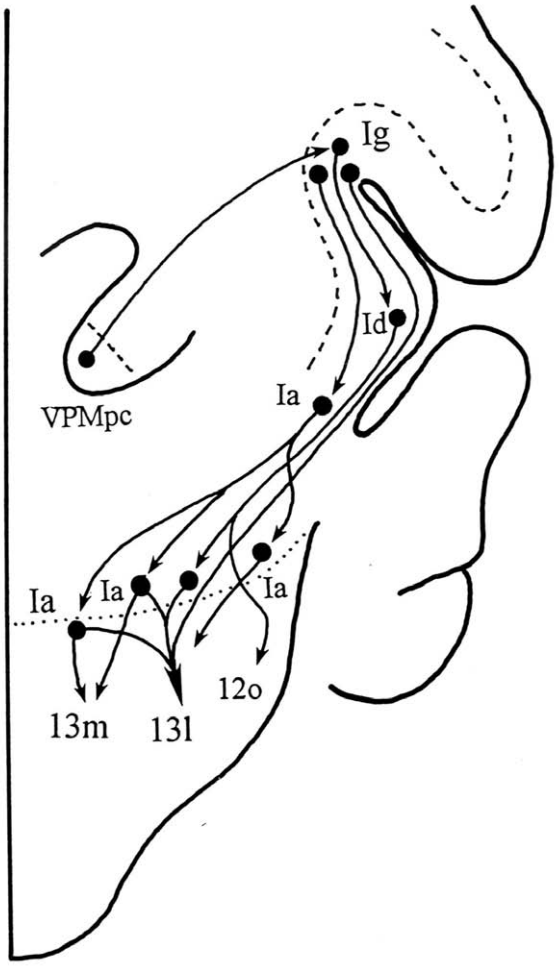

FIGURE 31.9 Thalamocortical and cortico-cortical gustatory projections of the macaque. The thalamic and insular gustatory relays are shown in the coronal plane appended to the ventral surface of the orbitofrontal cortex, oriented with its rostral pole downward. The dotted line indicates the posterior boundary of the orbitofrontal cortex. As shown in this schematic diagram, the orbitofrontal cortex receives more of its gustatory projections from the agranular insula than from either the dysgranular or granular insula. 12o, 13l, 13m, Brodmann areas; Ia, agranular insula; Id, dysgranular insula; Ig, granular insula.

FURTHER GUSTATORY PROCESSING

The ability of taste to provide both positive and negative reinforcement suggests that gustatory

afferent activity must gain access to the limbic system. In rodents and lagomorphs, gustatory information reaches the limbic system through the PB (Norgren, 1974, 1976), and, indeed, gustatory responsive neurons have been recorded in the hypothalamus (Norgren, 1970) and amygdala (Norgren, 1984; Schwartzbaum and Morse, 1978). Gustatory neurons represent only a small fraction of the neurons within the amygdala and the hypothalamus, and the majority of these cells also respond to other sensory modalities. In the monkey, gustatory neurons also are found within the hypothalamus (Nishijo *et al.*, 1986; Rolls *et al.*, 1986) and the amygdala (Scott *et al.*, 1993; Yan and Scott, 1996), but in each case, taste cells represent only a small fraction of

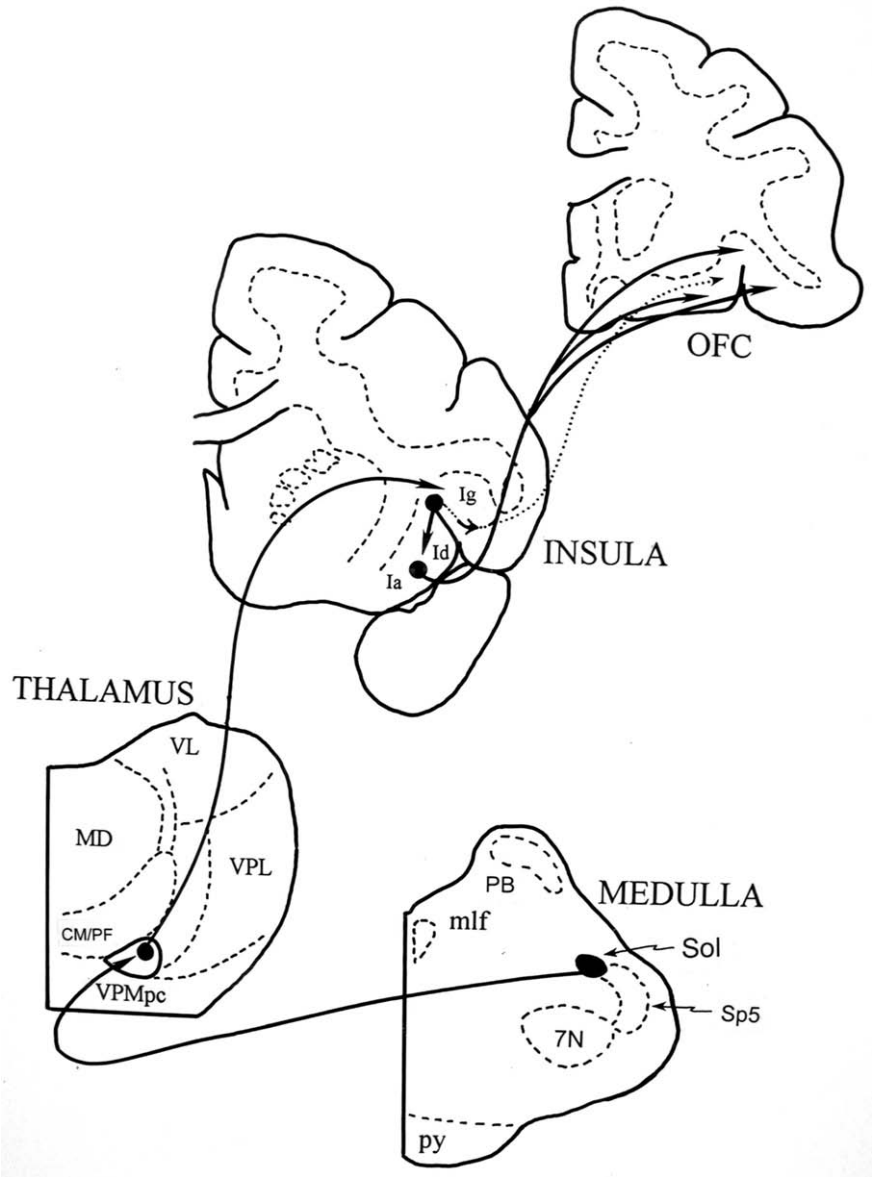

FIGURE 31.10 Central taste pathways of the Old World monkey. This schematic diagram shows the central taste pathways of the Old World monkey charted onto coronal sections of the rostral medulla, the posterior thalamus, the rostral insula, and the posterior OFC. As shown, second-order neurons in the Sol project to VPMpc. Third-order neurons in VPMpc project to the primary taste cortex, which is located in the granular insula (Ig) adjacent to the superior circular sulcus. Projections from the primary taste cortex ascend to the OFC directly and indirectly through the agranular (Ia) and dysgranular (Id) regions of the insula. 7N, facial nucleus; CM/PF, centromedian/parafascicular nuclei of the thalamus; Ia, agranular insula; Id, dysgranular insula; MD, medial dorsal nucleus of the thalamus; mlf, medial longitudinal fasciculus; py, pyramidal tract; Sp5, spinal trigeminal nucleus; VL, ventrolateral nucleus of the thalamus.

the neurons in the area. PET studies have shown that aversive concentrations of quinine and saline (but not sucrose) increase regional blood flow within the amygdala (Zald *et al.*, 1998, 2002), but this activity may have less to do with qualities of bitter and sour than the negative emotional valence of the stimuli (Aggleton, 1992). Following resection of the amygdala to treat pharmacologically intractble epilepsy, subjects report an increase in the intensity for QHCl (Small *et al.*, 2001a, b). If taste information is processed within the hypothalamus and amygdala, the route by which this information reaches these areas is unclear. The PB in primates projects to both the hypothalamus and the amygdala, but with no evidence to suggest that the PB is involved in gustatory function, another route to the ventral forebrain must be considered (Pritchard *et al.*, 1999). There are two possibilities. The thalamic gustatory relay in the cat projects to both the cerebral cortex and the lateral amygdala (Yasui *et al.*, 1987), but in rats and monkeys similar projections are either weak or absent (Aggleton *et al.*, 1980; Kosar *et al.*, 1986; Ottersen and Ben-Ari, 1978; Pritchard *et al.*, 1986; Turner and Herkenham, 1981). The orbitofrontal cortex and the insula both project to the amygdala, but there is no functional evidence that these projections convey gustatory afferent information (Aggleton *et al.*, 1980; McDonald, 1998; Turner *et al.*, 1980). This also applies to subcortical areas where taste-responsive neurons have been found such as the caudate, putamen, ventral striatum, and nucleus accumbens (Hollerman *et al.*, 1998; Tremblay *et al.*, 1998).

Given the logical relationship between taste, hedonic value, and reward expectation, it is not surprising that gustatory neurons have been found within the amygdala, the hypothalamus, and the striatum. Although the route by which taste information reaches the limbic system and striatum is uncertain, a more important issue is whether the minuscule number of taste neurons found in these areas can account for hedonic value and reward expectation.

SUMMARY

In this chapter, we relied heavily on experiments conducted in nonhuman primates and, where possible, reconciled these data with the few published clinical studies. Based upon this synthesis of the experimental and clinical literature, we concluded that all primary afferent gustatory neurons synapse in the rostral half of the nucleus of the solitary tract in the medulla. Unlike nonprimate species, neurons in the gustatory division of the nucleus of the solitary tract project to the thalamus rather than to the pons. The pontine gustatory relay found in rodents is either absent or attenuated in primates. Gustatory projections from the medulla, unlike most other sensory systems, are neither crossed nor lemniscal. They ascend primarily in the ipsilateral central tegmental tract and terminate in the most medial aspect of the ventral posterior nuclear complex, VPMpc. The thalamic gustatory relay projects primarily to the granular part of the rostral insula (primary taste cortex), which, in turn, projects to nearby dysgranular and agranular regions of the insula (secondary gustatory cortices). Subsequent projections across the orbitofrontal cortex may provide the anatomical substrate for integration of taste with visual, auditory, olfactory, somatosensory, and general visceral information.

In conclusion, a more complete view of the gustatory system in humans is available now than was available a decade ago when the first edition was published, but the picture remains incomplete. Most of the fundamental unanswered questions about the central organization of taste are likely to succumb to modern noninvasive imaging techniques. A decade from now, with the anatomical organization of taste reasonably complete, the emphasis in the field will likely shift to issues of function.

Acknowledgments

Our own research summarized here was supported by grants from the Public Health Service (NS20518 and DK59549, both TCP; DC00246 and MH43787, both RN), and the National Science Foundation (BNS9413025, TCP). During preparation of this review R.N. was supported by an NIMH Research Scientist Award (MH00653). Correspondence should be addressed to: Dr. T.C. Pritchard, Department of Neural and Behavioral Sciences, H181, The Pennsylvania State University College of Medicine, 500 University Drive, Hershey, PA 17033 (tcp1@psu.edu).

CHAPTER

32

Olfaction

JOSEPH L. PRICE
Department of Anatomy and Neurobiology
Washington University School of Medicine
St. Louis, Missouri, USA

As with other sensory modalities, olfactory information must be transmitted from peripheral olfactory structures (the olfactory epithelium) to more central structures (the olfactory bulb and cortex), integrated to detect and discriminate specific stimuli, and then transferred to other parts of the brain in order to reach sensory consciousness and affect behavior. The olfactory system is different from the other sensory systems, however, in three fundamental ways.

First, the olfactory receptor neurons turn over throughout life and are replaced by mitotic division of the basal cells of the olfactory epithelium. Although other receptor-related cells also turn over, such as the taste buds, these are not true neurons that make synapses within the central nervous system. The olfactory receptors are the only neurons that are inserted in the surface epithelium of the body and are, therefore, directly exposed to the environment. It is likely that this makes them more vulnerable to insult and necessitates their regenerative capacity.

Second, olfaction is the only sensory modality that is directly connected into the cerebral hemisphere (in a sense, the telencephalon developed in relation to olfactory input). Possibly because of this phylogenetic relationship, olfactory sensory activity is transferred directly from the olfactory bulb to the olfactory cortex, without a thalamic relay. Although there is a subsequent projection from the olfactory cortex to the mediodorsal thalamic nucleus and from there to the posterior orbital/agranular insular cortex, this transthalamic pathway is less substantial (in terms of the number of neurons involved) than a direct, monosynaptic projection from the olfactory cortex to the same orbital/insular areas. The transthalamic projection is, therefore, not essential for relay of sensory information to the neocortex.

The third difference is that neural integration and analysis of olfactory stimuli may not involve a topographic organization beyond the olfactory bulb. Olfactory stimuli are not intrinsically ordered along spatial axes, like vision and somatic sensation, or along a frequency axis, like audition. Although an organization has been found in the projection from the olfactory epithelium to the olfactory bulb (e.g., Mombaerts *et al.*, 1996), there is little if any solid evidence for a topographic organization from the bulb to the olfactory cortex. Although it is possible that a more complex organization may eventually be discovered, on the present evidence it is more likely that spatiotemporal patterns across large regions of the

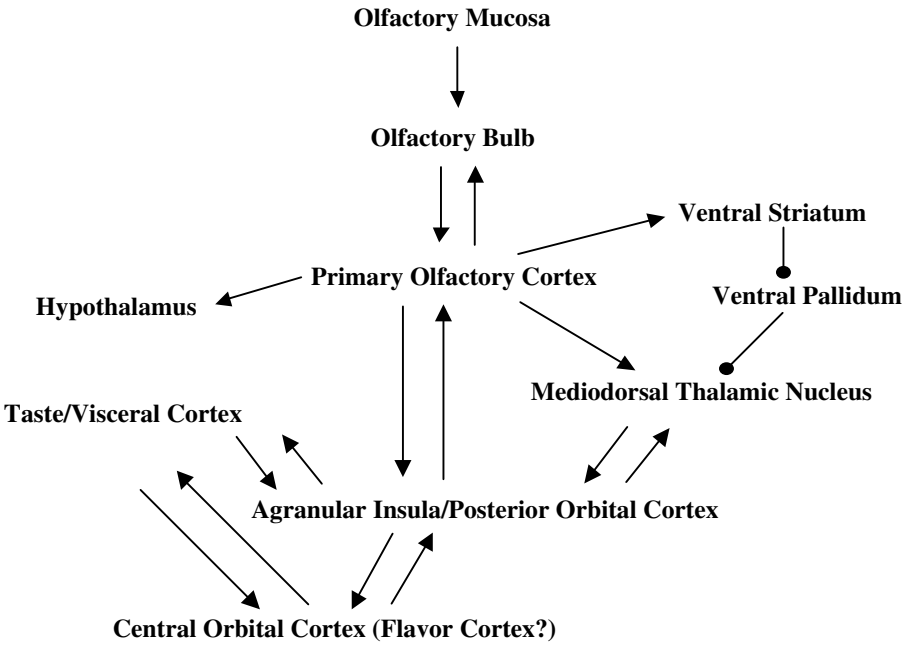

FIGURE 32.1 A schematic diagram of the major olfactory pathways that are discussed in this chapter.

olfactory cortex may be the critical factor in detecting and discriminating different odors.

This chapter will outline the human olfactory system, beginning with the peripheral receptor neurons in the nasal cavity and the first relay in the olfactory bulb (Fig. 32.1). The projections of the olfactory bulb to the primary olfactory cortical areas will be described in macaque monkeys, and the comparable olfactory areas in the human brain will be described. Finally, olfactory projections to the hypothalamus, thalamus, and frontal cortex will be discussed, based on experimental work in monkeys and on functional imaging studies in humans.

Humans are generally considered "microsmatic," with a relatively poorly developed olfactory system compared to that of "macrosmatic" mammals. Indeed, the structure and lamination of the olfactory bulb and primary olfactory cortex are not as well-defined in humans as in rodents and carnivores. Further, the olfactory structures certainly do not make up as large a fraction of the forebrain in humans as in rats and cats. However, almost all the major olfactory structures found in rats are also present in humans, and in absolute terms the human structures are far from rudimentary. For example, the volume of the olfactory bulb in a young adult human is reported to be 45–55 mm^3 (Bhatnager *et al.*, 1987), while it is only 15–20 mm^3 in rats (Hinds and McNelly, 1977). Similarly, the primary olfactory cortical areas such as the anterior olfactory nucleus, piriform cortex, and periamygdaloid cortex are readily recognizable around the junction of the frontal and temporal lobes of human brains.

The only major olfactory structures that may not be present in humans are the vomeronasal organ and the accessory olfactory bulb, which represent the peripheral receptors and first relay of the "accessory olfactory system" in other animals, including monkeys. The accessory olfactory system is anatomically and functionally distinct from the main olfactory system and has been implicated in perception of odors important for species-specific functions, including aspects of reproduction (Wysocki and Meredith, 1987). The vomeronasal organ has been reported to be present in human fetuses (Kreutzer and Jajek, 1980; Nakashima *et al.*, 1985), but reports of it in adult humans are sketchy (e.g., Zbar *et al.*, 2000). Further, an accessory olfactory bulb has not been recognized in humans (e.g., Meisami *et al.*, 1998). The major axonal target of the accessory olfactory bulb in rodents, the medial amygdaloid nucleus, is present in adult humans, but presumably has come to mediate nonolfactory functions.

OLFACTORY MUCOSA

Location

The peripheral olfactory receptor neurons in the human are situated within the olfactory epithelium, in the posterodorsal recess of the nasal cavity, 7 cm deep

to the nostril (e.g., see Jajek, 1983; Lovell *et al.*, 1982; Nakashima *et al.*, 1984). This specialized epithelium occupies an area of approximately 1 cm^2 (on each side) on the roof of the cavity (covering the cribiform plate), the adjacent nasal septum and superior turbinate. The remainder of the nasal cavity (60 cm^2 on a side) is occupied by a respiratory epithelium, which serves the major function of conditioning the air that passes through the nose. The inaccessibility of the olfactory epithelium serves an important role in protecting the receptor neurons, which are the only sensory neurons that are directly exposed to the external environment in the surface epithelium of the body.

Structure

The human olfactory epithelium is considerably thicker than the respiratory epithelium (70 versus 45 μm), and is generally described as containing bipolar receptor neurons, supporting or sustentacular cells, and basal cells. In addition, microvillar cells have been found near the surface, and Bowman's glands extend deep to the epithelium into the lamina propria. The epithelium is pseudostratified, and both the bipolar receptor cells and the sustentacular cells span the full thickness. Cilia or microvillae extend from the apical surface of the cells into a layer of mucus that covers the epithelium and separates it from the air of the nasal cavity.

The Bowman's glands are tubuloaveolar in nature, with ducts extending through the epithelium to the surface. In humans, they apparently secrete a serous fluid that contributes to the mucous layer overlying the epithelium (Jajek, 1983). Because of the number of these glands and their restricted distribution in the olfactory region, it has been suggested that the secretion of Bowman's glands may play a role in olfactory transduction, but this has not been well established.

The bipolar receptor neurons have a "dendrite" that extends to the surface of the epithelium and a thin (0.2–0.3 μm) axon that runs into the lamina propria. The axons then group together into small bundles or "fila" and run through the cribiform plate to the olfactory bulb. The cell bodies of the receptors occupy a broad band in the middle of the olfactory epithelium, deep to the nuclei of the supporting cells and superficial to the basal cells. Counts of the receptors in humans indicate that their density is about 30,000 per mm^2, or 6 million per nose (Moran *et al.*, 1982a). As in other mammals, the human receptor neurons and their processes show selective immunoreactivity for the olfactory marker protein (Nakashima *et al.*, 1985). Evidence from rats and other animals indicates that the transmitter used by the receptor neurons is glutamate (Berkowicz, *et al.*, 1994; Aroniadou-Anderjasska *et al.*, 1997).

Superficially, the receptor dendrite terminates in the knoblike olfactory vesicle, which protrudes above the surface of the epithelium. Ten to 30 nonmotile cilia arise from basal bodies in each olfactory vesicle and protrude into the mucous layer (Jajek, 1983). The cilia generally have the typical 9 pairs +2 microtubule structure, without dynein arms between the microtubule pairs. The ciliary membranes carry molecular odorant receptors, which mediate sensory transduction from odorant molecules to neural signals.

There are believed to be about 1000 odorant receptors, each of which binds a specific chemical moiety. The receptors are coded for by the largest known gene family in mammals (Buck and Axel, 1991; Glusman *et al.*, 2000). In humans, odorant receptor genes are distributed over at least 16 chromosomes, but as many as 72% of them are reported to have accumulated mutations that make them dysfunctional pseudogenes (Rouquier *et al.*, 1998). Studies in rodents have indicated that olfactory receptor neurons are organized into four zones within the olfactory epithelium, which express different groups of molecular odorant receptors (Ressler *et al.*, 1993; Vassar *et al.*, 1993; Mori *et al.*, 1999). Within each zone, neurons expressing specific odorant receptors are intermingled with neurons expressing other receptors.

The microvillar cells are flask-shaped cells in the superficial zone of the epithelium with a rapidly tapering neck that ends in a tuft of microvilli that extends out into the mucous layer (Jajek, 1983; Moran *et al.*, 1982b). Although the neuronal nature of these cells is not established, they have a thin, axon-like process that extends toward the deepest layer of the epithelium toward the olfactory bulb.

The supporting cells in the olfactory epithelium are columnar cells, with a microvillous border at their apex. Unlike similar cells in the adjacent respiratory epithelium, those in the olfactory epithelium do not show morphological specializations characteristic of mucous secretion. The function of the supporting cells is not clear, but several functions have been suggested, including secretion of a nonmucous substance, phagocytotic removal of substances from the mucous, or provision glia-like support for the receptor neurons (e.g., Jajek, 1983).

The basal cells are situated in the deepest zone of the olfactory epithelium. As in other vertebrates, the basal cells in humans are apparently stem cells, undergoing mitotic division and differentiation into receptor neurons lost to turnover or injury (Moran *et al.*, 1982a). Such replacement cannot keep up with degeneration over a human lifetime, however. In adults substantial

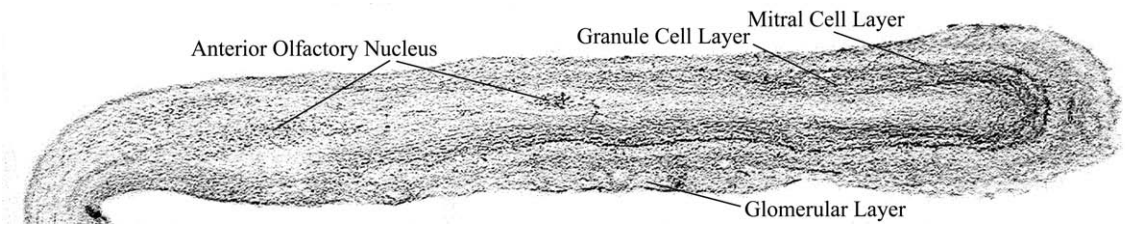

FIGURE 32.2 Photomicrograph of a sagittal section of the human olfactory bulb from a 61-year-old subject, stained with the Nissl method. The glomerular layer is relatively poorly formed, although the other layers are clear. Note the clusters of neurons that comprise the intrabulbar portion of the anterior olfactory nucleus.

areas of the olfactory epithelium are found to have degenerated or been replaced with respiratory epithelium (Nakashima, *et al.*, 1984, 1985; Morrison and Costanzo, 1992).

OLFACTORY BULB

In most primates, including humans, the olfactory bulb is pulled forward from its point of attachment to the cerebral hemisphere, remaining connected by a relatively long olfactory stalk or peduncle. The intrinsic structural features of the human olfactory bulb are similar to those in other species, but it is somewhat less sharply defined. As in all mammals, in humans the bulb has a concentric laminar structure with distinct neuronal somata and synaptic neuropil separated into layers (Fig. 32.2). Although our understanding of the synaptic organization of the olfactory bulb depends on observations made in rats and other animals (see Macrides *et al.*, 1985; Scott and Harrison, 1987; Mori *et al.*, 1999 for reviews), it is very likely that the human bulb has the same basic organization.

The olfactory nerve fibers ramify in the most superficial layer (olfactory nerve layer), after passing through the cribiform plate from the nasal cavity. Where the nerves first reach the olfactory bulb, rostrally and ventrally, the olfactory nerve layer is thick. It becomes progressively thinner in the more caudal and dorsal part of the bulb. Deep to the olfactory nerve layer, the fibers terminate in the characteristic glomerular formations both on the primary dendritic tufts of the "mitral" and "tufted" relay cells and on other cell types. In rats, the transmitter used at this synapse has been shown to be glutamate, which acts on both NMDA and non-NMDA receptors (Aroniadou-Anderjaska *et al.*, 1997).

In rodents, the organization of the olfactory epithelium into zones appears to be more or less preserved in the olfactory bulb, based on the distribution of zone-specific molecular markers (Mori *et al.*, 1999). Within each zone in the epithelium, axons from the several thousand receptor neurons that express a given molecular odorant receptor converge onto one or two glomeruli in the corresponding zone of the olfactory bulb (Vassar *et al.*, 1994; Ressler *et al.*, 1994). This suggests that the glomeruli are the unit structures for olfactory discrimination (e.g., Mori *et al.*, 1999). That is, the initial distinction between different odors is based on hard-wired connections between specific receptor neurons and specific glomeruli. Studies with 2-deoxygluclose as a functional imaging method have also shown that specific odorants activate a small, consistent portion of the olfactory bulb, again suggesting that initial olfactory discrimination depends on a spatial code in the olfactory bulb (e.g., Johnson and Leon, 2000; Xu *et al.*, 2000).

The synaptic neuropil of the glomeruli is outlined by somata of small "periglomerular cells." These interneurons send dendrites and axons into adjacent glomeruli and receive synapses from the olfactory nerves. Like the granule cells in the deeper part of the bulb, the periglomerular cell dendrites form "reciprocal" or bi-directional synapses with mitral and tufted dendrites. In humans as in other animals, most (at least) of the periglomerular cells are GABAergic and also contain one of the calcium-regulating proteins, parvalbumin or calbindin (Ohm *et al.*, 1990, 1991; Kosaka *et al.*, 1987). In addition, many are dopaminergic (Smith *et al.*, 1991). In rats it has been shown that GABA and dopamine colocalize within periglomerular cells (Kosaka *et al.*, 1985; Gall *et al.*, 1987). There are also a number of superficial "short axon cells" in the glomerular region.

Deep to the glomeruli is the external plexiform layer, with dendrites of mitral, tufted, and granule cells. The tufted cell somata are also scattered throughout this layer, but the mitral cell somata are located in a thin layer at the border between the external plexiform layer and the deeper granule cell layer. One or occasionally two "primary" dendrites of the mitral and tufted cells arise from the superficial aspect of the

somata and extend through the external plexiform layer to the glomeruli. Several "secondary" dendrites ramify in the external plexiform layer.

The small granule cells are by far the most numerous neuron type in the olfactory bulb, and the granule cell layer makes up approximately half of the volume of the bulb (Bhatnagar *et al.*, 1987). These interneurons lack an axon and instead send a superficial "dendritic" process into the external plexiform layer, where they form reciprocal synapses with mitral and tufted cell dendrites. Other dendrites ramify within the granule cell layer and are solely post-synaptic. There are also short axon cells in the granule cell layer, which synapse on the granule cells.

Studies in rats and other animals indicate that the mitral to granule cell component of the reciprocal synapse uses glutamate, acting on both NMDA and non-NMDA receptors (Chen *et al.*, 2000). The granule to mitral cell component of the synapse is GABAergic, acting on GABA-A receptors. The reciprocal synapses appear to allow for spatial and temporal modulation of activity in the relay cells, both on a local basis (at individual synapses) and on a more global level (through conduction along granule and mitral/tufted cell dendrites). It has been reported in nonhuman primates, including chimpanzees, that the somata and dendrites of many cells in the olfactory bulb may be ensheathed by compact myelin (Tigges and Tigges, 1980). Since many, at least, of these cells have presynaptic dendrites, it is possible that the myelin will affect conduction between different segments of the neuron.

In humans, approximately 8000 glomeruli and 40,000 mitral cells have been counted in young adults (Meisami *et al.*, 1998). There is a progressive decrease with age in the number and structural integrity of the glomeruli, and in the thickness of the glomerular/periglomerular layer (Bhatnagar *et al.*, 1987; Meisami *et al.*, 1998). In olfactory bulbs from very old individuals (>90 years old) less than 30% of the glomeruli and mitral cells were recognized. Together with the degeneration of the olfactory epithelium mentioned previously, this presumably is related to the decline in olfactory function with age (e.g., Murphy *et al.*, 2000).

PRIMARY OLFACTORY CORTEX

Cortical Structure and Projections of the Olfactory Bulb

The axons of mitral and tufted cells run through the granule cell layer and emerge from the caudolateral aspect of the olfactory bulb to form the lateral olfactory tract. This tract forms the bulk of the olfactory peduncle in humans and other primates. Although a "medial olfactory tract" has been described in the past, a large body of experimental studies in several mammalian species, including primates, has shown that all the axons from the olfactory bulb pass through the lateral olfactory tract. There is no medial olfactory tract in mammals. The lateral olfactory tract can be visualized readily in human brain sections stained for fibers or myelin. It runs just deep to the pial surface, from the olfactory peduncle onto the posterior ventral surface of the frontal lobe and then laterally around the junction between the frontal and temporal lobes (the limen insulae) and onto the anteromedial part of the temporal lobe. Most of the primary olfactory cortical areas have a relatively simple structure, with a broad plexiform layer composed of dendrites of neurons in deeper layers (I), a well-defined, compact layer of pyramidal-like cell somata (II) and a deeper layer(s) of pyramidal and nonpyramidal cells (III and higher).

The full efferent projection of the olfactory bulb can only be mapped with experimental methods, so the description of this projection is based on data from nonhuman primates (Heimer *et al.*, 1977; Turner *et al.*, 1978; Carmichael *et al.*, 1994; Fig. 32.3). As in lower animals, axons from the olfactory bulb in monkeys run caudally through the lateral olfactory tract and give off collaterals that extend medially, laterally, and deep to the tract to contact dendrites in the superficial part of layer I of the olfactory cortex. In addition, in primates a few axons from the olfactory bulb are found in and deep to layer II. In contrast to the olfactory bulb, there is very little evidence for a spatial organization that could support a spatial code in the olfactory cortex. That is, small areas of the olfactory bulb project to virtually the entire olfactory cortex, and small areas of the cortex receive fibers from virtually the entire olfactory bulb (e.g., Haberly and Price, 1977; Luskin and Price, 1982; Haberly 1985). There may be a more "fine-grain" organization within this (e.g., Ojima *et al.*, 1984), but it has not yet been recognized.

Anterior Olfactory Nucleus

The anterior olfactory (AO) nucleus is the most rostral of the tertiary olfactory structures (Figs. 32.3, 32.4, and 32.5). In primates, including humans, there is a "bulbar" part of this nucleus located in the rostral part of the olfactory peduncle, including several groups of pyramidal-like cells in the caudolateral part of the olfactory bulb. As in other olfactory cortical areas, axons of the mitral and tufted cells synapse on the distal segments of dendrites that extend into the plexiform layer around the neuron clusters. More

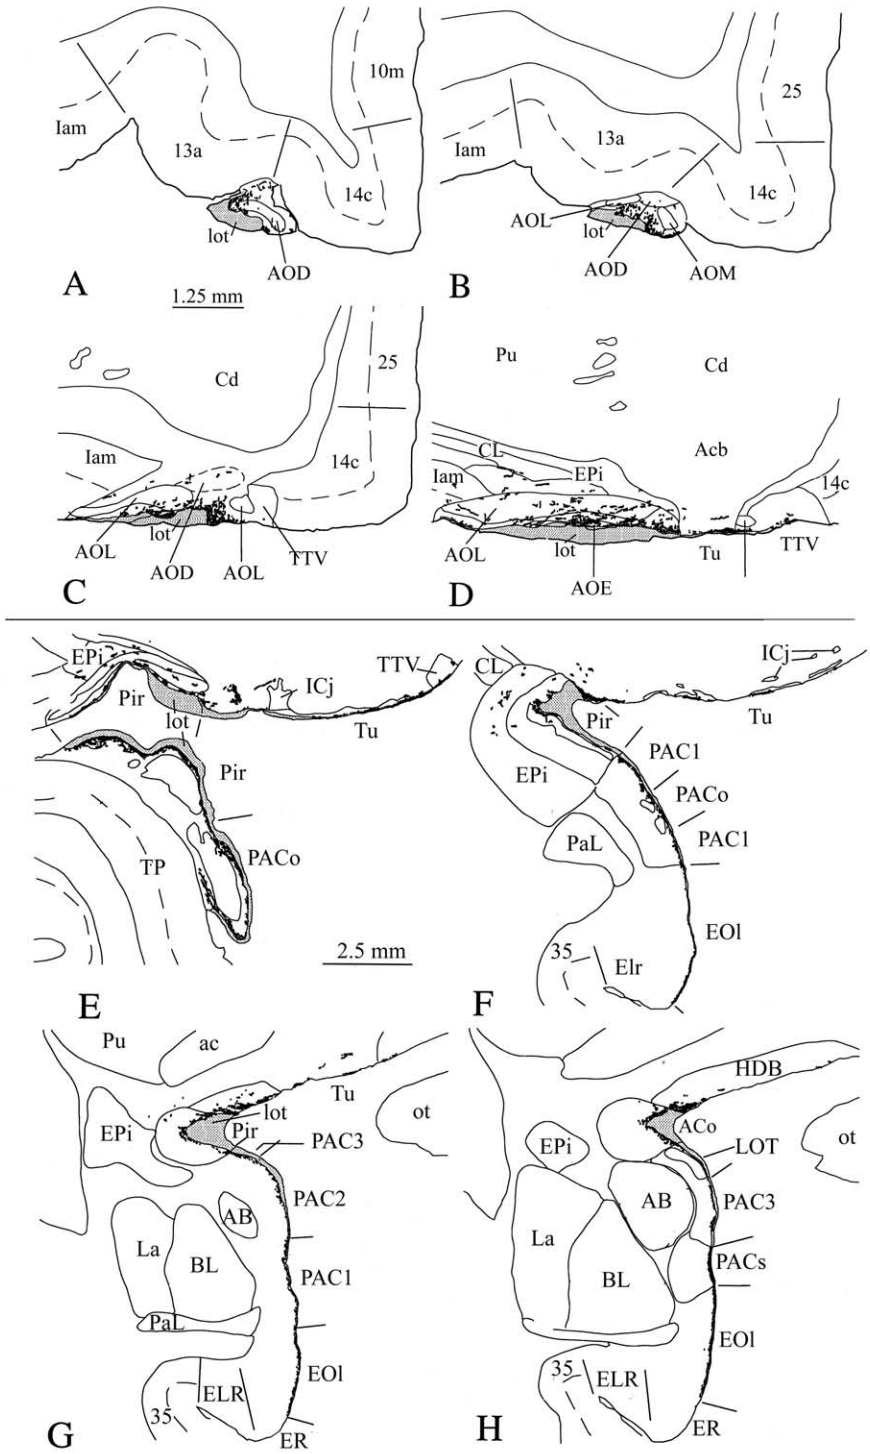

FIGURE 32.3 The distribution of fibers of the lateral olfactory tract in monkeys, that were labeled by an injection of the anterograde tracer biotinylated dextran amine into the olfactory bulb. The shaded area represents the lateral olfactory tract, which was heavily labeled. Dashes and dots represent labeled axons that extend from the tract into the primary olfactory cortex. Almost all of the fibers terminate in the most superficial layer of the olfactory cortex, just deep to the lateral olfactory tract or the pia. Taken from Carmichael *et al.* (1994). Note that the scale is different for the upper and lower parts of the figure.

FIGURE 32.4 Line drawings illustrating the location of the primary olfactory cortical areas in humans, on the ventral surface of the posterior frontal lobe and the anteromedial part of the temporal lobe.

caudal "medial" and "lateral" subdivisions of the AO are situated on either side of the lateral olfactory tract where it joins the orbital cortex, at the posterior end of the olfactory peduncle. In monkeys and other animals, "external" and "dorsal" subdivisions are also recognizable, but these are not readily distinguishable in humans.

Olfactory Tubercle

More caudally on the ventral surface of the frontal lobe, the lateral olfactory tract runs at the junction of the olfactory tubercle (Tu), medially, and the piriform cortex, dorsal and laterally (Figs. 32.3, 32.4, and 32.5). The olfactory tubercle is a prominent structure in rodents and carnivores with a well-developed laminar structure similar to that in other olfactory cortical areas. It is much less distinct in primates but still has a laminar arrangement of cell bodies and afferent fibers. In all mammals, collaterals of axons in the lateral olfactory tract leave the medial side of the tract and run through the superficial part of layer I of the olfactory tubercle to contact apical dendrites of cells with somata in layers II and III. Although this laminar structure is clearly cortical, other features of the olfactory tubercle resemble the underlying corpus striatum, and it has often been included with the nucleus accumbens in the "ventral striatum" (Chapter xx). For example, the tubercle has a high concentration of acetylcholinesterase (Hertz-Schuett and Mai, 1991), apparently related to intrinsic cholinergic neurons, and it receives a prominent dopaminergic input from the ventral midbrain. Its major output is to the "ventral pallidum," which is similar to and dorsally continuous with the globus pallidus.

The primary neurons of the olfactory tubercle closely resemble the "medium spiny" cells of other parts of the striatum in their dendritic structure and appearance. Between and deep to these cells are clusters of small neurons that constitute the islands of Calleja. In monkeys, ventral pallidal elements are distributed somewhat loosely within the deep part of the tubercle rostrally, although more distinct components of the ventral pallidum are found further caudally and dorsally. In humans, the olfactory tubercle is so poorly developed that it is difficult to delineate it precisely from the nucleus accumbens. The nucleus accumbens and, more caudally, the substantia innominata extend to the ventral surface in both monkeys and humans and occupy much of the area referred to as the olfactory tubercle in gross anatomical terms.

Piriform Cortex

The piriform cortex (Pir) is the largest and most distinctive olfactory cortical area. The area was previously referred to as the prepiriform or prepyriform cortex, apparently because it is partially situated

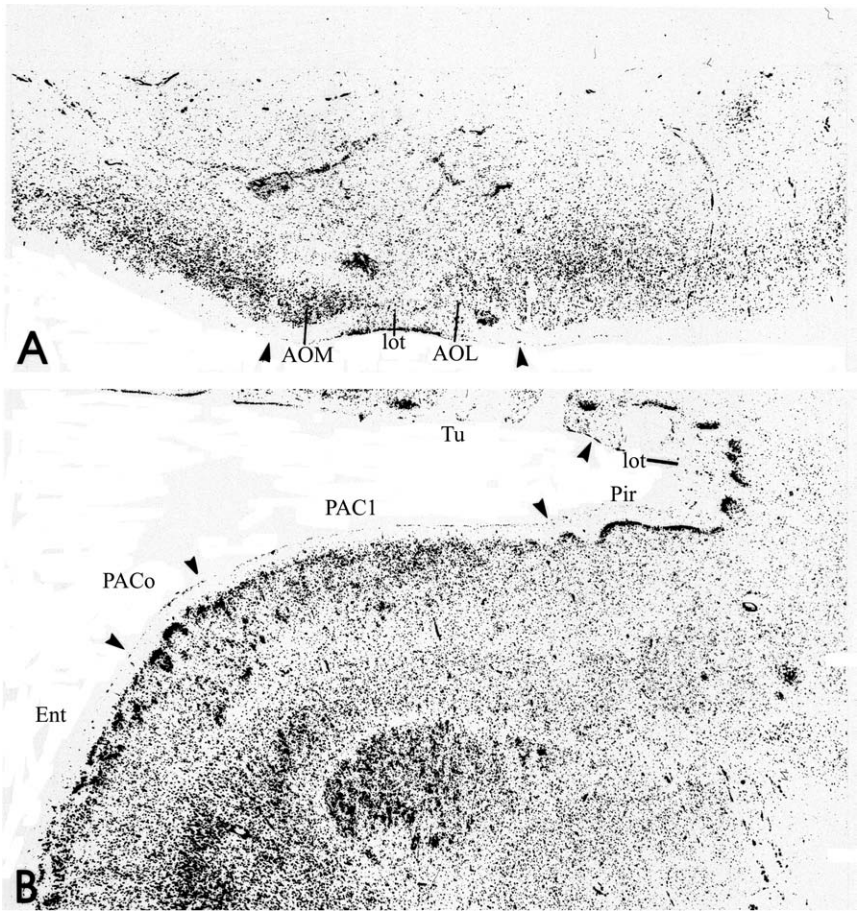

FIGURE 32.5 Photomicrographs of the human primary olfactory cortex. **(A)** The anterior olfactory nucleus, on the posterior orbital surface, just caudal to the point where the olfactory peduncle joins the frontal cortex. **(B)** The olfactory areas around the point of junction between frontal and temporal lobes. rostral to the "pyriform lobule" in carnivores. This designation is not descriptive in most animals, however, and the suffix "pre" has been dropped. In both monkeys and humans, the piriform cortex is situated deep and lateral to the lateral olfactory tract, from the caudolateral aspect of the frontal lobe, around the limen insulae, to the rostral dorsomedial aspect of the temporal lobe (Figs. 32.3 and 32.4). The piriform cortex is characterized by a densely packed layer II composed of moderately large pyramidal cell somata and a less dense layer III of slightly larger pyramidal cells and other neurons (Fig. 32.5). Layer II is found throughout the piriform cortex, but layer III is only well developed in the caudal part of the cortex. In monkeys, layer II is thick and prominent, but in humans layer II is relatively thin, and the boundaries of the cortex are not as distinct. Deep to the cortex, a ventral continuation of the claustrum forms the endopiriform nucleus. There is little data on this nucleus in primates, but in rodents it is closely interonnected with the overlying piriform cortex.

Axon collaterals leave the deep and lateral aspects of the lateral olfactory tract and terminate primarily on apical dendrites in the superficial part of layer I. In monkeys, although not in rodents or carnivores, a few fibers from the olfactory bulb also ramify in deeper layers. As discussed later, the piriform cortex gives rise to a substantial association fiber system that extends throughout all parts of the primary olfactory cortex.

Anterior Cortical Nucleus of the Amygdala and Periamygdaloid Cortex

Caudal and lateral to the piriform cortex, the axons from the olfactory bulb continue into several small areas on the medial surface of the amygdala (Figs. 32.3 and 32.4). The anterior cortical amygdaloid nucleus is

directly caudal to the piriform cortex and is characterized by a relatively loosely packed layer II and even more diffuse layer III. The periamygdaloid cortex is a larger area located ventrolateral to the piriform cortex. It is markedly heterogeneous and, in monkeys and humans, can be divided into five subdivisions—PAC_O, PAC_1, PAC_2, PAC_3, and PAC_S, based on architectonic differences (Price *et al.*, 1987; Amaral *et al.*, 1992; Carmichael *et al.*, 1994). All but the most caudal of these (PAC_S) receive input from the olfactory bulb in monkeys, although the layer of axons is thick only in PAC_O, and is quite thin in PAC_1, PAC_2, and PAC_3.

Rostral, "Olfactory" Entorhinal Cortex

In rodents and carnivores, a large fraction of the entorhinal cortex receives fibers directly from the olfactory bulb (e.g., Boeijinga and Van Groen, 1984; Price, 1973). In monkeys, however, olfactory bulb input is limited to a small "olfactory" zone at the rostral edge of the entorhinal cortex (Amaral *et al.*, 1987; Carmichael *et al.*, 1994; Figs. 32.3 and 32.4). Even in this region, the olfactory projection is relatively slight, both in density, and in the thickness of the superficial lamina in layer I in which the fibers end. EOl is characterized by a distinct but thin layer II, which is broken up into cell islands, as in other parts of the entorhinal cortex. The deeper layers are thicker and more complex than in other olfactory cortical areas, but less well developed than in other regions of the entorhinal cortex.

Accessory Olfactory Cortical Areas

Although humans lack an accessory olfactory bulb, the major target of the accessory olfactory tract in other animals, the medial amygdaloid nucleus, is present in humans. The medial nucleus is situated immediately caudal to the anterior cortical amygdaloid nucleus but has a slightly denser cellular layer II. In rodents, this nucleus has been shown to be involved in mating behavior and a variety of other related functions (Newman, 1999). Presumably, the medial amygdaloid nucleus may have similar functions in humans, but these may not be as strongly modulated by olfactory stimuli.

Centrifugal Projections to the Olfactory Bulb

All the olfactory cortical areas except the olfactory tubercle send fibers back to the olfactory bulb (Haberly, 1985; Price, 1987; Carmichael *et al.*, 1994). These fibers arise from cells in layers II and III of the cortex and end primarily in the granule cell layer of the olfactory bulb. The projection from the anterior olfactory nucleus and (in monkeys) the anterior part of the piriform cortex is bilateral, with fibers crossing in the anterior commissure. In addition, a thin "external" part of the anterior olfactory nucleus just deep to the most rostral part of the lateral olfactory tract projects solely or (in monkeys) primarily to the contralateral olfactory bulb.

There is also a substantial fiber projection from the nucleus of the diagonal band to the olfactory bulb (Mesulam *et al.*, 1983; Carmichael and Price, 1994). Although this fiber system is partially cholinergic, only about 10% of the cells stain for acetylcholinesterase (Mesulam *et al.*, 1983). In rats, other cells in the nucleus that project to the olfacotory bulb have been shown to be GABAergic (Zaborsky *et al.*, 1985).

Intracortical Associational Fiber System

Experimental studies in many mammals, including monkeys, have indicated that the "primary" olfactory cortex is organized in a very different way than other primary sensory cortices. In particular, there is an extensive system of intracortical connections with the primary olfactory cortex (e.g., Haberly, 1985; Price, 1973; Luskin and Price, 1983; Carmichael *et al.*, 1994; Johnson *et al.*, 2000). This system suggests that the olfactory cortex functions as a correlative region, comparable to a higher order "association" cortex in other sensory systems.

The greatest number of association fibers arises in the piriform cortex, but fibers originate in all of the olfactory cortical areas except the olfactory tubercle. The fibers are distributed throughout the olfactory cortex and to adjacent orbital and agranular insular areas. In rats, at least, individual neurons in the piriform cortex have axons that extend into all or most of these areas (Johnson *et al.*, 2000). Within the olfactory cortex itself, the association fibers terminate primarily in the deep part of layer I and in layer III. This laminar pattern of termination is complementary to the termination of the fibers from the olfactory bulb in the superficial part of layer I. In the tangential dimension of the cortex, there is a broad and relatively complex organization within the association fibers, which has been best defined in rats. Cortical regions near the lateral olfactory tract project to other parts of the olfactory cortex near the tract, while regions distant to the tract tend to project to regions at the edges of the olfactory cortex (Luskin and Price, 1983; Price, 1985; Carmichael *et al.*, 1994).

The association projections from the anterior olfactory nucleus and the anterior part of the piriform cortex also extend to the contralateral olfactory cortex, crossing in the anterior commissure (Luskin and Price, 1983; Carmichael and Price, 1994). The laminar and areal pattern of termination in the contralateral cortex are approximately the same as on the ipsilateral side.

Presumably, the association system interacts with the sensory activity being input to the cortex from the olfactory bulb to support olfactory discrimination. In contrast to the olfactory bulb, neither of these fiber systems has the sort of detailed topographic organization that would be expected if odors were represented in a spatial code. It is possible that cells related to different odors are dispersed in many parts of the cortex, and appropriate bulbar and association fibers synapse on them in a selective manner. It may be more likely, however, that olfactory discrimination depends on a system of spatiotemporal patterning across the cortex, in which adjustments in synaptic strength are built up from sensory experience.

OLFACTORY PROJECTIONS BEYOND THE PRIMARY OLFACTORY CORTEX

Olfactory information is transmitted from the primary olfactory cortex to several other parts of the forebrain, including the orbital cortex, amygdala, hippocampus, ventral striatum, hypothalamus and mediodorsal thalamus (Price, 1987; Russchen *et al.*, 1987; Carmichael *et al.*, 1994). Although these connections have been best studied in rodents, there is also some experimental data from monkeys, and functional imaging studies have recently provided data on humans (see following).

Projections to the Amygdala and Hippocampus

Both the amygdala and hippocampus have often been considered to be closely associated with olfaction, especially in lower animals. In primates, these limbic structures have become dominated by other sensory inputs, especially vision, but they still have direct olfactory connections. These arise primarily in the periamygdaloid cortex and the olfactory part of the entorhinal cortex, which project both to deep amygdaloid nuclei and to several parts of the hippocampus (Price, 1987; Jolkkonen *et al.*, 2001; Chapter 23).

Projections to the Hypothalamus

In rats, both electrophysiological recordings and axonal tracer experiments indicate that there are olfactory inputs to several parts of the hypothalamus (Price, 1985). The most direct projection arises from cells in the deepest layer of the piriform cortex and other olfactory cortical areas. Although the fibers run through the full rostrocaudal extent of the hypothalamus in the medial forebrain bundle, they terminate predominantly in the caudal half of the lateral hypothalamic area. Axons from the anterior cortical nucleus and medial nucleus of the amygdala end in more rostral and medial parts of the hypothalamus.

The olfactory inputs to the hypothalamus have not been as well defined in monkeys. Experiments with retrograde tracer injections in the lateral hypothalamus, however, label neurons in most of the olfactory cortical areas, as well as in related orbital/insular cortical areas (Öngür *et al.*, 1998). Electrophysiological responses to olfactory stimuli have also been recorded in the lateral hypothalamic area in monkeys (Tazawa *et al.*, 1987; Karadi *et al.*, 1989).

Olfactory Projections to the Striatum, Pallidum, and Thalamus

Along with the amygdala, the olfactory cortex projects to the ventral part of the striatum, including the accumbens nucleus and the olfactory tubercle. The olfactory projections are largely restricted to the olfactory tubercle and the caudal, ventrolateral part of the nucleus accumbens (Price, 1973; Luskin and Price, 1983; Fuller *et al.*, 1986; unpublished results in monkeys). These areas project out to the "ventral" pallidum, a continuation of the globus pallidus ventral to the anterior commissure. The major output of the ventral pallidum, in turn, is to the mediodorsal thalamic nucleus. As with the dorsal striato-pallidal-thalamic system, the inputs to the ventral striatum are glutamatergic, but the striatopallidal and pallidothalamic projections are GABAergic (Fuller *et al.*, 1986; Kuroda and Price, 1991).

As in other mammals, both electrophysiological recording and axonal tracing in monkeys also indicate excitatory olfactory input to the mediodorsal thalamic nucleus (MD) from the olfactory cortex (Yarita *et al.*, 1980; Russchen *et al.*, 1987). The neurons that project to MD are primarily located in the deep layers of the piriform cortex and other olfactory cortical areas. There are relatively small numbers of these neurons, and it appears that they may relay convergent activity from a relatively large portion of the olfactory cortex. Within MD in monkeys, fibers from small areas of the olfactory cortex or the amygdala end in small "patches," suggesting that inputs from restricted regions converge onto a few thalamic neurons (Russchen *et al.*, 1987; Ray and Price, 1993). Similarly, olfactory-responsive units are restricted to a relatively small region of the medial, magnocellular part of MD. Compared to the hypothalamus, the olfactory-related units in MD appear to be relatively broadly tuned and respond to many different odors (Yarita *et al.*, 1980).

In addition to MD, anatomical and electrophysiological studies in both rats and monkeys indicate that

there is an olfactory projection to the anteroventral portion of the submedial thalamic nucleus (SM; Price and Slotnick, 1983; Russchen *et al.*, 1987). SM is separated from MD only by the internal medullary lamina, and it may represent a portion of the same nucleus functionally. In rats, the projection to SM arises in a relatively restricted zone at the junction of the piriform cortex and olfactory tubercle (Price and Slotnick, 1983).

The portion of medial MD that receives olfactory input is reciprocally connected with several areas in the posterior orbital cortex and rostral agranular insular cortex (Russchen *et al.*, 1987). The cortical connections of SM are to a more restricted area near the junction of the olfactory peduncle and the frontal lobe (especially area 13a). It might be presumed, therefore, that MD would relay olfactory information to the orbital cortex. As discussed later, however, these same cortical areas receive more numerous, monosynaptic projections directly from the primary olfactory cortex. These corticocortical projections appear to be better suited to relay detailed sensory information. It is likely, therefore, that the transthalamic projection does not represent a sensory relay as such.

Olfactory Projections to Neocortical Areas

In the 1970s and 1980s, Takagi and his colleagues reported that odorant stimuli or electrical stimulation of the olfactory bulb could evoke neuronal responses in the orbital cortex (Tanabe *et al.*, 1975a, b; Yarita *et al.*, 1980; Takagi, 1986). Two areas, in the lateral and central parts of the posterior orbital cortex were identified. In the lateral area, the units were relatively specific, responding to only one or two odorants, whereas in the more central area units responded to several odorants. These studies suggested that the sensory information reached the orbital cortex from the primary olfactory cortex through the hypothalamus and thalamus. There is now clear anatomical evidence in monkeys and other animals, however, that the principal pathway is directly from the primary olfactory cortex to the orbital cortex.

Injections of anterograde axonal tracers in the piriform cortex of monkeys label axons in several areas of the agranular insula/posterior orbital cortex (areas Iam, Iapm, Iai, Ial, 13a, 13m, and 14c; Carmichael *et al.*, 1994; Fig. 32.6). All these cortical areas are agranular or dysgranular, and the areas nearest to the primary olfactory cortex have sometimes been referred to as the periallocortex. The projection is different from more usual sensory inputs to cortex that are relayed through the thalamus because the label is heaviest in layer I. Retrograde axonal tracer injections into the same agranular insula/posterior orbital areas label neurons in many parts of the primary olfactory cortex, including the anterior olfactory nucleus, piriform cortex, anterior cortical amygdaloid nucleus, periamygdaloid cortex, and olfactory part of the entorhinal cortex. The labeled cells are located in both layer II and layer III. Electrical stimulation of the olfactory bulb also evokes unit and field potential responses in most of the areas where there is anatomical evidence of olfactory input (Carmichael *et al.*, 1994).

The projections from the primary olfactory cortex are largely reciprocated by fibers from agranular insula/posterior orbital areas. Anterograde axonal tracer injections into several of the agranular insular areas label axons in the rostral parts of the primary olfactory cortex (Carmichael *et al.*, 1994). These include the olfactory tubercle, which is the only olfactory cortical area that does not project to the orbital cortex.

The agranular insula/orbital cortical areas that receive olfactory input interact with other areas on the orbital surface through corticocortical connections to integrate olfactory sensory information with other sensory modalities (Carmichael and Price, 1995, 1996). Taste information reaches the orbital cortex through the thalamic gustatory relay and the primary gustatory cortex (Chapter 31). The orbital cortex is the first place where olfactory and taste information converge, so it presumably underlies the sensation of flavor, which depends on both of the primary modalities. In addition, there are corticocortical somatosensory and visual inputs to the orbital cortex from the parietal and inferior temporal cortex. The somatosensory inputs appear to be related to the hand and mouth (Carmichael and Price, 1995). The corticocortical connections between orbital areas form an "orbital network" that appears to function in the integration and analysis of food-related sensory information (Carmichael and Price, 1996).

Recordings in the orbital cortex in monkeys show neuronal responses to food and food-related stimuli, including visual stimuli that are associated with food (Rolls, 2000). Importantly, the responses reflect the affective or reward significance of the stimuli as well as their sensory properties. For example, the neuronal response to a particular visual stimulus (e.g., a triangle) will change markedly if the association of the stimulus with a food reward changed. In addition, if the animal is feed to satiety with a food stimulus, the neuronal response to that food will decrease.

Imaging of Olfactory Sensory Activity in Humans

Several studies have used functional imaging methods to identify the human cortical areas activated by olfactory stimuli (see Zald and Pardo, 2000). Odorant-induced responses were first obtained in the

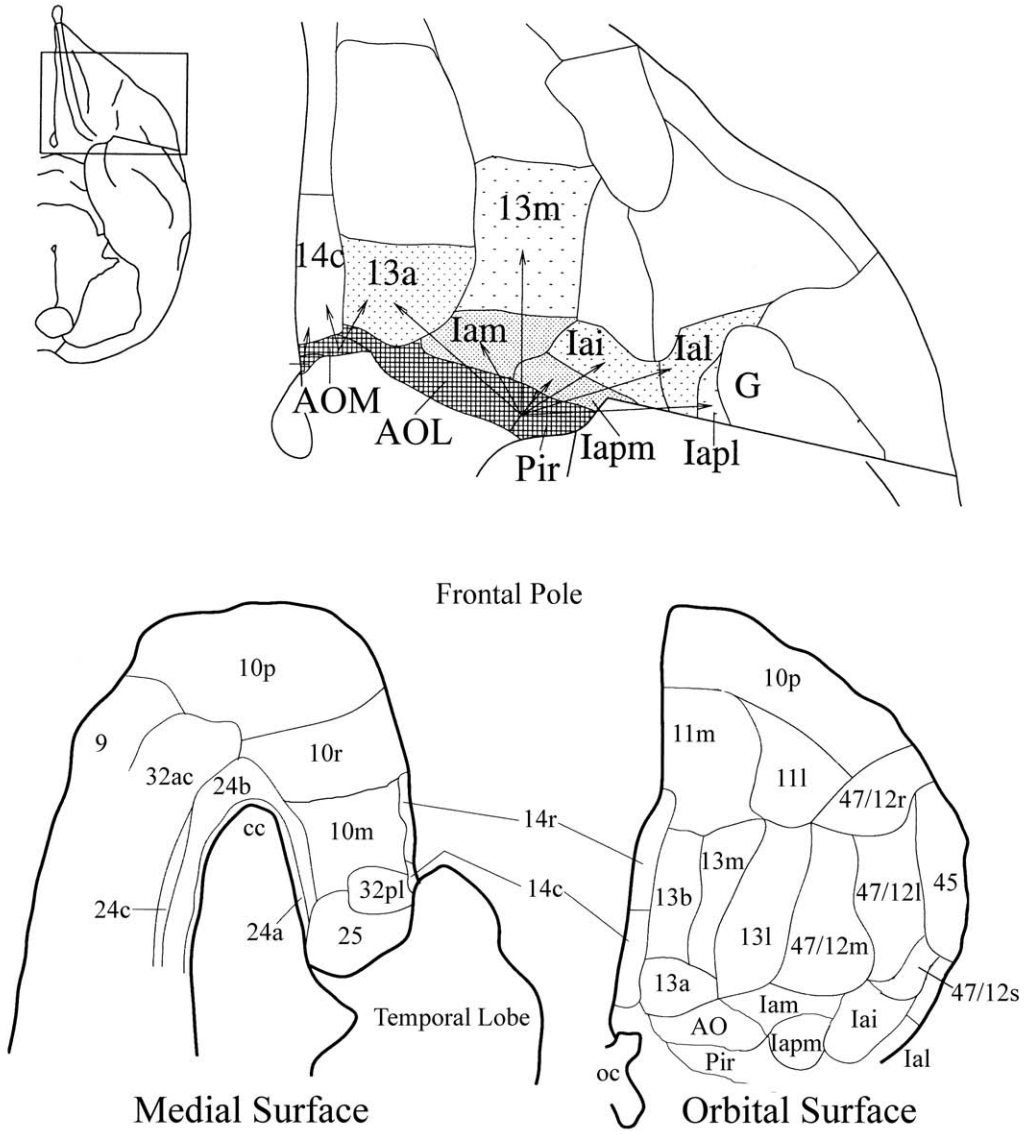

FIGURE 32.6 *Above:* A summary of the projections from the primary olfactory cortex to the agranular insula/posterior orbital cortex in monkeys. *Below:* A map of architectonic areas on the medial and orbital surface of frontal cortex in humans. The areas were delineated by applying the same criteria used to analyze the cortex in monkeys to analyze the human areas. Modified from Carmichael *et al.* (1994) and Öngür and Price (2000).

region of primary cortex by Zatorre *et al.* (1992) and have been confirmed by subsequent reports from the same research group (Small *et al.*, 1997; Dade *et al.*, 1998). Other studies have failed to find substantial activation of primary olfactory areas, however (e.g., Zald and Pardo, 1997; Yousem *et al.*, 1997; Sobel *et al.*, 1998). Several factors may explain the inconsistency. Technical factors such as the "susceptability" artifact related to nearby bone and air sinuses make it difficult to image this region with fMRI. Neuronal responses to odorants in the piriform cortex are also rapidly adapting and may be coded for by temporal or spatial patterns of activity instead of response amplitude. Further, sniff-related activity may mask odorant-related activity (Sobel *et al.*, 1998). When these are taken into account odorant-related activation can be visualized in the primary olfactory cortex (Sobel *et al.*, 2000).

Whether imaging studies did or did not detect activity in the primary olfactory cortex, olfactory-related activity has consistently been detected in the orbital cortex (e.g., Zatorre *et al.*, 1992; Small *et al.*, 1997; Zald and Pardo, 1997; Sobel *et al.*, 2000; Royet

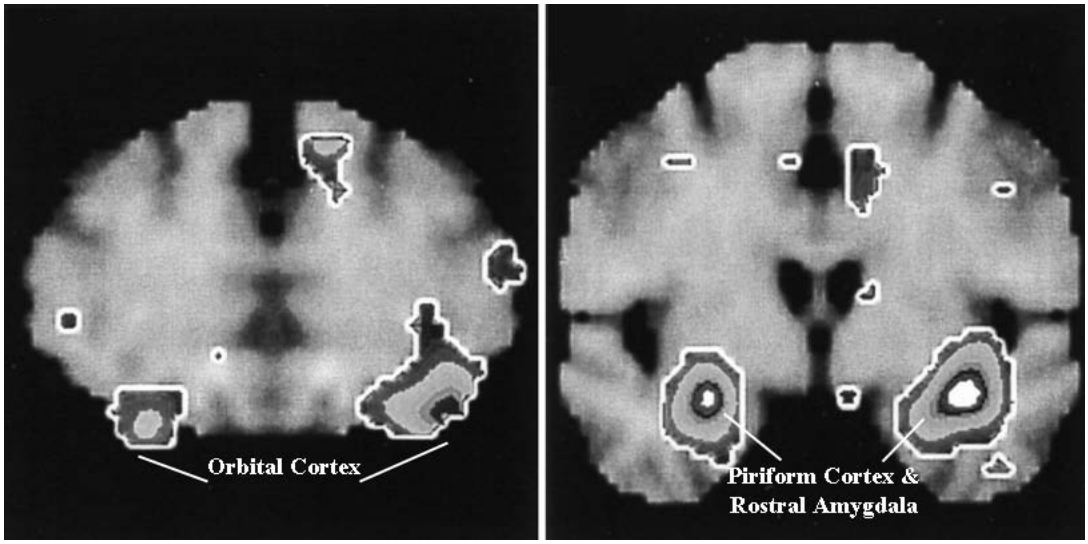

FIGURE 32.7 Cerebral activation (reflected as changes in regional cerebral blood flow) during exposure to aversive olfactory stimuli. On the left an area of activation is shown in the centrolateral orbital cortex, while on the right there is an area of activation in the region of the piriform cortex/anterior amygdala. Modified from Zald and Pardo (1997).

et al., 2001; Fig. 32.7). All these studies found an area of activation in the central orbital cortex, in some cases through the rostral to caudal extent (Sobel *et al.*, 2000). It is not yet possible to identify these areas in terms of the architectonic subdivisions of the orbital cortex, but they appear to correspond to the "orbital network" defined in monkeys (see previous discussion; Carmichael and Price, 1996). Zald and Pardo (1997) also identified an area in the lateral orbital/anterior insular cortex that was activated following stimulation with aversive odors; the region of the amygdala was also activated to the same odors.

The central orbital cortical region that responds to odorants also is activated by taste stimuli (Small *et al.*, 1999). This corresponds well with the anatomical evidence in monkeys that corticocortical interconnections within the orbital cortex relate olfactory and gustatory systems. The responses to simultaneous, matched taste and olfactory stimuli appear to be quantitatively different from both unimodal stimuli alone, suggesting that flavor is not a simple convergence of its component senses (Small *et al.*, 1997). As suggested by recordings in monkeys (see earlier discussion), the olfaction- and taste-related responses in the orbital cortex also depend on hedonic properties of the stimuli. For example, fMRI responses to food-related olfactory stimuli show specific decreases after feeding to satiety with that food (O'Doherty *et al.*, 2000). All together, the evidence indicates that the orbital cortex should be considered as part of a system for analysis of food and food-related stimuli, and more generally for the analysis of reward. It should not be considered as simply secondary olfaction cortex or secondary taste cortex.

Vestibular System

JEAN A. BÜTTNER-ENNEVER and NICOLAAS M. GERRITS

Institute of Anatomy, Ludwig-Maximilian University Munich
Munich, Germany, and
Department of Anatomy, Erasmus University
Rotterdam, The Netherlands

The vestibular complex is the collection of brainstem nuclei in receipt of primary afferents from the labyrinth of the inner ear *(see Koutcherov et al. Chapter 10)*. Long before axonal degeneration and tracer techniques were available, the different nuclei of the vestibular complex were outlined and described in great detail. These early observations started in human material. Later, after the introduction of Weigert's haematoxylin-method for impregnation of myelinated fibers, it became clear that a similar organization could be seen in all vertebrates (Straka *et al.*, 2001, 2002).

The first description of what in later years proved to be the vestibular nuclear complex comes from Clarke (1861), who distinguished on the basis of their fiber content a lateral area ("outer nucleus"), located within Stilling's (1843) juxtarestiform body, and a medial area ("inner nucleus"). Over the years, Clarke's outer nucleus became erroneously known as Meynert's (1871) "innere Abteilung des Kleinhirnstiels": loosely arranged (bundles of) fibers, considered an internal division of the restiform body. Giant cells in the rostral part of the juxtarestiform body were noted and described by Deiters (1865), whose name at present is still linked to this magnocellular nucleus. The caudal part of Clarke's outer nucleus contains characteristic rostrocaudally oriented fiber bundles, which were originally taken for descending acoustic root fibers. As a result of Roller's description (1882) of these fibers, this part of Clarke's outer nucleus was sometimes referred to as Roller's root or nucleus (Fuse, 1912), but more commonly as "spinale Acusticuswurzel" (Leidler, 1916). Its present name is spinal or descending vestibular nucleus and stems from the work of Ramón y Cajal (1896).

Bechterew (1885) traced the ascending branch of the vestibular nerve from the inner ear to a nucleus between the superior cerebellar peduncle and the dorsorostral aspect of Deiters' nucleus. This "angular" nucleus of Bechterew comprises the rostral pole of Clarke's inner nucleus; however, its caudal border has led to some dispute. According to Kohnstamm (1908),

Fuse (1912), and Van der Schueren (1914), the parvocellular region (known today as part of the medial vestibular nucleus), located medial to Von Monakow's (1890) acoustic striae in the lateral wall of the fourth ventricle, should be included in Bechterew's angular nucleus. The magnocellular portion of the medial nucleus, located lateral to the acoustic striae, contains a significant proportion of large cells and has often been included in Deiters' nucleus (Bechterew, 1887; Leidler, 1916; Ramón y Cajal, 1896). However, many authors recognized that this region's location outside the juxtarestiform body and its cytoarchitectonic features set it apart from the area with the giant Deiters' neurons (Fuse, 1912; Kohnstamm, 1908; Lewy, 1910; Sabin, 1897). It has become known under a variety of names, of which "magnocellular part of the medial vestibular nucleus" (Van der Schueren, 1914) seems the most appropriate.

The caudal extent of Clarke's inner nucleus retained for decades the name nucleus triangularis (Schwalbe, 1881). Although Ramón y Cajal (1909) refers to it as the dorsal or principal nucleus, it is known at present as the medial vestibular nucleus.

Since the turn of the century, the description and delimitation of the vestibular nuclei have not undergone significant changes. We still recognize the four "classical" components: the superior (Bechterew), lateral (Deiters), spinal or descending (Ramón y Cajal), and medial vestibular nucleus. Naturally, the elaboration of histological and axonal tracing techniques has provided more detailed understanding of the connections of the vestibular nuclei as well as the recognition of various subnuclei.

The subdivisions of the vestibular nuclei as used in this chapter largely correspond to those proposed by Brodal and Pompeiano (1957), Voogd (1964), and Gerrits *et al.* (1985b) for the cat; Van Rossum (1969) and Epema *et al*. (1988) for the rabbit; and Sadjadpour and Brodal (1968), Olszewski and Baxter (1982), and Suarez *et al*. (1997) for humans.

TOPOGRAPHY AND CYTOARCHITECTURE

Superior Vestibular Nucleus

The area with predominantly intermediate-sized cells, located dorsomedial to Deiters' nucleus, was first described by Bechterew (1885) and was subsequently referred to as the "angular nucleus of Bechterew" (Fuse, 1912; Jacobsohn, 1909). For unknown reasons Gray (1926) renamed it the superior vestibular nucleus (SuVe).

The SuVe is present in the lateral wall of the fourth ventricle (Fig. 33.1 and 33.4A, D; Paxinos and Huang, 1995, Figs. 29–36; Paxinos *et al.,* 2000, Figs. 98–107). Rostrally, at the level of the rostral pole of the principal sensory trigeminal nucleus, it flattens and is bordered by the parabrachial nuclei. At this level, SuVe is capped by the mesencephalic trigeminal tract (me5) and nucleus (Me5). Caudally SuVe tapers off and blends with group Y. Over most of its extent, SuVe is bordered dorsally by the superior cerebellar peduncle (scp). Laterally it is bordered by the juxtarestiform body, in which the giant Deiters' neurons are embedded. Sadjadpour and Brodal (1968) describe a ventral protrusion of the caudal part of SuVe into the lateral vestibular nucleus (LVe), but this view is not supported in the present study. Caudal to the facial nerve, SuVe is situated dorsal to the medial vestibular nucleus (MVe). It is difficult to distinguish SuVe from the parvocellular (MVpc) subdivision on cytoarchitectonic features alone.

The SuVe is characterized by the passage of a considerable number of fibers of presumably cerebellofugal nature. Corticovestibular fibers curve through the dorsal and lateral margin of SuVe and collect ventrally as bundles of the juxtarestiform body. Direct fastigiobulbar fibers form a rather compact bundle close to the ventricular surface and fan out ventrally through the rostral pole of MVpc. The most conspicious fiber system is present in the rostral part of the nucleus. Fibers with a presumed origin in ventral LVe, MVmc, and ventral SuVe suddenly change their course and run in the direction of the ventricle (Fig. 33.1A, planes 1, 2, 2B). They collect at the border between the reticular formation and the ventricular gray matter (Fig. 33.1A, planes1, 2; Fig. 33.2A) and join the medial longitudinal fascicle (mlf) in more rostral levels. These fibers were described by Winkler (1909) and Muskens (1913–14) as the "ascending tract of Deiters" (atd) see also introduction to this chapter).

Basically the topography of the human SuVe is not unlike the homologous structure in other mammals such as the rabbit (Epema *et al.,* 1988) and the cat (Brodal and Pompeiano, 1957; Gerrits *et al.,* 1985b). The largest difference is found in its rostral part. In most mammals, the initial segment of the superior cerebellar peduncle has a horizontal position, and SuVe envelops its lateral margin. In humans, the cerebellar peduncles are "pressed together" and leave no room for such lateral extension of SuVe.

The neurons of SuVe nucleus are small to medium sized (Fig. 33.3A), with cell size increasing from caudal to rostral (Suarez *et al.,* 1997). In primates, the medium-sized neurons form a central core with a small cells around the periphery, but the separation of the two

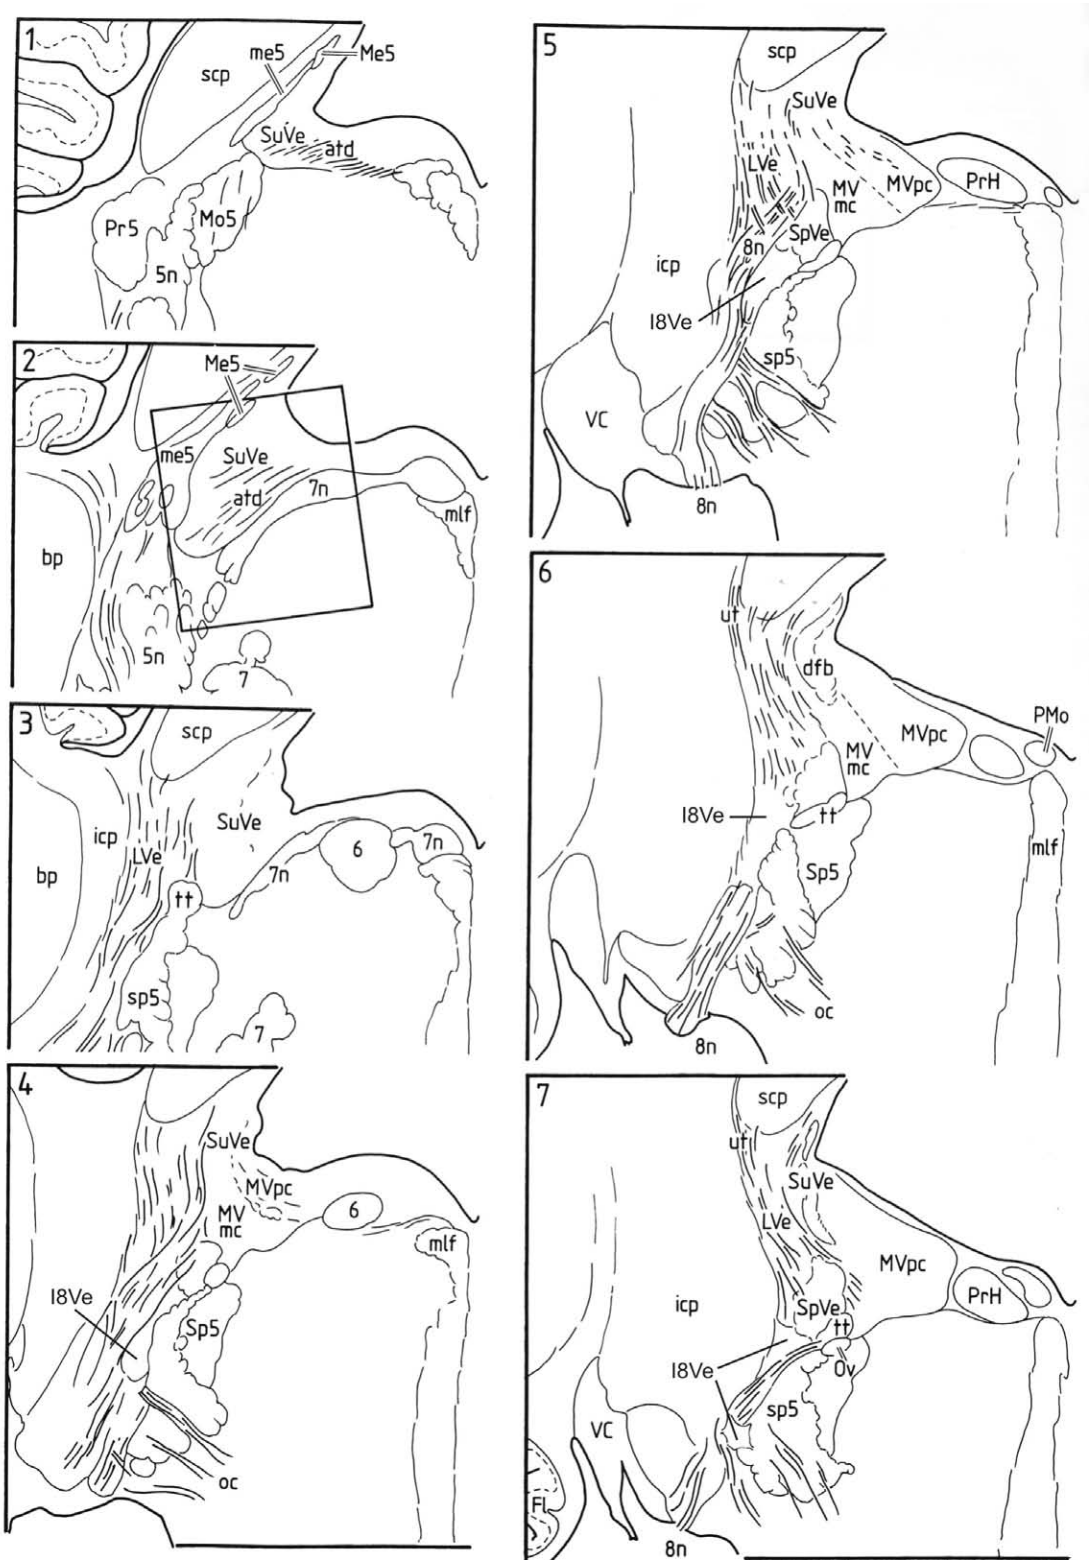

FIGURE 33.1 Drawings of equally spaced transverse levels (i.e., perpendicular to the long axis of the brainstem) through the left-sided human vestibular complex (interval 0.6 mm) based on 24-μm Klüver-Barrera stained frozen sections. The drawings are numbered in ascending order from rostral to caudal. Fibers running in the plane of sectioning are indicated with coarse lines, when cut across they are not indicated. The boxed area is illustrated in Figure 33.2. tt trigeminaothalamic (Wallenberg's) tract; Ov Nucleus ovalis; dfb direct fastigio-bulbar tract; ut uncinate tract. *Continued*

types is less pronounced than that described in the rabbit (Epema *et al.*, 1988) and in the cat (Gacek, 1969). Some medium-sized neurons within the SuVe are glutamate decarboxylase (GAD) immunoreactive presumably representing the inhibitory secondary vestibulooculomotor neurons of the vertical system (Fig. 33.4B; Wentzel *et al.*, 1995; Holstein, 2000).

Group Y

Brodal and Pompeiano (1957) described in the cat small cells located dorsolateral to Deiters' nucleus, capping the restiform body, which they named group Y. But much earlier than this in his description of the human brainstem, Jacobsohn (1909) described the caudal part of group Y under the name "nucleus marginalis corporis restiformis" and indicated its apparent continuity in the lateral direction with Essick's (1907) corpus pontobulbare.

Neither Sadjadpour and Brodal (1968) nor Suarez *et al.* (1997) in their study of the human vestibular nuclei were able to distinguish a group Y. However, we have identified it in the human brains we analyzed and found that its position is almost identical to that in other mammals. Riding on the caudal slope of the inferior cerebellar peduncle (icp), it does not extend far rostrally since in humans, unlike most mammals, the icp surges upwards into the cerebellum the moment the cerebellum and brainstem touch each other (Fig. 33.1B, planes 9, 10,11; Fig. 33.4G; Paxinos and Huang, 1995, Figs. 27–30; Paxinos *et al.*, 2000; Figs. 107–110). Rostrodorsally, group Y is bordered by the fiber bundles in the ventral aspect of the floccular peduncle and abuts on the icp. At the medial side of the icp, it merges with the caudal part of SuVe. Caudally, the cells of group Y can be distinguished from the somewhat larger and more rounded neurons of the cochlear nuclei, and group Y is separated from the dorsal surface of the icp by the acoustic striae (das). Its cells spread medially over the dorsal surface of the spinal vestibular nucleus (SpVe) and MVc. It is possible that the neurons described by (Olszewski and Baxter, 1982) and Sadjadpour and Brodal (1968) as nucleus supravestibularis form the caudalmost part of group Y.

Group Y is well developed in most mammals. Mehler and Rubertone (1985) and Voogd *et al.* (1985) noted that the term "group Y" has been used to indicate two differing cell groups in both cat and monkey. They reserved the name group Y for the more ventrally lying compact group of small cells located in the floor of the lateral recess, continuous with the dorsolateral part of SuVe. The dorsal division is located within the floccular peduncle (pFl) and contains larger cells, some spindle-shaped (Figs. 33.3G; 33.4G). It is called the infracerebellar nucleus (Inf) by Gacek (1977), who demonstrated that group Y receives saccular afferents from the vestibular nerve, whereas Inf does not. Furthermore, only the Inf projects to the oculomotor nucleus (Sato and Kawasaki, 1987). Numerous medium-sized neurons within the Inf +Y group contain the calcium-binding protein calretinin (Fig. 33.4H), and medium-sized neurons can be seen in

Fig. 33.4I as GAD-immunoreactive, confirming the inhibitory GABAergic nature of some of these neurons (see "Oculomotor Nuclei Connections"; Kevetter, 1996; Partsalis and Highstein 1996).

Medial Vestibular Nucleus

The medial vestibular nucleus (MVe) is the largest within the vestibular complex and has the greatest number of neurons (Suarez *et al*., 1997). In their description of the vestibular complex in the rabbit, Epema *et al*. (1988) suggest that the MVe should be divided into three parts: a parvocellular (MVpc), a magnocellular (MVmc), and a caudal (MVc) section. In the present study, an attempt is made to apply this tripartition to the human brainstem. In rabbits and cats, the border between MVmc and MVpc is clearly emphasized by the acoustic striae (das), because the das traverse the vestibular complex as a rather compact

bundle. In humans, however, this border is less clear because the das are loosely arranged and have a relatively caudal position in the vestibular complex owing to the strong development of icp.

Parvocellular Medial Vestibular Nucleus

The MVpc commences at the caudal pole of SuVe and continues in a caudal direction along the ventrolateral wall of the fourth ventricle (Figs. 33.1; 33.4A, D; Paxinos and Huang, 1995; Figs. 30–33; Paxinos *et al.*, 2000, Figs. 98–110). Its rostral aspect is characterized by small bundles of cerebellofugal fibers, which have descended through SuVe. The neurons are smaller than those in MVmc (Fig. 33.3B, C) caudally, the size of its neurons increases although, until MVe abuts on the dorsal column nuclei, no obvious cytoarchitectonic border is present. The glossopharyngeal nerve (9n) is taken as a landmark for the (artificial) border between MVpc and MVc, where most fibers of the juxtarestiform body have converged into the descending bundles of spinal vestibular nucleus (Fig. 33.1, planes 1–8). Rostral to 9n MVpc is, on its lateral side, accompanied by MVmc. Ventrally MVpc is bordered by the facial nerve (7n) and caudally by the dorsal reticular formation. Caudomedially it abuts on the abducens nucleus (6N) and the rostral pole of the prepositus hypoglossal nucleus (PrH), and it contains the cell group described as "the marginal zone" ("Prepositus Hypoglossus Nucleus Connections," PrH).

Magnocellular Medial Vestibular Nucleus

The early students of the vestibular complex noted the presence of an area with large neurons (in addition to medium-sized and small ones) in the rostral part of Clarke's inner nucleus. This area lies ventromedially to the part of the juxtarestiform body that contains the giant Deiters' neurons and is separated from MVpc in the wall of the fourth ventricle by the fiber bundles of the acoustic striae (das). In humans, these parvocellular and magnocellular regions are not as clearly separated by the das fibers, and the area with large neurons is present over a larger dorsoventral extent along the medial margin of the juxtarestiform body (Fig. 33.1). The caudal border is at the level of the glossopharyngeal nerve (9n). The MVmc contains neurons of various diameters; the largest ones are similar to the large neurons between the fiber bundles of the spinal vestibular nucleus and differ clearly from the typical Deiters' neurons, which most frequently have an excentric nucleus (Fig. 33.3C, D, F). The MVmc provides the main output pathways of the nucleus, which project for example directly to the oculomotor neurons and form the second neuron of the VOR; for a review see (Büttner-Ennever (1992b).

All parts of MVe have a high level of acetylcholinesterase (AChE) activity in their neuropil, while this is absent in the lateral vestibular nucleus (Epema *et al.*, 1988; Paxinos and Huang, 1995; Figs. 28, 30, 32; Paxinos *et al.*, 2000, Figs. 101, 103, 105). The ventral part of MVe delineated by Paxinos and Watson (1986) in the rat corresponds well with MVmc in humans. In the rat, the AChE reactivity of MVmc is less than that of MVpc, but the AChE reactivity is still greater than in the nearly negative lateral vestibular nucleus. Choline acetyltransferase (Chat)-immunostained neurons of various sizes are present throughout the MVe being most numerous in the caudal part (Carpenter *et al.*, 1987b; Barmack, 2000). Strong cell body and neuropil labeling is seen with parvalbumin-antibodies in the MVe, whereas calretinin labels small neurons within the MVpc and scattered medium-sized or large neurons laterally (Fig. 33.4F; Kevetter, 1996). In the monkey, GABA-immunoreactive neurons were found in the MVpc and MVmc, some of which provide commissural inhibitory connections (Holstein, 2000; Holstein *et al.*, 1999).

Caudal Medial Vestibular Nucleus

To create a clear distinction between MVmc and MVpc in the rabbit, Epema *et al.* (1988) introduced the name "caudal medial nucleus" (MVc) for the part of MVe caudal to the facial genu. In humans, the point of transition is suggested more caudally at the level of the glossopharyngeal nerve (9n) (Fig. 33.1). The MVc contains small to medium-sized neurons, and the largest ones are located in the center of the nucleus. Caudally, MVc is accompanied at its lateral side by the spinal vestibular nucleus (SpVe) and its characteristic fiber bundles. Over most of its length, it is bordered ventrally by the solitary tract (sol) and its nucleus (SOL) (Fig. 33.1, planes 8–14). Caudally, SpVe and MVc diminish, and their place is taken by the rostral poles of the (internal) cuneate and gracile nuclei. The function of MVc is not known; it is not associated with the variety of vestibular-oculomotor–related activity found in the rostral third of the vestibular complex in behaving primates. It does receive otolith afferents (see later), and a small region in MVc, called nucleus parasolitarius, provides a GABAergic pathway to the inferior olive, which is its only source of otolith input (Barmack *et al.*, 1998).

Lateral Vestibular Nucleus

Deiters' (1865) description of the presence of giant neurons in the rostral part of the juxtarestiform body has resulted in almost as many interpretations of the

borders as there are students of the nucleus. In humans, LVe probably contains the largest neurons of the whole vestibular complex (Suarez *et al.*, 1997), but the difference in size between the Deiters' neurons and the largest neurons in neighboring structures (i.e., MVmc, SpVe, I8Ve) is smaller than, for instance, in cats and rabbits. In humans, the typical Deiters' neurons with their rather excentric nuclei (Fig. 33.3D) are confined to the rostral part of the juxtarestiform body, which is characterized by fibers running in small bundles in a dorsoventral (or vice versa) direction. This area abuts rostrally on the trigeminal nerve and its various nuclei and is easy to distinguish: the medially located SuVe, which does not contain large neurons at its most rostral levels; the MVmc, which has a much lower content of myelinated fibers, at its caudal levels; and the SpVe (ventral to LVe), which is characterized by longitudinally oriented fiber bundles. The largest neurons in MVmc and SpVe are rounder and smaller than those in LVe (Fig. 33.3C, F). Over most of its length, LVe is bordered ventrally not only by SpVe but also by the vestibular nerve and its interstitial nucleus (I8Ve, see "Interstitial Nucleus of the Vestibular Nerve"; Paxinos and Huang, 1995, Figs. 30–33; Paxinos *et al.*, 2000, Figs. 99–106).

The strong development of the human inferior cerebellar peduncle and brachium pontis (bp) relative to the homologous structures in other mammals leads to a "disturbance" of the topographic relations in the region of LVe and the entering root fibers. The LVe is "pushed" further medially than in most animals; consequently, the nucleus stretches over a larger dorsoventral extent along icp. Therefore some caution is required in the interpretation of the cytoarchitectonic data; since some of the neurons between the entering root fibers, as well as the unusual giant neurons in SpVE or MVmc, may turn out to be Deiters' neurons functionally.

The present description of the extent of LVe departs considerably from the studies of Sadjadpour and Brodal (1968), Olszewski and Baxter (1982), and Suarez *et al.* (1997) in humans; Brodal and Pompeiano (1957) in the cat, and Meessen and Olszewski (1949) in the rabbit because these authors did not recognize the differences between MVmc and LVe. The LVe receives very few primary afferent from the labyrinthine canals; the majority appear to arise from the sacculus (Imagawa *et al.*, 1998). It is has reciprocal connections with the cerebellum and is the source of the lateral vestibulospinal tract (Fig. 33.6; "Spinal Cord Connections"; Holstege, 1988). The LVe receives a strong supply from GABA-immunoreactive terminals, which in part arise from Purkinje cells of the cerebellum (Fig., 4E; Walberg and Jansen, 1961; Walberg *et al.*, 1990).

Interstitial Nucleus of the Vestibular Nerve

Ramón y Cajal (1896) described clusters of large neurons embedded in the vestibular nerve as its "noyau interstiel." Many of these neurons are very large, especially in humans (Figs. 33.3E and 33.4A) and suggest a relation with the Deiters' neurons in LVe (Fuse, 1912; Jacobsohn, 1909). To reach the vestibular complex, the vestibular nerve in humans passes between the dorsolateral aspect of the spinal trigeminal root (sp5) and the inferior cerebellar peduncle (icp). In doing so, most root fibers curve around a large area ventrolateral to LVe and to the rostral SpVe (Figs. 33.1 and 33.4). This area has no equivalent in rabbits and cats and contains some small, but mostly medium-sized and large, neurons, while some vestibular nerve fibers can be seen entering it. The absence of juxtarestiform fibers sets it clearly apart from LVe and SpVe. This area is considered as the main part of I8Ve, although the continuity with cell clusters in more distal parts of the vestibular nerve is difficult to establish. Neurons of the I8Ve are parvalbumin-immunoreactive (Fig. 33.4C). The vestibular nerve contains numerous parvalbumin-, calretinin-, and calbindin-positive fibers, which may be involved in different functions (Kevetter and Leonard, 1997).

On the basis of retrograde degeneration experiments in the cat, Brodal and Pompeiano (1957) reported that the connections of the neurons of the interstitial nucleus of the vestibular nerve (I8Ve) were similar to those of Deiters' neurons, based on retrograde degeneration experiments (Brodal and Pompeiano, 1958; Brodal and Torvik, 1957). However, retrograde transport of HRP has demonstrated that the connections of the two nuclei differ. There are descriptions of I8Ve commissural vestibular projections (Epema *et al.*, 1988; Pompeiano *et al.*, 1978), intrinsic vestibular (Epema *et al.*, 1988; Ladpli and Brodal, 1968), and cerebellar projections (Epema *et al.*, 1990; Kotchabhakdi and Walberg, 1978), in particular to the flocculus (Langer *et al.*, 1985a). More recent studies show that I8Ve receives afferents from canal afferents (Gacek, 1969), but no otolith inputs have been seen (Imagawa *et al.*, 1995, 1998).

Spinal Vestibular Nucleus

The spinal vestibular nucleus was referred to earlier as (the nucleus of) the spinal root of the vestibular nerve. In 1896 it was renamed the descending vestibular nucleus by Ramón y Cajal, but the earlier descriptions deserve credit for pointing at the charactistic feature of SpVe: its longitudinally oriented fiber bundles. Whereas the central and dorsal parts of the nucleus are

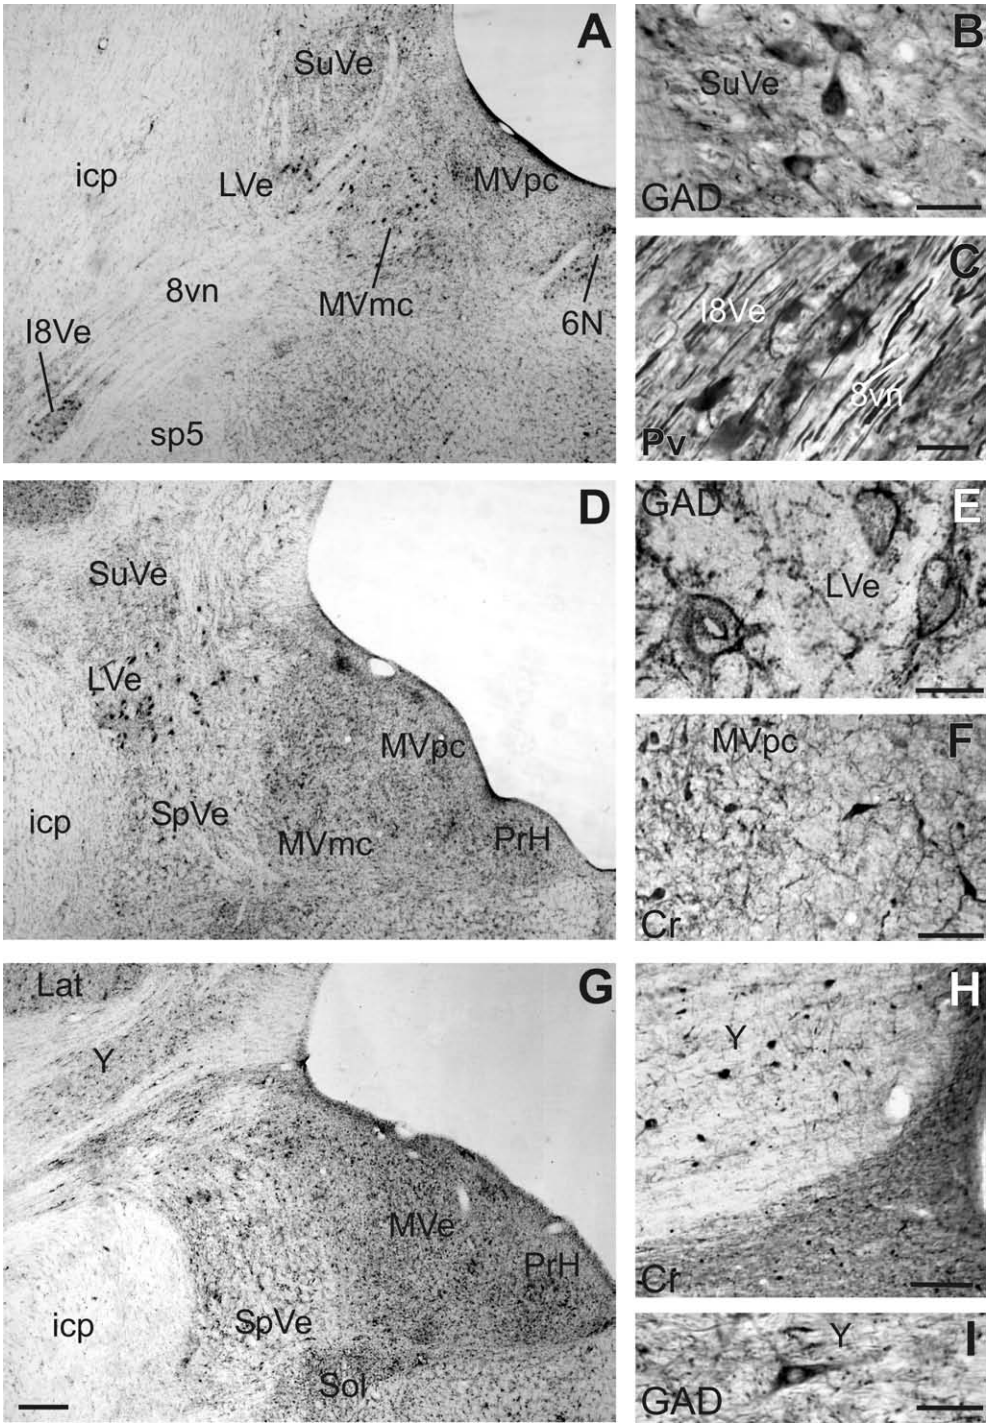

FIGURE 33.4 **(A, D, G)** Low-power microphotographs of frontal sections through the caudal brainstem of a macaque monkey to demonstrate the anatomical location of the vestibular nuclei. **(B, C, E, F, H, I)** High-power microphotographs to show histochemical properties of individual cells within the vestibular nuclei. **(B)** Medium-sized neurons within the superior vestibular nuclei (SuVe) are glutamate decarboxylase (GAD)-immunoreactive. **(C)** Many neurons of the interstitial nucleus of the vestibular nerve (I8Ve) contain parvalbumin (Pv) as most of the vestibular nerve (8vn) fibers. **(E)** The large Deiter's cells within the lateral vestibular nucleus (LVe) receive a very strong input from GAD-positive synaptic boutons. **(F)** Numerous small-sized neurons within the parvocellular medial vestibular nucleus (MVpc) are calretinin (Cr)-positive, medially bordered by a region containing scattered larger Cr-positve neurons; the dorsal part of group Y contain calretinin (H) and GAD (I). A, D, G calibration bar = 500 μm; B, C, E, I calibration bar = 50 μm; F, calibration bar = 100 μm; H, calibration bar = 200 μm.

rather "open," the organization of the fiber bundles becomes more compact toward its periphery. This nucleus has on average the smallest cells of the vestibular complex (Suarez *et al.*, 1997).

Over almost its entire length, SpVe is bordered laterally by the inferior cerebellar peduncle (Fig. 33.1B, planes 9–13; Paxinos and Huang, 1995; Figs. 21–31; Paxinos *et al.*, Figs. 101–118). A precise border between SpVe and icp is difficult to draw, because of the dense packing of the fiber bundles. Toward its caudal extreme, SpVe becomes separated from icp, first by group X and later by the external cuneate nucleus (ECu). The medial border of SpVe with MVc is sharp. The rostral pole of SpVe is easy to delineate from LVe because the fiber bundles of SpVe are longitudinally oriented, whereas LVe has transversely oriented fibers (Fig. 33.4D, G). The ventral border of SpVe is formed at rostral levels by the spinal trigeminal tract (sp5) and the trigeminothalamic fibers (tt) of Wallenberg's tract. Caudal from the level of the glossopharyngeal nerve (9n), SpVe is bordered ventrally by sp5, the solitary tract, and the solitary nucleus (Fig. 33.1, planes 9, 10; Fig. 33.4G). The nucleus ovalis (Ov) of Olzsewski and Baxter (1982), which is associated with SOL, is clearly visible at these levels. More caudally, where the Sp5 shifts lateralward, a loosely arranged cell group that may represent part of the repagulum cuneati of Braak (1971) lies between SpVe and the dorsal reticular formation (Fig. 33.1B, planes 11, 12). At the caudal tip of SpVe, olivocerebellar fibers (oc) enter through the gap between SOL and ECu.

The opinion that the fiber bundles in SpVe were composed of descending vestibular root fibers has never been rejected clearly, although Brodal and Pompeiano (1957) and Sadjadpour and Brodal (1968) suggest a contribution of cerebellofugal elements. Studies with anterograde axonal tracing in the rabbit in our laboratory have provided evidence that descending vestibular root fibers are almost exclusively present between the bundles. However, the bundles themselves are composed of fibers of the uncinate tract originating in the contralateral fastigial nucleus of the cerebellum, direct corticovestibular fibers from the flocculus and the uvula and nodulus of the caudal cerebellar vermis, and olivocerebellar climbing fibers (Gerrits, 1990, Fig. 5).

"Associated" Cell Groups

In their subdivision of the vestibular nuclei of the cat, Brodal and Pompeiano (1957) described a number of cell groups that do not receive afferents from the vestibular nerve (Walberg *et al.*, 1958; Brodal, 1984; Suarez *et al.*, 1997). For this reason alone, these cell groups should not be considered as part of the vestibular complex. To consider these cell groups as belonging to the vestibular nuclei on the basis of a spatial similarity rather than afferent inputs distorts the accepted definition of the vestibular nuclei (i.e., those in receipt of labyrinthine afferents; Brodal, 1974). Although Sadjadpour and Brodal (1968) described the groups F, G, and Z in the human brain, these groups could not be identified with certainty in the present study.

Group X of Brodal and Pompeiano (1957) is located between the ventrolateral caudal pole of SpVe and icp in the cat and the rabbit (Epema *et al.*, 1988). In humans, group X is located in the dorsolateral corner of SpVe, an area that contains only a few fiber bundles (Sadjadpour and Brodal, 1968; Suarez *et al.*, 1997; Paxinos and Huang, 1995, Figs. 25–27). As in the rabbit and the cat, the transition area between the rostral pole of the external cuneate nucleus (ECu) and SpVe contains neurons that are intermediate in size between those in the bordering nuclei and are considered here as group X (Fig. 33.1, planes 11,12). Although longitudinally oriented fiber bundles are present, a multitude of fibers in between give this area a fuzzy appearance.

CONNECTIONS

The vestibular nuclei are a sensorimotor complex that senses the movement and position of the head in space. Signals are generated in the labyrinth of the inner ear; the three canals responding to angular acceleration of the head, and the two otolith organs, the sacculus and the utricle responding to linear acceleration, including gravity. The information is conducted to the vestibular complex via the eighth cranial nerve and used to make compensatory eye and head movements as well as postural adjustments (Cohen, 1974). Hence, there are strong interconnections between the vestibular nuclei and the oculomotor system (see Chapter 16), to the spinal cord (see Chapter 8) and the cerebellum (see Chapter 11). There are several recent reviews of the afferent and efferent connections of the vestibular nuclei (Brodal, 1984; Carpenter, 1988; Highstein and McCrea, 1988; Cohen *et al.*, 1996; Voogd *et al.*, 1996; Büttner-Ennever, 1999, 2000; Graf *et al.*, 2002).

Vestibular Nerve Connections

Experimental studies in rabbits led to the recognition that the eighth cranial nerve is related to both the cochlea and the labyrinth (Forel, 1907; Onufrowicz, 1885). Bechterew (1887) showed in fetal human brain that the myelinization of the vestibular fibers in the

eighth nerve precedes that of the acoustic fibers. The individual character of both components was definitely proved by the experiments of Von Monakow (1890) who demonstrated the termination of the acoustic nerve in the acoustic tubercle, which in turn projects to the inferior colliculus by way of the acoustic striae.

The vestibular primary afferents are bipolar neurons with their cell bodies in the ganglion of Scarpa and utilize glutamate as a transmitter (Reichenberger *et al.*, 1997; Straka *et al.*, 1999). Golgi stains, and later tract tracing studies, have all demonstrated that the primary vestibular afferents enter the brainstem at the level of the Lve and divide into two branches, an ascending and a descending branch (Sato *et al.*, 1989; Hauglie-Hanssen, 1968; Lorente de Nó, 1933; Ramón y Cajal, 1909). The ascending branch passes through LVe to terminate in SuVe possibly continuing beyond into the cerebellar cortex), and the descending branch gives off terminal branches in SpVe and MVe.

The exact distribution of terminal branches in the vestibular complex has been controversial. Most of the early investigators assumed that the fibers distribute over the entire vestibular complex. Subsequent studies in the monkey, cat, and guinea pig (Stein and Carpenter, 1967; Carpenter *et al.*, 1972; Gacek, 1969; Kotchabachdi and Walberg, 1978; Korte, 1979; Gstoettner *et al.*, 1992) excluded only LVe from root input but included a hitherto unmentioned projection to the ventral group Y, as a recipient of sacculus afferents. For reviews, see Büttner-Ennever (1999, 2000), Brodal (1984), Carleton and Carpenter (1984), Carpenter *et al.* (1987a), Carpenter (1988), and Highstein and McCrea (1988).

In electron microscopic studies in the cat, Mugnaini *et al.* (1967) and Walberg and Mugnaini (1969) showed terminal degeneration in the central and ventral parts of their lateral vestibular nucleus, but these authors did not make a distinction into LVe and MVmc. Following injection of WGA-HRP into the vestibular ganglion of the rabbit-labeled fibers were found (in the light microscope) in LVe, although in low number as compared to Mvmc (Gerrits *et al.*, 1989). There are arguments to consider the LVe as one of the central cerebellar nuclei: the connections of LVe fit the monozonal, mononuclear organization proposed by Voogd (1964; Voogd and Bigare, 1980; Voogd *et al.*, 1996; see also Chapter 11): and LVe receives Purkinje cell axons from a single strip of cerebellar cortex (zone B) and shares a collateral climbing fiber innervation from the caudal dorsal accessory olive with this zone B (Groenewegen and Voogd, 1977).

Very little notice has been taken until recently of the differences in central projections of the canals compared to the otoliths (review: Büttner-Ennever, 1999). A differential termination of vestibular nerve axons from different canals and otoliths was proposed by Stein and Carpenter (1967), Gacek (1969), Carpenter *et al.* (1972), Carpenter and Cowie (1985a), Kevetter and Perachio (1986), and Maklad and Fritzsch (2002). The recent intraaxonal stains of identified canal primary afferents have shown that canal afferents terminate over most of the vestibular complex including MVe, SpVe, I8Ve, and SuVe, but excluding LVe and PrH (Sato *et al.*, 1989). In contrast, utricular afferents mainly target SpVe with some terminals also in MVe, LVe, SuVe, and the abducens nucleus (Imagawa *et al.*, 1995; Ishizuka *et al.*, 1980). Saccular afferents give off terminal branches mainly to LVe and SpVe; but up to now the intraaxonal labeling studies have not reported any saccular afferents to the ventral Y group, in contrast to the earlier tract-tracing experiments (Imagawa *et al.*, 1998). The otoliths also have direct projections to the cerebellum, which terminate mainly in the uvula, in contrast to the canals afferents that are associated primarily to the nodulus (Maklad and Fritzsch, 2003).

Following lesions close to the facial genu of the rabbit, Leidler (1916) observed degenerated fibers (bilaterally) in the vestibular nerve, which he interpreted as centrifugal. An efferent innervation of the labyrinthine sensory organs has been found in all vertebrates except the hagfish (review: Goldberg *et al.*, 2000). The cells of origin of the vestibular efferents, the so-called group e, are located directly lateral to the abducens nucleus and were also identified with retrograde tracers, histochemical and immunocytochemical methods (primates, Carpenter *et al.*, 1987a; Goldberg and Fernandez,1980; cat, Gacek *et al.*, 1965). The rat homologue has been termed the paragenual nucleus (Paxinos and Watson, 1986). Group e cells have long been known to use acetylcholine as a transmitter (Gacek and Lyon, 1974; Warr, 1975); more recent studies have also demonstrated the presence of the neuropeptide calcitonin gene-related peptide (Demêmes and Broca 1998; Tanaka *et al.*, 1988; Wackym *et al.*, 1991) and nitric oxide (Lysakowski and Singer, 2000).

Commissural Connections

Although all primary vestibular and cerebellar inputs to the vestibular nuclei are strictly ipsilateral, the vestibular nuclei of each side operate together owing to a massive commissural system (Büttner-Ennever, 1992b). Several studies have investigated its function in the control of sustained vestibular responses and vestibular compensation (Godaux and Cheron, 1993; Cartwright and Curthoys, 1996; Holler and Straka, 2001; Wearne *et al.*, 1997). The first mention of a vestibular commissure was by Ramón y Cajal

(1909) who erroneously took the vestibular efferent fibers described in the previous paragraph (his "faisceau vestibulaire croisé") for crossed vestibular root fibers. The presence of such fibers in the commissure was subsequently disproved in a number of studies using axonal degeneration techniques (Korte, 1979; Rasmussen, 1932; Stein and Carpenter, 1967; Walberg *et al.*, 1958).

Lesion studies (Carpenter, 1960; Ladpli and Brodal, 1968; Tarlov, 1969) and retrograde transport of HRP (Gacek, 1978; Ito *et al.*, 1985) have shown a large number of interconnections of SpVe, SuVe, and the ventral group Y with their contralateral homonyms (Fig. 33.10C). Other studies observed a much more divergent projection of individual vestibular nuclei to all vestibular nuclei on the contralateral side (Carleton and Carpenter, 1983; Carpenter and Cowie, 1985b; Pompeiano *et al.*, 1978; Carpenter 1988; Büttner-Ennever 1992b; Epema *et al.*, 1988). The neurons engaged in the commissural projection are distributed throughout the vestibular complex, with the exception of LVe and group X. The largest numbers of commissural connections arose from MVpc and MVc, the small-celled peripheral SuVe, and nucleus prepositus hypoglossi were also rich in commissural connections. A modest number was found in group Y, I8Ve and SpVe; very few were encountered in MVmc and the central, large-celled zone of SuVe. The commissural connections of nucleus prepositus hypoglossi arose from the principle cells (McCrea and Baker, 1985a). The crossing fibers from secondary vestibular neurons in MVe have an inhibitory effect on secondary vestibular neurons in the contralateral MVe, which is mediated by both GABA and glycinergic neruons (De Waele *et al.*, 1995; Holstein, 1999; Holstein *et al.*, 1999).

Investigations on the contribution of LVe fibers to the commissure have yielded ambiguous results. Some of the studies with lesions of LVe (Carpenter, 1960; Ladpli and Brodal, 1968; McMasters *et al.*, 1966) showed axonal degeneration in the contralateral LVe and SpVe. Later studies failed to demonstrate this connection in the rabbit (Epema *et al.*, 1988), the cat (Carleton and Carpenter, 1983; Carpenter and Cowie, 1985b; Gacek, 1978; Pompeiano *et al.*, 1978), and the monkey (Carleton and Carpenter, 1983; Carpenter, 1988).

Intrinsic Connections

The Golgi studies of Ramón y Cajal (1909) and Lorente de Nó (1933) suggested the presence of ipsilateral intrinsic vestibular connections, which were later experimentally verified (Ladpli and Brodal, 1968; Carleton and Carpenter, 1983; Carpenter and Cowie, 1985b; Epema *et al.*, 1988; Ito *et al.*, 1985; Rubertone *et al.*, 1983). In addition, observations on intracellularly stained vestibular neurons also support the earlier demonstration of intrinsic and commissural vestibular projections (Ishizuka *et al.*, 1980; McCrea *et al.*, 1980; Mitsacos *et al.*, 1983; Highstein and McCrea, 1988).

Epema *et al.* (1988) showed that within the vestibular complex of each side SuVe, Mve, and SpVe are reciprocally connected (Fig. 33.10D). However, the central SuVe and MVmc form a rostrocaudally oriented column of medium-sized and large neurons, which receives input from surrounding neurons but does not reciprocate this projection. Rather, it constitutes the origin of the main output pathways from the vestibular complex (Büttner-Ennever, 1992b). Efferents from ventral group Y terminate in SuVe, Mve, and SpVe. The infracerebellar nucleus and the interstitial nucleus of the vestibular nerve (I8Ve) supply fibers to MVe and SpVe. Studies using tract tracing combined with staining for nitric oxide NO-sensitive neurons revealed that the PrH receives projections from in the marginal zone and MVe, predominantly from the ipsilateral side, see following discussion (Moreno-Lopez *et al.*, 2001).

By comparing the commissural and intrinsic connections, Epema *et al.* (1988) concluded that quantitative differences in connectivity were present between a core region and the periphery. The core region (central SuVe, LVe, MVmc and rostral SpVe) receives predominantly intrinsic input from the peripherally located vestibular neurons but is itself only minimally involved in the commissural projection. This region is the origin of the major ascending and descending pathways leaving the vestibular nuclei (Büttner-Ennever, 1992b).

Oculomotor Nuclei Connections

Several parallel pathways, subserving compensatory and pursuit eye movements, run from the vestibular nuclei to the oculomotor nuclei, see also Figure 19.2 (Graf *et al.*, 2002). The best studied pathway is the three neuron arc involving the primary canal afferents projecting to the secondary vestibular neurons, which in turn send axons to the motoneurons in the abducens nucleus, the trochlear nucleus and the oculomotor nucleus, see Figures 33.5–33.9 (Epema, 1990; Carpenter and Cowie, 1985b; Gacek, 1977; Graybiel and Hartwieg, 1974; Tarlov, 1970). Most modern studies are consistent with the findings of careful intraaxonal staining reconstructions, which demonstrated that secondary vestibular neurons do not just excite or inhibit the motoneurons of one eye muscle but project to several pools of extraocular motoneurons (Fig. 33.6), and generate a particular *conjugate eye movement*, such as upward, downward, torsional, or horizontal movements. Many studies were used to compile the scheme

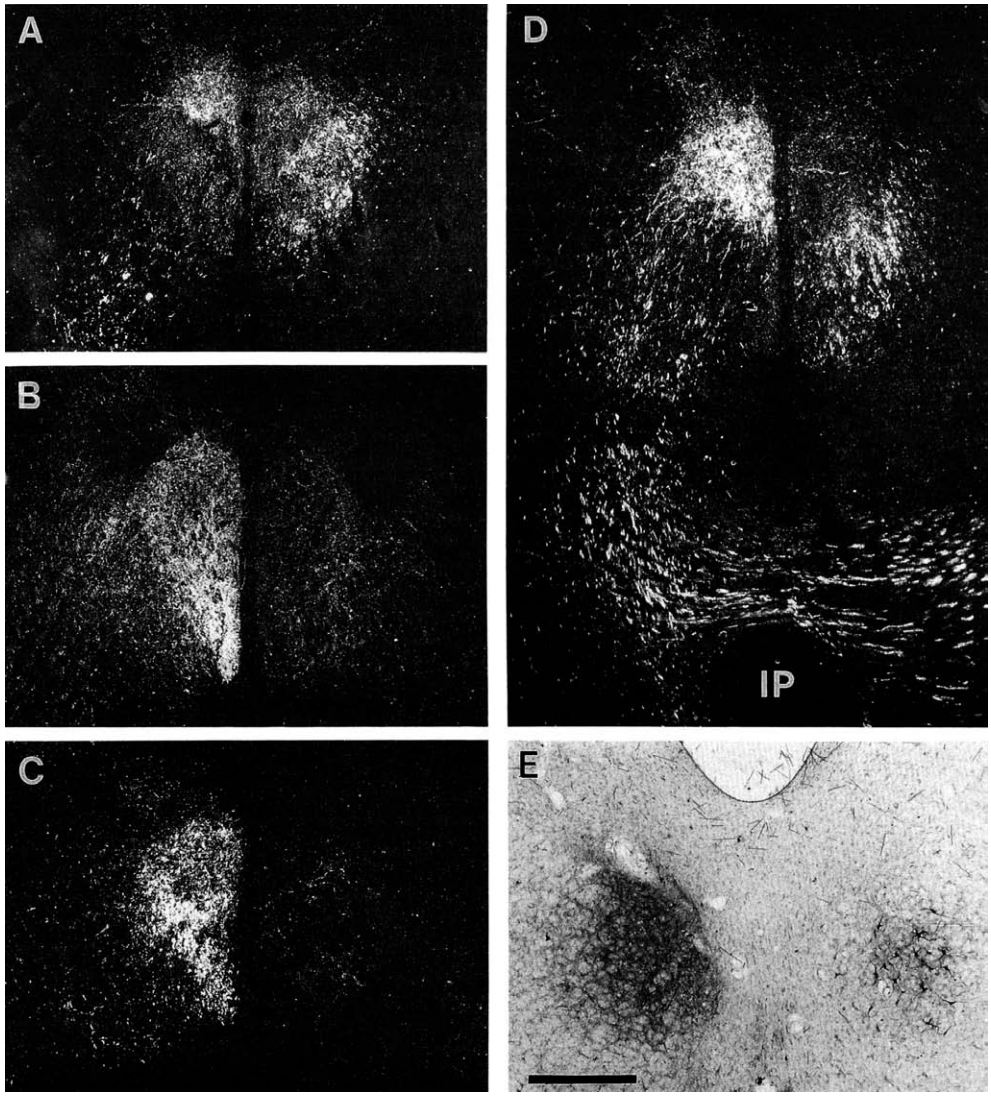

FIGURE 33.5 Distribution of terminal labeling in the oculomotor complex of the rabbit after injections of the anterograde tracer tritiated leucine into different regions of the vestibular complex. The results using this tracer are particularly valuable because, unlike others, it is not taken up by fibers of passage (all injection sites are shown on the right side of the illustrations). **(A)** Injection in SuVe: ipsilateral terminal labeling predominantly present in the medial and inferior rectus subdivisions. Contralateral terminal labeling mainly in the inferior oblique and superior rectus subdivisions. **(B)** Injection in MVc: mainly contralateral terminal labeling in the inferior oblique, and superior, medial and inferior rectus subdivisions, with an emphasis on the latter two. **(C)** Injection in SpVe: the labeling is similar to (B) MVc injections. **(D)** Injection in SuVe: labeled axons reach the ipsilateral medial and inferior rectus subdivisions through the mlf. The contralateral inferior oblique and superior rectus divisions are reached through the scp. Note the complementary pattern of labeling on the two sides, and the crossing of the scp fibers directly dorsal to the interpeduncular nucleus (IP). **(E)** Contralateral anterogradely labeled termination and ipsilateral retrogradely labeled neurons in the interstitial nucleus of Cajal following an injection of WGA-HRP involving MVc and the medial half of SpVe. All frames have the same magnification, scale bar = 200 μm.

of connections shown in Fig. 33.6 (Büttner-Ennever, 2000; Cohen, 1974; Graf *et al.*, 1983; Graf and Ezure 1986; Highstein, 1973; Hirai and Uchino, 1984; Isu *et al.*, 1988; Isu and Yokota, 1983; Ito *et al.*, 1973; McCrea *et al.*, 1980, 1987a, b; Mitsacos *et al.*, 1983; Ohgaki *et al.*, 1988; Precht, 1978, 1979). The secondary vestibular neurons have a dominant canal input and project to the motoneurons via the medial longitudinal fasciculus (mlf), or the superior cerebellar peduncle (scp) or crossing ventral tegmental tract (cvtt in Figs. 33.5D

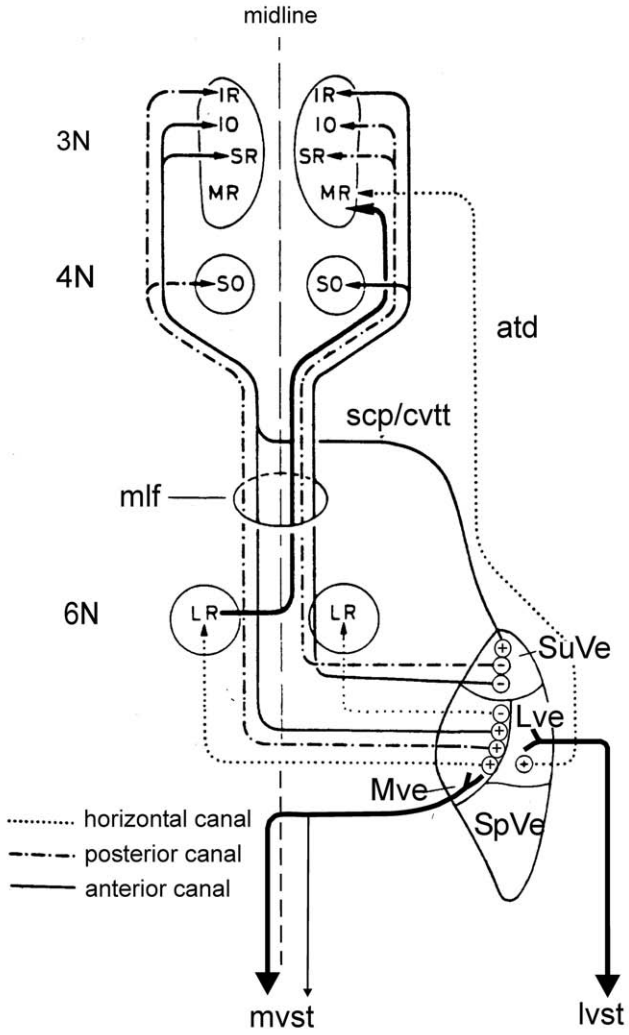

FIGURE 33.6 Direct pathways from secondary vestibular neurons to the oculomotor nuclei. The diagram indicates roughly the location of the cells of origin; it shows their dominant canal input, their excitatory or inhibitory character, and the extraocular motoneurons targeted to produce the compensatory eye movement after canal activation. The descending projections to the spinal cord are lvst and mvst.

and 33.6; Ghelarducci *et al.*, 1977; Carpenter and Cowie, 1985b; Sato *et al.*, 1984). Ipsilateral pathways are inhibitory and contralateral pathways excitatory; whereby the inhibitory transmitter for horizontal VOR is glycine that for the vertical VOR is GABA, and both use glutamate and/or aspartate as their excitatory transmitter (McElligott and Spencer, 2000; Spencer *et al.*, 1989, 2003). These second-order vestibular cells tend to lie in the central magnocellular regions of the vestibular complex in MVmc and the central SuVe (Büttner-Ennever, 2000).

Axons arising from the same region, MVmc and ventral LVe, project into the lateral mlf as the ascending tract of Deiters (Figs. 33.2 and 33.6). They terminate on ipsilateral medial rectus motoneurons in 3N and are modulated by both utricular inputs and the viewing distance of a visual target (Chen-Huang and McCrea, 1998; McCrea *et al.*, 1987b).

Many non–second order vestibular neurons also project to the oculomotor nuclei; they include those in the rostral MVpc and some inhibitory neurons in the marginal zone adjacent to PrH, which are particularly prominent in primates and may play a role in pursuit eye movements (Langer *et al.*, 1986; McFarland *et al.*, 1992). In addition, the dorsal division of the Y group, called the infracerebellar nucleus, has a strong monosynaptic connection to the trochlear and inferior rectus motoneurons, which may be inhibitory (Sato and Kawasaki, 1987). The function of Inf is considered to be related to motor learning or plasticity of the vertical vestibuloocular reflex and the generation of vertical smooth pursuit eye movements (Chubb and Fuchs, 1982; Partsalis and Highstein, 1996). A further non–second order vestibular group of neurons scattered over a large area of MVe and SpVe and possess bifurcating axons that project both to the oculomotor nuclei and to the spinal cord. They are called vestibulooculocollic neurons. Their axons travel caudally mainly in the contralateral mvst (Fig. 6; Minor *et al.*, 1990).

Interstitial Nucleus of Cajal Connections

In the older literature, specific connections between the vestibular nuclei and the interstitial nucleus of Cajal (InC; see Chapter 16) were rarely mentioned. Pompeiano and Walberg (1957) and Mabuchi and Kusama (1970) were the first to demonstrate, in degeneration studies, ipsilaterally descending fibers to a termination in MVe. Studies with retrograde transport of HRP have confirmed this projection (Fig. 33.5E; Carleton and Carpenter, 1983; Carpenter and Cowie, 1985b) and recent anterograde tracing in the squirrel monkey demonstrated fibers from the InC descending in the mlf and their terminations in the SuVe and MVe (Fig. 33.10E; Kokkoroyannis *et al.*, 1996). This projection may include neurons with downward on directions of the eyes that were identified in the InC of the cat and found to form a separate population from downward on direction neurons with commissural projections to the contralateral InC (Chimoto *et al.*, 1999). In turn, the vestibular nuclei send bilateral efferents to the InC. The degeneration that was observed in the InC following lesions of the mlf (Carpenter and Hanna, 1962; Carpenter and Strominger, 1965) was later attributed to an origin in the vestibular nuclei. The projection from SuVe is predominantly ipsilateral, that from MVe and SpVe is predominantly contralateral (Carleton and

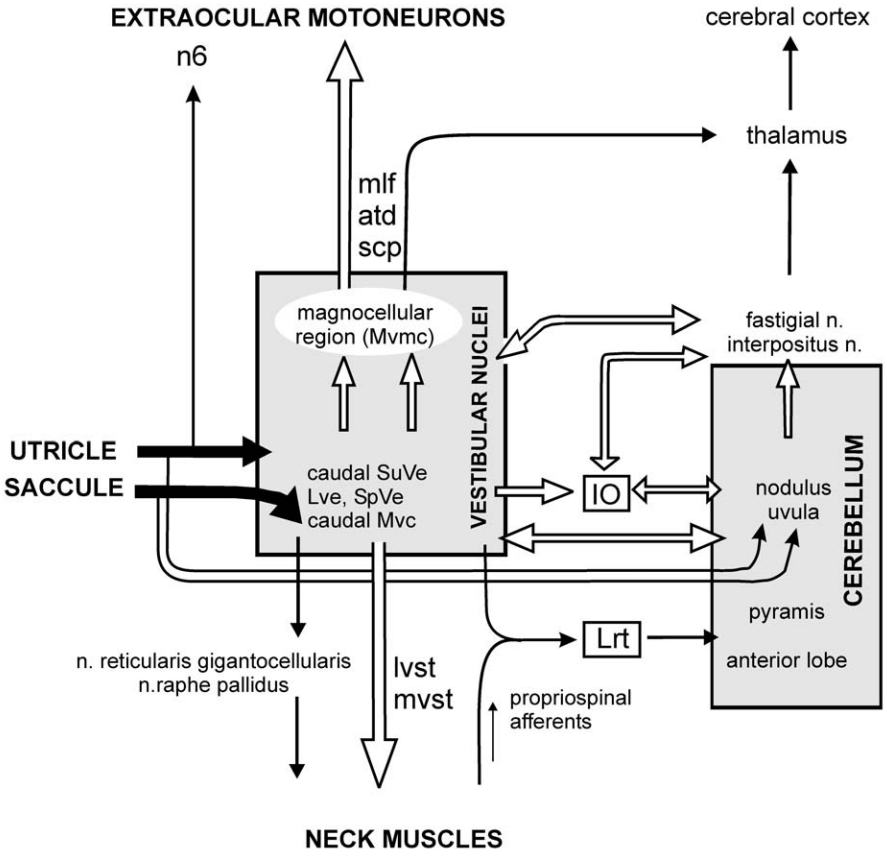

FIGURE 33.7 Summary of the structures and pathways carrying otolith signals. They are concentrated in the vestibular nuclei and cerebellum; they influence neck and postural muscles and probably the extraocular eye muscles.

Carpenter, 1983; Carpenter and Cowie, 1985b; Tarlov, 1969, 1970) (Fig. 33.10E). These projections may stem from collaterals of the secondary vestibular neurons mediating the vertical VOR (see "Oculomotor Nuclei Connections") as shown by intraaxonal HRP-injection studies in cat and monkey (Fig. 33.9, dashed arrows; McCrea *et al.*, 1987, a, b; Iwamoto *et al.*, 1990).

Nucleus Prepositus Connections

The nucleus prepositus hypoglossus (PrH) lies medial to the MVe (Fig. 33.4D, G) and is one site in the brain where there is an interaction between visual and vestibular systems. It is thought to contribute to the maintenance of eye position or gaze in the horizontal plane (Godaux *et al.*, 1993; Kaneko, 1997; McCrea, 1988). The major cytological features of the nucleus appear to be present in all species, including man. The reader is referred to the studies by Brodal and McCrea (Brodal 1983; McCrea 1988; McCrea and Baker, 1985a, b) for detailed reviews of the cytoarchitecture of the PrH in primates and cats, respectively. Three different types of soma-dendritic architecture were observed: (1) "multidendritic" cells in the caudomedial PrH; (2) small cells in the dorsolateral PrH; and (3) medium-sized "principal" cells in the rostral, central region of the PrH. Because afferents from the vestibular nerve do not terminate in the PrH, it is not included in the vestibular complex strictly speaking. However, with respect to its efferent connections, the PrH behaves like the vestibular nuclei (Belknap and McCrea, 1988; McCrea, 1988; McCrea and Baker, 1985a; McCrea *et al.*, 1979).

The PrH projects to almost all oculomotor structures see Figure 33.10: it projects to the abducens nucleus (Hikosaka and Igusa, 1980; Maciewicz *et al.*, 1977; Langer *et al.*, 1986), the oculomotor nucleus (Graybiel, 1977; Graybiel and Hartwieg, 1974; Hikosaka and Igusa, 1980; Steiger and Büttner-Ennever, 1979), the vestibulocerebellum (Epema *et al.*, 1990; Kotchabhakdi *et al.*, 1978; Thunnissen *et al.*, 1989; Langer *et al.*, 1985b) the pontomedullary reticular formation and the superior colliculus (Corvisier and Hardy, 1997). The PrH neurons that project to the ipsi- and contralateral

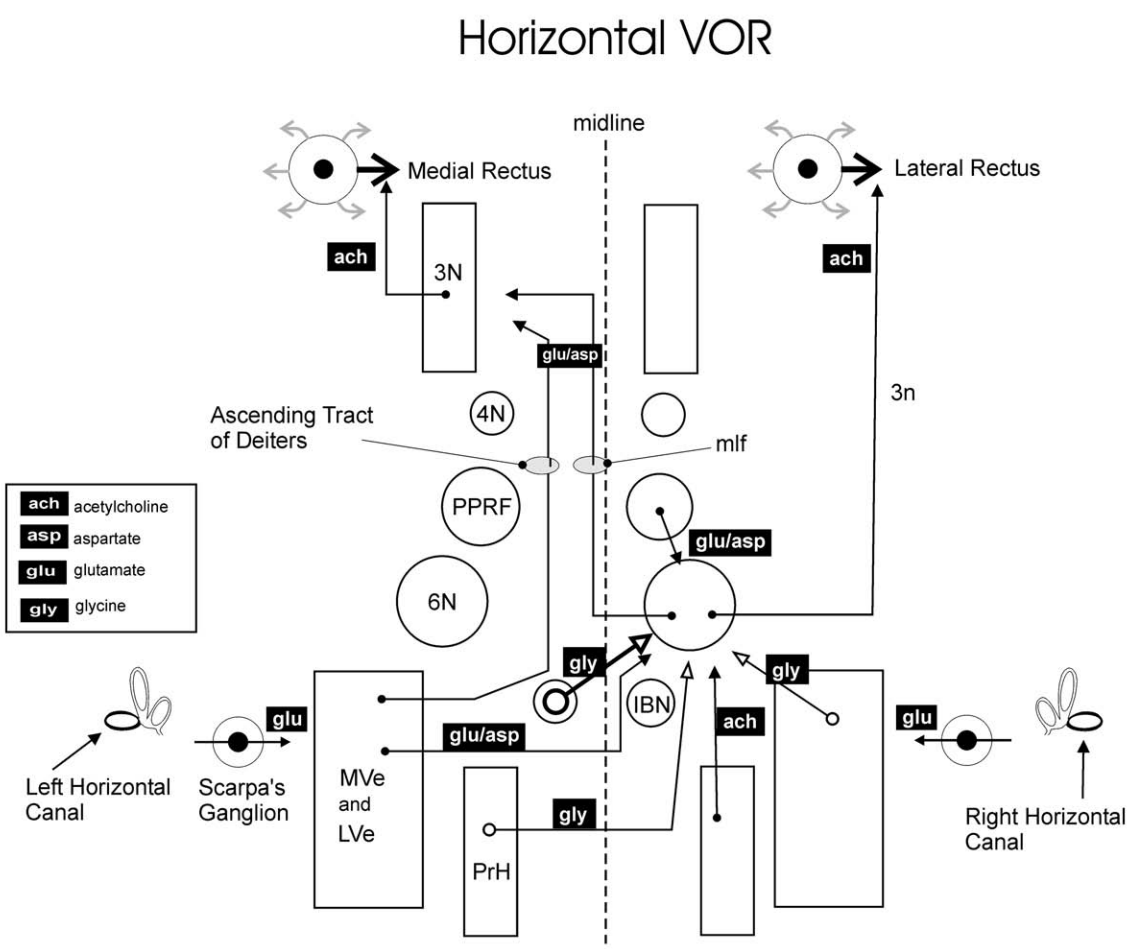

FIGURE 33.8 The principle pathways for the horizontal VOR and their major transmitters (modified from McElligott and Spencer, 2000). Open circles and arrows represent inhibitory paths, and closed circles and arrows, excitatory paths.

vestibular complex seem to be located peripherally in the caudal half of the nucleus (Epema *et al.*, 1988; McCrea *et al.*, 1979).

In primates, a subnucleus of the medial vestibular nucleus, the "marginal zone," forms the lateral border of the rostral half of PrH (Langer *et al.*, 1986). The marginal zone of the medial vestibular nucleus contains tightly packed, medium-sized neurons, most of which project either to the ipsilateral or to the contralateral abducens nucleus (Spencer *et al.*, 1989; Belknap and McCrea, 1988). In contrast to the PrH, the marginal zone is strongly parvalbumin immunoreactive, lacks calretinin, and contains GAD-immunoreactive neurons (McCrea and Horn, personal communication).

Nitric oxide (NO) is a diffusible gas, which was shown to act as an intercellular messenger participating in many functional roles (i.e., in ischemia, neurotoxicity, and neurodegenerative processes, and modulation of sensory function; Cudeiro and Rivadulla, 1999). It is converted from L-arginine to NO by the NADPH-dependent NO-synthase. The PrH of the cat and monkey exhibits a strong NO-synthase-immunoreactivity of neurons and the neuropil (monkey: Satoh *et al.*, 1995; Moreno-Lopez *et al.*, 2001). Interestingly, the marginal zone between the PrH and MVe contains numerous strongly NO-sensitive neurons but is devoid of NO-releasing (i.e., NO-synthase) neurons. This histochemical distinction between the PrH, and MVe was used to define the marginal zone in the cat anatomically for the first time (Moreno-Lopez *et al.*, 2001). The functional role of the NO system is not fully understood, but a pharmacological study in the alert cat demonstrated that the balanced production of NO by the PrH is neccessary for the correct performance of eye movements because unilateral injections of NO-synthase inhibitors into the PrH resulted in a severe long-lasting nystagmus (Moreno-Lopez *et al.*, 1996, 1998). The most important inputs arise from brainstem

areas (Belknap and McCrea, 1988): the perihypoglossal nuclei including the nucleus intercalatus and particularly the contralateral prepositus; the MVe and SpVe and a region of the ventrolateral vestibular complex, bilaterally (McCrea *et al.*, 1987a); the paramedian medullary reticular formation especially the regions contralateral to the PrH that contain inhibitory saccadic burst neurons including the ipsilateral paramedian pontine reticular formation (Büttner-Ennever and Henn, 1976; Gerrits and Voogd, 1986) and the vertical premotor cell groups of the mesencephalon (the ipsilateral rostral interstitial nucleus of the mlf, the interstitial nucleus of Cajal.); and the periextraocular motor nuclei and the surrounding regions including the vestibulocerebellum (Langer *et al.*, 1985a) and the fastigial nucleus (Noda *et al.*, 1990). In addition, the PrH receives visuomotor brainstem pathways from areas such as the ventral lateral geniculate nucleus (Belknap and McCrea, 1988) accessory nuclei of the optic tract (Cazin *et al.*, 1982; Graybiel, 1977; Büttner-Ennever *et al.*, 1996). The PrH of the human is displayed in Figures 25–30 (Paxinos and Huang, 1995); see Chapter 16 (Fig. 16.4L, M).

Cerebellar Connections

Vestibulocerebellar

The vestibular nuclei are the source of cerebellar mossy fibers transferring both canal and otolith information to the cerebellar cortex and deep nuclei, see Fig. 33.7 (for a reviews, see Chapter 11; Brodal, 1974; De Zeeuw *et al.*, 1997; Voogd *et al.*, 1996; Bower, 2002; Cohen *et al.*, 2002). The main recipients of the secondary mossy fibers afferents are the flocculus and the nodulus

(lobule 10), the ventral aspect of the uvula (lobule 9), and deep in the fissures of the lobules 1 and II of the anterior lobe. In a large number of experimental studies the origin of the projection has been reported to be in all vestibular nuclei, including group X and Y, but with the exception of LVe: specifically, the rat (Blanks *et al.*, 1983), the rabbit (Tan and Gerrits, 1992; Epema *et al.*, 1990; Magras and Voogd, 1985; Thunnissen *et al.*, 1989; Yamamoto, 1979), the cat (Brodal and Torvik, 1957; Carpenter, 1960; Kotchabhakdi and Walberg, 1978; Sato *et al.*, 1983), the bush-baby (Rubertone and Haines, 1981), and the macaque monkey (Brodal and Brodal, 1985; Langer *et al.*, 1985b). Different populations of neurons in the vestibular nuclei, which are not topographically separated, provide mossy fiber connections to individual lobules in each hemicerebellum (i.e., bilaterally).

Several transmitter specific pathways interconnect the vestibular system to the cerebellum (Barmack *et al.*, 1993): the vestibular nerve projects directly to the nodulus and uvula (but not the flocculus) through a glutaminergic primary afferents, the vestibular nuclei provide a cholinergic input from secondary vestibular neurons, the PrH relays its cholinergic efferents in the dorsal cap of the inferior olive which then projects via climbing fibers to the nodulus and uvula, and finally otolith signals from the vestibular complex are carried in a GABAergic pathway to the b-nucleus of the inferior olive and relayed, again by climbing fibers, to lobules 9 and 10 (Barmack, 1999). The zonal or modular organization of the climbing fiber inputs stands in sharp contrast to the more diffuse mossy fiber vestibular complex inputs (Voogd *et al.*, 1996).

Corticovestibular

The efferents of the cerebellum are arranged in a modular pattern (Chapter 11; Voogd *et al.*, 1996). The earliest observations of a corticovestibular projection from the anterior lobe (Ferrier and Turner, 1894; Klimoff, 1899; Probst, 1902; Hohman, 1929) were found to originate from a position directly lateral to the vermis and terminate in the ipsilateral LVe (Jansen and Brodal, 1940; Walberg and Jansen, 1961). Voogd (1964) demonstrated that the origin of the projection from the anterior lobe to LVe was a single strip of Purkinje cells, forming the B-zone of the cerebellar cortex. Retrograde transport of HRP showed that, in addition, Purkinje cells in the A2-zone project to MVmc (Voogd and Bigare, 1980).

In the caudal vermis, Purkinje cells projecting back to the vestibular complex were found in two longitudinal strips in lobules 8 (pyramis) and 9 (uvula) and through the mediolateral extent of the cortex of lobule 10 (flocculus) (Balaban, 1984; Epema *et al.*, 1985; Matsushita and Wang, 1986; Voogd and Bigare, 1980; Shojaku *et al.*, 1987). Terminal axons from nodulus Purkinje cells are found in the periphery of SuVe, and in MVe, SpVe and group X, while their presence in LVe is uncertain (Angaut and Brodal, 1967; Voogd and Bigare, 1980). The termination from lobules 8 and 9 has a similar distribution, although the medial Purkinje cells show a preference for MVe and those of the intermediate strip for SuVe (Voogd *et al.*, 1996; Wylie *et al.*, 1994).

The terminations from the flocculus efferents are distributed over the larger celled central and ventral parts of SuVe, the lateral half of MVe including the marginal zone, and group Y; few terminals are present in MVmc (Langer *et al.*, 1985a). Studies with retrograde transport of HRP following injections in the vestibular nuclei revealed in the flocculus a zonal arrangement of Purkinje cells. A central strip of Purkinje cells projecting to SuVe is flanked by strips projecting to MVe (Haines, 1977; Voogd and Bigare, 1980; Yamamoto and Shimoyama, 1977; Graf *et al.*, 2002). Current hypotheses consider these connections can be used to aid plasticity and "learning" in vestibulo-ocular functions (Hirata and Highstein, 2002).

Nucleovestibular

The caudal vermis projects not only back to the vestibular nuclei, but also to the fastigial nucleus, the most medial of the deep cerebellar nuclei. The projection arises from the most medial zone of Purkinje cells and is GABAergic. The early experiments of Ferrier and Turner (1894), Thomas (1897), Russel (1897), and Klimoff (1899) demonstrated the presence of direct and indirect fastigiofugal fibers in the rostral part of the juxtarestiform body. The direct fibers from the rostral part of the ipsilateral fastigial nucleus enter the vestibular complex close to the lateral wall of the fourth ventricle as the "direct fastigio-bulbar tract" (dfb, Fig. 33.1-6 and 8). Fibers from the caudal part of the contralateral fastigial nucleus cross in the cerebellum and curve around the dorsal and lateral side of the brachium conjunctivum as Russel's uncinate tract (ut, Fig. 33.1-7). The uncinate tract descends in the bundles of SpVe.

The fastigial fibers terminate in MVmc, SpVe, and the caudolateral MVc (Carpenter *et al.*, 1959; Noda *et al.*, 1990; Sugita and Noda, 1991). Voogd (1964) considered the labeling sometimes observed in LVe to result from transection of corticovestibular fibers. The autoradiographic tracing study of Batton *et al.* (1977), which has the advantage that label is not taken up by passing fibers, confirms Voogd's opinion. These pathways participate both in the control of vestibuloocular (caudal fastigial) and vestibulospinal (rostral fastigial) mechanisms (Büttner *et al.*, 1999).

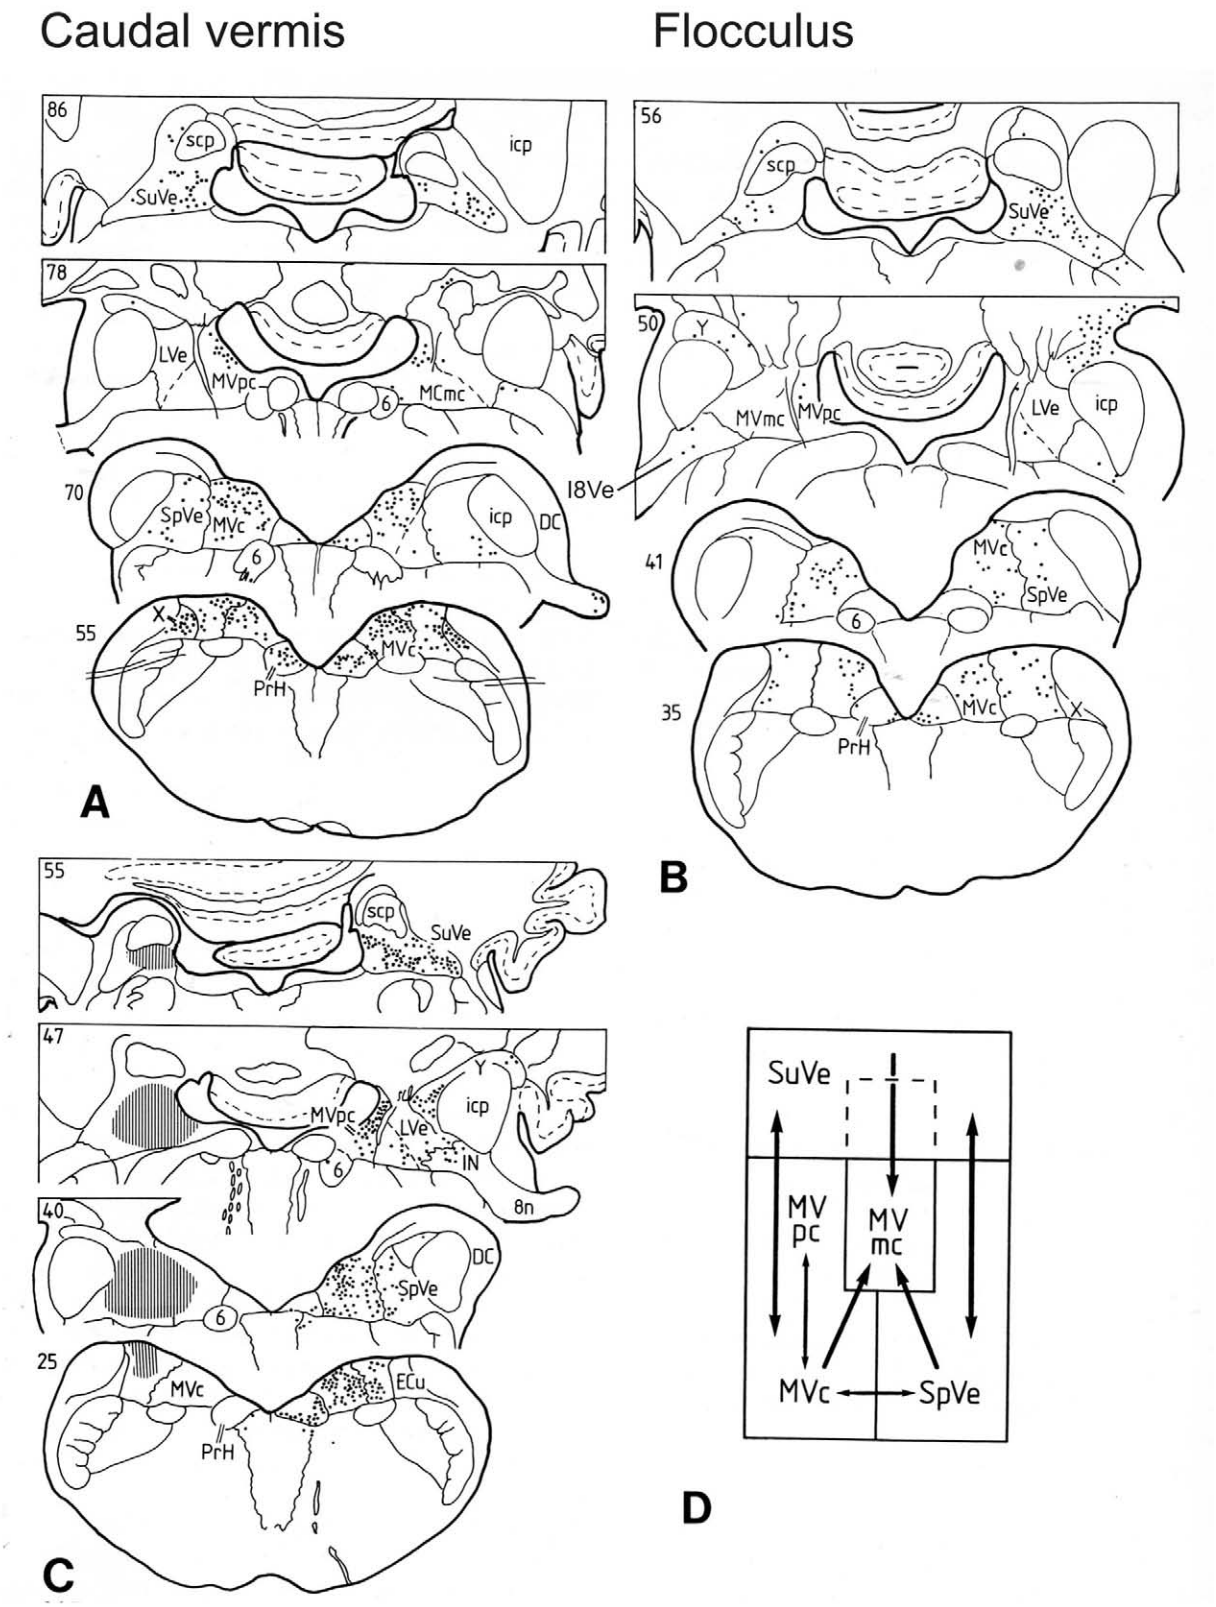

FIGURE 33.10 Distribution of efferent neurons in the rabbit vestibular complex, retrogradely filled by injections of horseradish peroxidase into **(A)** the caudal vermis; **(B)** the flocculus; **(C)** the contralateral vestibular complex. In each case,the injections are on the left side. From Epema *et al*. (1988). **(D)** The diagram shows how MVmc receives inputs from the surrounding nuclei by intrinsic connections: MVmc also provides a major output of the vestibular complex to the oculomotor nuclei (see text).

Inferior Olive Connections

Evidence for a vestibulo-olivary projection was first presented by Muskens (1934). Anterograde axonal tracing has corroborated this finding in different mammals (Martin *et al.*, 1975; Saint-Cyr and Courville, 1979; Swenson and Castro, 1983). One description of this projection is in the cat from Gerrits *et al.* (1985b), who confirmed a heavy projection from MVe and SpVe to subnucleus beta and the dorsomedial cell column. This region is referred to as the parasolitary nucleus by Barmack and colleagues (Barmack 1996; Barmack *et al.*, 1998) who showed that the connection was GABAergic and carried otolith signals to the inferior olive, which were relayed to the contralateral nodulus and uvula (Büttner-Ennever, 1999). The olivary subdivisions that do not receive a vestibular projection are the dorsal accessory olive, and perhaps the dorsal cap of Kooy whose cholinergic afferents arise from PrH (Barmack, 2000).

Olivovestibular connections have been convincingly demonstrated between the caudal part of the dorsal accessory olive and LVe containing Deiters' neurons (Groenewegen and Voogd, 1977; Gerrits 1990, Fig. 33.5C). Their results show a relatively large number of olivocerebellar fibers passing through the vestibular complex. These passing axons cast doubt on the results of Balaban (1984) who proposed climbing fiber collaterals terminated in different parts of the vestibular complex, based on retrograde transport of WGA-HRP.

Reticular and Paramedian Connections

Axonal tracing studies have demonstrated the sparse and diffuse nature of the reticulovestibular projections (degeneration techniques: Hoddevik *et al.*, 1975; Mehler, 1968; tritiated leucine: Büttner-Ennever and Henn, 1976; Gerrits and Voogd, 1986; retrograde transport of HRP: Carleton and Carpenter, 1983; Corvaja *et al.*, 1979; Pompeiano *et al.*, 1978; Kitama *et al.*, 1995). The intracellular staining of identified reticular formation neurons in PPRF showed that axonal branching of excitatory burst neurons reached PrH and medial MVe (Strassman *et al.*, 1986a), whereas from inhibitory burst neurons the terminals covered the magnocellular "output" region in the center of the vestibular complex (i.e., MVmc; Strassman *et al.*, 1986b). Other vertical premotor reticular areas in the mesencephalon also project to the vestibular nucleus but the exact topography of these projections is unclear.

Efferents of the vestibular complex to the reticular formation were described in early Golgi material (Lorente de Nó, 1933; Ramón y Cajal, 1909). More recent studies demonstrated the nonterminal nature of most vestibuloreticular fibers (Gerrits *et al.*, 1985a; Gerrits and Voogd, 1986). However one set of vestibular efferents that has recently been more clearly defined is that to the "cell groups of the paramedian tracts" (PMT cell groups; for reviews see Büttner-Ennever and Büttne, 1988; Büttner-Ennever, 1992a; Büttner-Ennever and Horn, 1996). These neurons lie in tight "nests" amongst the midline fiber bundles, just lateral to the raphe nuclei; they are seen in the pons and medulla in rat, cat, monkey, and man and project to the flocculus (Langer *et al.*, 1985b). They receive inputs from all oculomotor premotor nuclei including the secondary vestibular neurons (McCrea *et al.*, 1987a, b; see Chapter 16). However the projections are often described as innervating raphe nucle earlier, before the identity of the floccular-projecting PMT cell group were discovered.

Spinal Cord Connections

Vestibulospinal connections descend in two separate pathways: the ipsilateral lateral vestibulospinal tract (lvst) and the bilateral medial vestibulospinal tract (mvst) (Fig. 33.6; see Chapter 8; Pompeiano 1972; Matsushita and Li Wang 1986; Holstege, 1988). They carry canal and otolith signals to modulate spinal motoneuron activity (Isu *et al.*, 1988; Sato *et al.*, 1996, 1997; Shinoda *et al.*, 1994). Noradrenergic and cholinergic systems also have a modulatory effect on the vestibulospinal reflexes (Pompeiano, 2000).

The lvst was originally described in Golgi material (Held, 1893) although Deiters himself (1865) was already aware of the probability of spinal connections. It is the principal pathway through which gravito-inertial signals from the otoliths can regulate the body's extensor musculature (Pompeiano and Brodal, 1957a). It runs through the ventral reticular formation into the ventrolateral funiculus of the spinal cord, terminating in Rexed's laminae VII–IX (Holstege, 1988; Isu *et al.*, 1996). The pathway is somatotopically organized, with the dorsocaudal, a central, and a rostroventral (the equivalent of MVmc) subdivision, projecting respectively to the lumbosacral, the thoracic, and the cervical cord segments (Akaike, 1983). Neurons in SpVe and MVmc also contribute to the lvst (Fig. 33.11; Rapoport *et al.*, 1977). Three principal inputs drive the activity of lvst neurons and hence modulate vestibulospinal reflexes: the otolith input, the cerebellar vermis relayed via the fastigial nucleus, and ascending proprioceptive signals in spinovestibular pathways (Fig. 33.7; Büttner-Ennever, 1999; Pompeiano, 1972). The morphology of the lvst axons and their terminal fields has been elegantly demonstrated by intracellular recording and staining techniques (Boyle, 2000; Boyle *et al.*, 1996; Shinoda *et al.*, 1988).

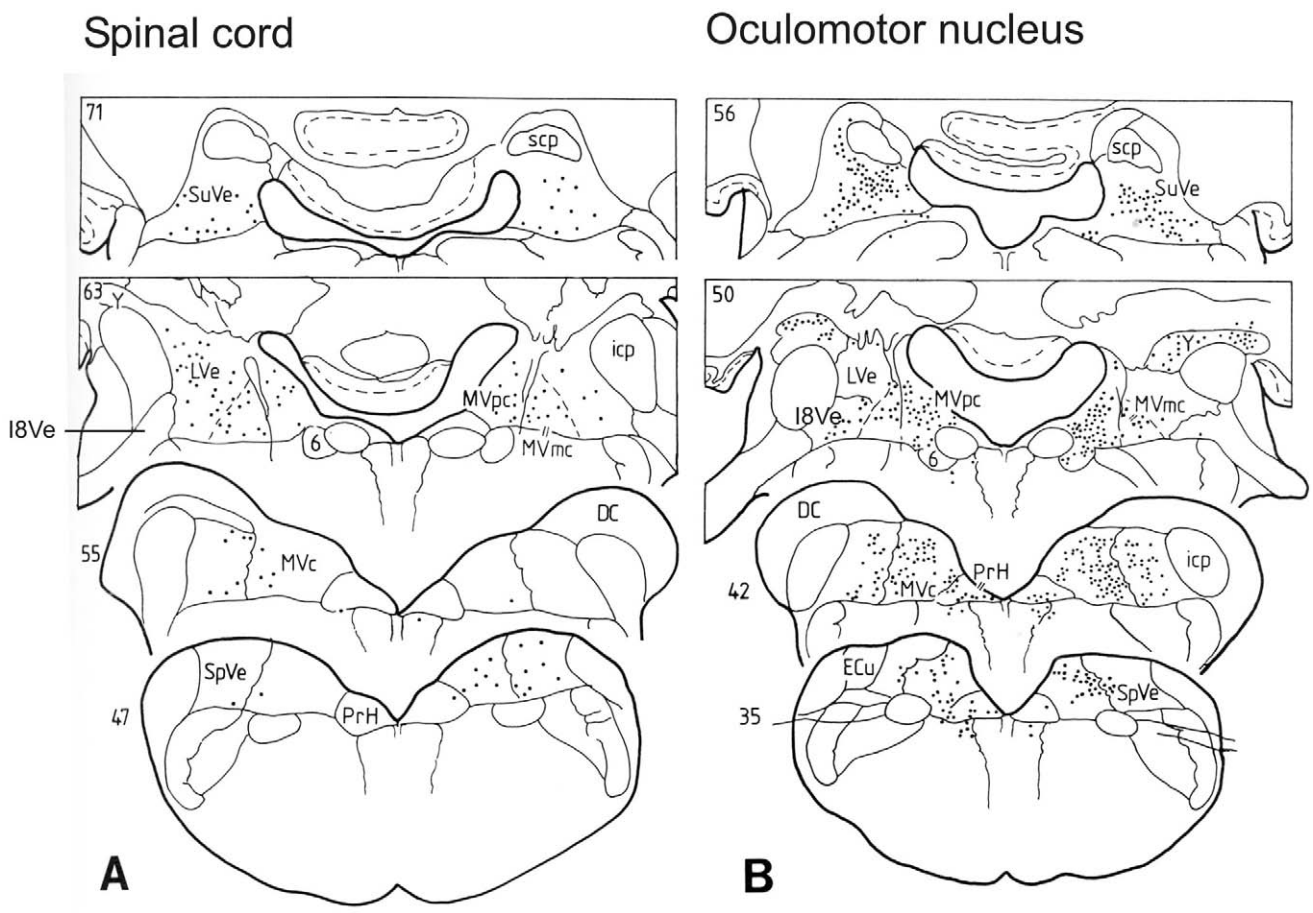

FIGURE 33.11 Distribution of efferent neurons in the vestibular complex of the rabbit projecting to the spinal cord and the oculomotor nucleus. Neurons are retrogradely labeled with horseradish peroxidase injections into **(A)** the left side of the spinal cord and **(B)** the left side of the oculomotor nucleus (Epema, 1990).

Vestibulospinal fibers descending bilaterally in the medial longitudinal fascicle (mlf) terminate in Rexed's laminae VII, VIII, and IX, mainly in the upper cervical cord (Shinoda *et al.*, 1992). Retrograde tracer studies and electrophysiological studies have shown that neurons in MVe mainly contribute to mvst, with a lesser contribution from SpVe and LVe (Huerta and Harting, 1982; Kuypers and Maisky, 1975; Minor *et al.*, 1990; Isu *et al.*, 1988), and some cells can be seen in SuVe in rabbit (Fig. 33.11; Epema, 1990). It was originally suggested that mvst inhibits neck and axial musculature but some excitatory axons have been reported in the tract (Akaike, 1983). Many of the contralaterally projecting mvst axons also have an ascending branch that terminates in the oculomotor nuclei and other regions of the brainstem such as the nucleus of Roller (Minor *et al.*, 1990).

Ascending proprioceptive influences are also intergrated into the activity of the vestibular complex (Pompeiano and Brodal, 1957b; Mehler and Rubertone, 1985; Pompeiano, 1972). The central cervical nucleus, at C1–C4, is an important relay for neck muscle afferents to the contralateral vestibular nuclei (Vincent and Rubertone, 1984).

Thalamocortical Connections

Vestibular fibers ascending into the thalamus have been described in the old degeneration studies by Van Gehuchten (1904), Whitaker and Alexander (1932), Hassler (1948), and Brodal and Pompeiano (1958). More convincing evidence was presented with anterograde axonal tracing in the studies by Lang *et al.* (1979), who used tritiated leucine autoradiography; Mehler and Voogd (1984) using WGA-HRP; and Shiroyama *et al.* with Phaseolus lectin (Lai *et al.*, 2000; Shiroyama *et al.*, 1995). The thalamic projections are bilateral and end in diffuse scattered patches in nucleus ventroposterior lateralis, pars oralis and to a lesser extent in ventroposterior inferior nucleus and ventroposterior centralis

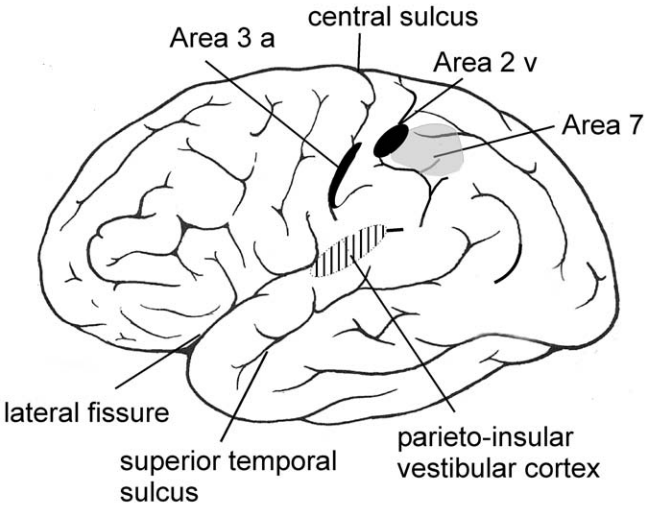

FIGURE 33.12 Homologous areas of vestibular cortex in human, based on results for monkey (Guldin and Grüsser, 1998) and for human (Foerster, 1936).

lateralis. An additional vestibulothalamostriatal pathway has been proposed in rat (Lai *et al.*, 2000). These studies confirm the observation of Kotchabhakdi *et al.* (1980) that MVc and the caudal part of SpVe project to the ventral posterolateral and ventrolateral thalamus, and SuVe and group Y project to the intralaminar region (see also Chapter 20). In turn, the regions of the thalamus targeted by the vestibular nuclei send efferents to vestibular cortical areas such as parietal area 2v, 7a and 7b, as well as to area 3a and the parietoinsular and retroinsular vestibular cortex (see Fig. 33.12) (Akbarian *et al.*, 1993; Brandt *et al.*, 1994; Büttner-Ennever, 2000; Friberg *et al.*, 1985; Guldin and Grüsser, 1998; Guldin *et al.*, 1992).

Descending pathways from the cerebral cortex to the vestibular nuclei have also been reported and may play a role in the suppression of reflex vestibular responses during voluntary movements (Akbarian *et al.*, 1994; Faugier-Grimaud and Ventre, 1989; Ventre and Faugier-Grimaud, 1988)

CONCLUSION

A clear cytoarchitectural pattern in the vestibular complex can be followed through vertebrate species (Straka *et al.*, 2002). However, experimental data on the afferent and efferent connections of the nuclei show that axon terminals do not respect these cytoarchitectural borders, perhaps with the exception of LVe. Primary afferents project throughout the majority of the vestibular complex, although it is only the rostral regions that are concerned with oculomotor "output" function. The central magnocellular regions of the vestibular complex are the source of the output projections; the parvocellular surrounds are engaged in either commissural, intrinsic, or cerebellar connections, and these comprise the majority of vestibular neurons. Caudal vestibular regions sustain otolith afferents that interact heavily with the cerebellum; and particularly saccular activity appears to be directed mainly toward spinal neural networks. Experiments on single unit recordings in head free behaving primates have shown that many new categories of neurons are discovered as soon as new techniques are established (McCrea *et al.*, 1999). Recent information on the transmitters used by the neurons, and their histochemical properties can be more easily related to the cytoarchitecture and functional subdivisions.

The interconnectivity of the vestibular complex with the cerebellum dominates the activity of the vestibular nuclei, a point that has been convincingly demonstrated, functionally and histochemically, by the series of experiments of Grüsser and colleagues, on mutant mice (Grüsser-Cornehls and Bäurle, 2001). Their work showed that the compensatory capacity of the vestibular complex, owing to the enhancement of intranuclear inhibitory circuits, is only evident when the overriding control from the Purkinje cells of the cerebellar cortex, or the cerebellar nuclei, is totally eliminated. In cases of cerebellar dysfunction, this can mean that the actual *destruction* of the remaining cerebellar cortex leads to a significant improvement in motor performance as a result of the release of adaptation mechanisms in vestibular circuitry. This has evident clinical consequences.

Acknowledgments

The authors thank Dr. Anja Horn and Rita Büttner for their assistance with the figures.They are indebted to Mrs. E.M. Rijpma, librarian at the Anatomical Laboratory in Leiden. Dr. E. Marani from the same institute is kindly thanked for giving permission to use the historical "Jelgersma collection" of human brain sections. The work was supported by the German Research Council SFB 624/B3.

Auditory System

JEAN K. MOORE and FRED H. LINTHICUM, JR.
House Ear Institute
Los Angeles, California, USA

The purpose of this chapter is to review the structure of the human auditory system and to consider how its structural organization reflects its function. Although much of our understanding of the structure and function of the auditory system is based on the large body of work done in nonprimate mammals, this chapter emphasizes the specific organization of the human auditory system and cites, wherever possible, studies done in other species of primates. In general, the chapter focuses on the process of information transfer through progressively higher levels of the auditory system, beginning with the passage of mechanical impulses through the middle and inner ear, and continuing with the subsequent cellular and neural processes occurring at cochlear, brain stem, and forebrain levels. Evoked activity, functional imaging, and the effects of pathological conditions are considered from the standpoint of the insight they provide into normal auditory function.

An overview of the anatomy and dimensions of the human auditory system is provided by Figure 34.1. This diagram is a projection based on histological sections through the human brain stem and temporal lobe. The position and dimensions of the thalamus were recreated from human brain atlases (DeArmond *et al.*, 1989; Paxinos and Huang, 1995). As suggested by this diagram, the pattern of activity generated by sound stimuli in the cochlea is carried to the brain stem by the cochlear nerve. In the brain stem, the nerve terminates on neurons in the dorsal and ventral cochlear nuclei. Ascending pathways leave the cochlear nuclei in the dorsal, intermediate, and ventral acoustic striae and cross the midline as the trapezoid body. One ascending pathway provides information to the medial and lateral superior olivary nuclei, centers that reconstruct the spatial dimension of a sound stimulus. The surrounding periolivary cell groups receive ascending axons, but also receive descending projections and give rise to a feedback pathway to the inner ear (not shown). Other projections from the cochlear nuclei run directly to the upper brain stem, where they terminate mainly in the dorsal lemniscal nucleus and inferior colliculus. Both of these structures form commissures, namely, the dorsal commissure of the lateral lemniscus and the commissure of the inferior colliculus. Within the inferior colliculus, input from the lower brain stem auditory nuclei is synthesized to provide a

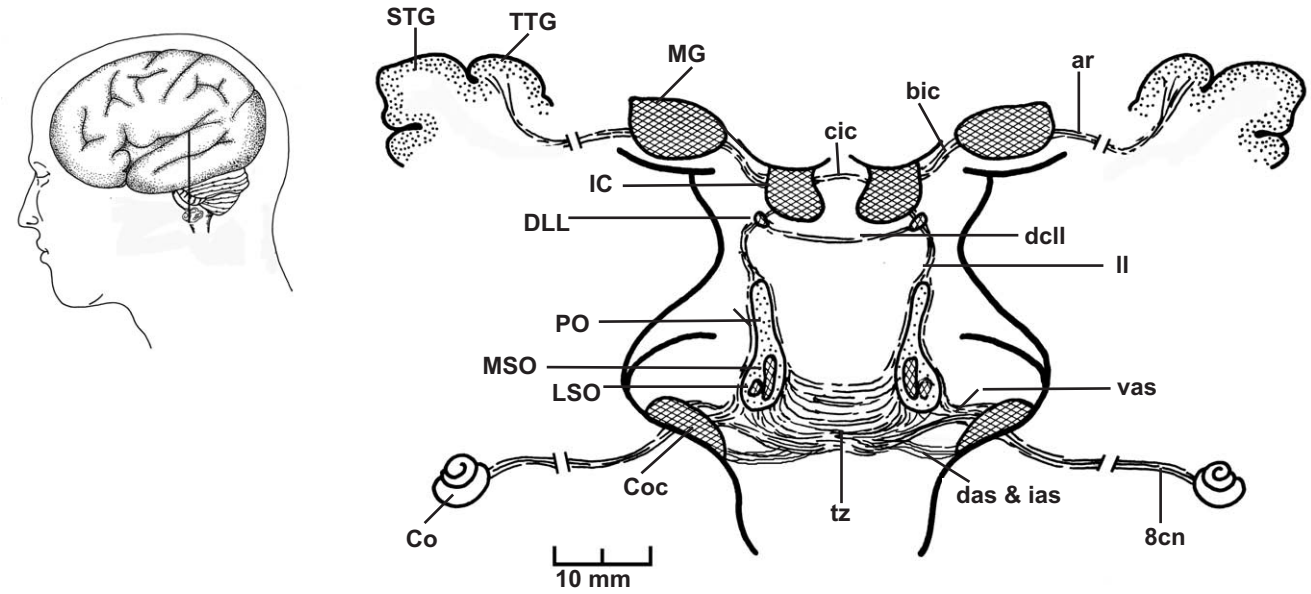

FIGURE 34.1 Diagramatic representation of the topography of the human auditory system in the plane shown in the inset figure. The diagram approximates the actual topography of the human auditory pathway, except that the full lengths of the cochlear nerve and auditory radiations are not represented. Nuclei are labeled on the left side and axonal pathways on the right side. bic, brachium of inferior colliculus; cic, commissure of inferior colliculus; Co, cochlea; Coc, cochlear nuclei; das, dorsal acoustic stria; dcll, dorsal commissure of lateral lemniscus; DLL, dorsal lemniscal nucleus; IC, inferior colliculas, ias, intermediate acoustic stria; ll, lateral lemniscus; LSO, lateral superior olivary nucleus; MG, medial geniculate; MSO, medial superior olivary nucleus; PO, periolivary nuclei; STG, superior temporal gyrus; TTG, transverse temporal gyrus; tz, trapezoid body; vas, ventral acoustic stria; 8cn, cochlear nerve.

cohesive representation of stimulus type and location. This synthesized auditory information is carried by the brachium of the inferior colliculus to the medial geniculate complex in the posterior thalamus. From the medial geniculate, information passes through the auditory radiations to reach the primary auditory cortex within the transverse temporal gyrus. Geniculate input is sparse outside of the primary auditory area, but transcortical pathways carry auditory information to higher levels of cortical processing in the superior temporal gyrus. Further projections to cortex outside of these classical auditory areas allow auditory information to play a role in the highest levels of cognition.

THE COCHLEA AND COCHLEAR NERVE

Middle Ear and Cochlea: Mechanical Transmission of Sound

Although the emphasis in this chapter is on neural mechanisms of information transfer, any description of the auditory system must begin with consideration of the structures of the external, middle, and inner ear that are involved in mechanical transmission of sound. These structures are depicted in a classic drawing by Brödel (1946) (Fig. 34.2). In this drawing, we see that the external ear consists of the auricle, or pinna, and the external auditory canal. The external canal ends at the tympanic membrane (ear drum), which separates it from the air-filled cavity of the middle ear. The middle and inner ears are housed within a portion of the temporal bone that is sometimes called the petrous ("stonelike") bone because of its density. The middle ear is ventilated by the eustachian tube, which passes to the nasopharynx, ending just above the soft palate. In sound transmission, pressure waves are collected by the auricle and passed through the external auditory canal, which slightly modifies the character of the waves (von Békésy, 1932). As pressure waves cause vibration of the tympanic membrane, its motion is transmitted across the middle ear by the chain of three ossicles (middle ear bones). The ossicles are named the malleus, incus and stapes because of their imagined resemblance to a hammer, anvil, and stirrup (Fig. 34.3A, B). Motion of the ossicles is modified by two small muscles that are attached to the wall of the middle ear. One of these, the stapedius muscle, is inserted into the stapes and contracts in response to

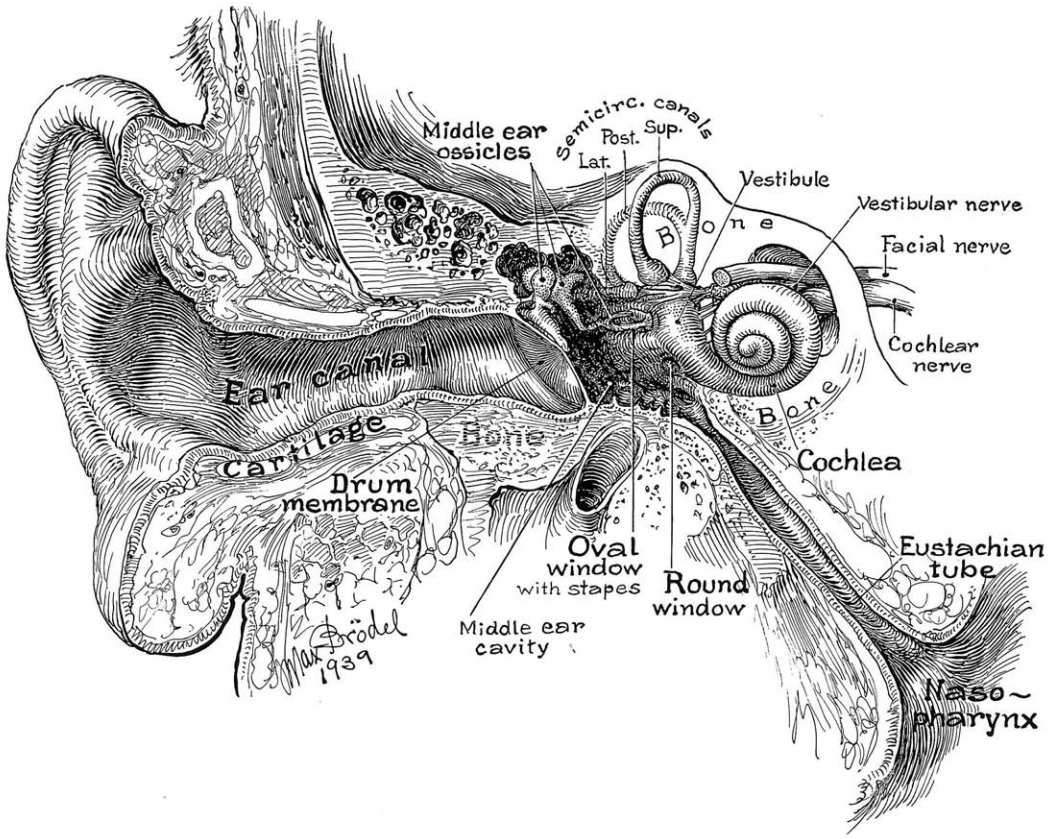

FIGURE 34.2 An artist's rendering of the structures of the human peripheral auditory system. Reprinted from M. Brödel, figure 1, "Three unpublished drawings of the anatomy of the human ear," 1946, with permission from W.B. Saunders Publishing Company.

sounds above 70 dB, the intensity of loud conversation. The other muscle, the tensor tympani, inserts into the malleus and contracts to louder sounds, especially impulse noises. By restricting ossicular motion, these muscles are believed to offer protection to the inner ear from damaging noise. In addition to ossicular transmission, sound is transmitted with a slight delay through the air of the middle ear to the round window membrane.

The auditory portion of the inner ear is a fluid-filled tube that is coiled two and a half times and named the cochlea because of its similarity to a snail. When seen in cross-section, it has a broad base, a pointed apex, and a central pillar called the modiolus (Fig. 34.4A). The cochlear lumen is divided into two compartments by a median partition. The fluid space on the apical side of the partition is known as the scala vestibuli, and that on the basal side is termed the scala tympani. The two perilymph compartments are, in fact, one space because they are continuous with each other at the extreme apical end of the cochlea, at a point called the helicotrema. Both compartments are filled with perilymph, a fluid that resembles extracellular fluid in being high in sodium and low in potassium. Ossicular motion is transmitted to the inner ear through the footplate of the stapes, which is held in place by the flexible annular ligament in the oval window of the cochlea. This aperture opens into the extreme basal end of the cochlea, near its junction with the vestibular organs. When acoustic stimuli impart oscillatory motion to the tympanic membrane and ossicles, the piston-like driving force of the stapes footplate creates waves in the fluid of the scala vestibuli. The confluence of the scalae at the helicotrema permits pressure exerted by movement of the stapes footplate to be relieved by a compensatory movement of the flexible round window membrane located at the basal end of the scala tympani. Congenital deformities that disrupt the integrity of the fluid channels, such as Mondini's deformity (Fig. 34.4B), can interfere with the normal hydrodynamic function of the cochlea.

The median partition of the cochlea extends from the shelf-like osseous spiral lamina medially to the spiral ligament on the lateral wall of the cochlea (Fig. 34.4C).

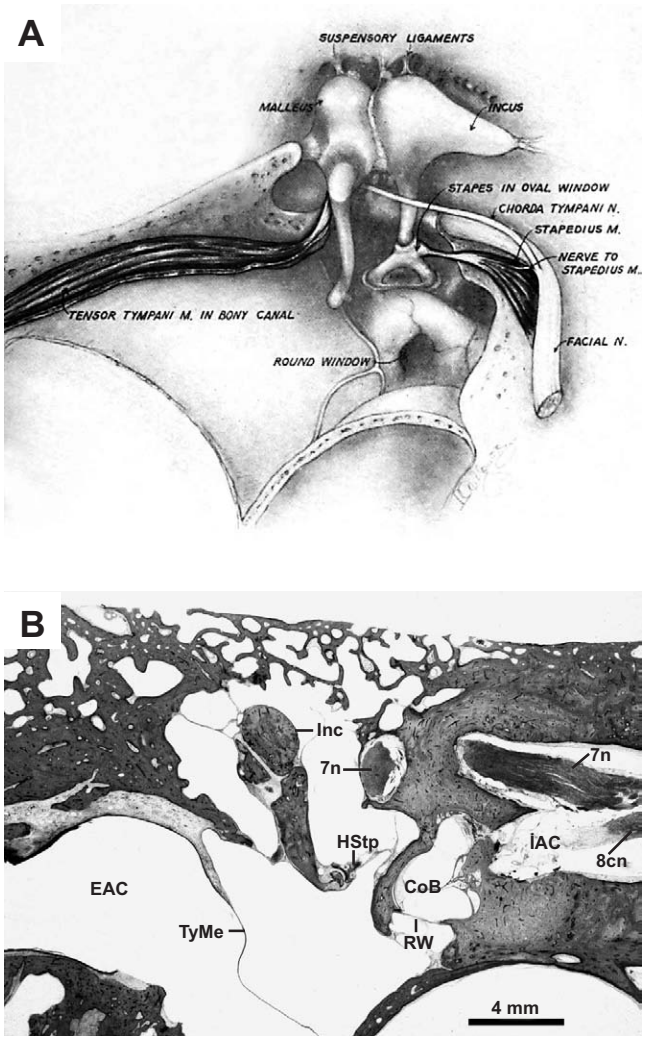

FIGURE 34.3 **(A)** Drawing of the human middle ear with the lateral wall and eardrum removed, illustrating the position of the ossicles and of the tensor tympani and stapedius muscles. Reprinted from *Archives of Otolaryngology* **86,** C.E. Blevins, figure 1, Innervation patterns of the human stapedius muscle, pp. 136–142, 1967, with permission from the Archives of Otolaryngology. Copyrighted 1967, American Medical Association. **(B)** In the human middle ear, the tympanic membrane (TyMe) separates the middle ear from the external auditory canal (EAC). The section passes through the incus (Inc) and a portion of the head of the stapes (HStp). The facial nerve (7n) can be seen on the medial wall of the middle ear and within the internal auditory canal (IAC). The cochlear branch of the eighth nerve (8cn) also passes through the internal auditory canal. Part of the wall of the basal turn of the cochlea (CoB) is formed by the membrane of the round window (RW). Celloidin section, hematoxylin–eosin stain.

A third fluid space, the scala media or cochlear duct, lies between the lateral end of the cochlear partition and the thin Reissner's membrane. This inner channel contains the sensory elements of the cochlea that make up the organ of Corti. The lateral wall of the cochlear duct is formed by the stria vascularis, a cellular layer on the surface of the spiral ligament. Through the action of the stria vascularis, the endolymphatic fluid of the scala media is held in a unique ionic composition of low sodium and high potassium. Maintenance of the ionic difference between perilymph and endolymph is a vital factor in cochlear function. Atrophy and degeneration of the stria (Fig. 34.4D) results in a loss of hearing across all frequencies that is proportional to the degree of loss of strial tissue (Pauler *et al.*, 1988).

The sensory organ of the cochlea, the organ of Corti, rests on an elastic portion of the cochlear partition, the basilar membrane. Oscillation of the stapes head produces an undulation, or rippling motion, along the basilar membrane. This motion was termed the traveling wave by von Békésy (1947). The basilar membrane varies in width along its length, being narrow at the base of the cochlea and wide at the apex. It also varies in stiffness, being stiffer at the base and more flaccid at the apex. As a result, the shape of the traveling wave varies from base to apex, with the short waves created by higher frequencies maximally displacing the narrower basal part of the membrane and the long waves generated by lower frequencies maximally displacing the broader apical segments. Approximately 10 octaves of sound, from 20 Hz to 20,000 Hz (20 kHz), are represented along the length of the basilar membrane. Because motion of the basilar membrane reflects the frequency–intensity pattern of the sound initiating the wave, distinct populations of cochlear hair cells in the organ of Corti will be set in motion by different sound stimuli. This differential displacement of the basilar membrane is the basis of tuning (frequency specificity) in auditory function.

Cochlear Hair Cells: Transduction and Amplification

Transduction, the conversion of mechanical energy to intracellular electrochemical events, occurs in the sensory cells of the organ of Corti. Views of the organ of Corti in a stained section (Fig. 34.5A) and a drawing (Fig. 34.5B) illustrate the single row of inner hair cells on the modiolar side of the cochlea and three rows of outer hair cells on the strial side. They also illustrate supporting cells and the triangular endolymph-filled space between the inner and outer hair cells, the tunnel of Corti. The name hair cell derives from the array of hairlike stereocilia on the free surface of these sensory cells. Electron microscopic images of the apical surface of human hair cells (Fig. 34.6A, B) demonstrate the different morphology of the stereociliary bundles on inner and outer hair cells. Stereocilia on inner hair cells are arranged in a shallow U curve, while those on outer hair cells have a more precise geometry, forming

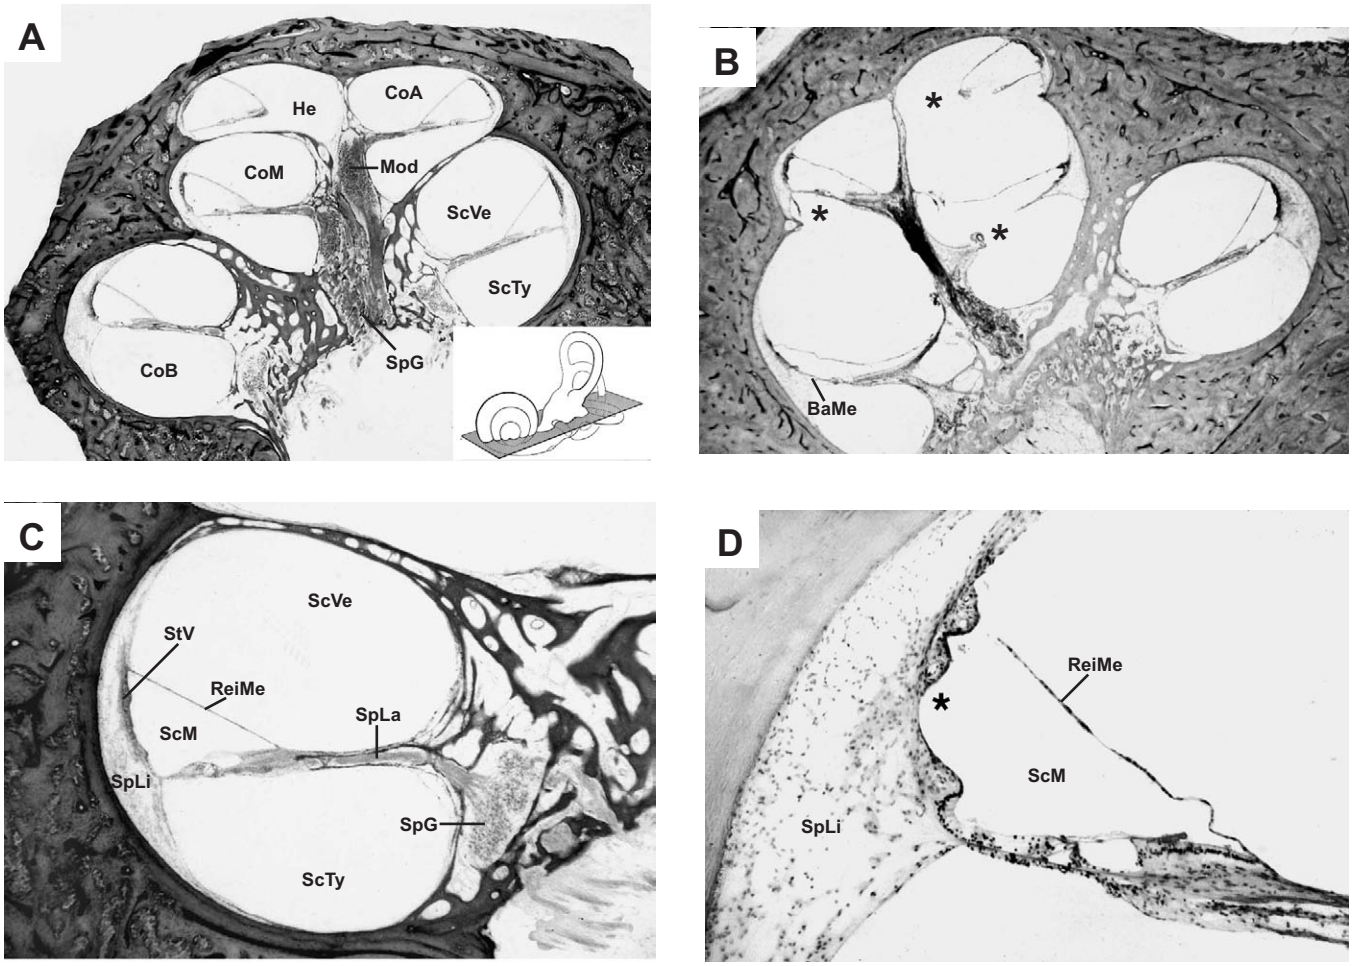

FIGURE 34.4 **(A)** A horizontal section through the human inner ear (plane shown in inset drawing) passes through the basal (CoB), middle (CoM) and apical (CoA) turns of the cochlea. The central pillar of the cochlea, the modiolus (Mod), contains the neurons of the spiral ganglion (SpG). Each turn of the cochlea is divided by a central partition into a scala tympani (ScTy) on the basal side and a scala vestibuli (ScVe) on the apical side. At the apex, the absence of this partition creates a confluence of the two scalae, the helicotrema (He). **(B)** In Mondini's deformity, a type of cochlear dysplasia, absence of the interscalar septum *(asterisks)* results in a confluence of the middle and apical turns. In addition, there is an abnormal basilar membrane (BaMe). **(C)** A single turn of the human cochlea is shown at higher magnification. A bony shelf, the spiral lamina (SpLa), divides the cochlea into two perilymph-containing compartments, the scala vestibuli (ScVe) and the scala tympani (ScTy). The lateral wall of the cochlea is formed by the spiral ligament (SpLi). On the surface of the spiral ligament is a densely cellular structure, the stria vascularis (StV). The thin Reissner's membrane (ReiMe) separates the scala vestibuli from the scala media (ScM). **(D)** Despite a normal-appearing organ of Corti, degeneration of the stria vascularis *(asterisk)* can cause hearing loss due to loss of normal electrolyte levels in the scala media. Celloidin sections, hematoxylin–eosin stain.

a V- or W-shaped bundle (Wright, 1981). On both types of hair cell, the rows of stereocilia are ordered in increasing height from inner to outer. A greater range from short to tall occurs in outer hair cells. In Figure 34.5A, as is usual after fixation and histological processing, the gelatinous tectorial membrane is not in contact with the hair cells. However, high-voltage electron microscopy on thick tissue sections (Takasaka *et al.*, 1983) has demonstrated that the tips of the tallest row of outer hair cell stereocilia are embedded in the underside of the tectorial membrane. Thus, the traveling wave displacement of the basilar membrane, with the organ of Corti on its surface, results in a shearing force exerted between the tallest row of stereocilia and the tectorial membrane.

Since only the tallest row of outer hair cell stereocilia is attached to the tectorial membrane, the shearing force might be expected to deflect only this

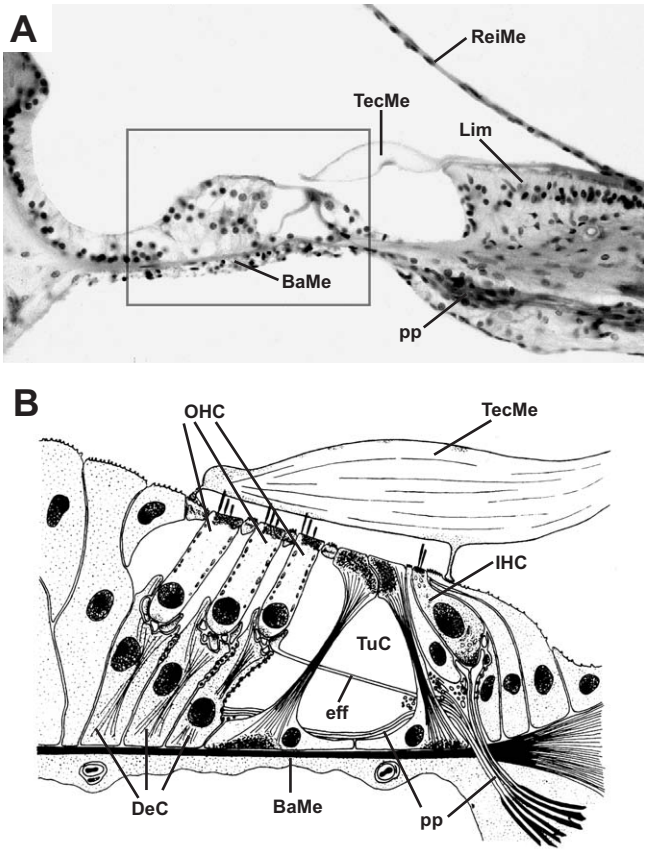

FIGURE 34.5 **(A)** Hair cells and other sensory structures are located in the organ of Corti *(boxed area)*. The gelatinous tectorial membrane (TecMe) is attached medially to a prominence, the limbus (Lim). Running medially from the organ of Corti are the peripheral processes of spiral ganglion cells (pp). Celloidin section, hematoxylin–eosin stain. **(B)** The organ of Corti rests on the basilar membrane (BaMe). Flask-shaped inner hair cells (IHC) are contacted by numerous peripheral processes of spiral ganglion neurons (pp). Outer hair cells (OHC) form three rows: they are more tubular in shape, and their bases are enclosed by Deiter's cells (DeC). A limited number of peripheral processes cross the tunnel of Corti (TuC) to contact outer hair cells. The longest stereocilia of outer hair cells are attached to the underside of the tectorial membrane. Adapted from A. Ryan and P. Dallos, figure 2–4, The physiology of the cochlea, pp. 15–31, in "Hearing Disorders", Ed., J. Northern, published by Allyn and Bacon, Boston, 1996, with permission.

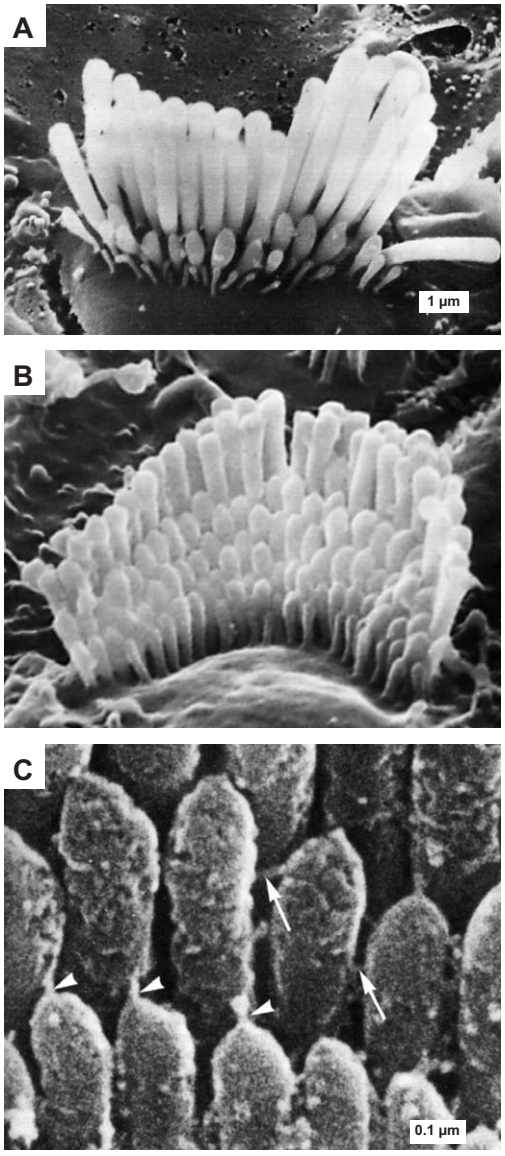

FIGURE 34.6 **(A)** Scanning electron micrographic image of the U-shaped array of stereocilia on the upper surface of a human inner hair cell. Stereocilia of the same row on each hair cell are joined by horizontally running links *(arrows)*. Each shorter stereocilium gives rise to a single vertically pointing link that runs upward to attach to the adjacent taller stereocilium *(arrowheads)*. Reprinted from *Journal of Laryngology and Otology* **99,** P.H. Rhys Evans, S.D. Comis, M.P. Osborne, J.O. Pickles, and J.R. Jeffries, figure 6, Cross-links between stereocilia in the human organ of Corti, pp. 11–19, 1985, with permission from the Royal Society of Medicine Press Limited, London.

row. In fact, this does not occur because of a network of fine filaments linking the stereocilia within each bundle. Side links join stereocilia in the same row, and tip links pass from the tips of stereocilia in the shorter rows to the next tallest row, both in animals (Pickles *et al.*, 1984) and in the human cochlea (Rhys Evans *et al.*, 1985) (Fig. 34.6C). These side-to-side and row-to-row connections form a regular lattice such that when the tallest row of stereocilia is displaced by the tectorial membrane the stereociliary bundle moves as a unit. In addition to their purely mechanical role in bundle

motion, stretching of stereociliary cross-links appears to activate ion channels in the stereociliary membrane (Hudspeth, 1989; Denk *et al.*, 1995). Deflection of the bundle toward tall stereocilia stretches tip links and opens the membrane channels, while deflection toward the shortest row relaxes the links and allows the ionic channels to close. Because hair cells and their stereocilia lie in high-potassium endolymph, it is possible that potassium ions enter through the membrane channels. One immediate result of inward ion flow is activation of contractile molecules within the stereocilia. Each stereocilium is filled with long actin filaments, organized into bundles and arrays by fimbrin (Flock *et al.*, 1981, 1982). The actin filaments extend through the rootlets of the stereocilia, anchoring them into the cuticular plate on the free surface of the hair cell. When traction on the fibrous links opens channels in the stereociliary membrane, the ionic influx activates these contractile molecules, stiffening the stereocilia.

A continuing question in cochlear function is the fact that the stereociliary bundles of inner hair cells do not seem to have a direct attachment to the tectorial membrane. It is possible that their stereocilia are deflected by viscous drag of the fluid in the subtectorial space. This difference may account for the fact that inner hair cell stereocilia are less anatomically specialized than those of outer hair cells. In addition, it appears that inner and outer hair cells have different roles in the transduction of activity within the cochlea. Inner hair cells provide direct input to virtually all of the axons in the cochlear nerve. However, their activity is modified by local amplification of the motion of the basilar membrane produced by outer hair cells. This role in amplification is related to an active contractile process located in their lateral cell wall. The contractile molecules in their cell membrane cause isolated outer hair cells to undergo rapid length changes when stimulated by an electric current (Brownell *et al.*, 1985; Kachar *et al.*, 1986; Ashmore, 1987), by a tone stimulus (Brundin *et al.*, 1989), or by deflection of the stereociliary bundle (Evans and Dallos, 1993). In an intact cochlea, the active shape changes occurring in populations of outer hair cells in response to stimulation by a tone (Brundin *et al.*, 1992) or electrical current (Mammo and Ashmore, 1993) are capable of displacing the basilar membrane. Observations in intact cochleas indicate that outer hair cell–related supporting cells (Dieter's and Hensen's cells) are also involved in the process of displacing the basilar membrane (Flock *et al.*, 1999). This localized amplification of basilar membrane motion can enhance the response of inner hair cells in a narrow frequency range, and is generally believed to be the basis of low threshold (sensitivity) in mammalian hearing.

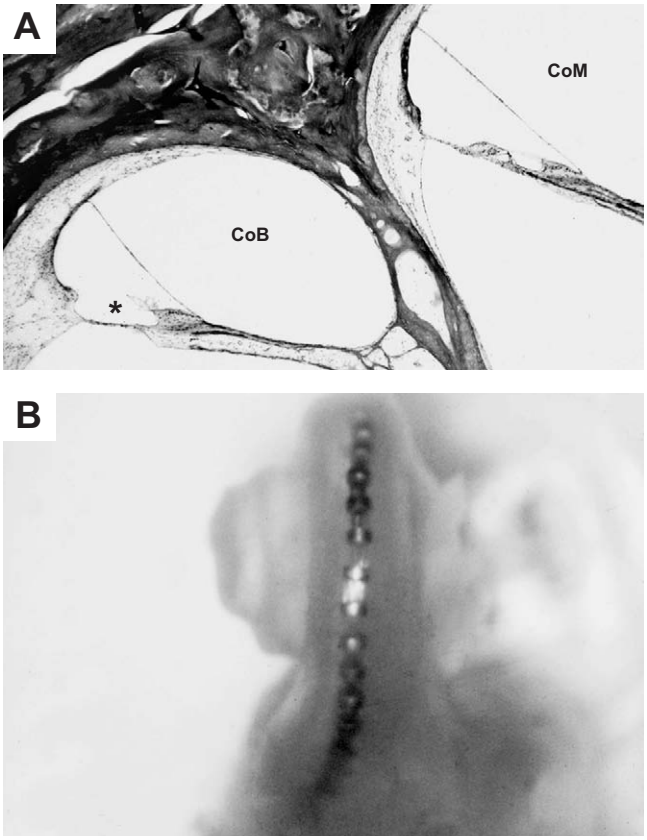

FIGURE 34.7 **(A)** Illustration of degeneration of the organ of Corti *(asterisk)* in the basal turn (CoB) of a human cochlea. The organ of Corti in the middle turn (CoM) is intact. Celloidin section, hematoxylin–eosin stain. **(B)** A multielectrode implant is shown in place in the basal turn of a skeletonized and cleared human cochlea.

Because hair cell transducer and amplification mechanisms are essential to the hearing process, it is not surprising that hair cell loss is the most common cochlear defect causing hearing loss. The base of the cochlea, where higher frequencies are transduced, is usually the most affected (Fig. 34.7A). In presbycusis, the hearing loss of the aged, the loss begins in midlife with degeneration of outer hair cells at the extreme basal end of the cochlea but does not seriously affect hearing until the upper range of speech frequencies, around 3000 Hz, is affected. Noise-induced hearing loss and severe blows to the head tend to affect the anterior basal turn of the cochlea, the region that processes 3000–4000 Hz (Linthicum, unpublished observations). The cause of the sensitivity of this specific area is unknown. Hearing loss due to inner hair cell absence is rare, but may occur as a congenital defect or as a result of advanced degeneration of the organ of Corti. In cases of hearing loss attributable to hair cell loss, some degree of hearing can be achieved by implantation of

a multiple-electrode stimulating device (Fig. 34.7B). Such a device bypasses cochlear hair cells and provides direct stimulation to the neural elements of the cochlea, the next step in the process of sound transmission.

Spiral Ganglion Cells and Cochlear Nerve: Neural Transmission

The transition from hair cell activity to neural activity occurs within the cochlea. Activation of the stereocilia creates changes in the intracellular potential that, in turn, lead to the release of a neurotransmitter from aggregations of synaptic vesicles located at the base of the hair cell. Opposite the cluster of synaptic vesicles, on the outer surface of the cell wall, are bulbous nerve terminals. Electron microscopy of human hair cells has demonstrated that from six to eight such terminals are present on the base of each inner hair cell, and a smaller number are located on each outer hair cell (Nadol, 1990). Each synaptic terminal continues into a short unmyelinated process, approximately 100 μm in length. The terminals, together with the short length of unmyelinated process beyond them, constitute the dendritic (information receiving) segment of cochlear nerve fibers. The unmyelinated processes pass through a series of small apertures in the osseous spiral lamina, the habenula perforata. At this point they become surrounded by a sheath of myelin created by Schwann cells (Spoendlin and Schrott, 1989) and thus become axons capable of rapid conduction. The entire cell process, including the unmyelinated tip and its myelinated continuation, is often referred to as a dendrite but is more correctly called the peripheral process of a spiral ganglion neuron because it includes both dendritic and axonal segments. In an osmicated cochlea (Fig. 34.8A), small bundles of peripheral processes can be seen passing from the organ of Corti toward the modiolus. As they leave the organ of Corti, these fascicles run between the two lamellae of bone that form the osseous spiral lamina (Fig. 34.8B).

The myelinated peripheral processes run along the spiral lamina, bend slightly downward as they enter the modiolus, and reach their cells of origin in the spiral ganglion (Fig. 34.8C). The spiral ganglion is so named because it spirals within Rosenthal's canal from the base of the modiolus to its midpoint. At the midpoint of the modiolus, the canal disappears and ganglion cells become a confluent mass. Because the ganglion reaches only halfway from the base of the cochlea to the apex, the peripheral processes contacting hair cells in the apical and upper middle turns of the cochlea extend down through the modiolus to reach the most apical ganglion cells. The number of human spiral ganglion cells varies with age from 36,000 in infants and 27,000 in the fourth decade, to only 18,000 in the elderly (Otte *et al.*, 1978). Human spiral ganglion cell bodies are unmyelinated, except for a few that become myelinated with age (Ota and Kimura, 1980).

Two types of neuron have been identified in the spiral ganglion of mammals (Kiang *et al.*, 1982) and humans (Spoendlin, 1985). A majority (90–95%) of the spiral ganglion neurons are type I cells, large round cells about 25–30 μm in diameter (Fig. 34.8D). Type I cells have peripheral processes contacting inner hair cells in a highly convergent manner in that each inner hair cell is contacted by terminals of peripheral processes of several type I ganglion cells. Thus, each inner hair cell drives a group of type I ganglion cells with its activity. In contrast, about 5–10% of the total number of cells in the spiral ganglion are type II cells, which are considerably smaller (15 μm in diameter; Fig. 34.8E) and generally located near the periphery of the ganglion. Their thin unmyelinated peripheral processes cross the tunnel of Corti (Fig. 34.5B) and branch to synapse with outer hair cells in a highly divergent manner, with one type II peripheral process contacting a number of outer hair cells. Because type II peripheral processes branch widely and overlap in their distribution, each outer hair cell is contacted by multiple terminals. The result of this differential innervation of inner and outer hair cells is that type I ganglion cells, relaying the activity of inner hair cells, constitute almost the entire volume and information content of the cochlear nerve. The contribution of outer hair cells to the pattern of activity in the nerve is mainly an indirect one, based on their ability to amplify the activity of subpopulations of inner hair cells.

Spiral ganglion cells of both types give rise to central processes that pass through the center of the modiolus and the cribriform area at its base to form the cochlear nerve. The central processes of ganglion cells innervated by apical hair cells are at the center of the nerve, and those representing the middle and basal segments of the cochlea are progressively more peripheral (Spoendlin and Schrott, 1989). The spiraling course of the cochlear nerve can be observed in the human nerve as it passes into the internal auditory canal within the temporal bone (Fig. 34.9A). Near the outlet from the internal auditory canal, the internal auditory meatus or porus acusticus, there is an abrupt change in the myelin sheath from one produced by Schwann cells to one produced by glial (oligodendroglial) cells of the central nervous system. It is the glial portion of the nerve that exits from the internal auditory canal and crosses the intradural space to reach the brain stem. Just medial to the cochlea in the internal auditory canal, the auditory nerve comes into contact with the

nerve from the vestibular organs (Fig. 34.9B). Though there may be mingling of the fibers of the adjacent nerves, axons of the two nerves are generally distinguishable by their diameter (Natout *et al.*, 1987). Vestibular nerve axons are larger and more variable in size, with a majority of the fibers in the 7- to 15-µm size range. Cochlear nerve axons are smaller and more uniform, generally 3–5 µm in diameter.

Auditory Periphery: Generation of Evoked Activity

Because outer hair cell contraction can produce motion of the basilar membrane, it is thought to be responsible for otoacoustic emissions, which are audible sounds emitted by the ear (Kemp, 1978). The production of otoacoustic emissions is termed reverse transduction because it reverses the usual sequence of events during audition. Rhythmic contraction of outer hair cells, and possibly also their supporting cells, causes vibration of the basilar membrane. This, in turn, produces pressure waves in perilymph, motion of the ossicles, and oscillation of the tympanic membrane. Vibration of the tympanic membrane results in recordable sound waves being emitted from the ear. Otoacoustic emissions can be diminished or abolished by overexposure to substances, such as salicylates and quinine, which produce tinnitus and hearing loss in human subjects (Brownell, 1990). Microscopic examination of outer hair cells in guinea pigs exposed to salicylate reveals changes in the hair cell wall, including diliatation and vesiculation of subsurface cisternae

Plastic section, toluidin blue stain with osmium.

(Deiler *et al.*, 1991; Lue and Brownell, 1999). Similar changes are observed in guinea pig hair cells after treatment with quinine (Karlsson *et al.*, 1991). The pathological effects of these substances, and their interference with the lateral cell wall contractile mechanism, supports the idea that outer hair cell motion is a necessary part of the generation of otoacoustic emissions.

The activity of cochlear sensory cells and neurons also generates externally recordable bioelectric potentials. One of these early potentials, the cochlear microphonic, is a low-amplitude potential recorded from the external auditory canal or surface of the tympanic membrane during a sound stimulus. The cochlear microphonic disappears in guinea pigs whose hair cells have been destroyed by administration of the antibiotic kanamycin (Dallos and Cheatham, 1976). These experiments also demonstrated an imbalance in the contribution of inner and outer hair cells to the cochlear microphonic. On schedules of kanamycin administration that destroyed primarily inner hair cells, leaving an almost normal complement of outer hair cells, the cochlear microphonic was essentially normal. When outer hair cells were destroyed, the microphonic was only a small fraction of normal. Thus, the cochlear microphonic is believed to reflect hair cell activity, principally or exclusively that of outer hair cells, during the transduction process.

True neural activity is reflected in the auditory brain stem response (ABSR), an externally recordable series of small amplitude and short, latency wave-like potentials evoked by a transient stimulus, such as a click. Several studies in human subjects have shown that the earliest ABSR waves, waves I and II, are generated by the cochlear nerve. Intrasurgical recordings, made with a wire electrode placed directly on the auditory nerve and brain stem (Moller and Jannetta, 1982), concluded that the first two ABSR waves are generated prior to the entrance of the nerve into the brain stem. In animal studies, sectioning of the cochlear nerve at the internal acoustic meatus leaves wave I intact but abolishes all subsequent ABSR waves (Buchwald and Huang, 1975), indicating that wave I reflects activity in the most peripheral portion of the nerve fibers. A potential corresponding to wave II of the scalp-recorded ABSR can be recorded intrasurgically from the surface of the human cochlear nerve as it passes through the internal auditory meatus and crosses the intradural space (Martin *et al.*, 1995). In addition, a dipole localization study concluded that human wave II is generated as action potentials in the auditory nerve cross the conductivity boundary at the interface of the temporal bone and cerebrospinal fluid space (Scherg and von Cramon, 1985). Thus, both waves I and II of the human ABSR appear to be generated by activity in axons of the cochlear nerve.

The distinction between potentials generated by hair cells and neural potentials is supported by clinical observations in subjects with a condition known as auditory neuropathy. In these subjects, hearing thresholds measured by pure-tone audiometry are normal, but there is relatively poor speech perception (Starr *et al.*, 1991). Physiologically, normal cochlear microphonic potentials and otoacoustic emissions are present, implying that hair cell motility is intact. However, ABSR recordings are either highly distorted or completely absent in these subjects. Because a recordable potential requires synchronous activity in a population of axons, the loss of all waves of the ABSR in

these subjects suggests that transient stimuli do not produce synchronized firing in the cochlear nerve. The idea that absence of the ABSR represents a loss of neural synchrony is supported by the defects in myelination and neural conduction identified in some cases of this condition (Starr *et al.*, 1996).

THE BRAIN STEM AUDITORY SYSTEM

Cochlear Nuclei: Diversification of Cochlear Input

Activity generated in the cochlea is carried to the brain stem by the cochlear nerve. In man, as in other mammalian species, the cochlear nerve enters the ventral cochlear nucleus and forms a wedge-shaped nerve root tapering dorsally (Moore and Osen, 1979) (Fig. 34.10). The axons entering the nerve root are grouped into small fascicles that appear to have traveled together from their point of origin in the organ of Corti. Cochlear nerve axons bifurcate within the nerve root to form an ascending branch running toward the rostral end of the nucleus and a descending branch running caudally. The territory pierced by the ascending branches is termed the anteroventral cochlear nucleus, and the region innervated by the descending branches is the posteroventral cochlear nucleus. In most mammalian species, the nerve root forms a partition dividing the anteroventral and posteroventral divisions of the nucleus. In man, these two subdivisions are broadly confluent lateral to the nerve root, so that the division between the two regions is somewhat arbitrary. Though the greater part of the human ventral cochlear nucleus consists of cells lying among the ascending and descending cochlear nerve branches, there is a relatively large cap area that lies outside of the field of the primary fibers. The cap is saddle shaped, rising high above the ventral nucleus dorsally and extending down on both sides, with greater thickness on the lateral side of the nucleus. The cap area is traversed by very thin myelinated fibers that have been shown to be collaterals of the ascending and descending primary branches (Feldman and Harrison, 1969). At the surface of the nuclear complex, there is an amorphous zone of tissue that appears featureless in cell or myelin stains, but which is shown by immunostaining to be composed of massed astrocytic processes. This superficial glial layer, which is more prominent in the brain stems of humans and other higher primates than in nonprimate species, extends beyond the cochlear nuclei over the brain stem surface.

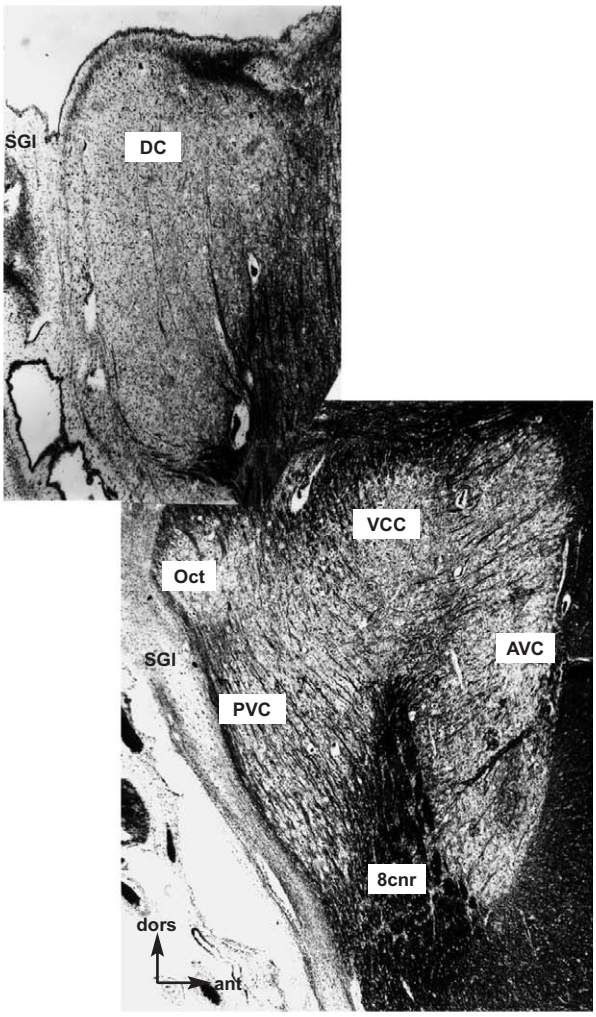

FIGURE 34.10 Collage of two myelin-stained sagittal sections through the human dorsal and ventral cochlear nuclei. Cochlear nerve fibers bifurcate in the cochlear nerve root (8cnr) in the center of the ventral cochlear nucleus. From the nerve root, ascending branches pass into the anteroventral nucleus (AVC). Descending branches of the nerve run through the posteroventral nucleus (PVC), including the octopus cell area (Oct), and continue into the dorsal cochlear nucleus (DC). Main-stem branches of the cochlear nerve do not enter the cap area (VCC) dorsal to the nerve root. Celloidin sections, Woelcke hematoxylin stain. A superficial glial zone (SGI) covers the surface of the nuclei.

A cochleotopic organization of the axons within the nerve has been demonstrated in squirrel monkeys with restricted cochlear lesions (Moskowitz and Liu, 1972). Axons of spiral ganglion cells innervating hair cells in the apex of the cochlea (activated by low tones) bifurcate in the ventral part of the nerve root, near the point of entry of the nerve. Axons of spiral ganglion cells innervating hair cells located at the base of the cochlea (activated by high tones) extend to the dorsal tip of the nerve root and bifurcate there. From the

nerve root, axons representing a point on the organ of Corti maintain their relative positions as they project through the cochlear nuclei as ascending and descending branches. Thus, in their course, each group of branches representing a point on the cochlea spreads to form a plane of fibers crossing the nuclei. Because the cochleotopic sequence of nerve distribution shown in the squirrel monkey is identical to that seen in other mammalian species, it is assumed that a similar organization exists in the human cochlear nerve.

The descending branches of the cochlear nerve run relatively straight caudally through the posteroventral nucleus until they reach its posterior tip, at which point they become distinctly convergent (Fig 34.10). From the posterior tip of the ventral nucleus, most of the descending branches continue into the dorsal nucleus. In most mammals, the descending cochlear branches entering the dorsal nucleus turn to run toward the surface of the nucleus, forming tonotopic planes orthogonal to the nuclear surface. In humans, however, the descending branches fan out across the width of the dorsal nucleus and run parallel to its surface. This change in direction is presumably related to altered cytoarchitecture in the human dorsal nucleus, changes that are discussed in the following sections. Ascending branches of the cochlear nerve do not, like the descending branches, converge in their course. Instead, the planes of axons retain the same spacing from their point of emergence from the nerve root, or may even diverge slightly. A regular laminar structure, with palisades of ascending branches alternating with tiers of cells, is characteristic of the entire anteroventral nucleus and is particularly clear at its rostral tip.

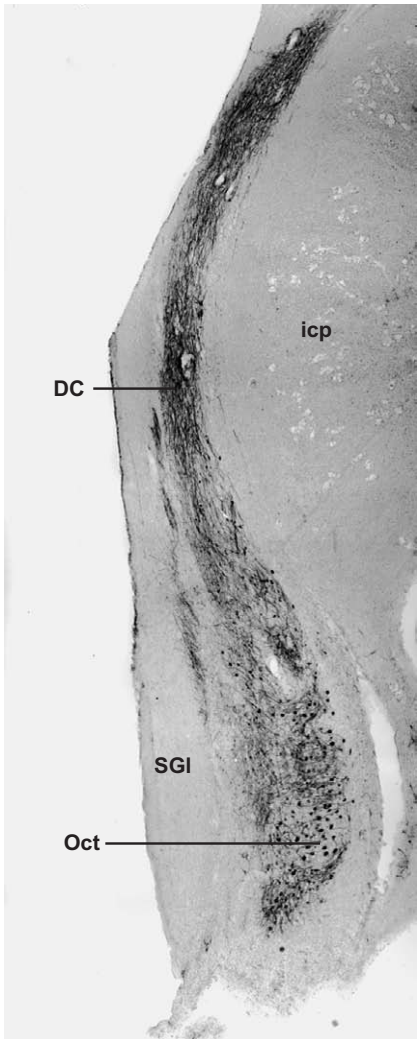

FIGURE 34.11 Transaxial section through a caudal level of the human cochlear nuclei. The dorsal cochlear nucleus (DC) is curved and flattened over the inferior cerebellar peduncle (icp). The posterior tip of the ventral nucleus consists of the octopus cell area (Oct). A superficial glial zone (SGl) covers the surface of the nuclei. Celloidin section, immunostained for MAP2 (microtubule-associated protein).

Projection Pathways

The cochlear nuclei are composed of a variety of neuronal types with distinctive patterns of dendritic branching. The cell types described in the human cochlear nuclei (Moore and Osen, 1979; Adams, 1986) are generally, but not always, similar to those of other mammalian species. An indication of this varied cellular morphology can be seen in transaxial sections immunostained for the neurofilaments in neuronal somata and dendrites. At the caudal end of cochlear nuclear complex, the elongated and flattened dorsal cochlear nucleus curves around the inferior cerebellar peduncle (Fig. 34.11). Ventrally, the most posterior tip of the ventral nucleus is seen as an oval region of larger cells, the octopus cell area (Fig. 12.8). Because the cochlear nerve terminates on a number of populations of neurons, the cochlear nuclei are a point of diversification where the single representation of cochlear activity carried in the nerve is transformed into multiple patterns traveling in parallel pathways up through the brain stem.

One projection pathway originates from the larger cells of the dorsal cochlear nucleus. These neurons are slender fusiform or bipolar cells with long polar dendrites extending parallel to the overlying surface (Fig. 34.12A, B). They were considered by Moore and Osen (1979) to be equivalent to fusiform cells of other species, despite their divergence from the characteristic mammalian morphology and orientation. Fusiform cells in most mammals are oriented radial to the nuclear surface and have two distinctive dendritic arbors extending from the cell soma, one toward the

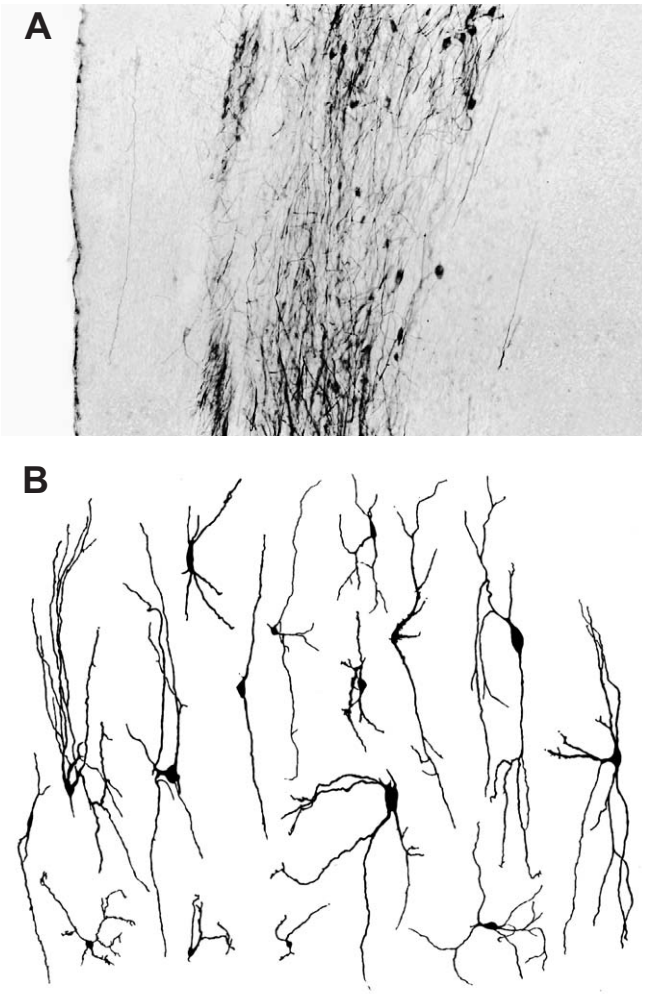

FIGURE 34.12 **(A)** Fusiform cells of the human dorsal cochlear nucleus are oriented along the long axis of the nucleus, parallel to the surface. Reprinted from *Archives of Otolaryngology, Head and Neck Surgery* **112,** J.C. Adams, figure 7, Neuronal morphology in the human cochlear nucleus, pp. 1253–1261, 1986, with permission from the American Medical Association.

surface of the nucleus and one into its central region. The chief basis for equating human dorsal nucleus neurons to fusiform cells in other mammals is the series of changes occurring in the dorsal nucleus in higher primates (Moore, 1980). Fusiform cells in prosimian primates and monkeys are peripherally located and orthogonally oriented, as in other mammals. In apes, however, with regression of the granule cell system (see discussion on intrinsic systems of cochlear nuclei), fusiform cells become progressively incorporated into the central part of the dorsal nucleus and come to lie horizontally within the field of cochlear nerve axons. This configuration is essentially identical to human dorsal nucleus cytoarchitecture. As in nonprimates, processed information leaves the primate and human dorsal nucleus through the dorsal acoustic stria, a band of thin myelinated axons running over the top of the inferior cerebellar peduncle (macaque, Strominger, 1973; chimpanzee, Strominger *et al.*, 1977; man, Moore and Osen, 1979).

A second brain stem pathway originates from a population of neurons located at the caudal end of the ventral nucleus, the octopus cells. The cells of this region were so named by Osen (1969) because of the emergence of several long thick dendrites from one side of the rounded cell soma, giving the cell a resemblance to an octopus (Fig. 34.13A, B). Because octopus cells are located at the point of maximal convergence of the descending branches of the cochlear nerve, their dendrites cross a large number of axons and receive a very wide spectrum of input from the cochlear nerve. This broad band input is reflected in their detection of coincident firing across groups of auditory nerve fibers and in their well-timed responses to periodic broad-band sounds such as clicks (Oertel *et al.*, 2000). In the macaque, chimpanzee, and man, as in nonprimate mammals, axons from the posterior tip of the ventral cochlear nucleus leave the nucleus in the intermediate acoustic stria, a band of thick beaded axons running deep to the dorsal stria over the top of the inferior cerebellar peduncle and into the brain stem (Strominger, 1973; Strominger *et al.*, 1977; Moore and Osen, 1979).

Farther rostral, at the level of cochlear nerve root, the ventral nucleus has a more compact, roughly triangular configuration (Figs. 34.14, 12.9). The central region of the ventral nucleus contains a heterogeneous population of neurons that vary in size and staining patterns. The name multipolar cell has been applied to all of these cell groups because of the multiple straight, relatively unbranched and appendage-free dendrites radiating from their somas (Fig. 34.15A, B). As a class, they are the most common cell type in the human cochlear nuclei. Many multipolar cell dendrites are oriented parallel to the tonotopic planes of the cochlear nerve and thus would receive relatively narrow band input from its axons. However, multipolar cells also give rise to dendrites that cross the tonotopic planes dorsoventrally. Numerous small bouton-type endings are formed by the cochlear nerve on the somata and extensive dendrites of multipolar cells (Tolbert and Morest, 1982). Efferent axons of neurons the central ventral nucleus leave the nucleus in the ventral acoustic stria and cross the midline in the trapezoid body (Strominger and Strominger 1971; Strominger *et al.*, 1977; Moore and Osen, 1979).

The anterior ventral nucleus contains a population of neurons that are distinguishable from multipolar

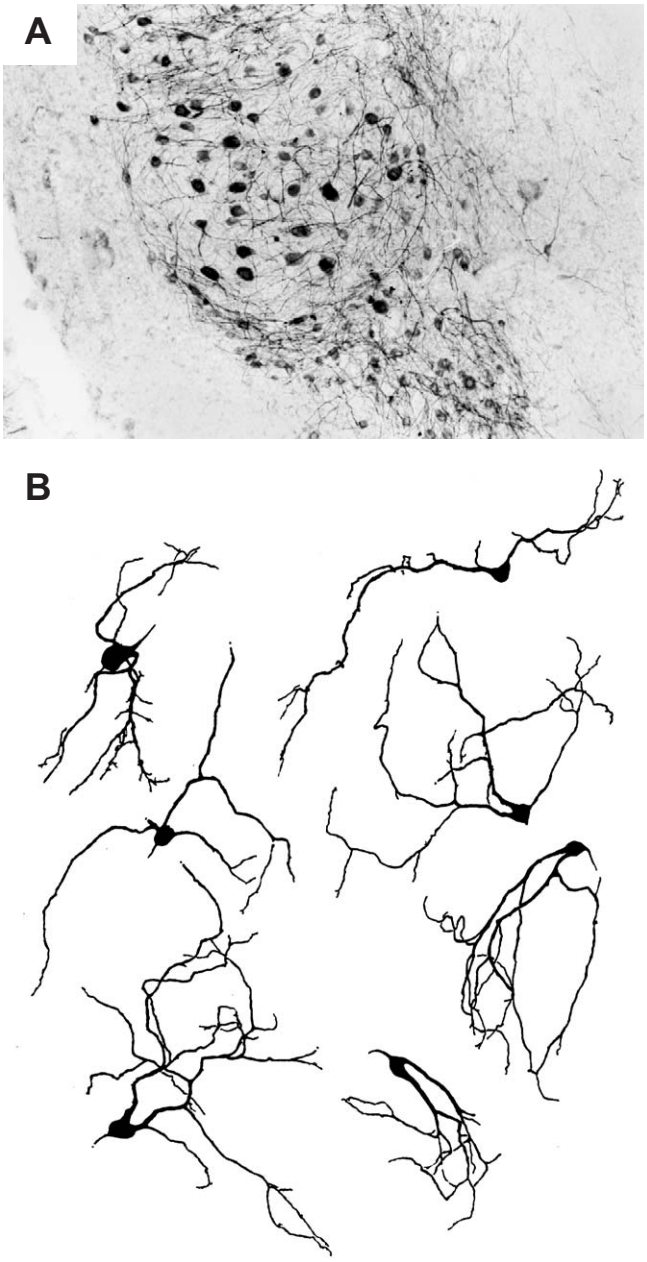

FIGURE 34.13 **(A)** Octopus cells of the human ventral cochlear nucleus are large ovoid neurons with thick radiating dendrites. Celloidin section, MAP2 immunostaining. **(B)** Drawing of Golgi-impregnated octopus cells in the human ventral cochlear nucleus. cells because of their rounded somata, short-stem dendrites, and tufted dendritic arbors (Fig. 34.16A, B). These neurons were given the name bushy cells by Brawer *et al.* (1972) because of their terminal dendritic tufts. They have been divided into two subtypes,

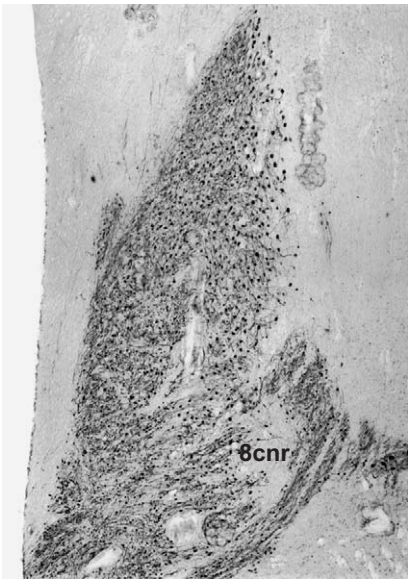

FIGURE 34.14 Transaxial section through the human ventral cochlear nucleus at the level of the cochlear nerve root (8cnr). Celloidin section, MAP2 immunostaining.

globular bushy cells and spherical bushy cells, both of which have been identified in the human ventral cochlear nucleus (Moore and Osen, 1979; Adams, 1986). Globular cells have somewhat longer, sparser dendrites and are most numerous close to and within the nerve root. Spherical cells have shorter, more distinctly tufted dendrites and are aligned in rows at the rostral pole of the nucleus. Both globular and spherical cells receive expanded bulb and calyceal-type endings that cover much of the cell soma and form multiple synaptic junctions (Cant and Morest, 1979; Ostapoff and Morest, 1991). Bushy cell innervation is thus quite different from the multiple small terminals contacting dendrites of octopus and multipolar cells. Because the somatic terminals arise from only a few cochlear nerve axons, bushy cells tend to reflect stimulus parameters very accurately in their firing pattern. Axons of both types of bushy cell leave the nucleus through the ventral acoustic stria and trapezoid body (Strominger and Strominger, 1971; Strominger *et al.*, 1977; Moore and Osen, 1979).

Intrinsic Systems

Not all cells in the cochlear nuclei are projection neurons forming ascending pathways. Some cell groups, particularly the smaller cells, appear to be intrinsic neurons with axons terminating entirely within the nuclei. Undoubtedly, much of the complexity and multiplicity in the transformation of auditory nerve input by cochlear nucleus neurons arises from the interaction of auditory nerve and intrinsic cochlear

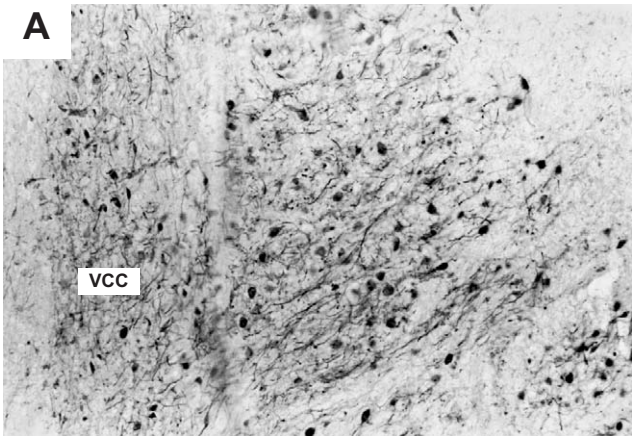

FIGURE 34.15 **(A)** Multipolar cells in the main portion of the human ventral cochlear nucleus have long dendrites that run parallel to the planes of entering cochlear nerve axons. In the cap area (VCC), dendrites are more randomly oriented. Celloidin section, MAP2 immunostaining. **(B)** Drawing of Golgi-impregnated multipolar cells in the human ventral cochlear nucleus. activity. Many modulatory neurons have been identified by their content of the inhibitory amino acid neurotransmitters, γ-aminobutyric acid (GABA) and glycine. Studies of inhibitory neurons in the cochlear nuclei of the baboon (Moore *et al.*, 1996a) demonstrate the same four inhibitory systems as are seen in other mammals, namely, a granule–cartwheel cell system, a commissural projection, an association projection from the dorsal nucleus to the ventral nucleus, and a cap area. However, the anatomy of the human cochlear nuclei suggests that only the latter three modulatory systems are present in humans.

In regard to the granule cell system, the previous description of the human dorsal nucleus noted that its cytoarchitectural organization is different from that of most mammals. In nonprimates, the dorsal cochlear nucleus is covered by a thick molecular layer, formed by axons of cells in the superficial granular layer (Mugnaini *et al.*, 1980). The internal synaptic organization of the granule cell system is complex and very

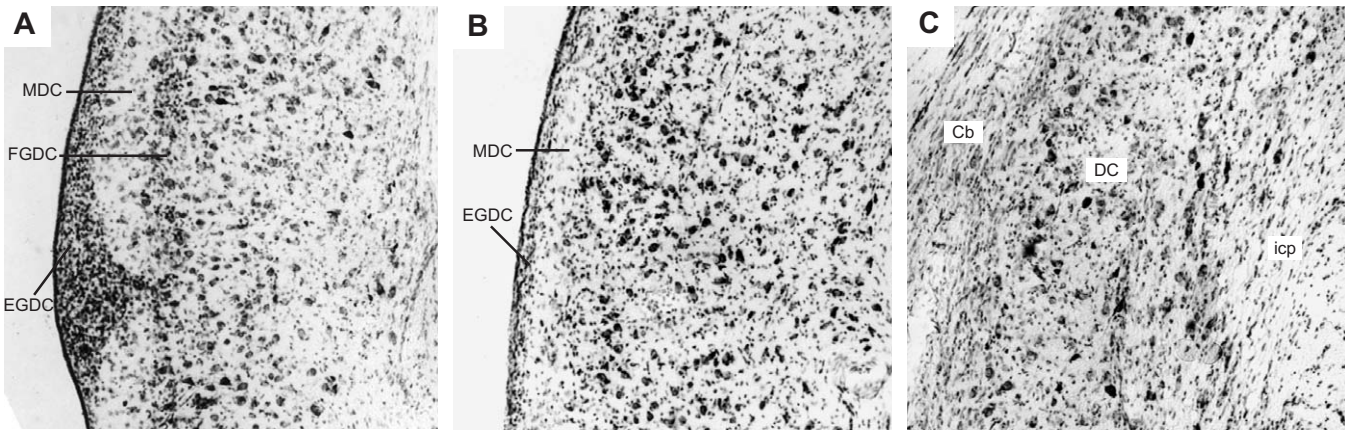

FIGURE 34.17 Progressive changes in the cytoarchitecture of the dorsal cochlear nucleus in primates. **(A)** In a prosimian, the loris, most granule cells are located on the surface of the nucleus in the external granular layer (EGDC). A smaller number of granule cells are present in the fusiform-granule cell layer (FGDC). Granule cell axons form a superficial molecular layer (MDC). **(B)** In a ceboid primate, the owl monkey, there is a thin external granular layer and a molecular layer. Fusiform cells are scattered through the body of the nucleus. **(C)** In the gibbon, with the disappearance of the granule cell layers, there is no evidence of lamination in the dorsal nucleus. Cb, cerebellum; icp, inferior cerebellar peduncle. Celloidin sections, Nissl stain. Adapted from *Journal of Comparative Neurology* **193,** J.K. Moore, 1980, figures 2, 3, and 4, The primate cochlear nuclei: loss of lamination as a phylogenetic process, pp. 609–629, 1980, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons Inc., New York.

similar to that of the cerebellar cortex in that it includes several types of small inhibitory neuron, i.e., Golgi cells with strong glycine and GABA activity, small stellate cells with single GABA activity, and cartwheel cells with both glycine and GABA activity (Kolston *et al.*, 1992). In mammals, the granule cell system as a whole projects to the apical dendrites of dorsal nucleus fusiform cells and strongly modifies their activity. Across primates, however, there is a steady dissolution of this intrinsic inhibitory circuitry (Moore, 1980). In prosimian primates, the presence of an external granule cell layer indicates an incipient failure of inward migration and maturation of granule cells (Fig. 34.17A). The failure of migration is more pronounced in New and Old World monkeys, with the result that the granular layers are very reduced (Fig. 34.17B). In the baboon, GABA-glycine immunohistochemistry indicates that the number of granule cell–related inhibitory interneurons is reduced compared to nonprimate mammals. In apes (Fig. 34.17C) and humans, there are only vestigial clusters of granule cells near the surface of the dorsal and ventral nuclei. The reduction of this system in higher primates and its loss in the human cochlear nuclei must affect the information processing the human dorsal nucleus, but in a way that at present is difficult to assess.

In nonprimate mammals, large glycine-positive cells have been shown to project to the cochlear nuclei on the contralateral side of the brain stem (Wenthold, 1987), where their axons branch and distribute inhibitory terminals widely (Cant and Gaston, 1982). These anatomical findings agree with physiological evidence for inhibitory interactions between the cochlear nuclei. In an *in vitro* whole-brain study in guinea pigs, short-latency (3–9 ms) inhibitory potentials were recorded from most neurons after stimulation of the contralateral cochlear nerve (Babalian *et al.*, 1999). This widespread inhibition is presumably mediated by the glycinergic commissural axons. In the baboon, similar glycine-labeled neurons are found scattered throughout the central region of the ventral nucleus and occasionally in the overlying cap area (Fig. 34.18), and their thick glycine-positive axons leave the nuclei in the acoustic striae. In the human cochlear nuclei, giant cells are believed to be homologous to glycinergic commissural neurons in other species and, like those cells, should affect the balance of the level of activity in the cochlear nuclei on the two sides of the brain.

The human dorsal cochlear nucleus contains a number of small spindle-shaped neurons, less that 15 μm in diameter, oriented parallel to the nuclear surface (Fig. 34.13A). These small cells in man probably correspond to the glycine- and GABA-positive neurons in the central part of the dorsal nucleus of nonprimate mammals (Saint Marie *et al.*, 1991; Kolston *et al.*, 1992) and baboon (Moore *et al.*, 1995) (Fig. 34.18). They have been referred to as vertical cells, corn cells, or fan cells, and were designated tuberculoventral cells by Oertel

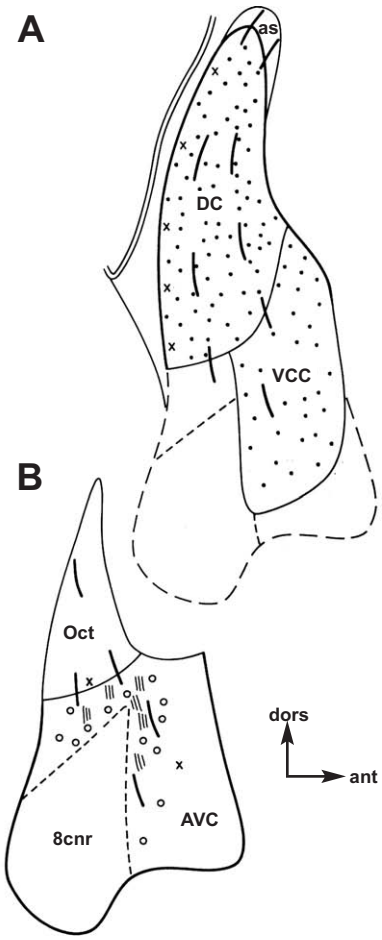

FIGURE 34.18 The distribution of GABA- and glycine-positive structures in the baboon cochlear nuclei is illustrated in schematic drawings of two sagittal sections. **(A)** In a more laterally located section, a few single-labeled GABA cells (**x**) are found around the margin of the dorsal nucleus. Neurons colocalizing GABA and glycine (✳) are numerous in the dorsal cochlear nucleus (DC) and the cap area (VCC). Solitary large-diameter glycine-positive commissural axons *(thick lines)* course obliquely upward toward the acoustic striae (as). **(B)** Large neurons in the central portion of the ventral cochlear nucleus (**o**) that are single labeled for glycine are the presumed origin of the commissural axons. Fascicles of double-labeled tuberculoventral axons *(thin lines)* run from the dorsal nucleus to the central portion of the ventral nucleus. Adapted from *Journal of Comparative Neurology* **369,** J.K. Moore, K.K. Osen, J. Storm-Mathisen, and O.P. Ottersen, figure 14, γ-aminobutyric acid and glycine in the baboon cochlear nuclei: an immunocytochemical colocalization study with reference to interspecies differences in inhibitory systems, pp. 497–519, 1996, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc., New York.

and Wu (1989) because they form a very precise projection system from the dorsal nucleus (tuberculum acusticum) to the ventral nucleus. The projection is carried by small bundles of GABA- and glycine-positive axons passing into the central ventral nucleus, fascicles that are identical in size and location in the baboon to those observed in the cat and guinea pig. Tuberculoventral cells in the dorsal nucleus have been shown to project to bands of neurons in the ventral nucleus that are innervated by the same group of auditory nerve axons (Wickesberg and Oertel, 1988; Snyder and Leake, 1988). Thus, this system forms a frequency-specific feedback circuit to neurons in the ventral nucleus lying in the corresponding isofrequency plane.

As previously described, the cap area is a saddle-shaped region, extending over the top of the ventral nucleus and down its lateral and medial sides, and also abutting on the dorsal nucleus. In the baboon, as in mammals generally, the cap area is somewhat inconspicuous in normal histological sections but presents a uniformly dense distribution of labeled cells and synaptic terminals in GABA/glycine immunostaining (Fig. 34.18). These inhibitory terminals are not clustered into perisomatic arrays of the type that characterize the ventral nucleus but rather are more evenly scattered. This is in agreement with observations that many synaptic terminals in the cap area contain flattened or pleomorphic vesicles contacting dendritic shafts (Cant, 1993). At present, the only clue to the function of the cap area lies in its comparative anatomy. It is larger in carnivores than in rodents, is prominent in all primates, is strikingly large in the human cochlear nuclear complex, and constitutes a considerable fraction of the total volume of the cochlear nuclei in the porpoise (Osen and Jansen, 1965). Hypertrophy of the human cap area suggests an increasingly important role in information processing, but that role remains to be elucidated.

Superior Olivary Complex: Recreation of Auditory Space

Information processing in the auditory system differs in one respect from that in the visual or somatosensory systems in that locus of the stimulus is not directly coded in the peripheral receptor. Instead, the spatial dimension of sound stimuli must be recreated by the central auditory system. Behavioral studies in cats have implicated the superior olivary complex in this process. Cats with lesions above the level of the superior olivary complex, in the lateral lemniscus, inferior colliculus, medial geniculate body, or auditory cortex, are unable to locate a sound source in the spatial field contralateral to the lesion, whereas cats with lesions below the level of the olivary complex have more diffuse deficits (Casseday and Neff, 1975; Thompson and Masterton, 1978; Jenkins and Masterton,

1982). An analogous deficit has been observed in a human subject with an extensive midline pontine lesion that eliminated crossed input to the superior olivary complex on both sides (Griffiths *et al.*, 1997a). This patient had no difficulty in detecting frequency and amplitude modulation and no general deficit in detection of auditory temporal information, but was unable to determine by sound alone the location and direction of motion of objects in the environment, such as ringing telephones and passing trains. These human and animal studies suggest that the auditory spatial field is recreated in the brain stem by transformations occurring at the level of the superior olivary complex.

Medial and Lateral Olivary Nuclei

Ascending axons from the cochlear nuclei project to the superior olivary complex on both sides of the brain stem (Strominger, 1973; Strominger *et al.*, 1977). Cochlear nucleus axons innervate the lateral olivary nucleus on the same side of the brain stem, as well as the lateral neuropil of the medial olivary nucleus (Fig. 34.19). The axons then cross the midline in the trapezoid body and terminate on the medial neuropil of the contralateral medial nucleus. Because the configuration of the human medial and lateral olivary nuclei is similar to that of other primates (Figs. 10.10 and 10.11), their pattern of input is assumed to be similar. The projection to the medial and lateral olivary nuclei has been shown to be formed by axons of spherical bushy cells of the anteroventral cochlear nucleus (Warr, 1982; Smith *et al.*, 1993). Because spherical cells receive narrow band input and accurately preserve the pattern of activity in cochlear nerve axons, they are able to transmit precise information on stimulus parameters to the olivary nuclei.

The human medial olivary nucleus is a laminar structure, with long primary dendrites extending medially and laterally from a central column of cell bodies into the surrounding area of fine-fiber neuropil (Fig, 34.20A, B). As indicated in Figure 34.19, the laterally directed dendrites are innervated by the ipsilateral ventral cochlear nucleus and the medially directed dendrites by the nucleus on the contralateral side. The bilateral innervation of the medial nucleus allows its neurons to create a map of interaural time differences along the rostrocaudal axis of the nucleus (Yin and Chan, 1990). In both its input and its physiology, the medial nucleus is biased toward low-frequency information. Spherical cell axons representing the 1.2- to 5-kHz region of the ventral cochlear nucleus innervate most of the length of the medial nucleus (Warr, 1982). Physiologically, most medial nucleus neurons have best frequencies of less than 3–4 kHz (Galambos *et al.*, 1959; Goldberg and Brown, 1968; Guinan *et al.*, 1972).

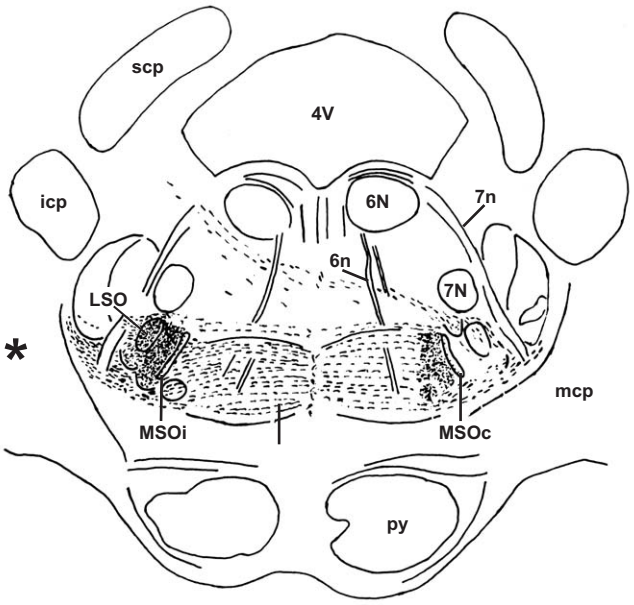

FIGURE 34.19 The pattern of projection by the cochlear nucleus axons into the superior olivary complex is shown by degenerating axons in the brain stem of the chimpanzee after a large lesion of the cochlear nuclei (lesion side indicated by asterisk). Axons run to the lateral olivary nucleus (LSO) ipsilaterally and to the neuropil on the facing side of the medial olivary nucleus, both ipsilaterally (MSOi) and contralaterally (MSOc). Dougherty, figure 4, Second order auditory pathways in the chmpanzee, pp. 349–365, 1977, with permission from Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc., New York.

Because large head size increases the range of frequencies that can be utilized for interaural phase difference cues, our relatively large head size and low-frequency hearing range may account for the prominence of the human medial nucleus.

The human lateral olivary nucleus is a compact rounded nucleus (Fig. 34.20A, B), and thus differs from that of carnivores and rodents in which it is a prominent S- or U-shaped structure. As in other species, the human lateral nucleus is composed of neurons whose short dendrites are confined to the body of the nucleus. Recordings in the lateral olivary nucleus of the cat demonstrate an orderly representation of best frequencies, with low tones represented in the lateral limb of the nucleus and high tones in its medial limb (Guinan *et al.*, 1972). The best frequencies span the cat's entire auditory range, with much of the nucleus devoted to frequencies in the 10- to 40-kHz range. Because of its emphasis on higher frequencies, the lateral olivary

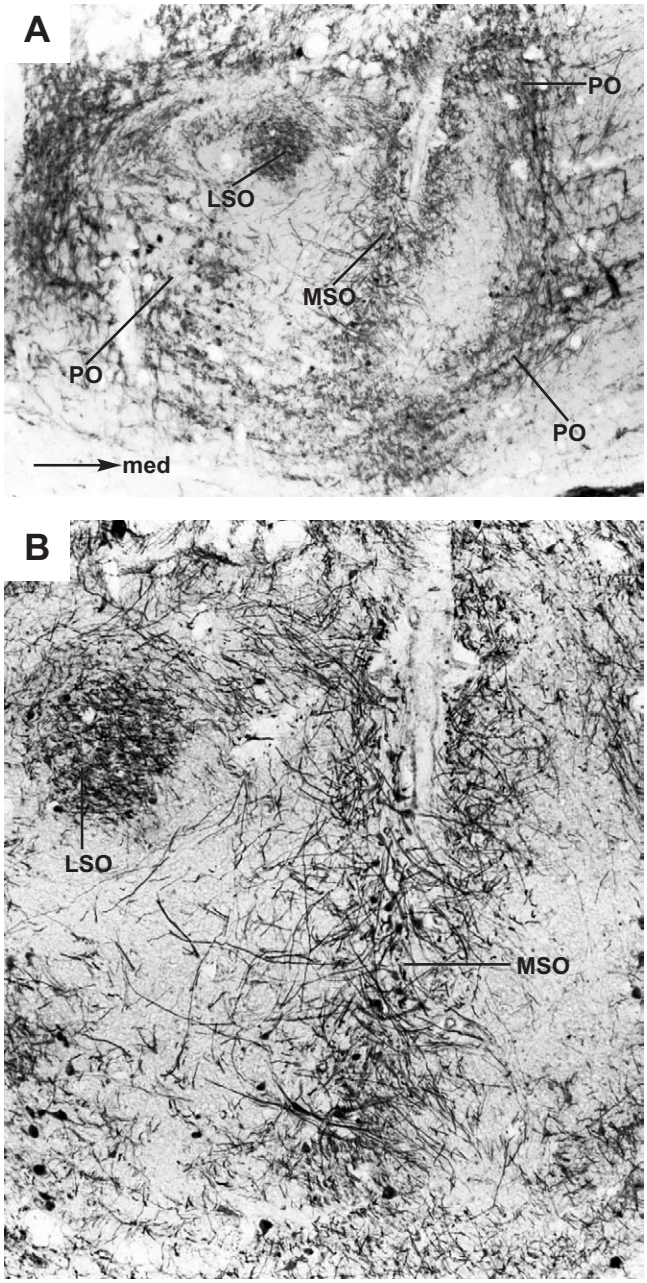

FIGURE 34.20 Morphology of the human superior olivary complex. **(A)** The lateral olivary nucleus (LSO) and medial olivary nucleus (MSO) are surrounded by a ring of periolivary neurons (PO). **(B)** In a higher power view of the same section, the cells of the medial olivary nucleus are seen to have elongated dendrites extending medially and laterally into the surrounding neuropil. Dendrites of neurons in the lateral olivary nucleus are short and confined to the body of the nucleus. Celloidin section, MAP2 immunostaining.

nucleus is extremely large in echolocating mammals with extended high-frequency hearing, such as bats and porpoises (Zvorykin, 1964; Irving and Harrison, 1967; Zook and Casseday, 1982). It is possible that the lateral olivary nucleus is small in humans because our range of usable frequencies is, by general mammalian standards, limited to low frequencies.

In most mammals, the superior olivary complex includes a prominent nucleus of the trapezoid body, a group of darkly staining oval cells lying among the fibers of the trapezoid body on the ventromedial aspect of the complex. The trapezoid nucleus is clearly identifiable in prosimian primates and monkeys, but is very indistinct in apes and is vestigial in the human olivary complex, consisting only of a few scattered, pale oval cells (Moore and Moore, 1971; Moore, 2000). The trapezoid nucleus of the cat has been shown to form a projection to the lateral olivary nucleus that is glycinergic and therefore inhibitory (Glendenning *et al.*, 1985; Bledsoe *et al.*, 1990), but the low-frequency end of the lateral nucleus receives less dense glycinergic input. It is possible that the human lateral olivary nucleus is equivalent to the low-frequency end of the mammalian lateral olivary nucleus and hence receives only a restricted inhibitory innervation. Little attention has been paid to the fact that the trapezoid nucleus also provides inhibitory input to medial nucleus neurons (Smith *et al.*, 1998). These findings suggest that the extreme reduction of the human nucleus of the trapezoid body affects the mechanism of information processing in both the medial and lateral olivary nuclei.

Periolivary Cell Groups

In the immunostained human olivary complex, the medial and lateral nuclei are seen to be surrounded by a capsule of dendrites of periolivary neurons (Fig. 34.20A). Periolivary cells, as their name implies, lie at the outer margin of the olivary complex, surrounding the main nuclei. In nonhuman species, periolivary cells are clustered into a number of distinct nuclei. In humans, they tend to be concentrated into medial, ventral, and lateral periolivary cell groups (Moore *et al.*, 1999) (Figs. 10.10–10.12). Human periolivary cells also form a rostral periolivary nucleus, a slender column of cells extending forward from the main part of the olivary complex through the pons (Figs. 34.1, 10.12–10.16). Along its length, ascending auditory axons lie ventral and lateral to the cell column. Periolivary neurons receive ascending input from multipolar cells of the ventral cochlear nucleus (Friauf and Ostwald, 1988; Thompson and Thompson, 1991), but their major connections are descending and will be discussed in "The Descending Auditory System".

Upper Brain Stem: Integration of Ascending Pathways

As ascending axons from the cochlear nuclei run past the olivary complex, they are joined by axons from the main olivary nuclei and periolivary cell groups. The total assembly of ascending axons constitutes the lateral lemniscus (Figs. 12.12–12.21). Anterograde projection studies in the monkey (Strominger and Strominger, 1971; Strominger, 1973) and the chimpanzee (Strominger *et al.*, 1977) demonstrate the primate pattern of termination of lemniscal axons in the nuclei of the lateral lemniscus and in the inferior colliculus (Fig. 34.21).

Lemniscal Nuclei

In most mammalian species, the lemniscus contains sizable ventral and intermediate lemniscal nuclei. These two nuclei are prominent in the cat (Moore, 1987) and are extremely large in mammals, such as the porpoise and bat that utilize ultrahigh frequencies (Zvorykin, 1964; Zook and Casseday, 1982; Covey and Casseday, 1991). However, they are indistinct in New World monkeys and difficult to define in apes (J. K. Moore, unpublished observations). In the human brain stem, sparse areas of neuropil in the lemniscus contain scattered cell clusters that appear to be vestiges of the ventral and intermediate nuclei (Figs. 12.17 and 12.18). The comparative development of the lower lemniscal nuclei across mammals suggests that their reduction in the human brain stem, like that of the lateral olivary nucleus, is related to our low-frequency range of hearing.

In contrast, the human dorsal lemniscal nucleus is a well-developed cell group, consisting of clusters of neurons lying in an island of neuropil in the upper lateral lemniscus (Geniec and Morest, 1971; Moore, 1987) (Figs. 34.22 and 10.18). Its axons form the dorsal commissure of the lateral lemniscus, a pathway that can be identified in human material stained for myelin (Moore, 1987) or immunostained for axonal neurofilaments (Moore *et al.*, 1997). Neurons of the dorsal lemniscal nucleus project to the inferior colliculus on the same side, and through the dorsal commissure to the dorsal lemniscal nucleus and inferior colliculus on the opposite side of the brain stem (Kudo, 1981). The dorsal nucleus has been shown to consist largely of neurons that are immunopositive for GABA (Adams and Mugnaini, 1984; Saint Marie *et al.*, 1997). Thus, its commissure forms a symmetrical and reciprocal inhibitory projection. Due to its inhibitory nature, the dorsal lemniscal nucleus is presumed to play a role in the balance of ipsilateral and contralateral activity in the inferior colliculus. Because afferent input to the dorsal nucleus comes mainly from the medial and lateral superior olivary nuclei (Glendenning *et al.*, 1981; Yang *et al.*, 1996), this balance may integrate activity reflecting the spatial location of sound stimuli.

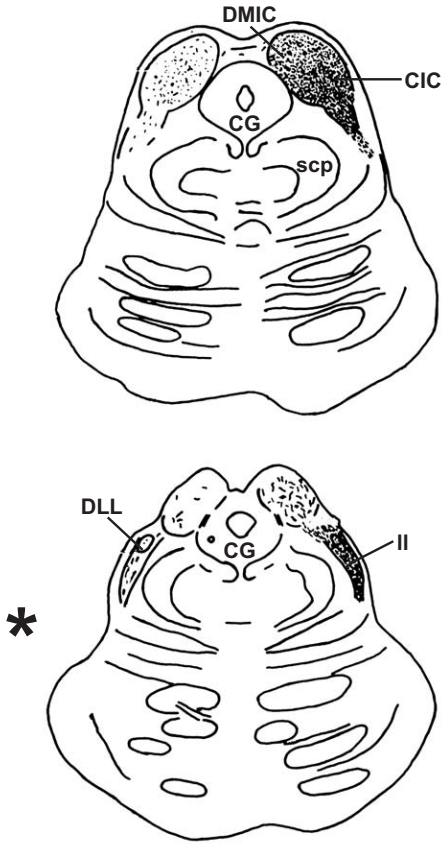

FIGURE 34.21 Projection pattern of the lateral lemniscus of the chimpanzee. After large lesions of the cochlear nuclei (lesion side indicated by asterisk), degenerating axons fill the contralateral lateral lemniscus (ll) and terminate heavily in the dorsal nucleus of the lateral lemniscus (DLL). Within the inferior colliculus contralateral to the lesion, there is dense terminal degeneration in the central nucleus (CIC) and somewhat less dense degeneration in the dorsomedial area (DMIC). Much lighter degeneration is seen in the side ipsilateral to the lesion. CG, central gray; scp, superior cerebellar peduncle. Adapted from *Journal of Comparative Neurology* **172,** N.L. Strominger, L.R. Nelson, and W.J. Dougherty, figure 3, Second order auditory pathways in the chmpanzee, pp. 349–365, 1977, with permission from Wiley-Liss Inc., a subsidiary of John Wiley & Sons, Inc., New York.

The Inferior Colliculus

The inferior colliculus consists of several subdivisions (Figs. 34.23A, 10.20, and 10.21), but the region of densest termination of lemniscal axons is the cup-shaped central nucleus. Retrograde labeling studies in nonprimate species (e.g., Adams, 1979; Brunso-Bechtold *et al.*, 1983) have demonstrated that the central nucleus

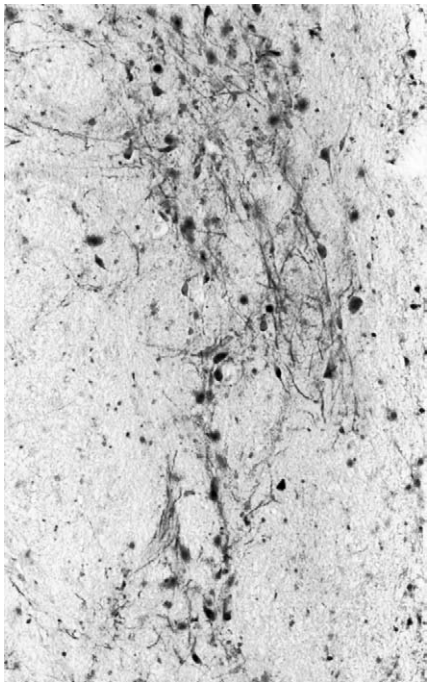

FIGURE 34.22 The human dorsal nucleus of the lateral lemniscus consists of patches of cells lying in an island of neuropil at the rostral end of the lateral lemniscus. Celloidin section, MAP2 immunostaining.

of the colliculus receives input from all of the lower brain stem auditory centers. A direct projection comes from the contralateral cochlear nuclei, originating in multipolar cells of the ventral cochlear nucleus and fusiform cells of the dorsal cochlear nucleus. The projection originating from the ipsilateral medial olivary nucleus is a major source of afferents to the low-frequency region of the central nucleus. Broader spectrum input comes from the lateral olivary nucleus on both sides of the brain stem. The periolivary projection arises mainly from the ipsilateral ventral periolivary region, but other periolivary cell groups on both sides of the brain stem also contribute. Finally, as just discussed, there is a projection from both the ipsilateral and contralateral dorsal lemniscal nuclei, with the contralateral projection coming though the dorsal commissure of the lateral lemniscus.

As axons enter the central nucleus, they form bands running from ventrolateral to dorsomedial. These axonal bands run parallel to cellular planes formed by neurons with flattened, disk-shaped dendritic fields (Fig. 34.23A). The laminar cytoarchitecture formed by alternating bands of axons and flattened cells characterizes the human central nucleus (Geniec and Morest, 1971) and that of the squirrel monkey (FitzPatrick, 1975), as well as most nonprimate mammals. Studies of evoked

activity and 2-deoxyglucose labeling in primates have shown that the laminae represent frequency-specific planes of the central nucleus (FitzPatrick, 1975; Webster *et al.*, 1984; Garey and Webster, 1989). The tonotopic planes are curved and tipped at about 20–30° from the horizontal (Fig. 34.23B), with a regular progression of best frequencies from low dorsally to high ventrally.

In addition to tonotopy, collicular processing includes information on the time parameters of neuronal activity and on the spatial localization of stimulus sources. Recordings in the cat show that neurons in the central nucleus respond to simulations of natural combinations of interaural time and intensity differences and to spectral cues indicating location of a sound source (Delgutte *et al.*, 1999). Most cells are sensitive to stimulus location along the horizontal azimuth, and about half of the neurons tested are sensitive to elevation. Overall, it seems safe to assume that multiple parameters of auditory stimuli, including frequency spectrum, loudness, time patterning, and spatial location, are correlated within the central nucleus to produce an integrated neural representation of the stimulus. Integrated information from the central nucleus is then passed on to the forebrain by axons running laterally across the nucleus to the lateral zone of the colliculus (Fig. 34.23A). Within the lateral zone, the axons coalesce to form the brachium of the inferior colliculus. Brachial axons then continue forward on the surface of the brain stem, lateral to the superior colliculus (Figs. 10.21 and 10.22).

The dorsomedial subdivision of the inferior colliculus (Fig. 34.23A) is distinguished from the central nucleus by the greater packing density of its cells and by its lack of laminar organization, both in humans (Geniec and Morest, 1971) and in squirrel monkeys (FitzPatrick, 1975). It receives somewhat lighter lemniscal input than the central nucleus and the terminals are diffusely distributed rather than forming bands. The dorsomedial area gives rise to the commissure of the inferior colliculus (Figs. 10.20 and 10.21), through which axons project to the opposite inferior colliculus and to the contralateral forebrain. The origin of the commissure is demonstrated by the increasing density of degenerating axons in primates with lesions invading the dorsomedial area (Moore *et al.*, 1977). In humans, the collicular commissure is a prominent structure that is clearly visible in myelin-stained material (Moore, 1987) and in material immunostained for axonal neurofilaments (Moore *et al.*, 1997).

Lemniscal input is very sparse into the pericentral zone of the colliculus, i.e., the portion of the colliculus outside of the central nucleus and dorsomedial region. The dorsal and caudal part of the pericentral zone is known as the dorsocaudal cortex (Figs. 10.19–10.21). Because this area is primarily a relay in the descending auditory pathway, it is discussed in "The Descending Auditory System". The rostral and ventral portion of the pericentral zone is termed the external cortex (Figs. 10.19–10.22). This region is also called the intercollicular area because it forms a bridge, anatomically and functionally, between the inferior and superior colliculi. Few or no lemniscal axons terminate in this area, but it receives auditory input from the central nucleus of the inferior colliculus and from both dorsal lemniscal nuclei (Coleman and Clerici, 1987; Olazábal and Moore, 1989). In addition, this area receives retinal input via the optic tract (Itaya and van Hoesen, 1982) and somatosensory input from the spinal trigeminal nucleus and the dorsal column nuclei (Wiberg *et al.*, 1987) (Fig. 34.24). Electrophysiological studies of the external cortex show that many cells are influenced by both auditory and somatosensory stimuli, and most have relatively nonspecific response fields, reflecting broad frequency ranges and large areas of the body (Aitkin *et al.*, 1981). The multisensory input and lack of precise tonotopic or somatotopic mapping within this region have led to the idea that it plays a role in spatial mapping of sound relative to body position. An organized map of auditory space has been demonstrated here (Binns *et al.*, 1992), and lesions in this area cause deficits in the ability to orient to sound (Thompson and Masterton, 1978). Neurons in the external cortex project to the deep layers of the superior colliculus (Edwards *et al.*, 1979; Olazábal and Moore, 1989), an area that projects in turn to the motor nuclei controlling head and eye turning. Thus, the external cortex of the inferior colliculus is the beginning of the process of integration of auditory input with visual and somatosensory information, leading to creation of a spatial map and, ultimately, direction of head and eye position by that map.

Brain Stem Topography: Generation of Evoked Potentials

As discussed in "The Cochlea: Generation of Evoked Activity," waves I and II of the auditory brain stem response are believed to be generated peripherally, by the auditory nerve. The subsequent waves III, IV, V, and VI are generated within the brain stem. The human brain stem auditory pathway is composed of essentially the same nuclear groups as that of other mammals, but because of the much larger size of the human brain stem, these auditory centers are spread across a considerably longer pathway. An estimate of the length of the human brain stem auditory pathway was obtained by computer reconstruction, based on

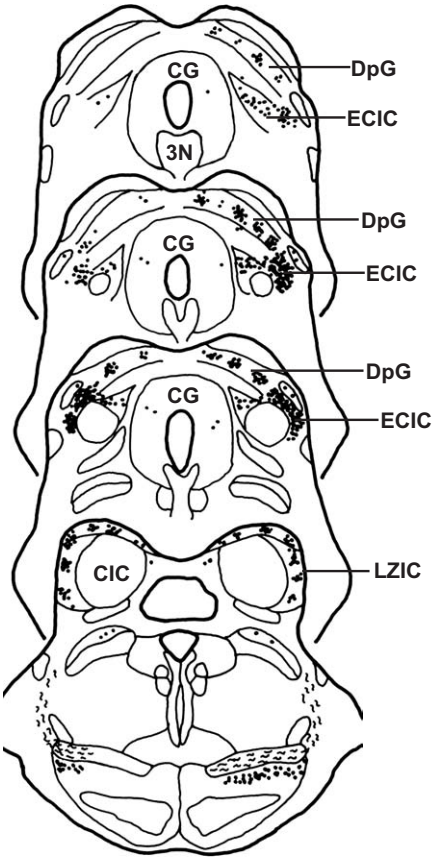

FIGURE 34.24 Projections into the tectum of the macaque monkey following injection of the dorsal column nuclei. Labeled terminals are absent from the central nucleus of the inferior colliculus (CIC), but are present in the lateral zone (LZIC), external cortex (ECIC) and deep gray layers of the superior colliculus (DpG). CG, central gray; 3N, oculomotor nuclei. Adapted from *Journal of Comparative Neurology* **264,** M. Wiberg, J. Westman, and A. Blomqvist, figure 10, Somatosensory projection to the mesencephalon: an anatomical study in the monkey, pp. 92–117, 1987, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc., New York.

point-to-point measurements from digitized sections (Moore *et al*., 1996b). In humans, the distance that the axon of a neuron in the ventral cochlear nucleus travels to reach the ipsilateral medial superior olivary nucleus is approximately 10 mm (1 cm); to reach the contralateral medial superior olivary nucleus is 25 mm (2.5 cm); to reach the upper level of the contralateral lateral lemniscus is 40 mm (4 cm); and to reach the center of the contralateral inferior colliculus is 45 mm (4.5 cm). In the cat, by comparison, the total distance from the center of the cochlear nuclei to the center of the contralateral inferior colliculus is 18–20 mm.

Because of the differential length of the human and mammalian brain stem pathways, animal studies of ABSR wave generators have limited applicability. Instead, information has been gained from intrasurgical recordings made from the surface of the human brain stem. Electrodes placed over the cochlear nuclei record a wave, attributed to the firing of axons exiting the cochlear nuclear complex, that coincides with wave III of the scalp record (Moller and Janetta, 1982). In addition, human dipole studies concluded that wave III is generated by a volley of action potentials in axons emerging from the cochlear nuclei in the ventral acoustic stria (Scherg and von Cramon, 1985). Other evidence indicates that waves IV and V are generated further rostrally in the brain stem. When electrodes are placed on the pons during intrasurgical recording, potentials are recorded that correspond to scalp-recorded waves IV and V (Hashimoto *et al*., 1981; Moller and Jannetta, 1982). The same studies attribute the broad negative potential following the IV/V complex to depolarization of inferior colliculus neurons. In the computer reconstruction study that derived length of the human auditory pathway, that length was correlated with the latencies of waves IV and V to derive axonal conduction velocity (Moore *et al*., 1996b). The most reasonable conduction velocity, one closely matching that of the known conduction velocity of eighth nerve axons, was obtained by assuming that waves IV and V were generated at the level of the superior olivary complex contralateral to the stimulated ear, presumably by the bend in the axonal pathway occurring at that point.

The idea that waves IV and V are generated at the level of the superior olivary complex is supported by studies of the binaural interaction component of the auditory brain stem response. The binaural interaction component is obtained by subtracting the response to a binaural stimulus from the algebraic sum of the right and left ear monaural responses to the same stimulus. The reduction in total activity in the interaction component is presumed to reflect the fact that the binaural response involves convergence of activity from the right and left ears on some subset of brain stem auditory neurons. In recording responses to monaural and binaural clicks with a variety of interaural time and intensity differences, the binaural interaction component was localized to the pons (Polykov and Pratt, 1996). In further studies, six patients with small vascular lesions in the trapezoid body were shown to have absent or abnormal dipole orientation of the binaural interaction component occurring at the time of waves IV and V, whereas lesions in the rostral lateral lemniscus caused abnormalities in a dipole occurring later, at the time of wave VI (Pratt *et al*., 1998). These findings support the idea that waves IV and V are generated at the level of the superior olivary complex and wave VI higher in the brain stem.

THE FOREBRAIN AUDITORY SYSTEM

Auditory Thalamus: Information Relay

Auditory information reaching the forebrain originates primarily in the central nucleus of the inferior colliculus and is relayed through its brachium (Figs. 10.21–10.24). A similar pattern of degenerating axons is seen after lesions of the inferior colliculus in the loris, marmoset, squirrel monkey, macaque, and gibbon (Moore and Goldberg, 1966; Moore *et al.*, 1977) (Fig. 34.25). In all of these primate species, brachial axons distribute a small number of terminals to neurons in the adjacent parabrachial region and to cells interstitial to the brachium, but the majority of the axons continue forward on the surface of the brain stem. At the level of the superior colliculus, the medial geniculate forms a prominent tubercle on the surface of the midbrain. Further rostrally, the medial geniculate is bounded laterally, first by the inferior division of the pulvinar and then by the lateral geniculate nucleus (Figs. 10.23–10.25). Brachial axons bypass the caudal tip of the medial geniculate, but further rostrally they form a dense meshwork of pericellular terminals. In addition to the axons ascending in the brachium ipsilaterally, a number of fibers cross in the commissure of the inferior colliculus and ascend in the contralateral brachium to terminate in the medial geniculate on the opposite side. The contralateral projection is identical to that on the ipsilateral side but lighter and is heaviest if the lesion invades the dorsomedial division of the colliculus.

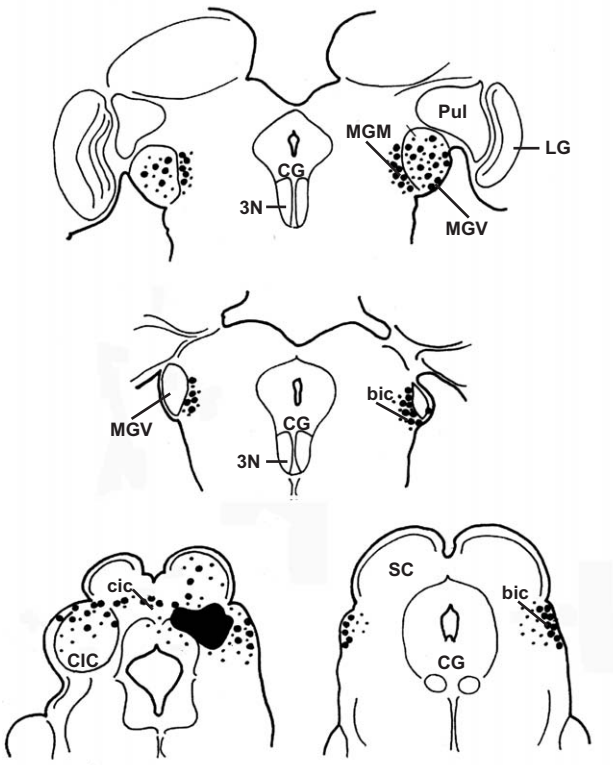

FIGURE 34.25 A lesion *(shaded black)* in the inferior colliculus in the squirrel monkey results in degenerating axons ascending in the brachium of the inferior colliculus (bic) bilaterally. Large dots represent degenerating axons and small dots indicate terminal degeneration. On the side ipsilateral to the lesion, degenerating axons bypass the caudal tip of the medial geniculate and end densely in its ventral division (MGV). More scattered fibers and terminals end in the medial division of the geniculate (MGM). The pattern of degeneration on the side contralateral to the lesion is similar but lighter. No degenerating axons are present within the pulvinar complex (Pul). CG, central gray; LG, lateral geniculate; SC, superior colliculus; 3N, oculomotor nucleus. Adapted from *Brain, Behavior and Evolution*, **14,** J.K. Moore, F. Karapas, and R.Y. Moore, figure 2, Projections of the inferior colliculus in insectivores and primates, pp. 301–327, 1977, with permission from S. Karger AG, Basel.

The cytoarchitecture of the medial geniculate has been described in lorisoid prosimians (Kanagasuntheram *et al.*, 1968), ceboid monkeys (FitzPatrich and Imig, 1978), cercopithecoid monkeys (Walker, 1937), apes (Walker and Fulton, 1938), and humans (Winer, 1984). Its largest subdivision, and the principal target of brachial axons, is the ventral nucleus, also known as the principal or parvocellular nucleus. This subdivision of the geniculate is a compact group of small to medium-sized ovoid neurons that are densely packed and aggregated in clusters. The ventral nucleus is very similar in apes and humans in absolute number of neurons (Armstrong, 1979), indicating that it is a stable and conservative part of the thalamus. In all primate species, there is some indication of an orientation of the cells in rows parallel to the entering brachial fibers. This tendency is most pronounced in the gibbon, in which infolding of the cell laminae gives the nucleus a distinctly convoluted appearance. In the human medial geniculate as well, a laminar cytoarchitecture is formed by planes of cells with bushy dendrites and fascicles of brachial axons running parallel to the dendritic planes (Winer, 1984). The dense input from the auditory brain stem to the ventral nucleus is reflected in the responses of these neurons to auditory stimuli. Electrophysiological studies in the squirrel monkey show responses to clicks, tone bursts, and noise bursts from almost all of the cells in the ventral nucleus (Symmes *et al.*, 1980). Though most neurons respond to species vocalizations, there is little selectivity to different calls.

Other subdivisions of the medial geniculate receive much less dense input from the brain stem. There is light terminal degeneration in the medial nucleus of the geniculate, also known as the magnocellular or

internal nucleus. In primates, as in other mammals, the medial nucleus of the geniculate lies medial and rostral to the ventral nucleus, but the nucleus is smaller in primates than in carnivores. Its cells are more dispersed than those in the ventral nucleus, and it exhibits the greatest range in cell size from large to small of any subdivision of the geniculate. A dorsal nucleus of the medial geniculate has also been described in monkeys and apes. Like the medial nucleus, it receives sparser input from the inferior brachium than does the ventral nucleus. In primates, no brachial axons have been traced into the pulvinar complex of the thalamus or into other thalamic areas surrounding the medial geniculate.

Auditory Cortex: Sequential Levels of Processing

Organization of Auditory Cortex

The classical area of human auditory cortex is located within the superior temporal lobe. This region is portrayed in the *Atlas of the Human Brain* (Mai *et al.*, 1997) in both diagrams (Figures 17–34) and photographs (Figures 53–65). A human brain from which the parietal lobe has been removed (Fig. 34.26A) allows a view of the superior temporal plane, i.e., the superior surface of the temporal lobe that is normally hidden within the lateral fissure. The transverse temporal gyrus (Heschl's gyrus) crosses the plane at an angle from caudomedial to rostrolateral. The transverse gyrus is often partially duplicated into a double, or occasionally triple, convexity (Leonard *et al.*, 1998). In this brain, the gyrus is bifid at its lateral end. A lateral view of the temporal lobe (Fig. 34.26B) illustrates the superior and middle temporal gyri, separated by the superior temporal sulcus. Though human auditory cortex has generally been considered to be limited to the superior temporal gyrus, functional studies reveal that auditory activation often extends into the middle temporal gyrus and into ventral portions of the parietal lobe.

The cytoarchitecture of human auditory cortex has been described by Brodmann (1908), von Economo (1929), and Galaburda and Sanides (1980). The primary auditory cortex (koniocortex or granular cortex) is identified as an area approximately 1 inch square on the medial end of the transverse temporal gyrus. It was designated area 41 by Brodmann, TC by von Economo, and KAm and KAlt (medial and lateral auditory koniocortex) by Galaburda and Sanides. In the latter classification, KAm is the most medial and the most granular area, while KAlt is located relatively more lateral and is less granular. As in all primary

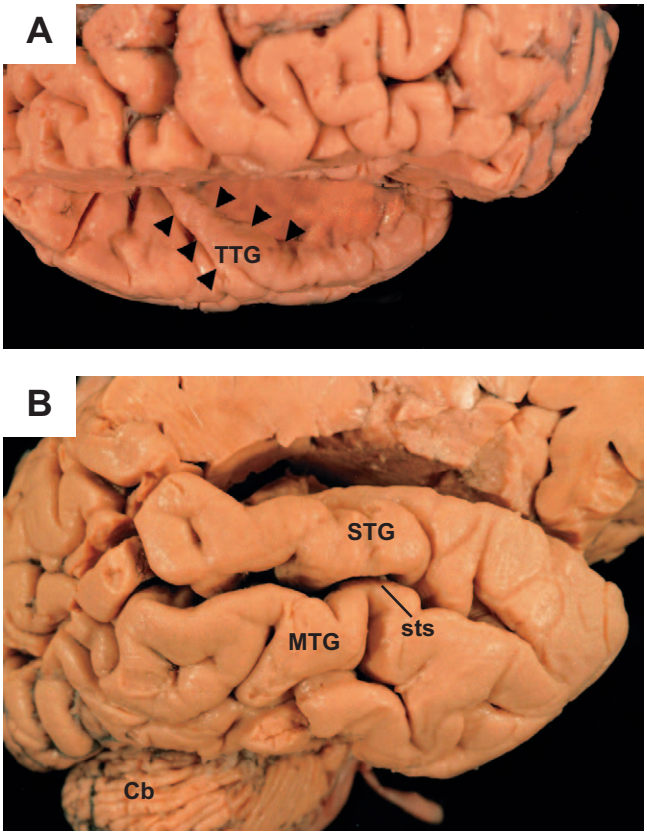

FIGURE 34.26 Photographs of the surface of the human temporal lobe. **(A)** Partial removal of the parietal operculum and frontal lobe provides a view of the superior temporal plane, including the transverse temporal gyrus (TTG, demarcated by arrowheads). **(B)** A side view of the temporal lobe illustrates the superior temporal gyrus (STG) and middle temporal gyrus (MTG), separated by the superior temporal sulcus (sts). Cb, cerebellum.

sensory areas, cell packing density is high in layers II-IV, while layers V and VI are thin and parvocellular. Layer IV is prominent, and the cells in layers II-IV form fine columns ("rain shower" formation) (Fig. 27.25a). There is considerable variability in size of the koniocortex, and its extent does not coincide with gyral and sulcal anatomy (Galaburda and Sanides, 1980; Rademacher *et al.*, 2001a). The absolute size of this area varies across individuals and between the right and left sides of the same individual, with areal values as high as 1840 mm^2 and as low as 860 mm^2 given by Galaburda and Sanides. A study comparing the size of auditory koniocortex in males and females found it to be consistently larger bilaterally in women (Rademacher *et al.*, 2001b).

Human auditory koniocortex (area 41/TC/KA) is homologous to the core area of auditory cortex identified in monkeys. The simian core area, usually called KA or A1, is located in the center of the superior

temporal plane (Merzenich and Brugge, 1973; Pandya and Sanides, 1973; Galaburda and Pandya, 1983; Luethke *et al.*, 1989). In addition to KA/A1, some studies identify primary areas termed R (rostral; Imig *et al.*, 1977; Morel *et al.*, 1993) and RT (rostrotemporal; Morel and Kaas, 1992; Hackett *et al.*, 1998a). The monkey core area can be identified by its high levels of acetylcholinesterase and cytochrome oxidase (Morel and Kaas, 1992; Morel *et al.*, 1993; Jones *et al.*, 1995; Hackett *et al.*, 1998a), features that also characterize human auditory koniocortex (Rivier and Clarke, 1997; Hackett *et al.*, 2001). The cellular density of layers III and IV in monkey core cortex, as well as its dense array of myelinated fibers, reflects the heavy input to the core area from the medial geniculate. In marmosets and monkeys, most neurons in the ventral division of the medial geniculate project to core cortex (Mensulam and Pandya, 1973; Burton and Jones, 1976; Aitkin *et al.*, 1988; Luethke *et al.*, 1989; Rauschecker *et al.*, 1997). The afferents from the ventral medial geniculate terminate in layers IV and lower III in regular patches of higher density label, separated by areas of less dense label (Pandya and Rosene, 1993; Hashikawa *et al.*, 1995). In contrast, the medial and dorsal divisions of the medial geniculate project to the core area diffusely, with axons from the medial nucleus becoming tangential fibers in layer I.

It seems likely that human primary auditory cortex also receives dense thalamic input, and that this input accounts for the cochleotopic organization shown in this area by functional imaging, including magnetoencephalography (Elberling *et al.*, 1982), positron emission tomography (Lauter *et al.*, 1985) and functional magnetic resonance imaging (Wessinger *et al.*, 1997). In the human transverse temporal gyrus, activation for high-frequency tones is located more posteriorly and medially than that for low-frequency tones (Fig. 34.27). This sequence of activation is often referred to as tonotopic, and many mapping studies have utilized pure tone stimuli. However, work with complex stimuli indicates that the organization in human cortex reflects, not stimulus frequency, but rather perceived pitch, including virtual pitch that is not actually present in the physical spectrum of the stimulus (Pantev *et al.*, 1989).

Human auditory koniocortex is surrounded rostrally, laterally and posteriorly by an area of parakoniocortex. This region covers the lateral portion of the transverse temporal gyrus, and extends anteriorly and posteriorly onto the superior temporal plane. In parakoniocortex, layer IV is thin and layers V and VI are somewhat thicker than in the koniocortex. Layer III is very well developed and is characterized by columns of small pyramidal cells ("organ-pipe" formation) (Fig. 27.25b).

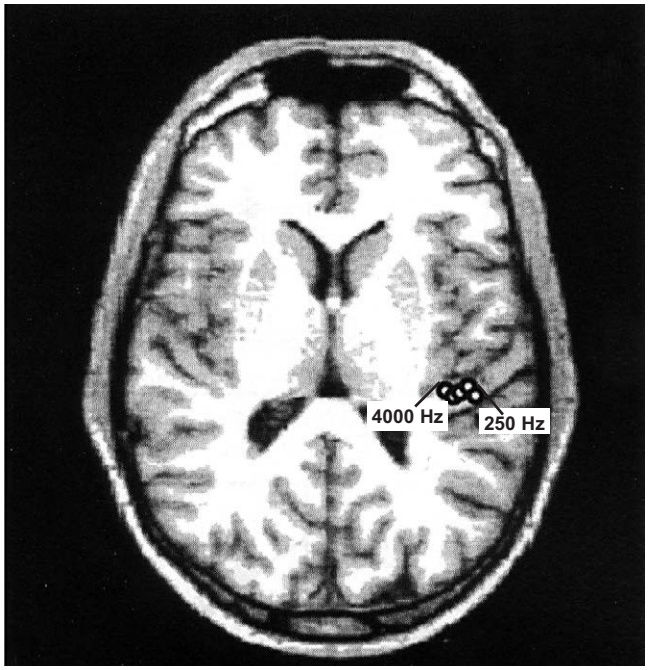

FIGURE 34.27 Tonotopic organization of human primary auditory cortex, as shown by magnetoencephalography. A view in the axial plane illustrates an area of demonstrated tonotopy at the medial end of the transverse temporal gyrus. Responses to high tones (4000 Hz) are represented medially and those to low tones (250 Hz) are located more laterally. Adapted from *Hearing Research* **101,** C. Pantev, L.E. Roberts, T. Elbert, B. Ross, and C. Wienbruch, figure 5, Tonotopic organization of the sources of human auditory steady-state responses, pp. 62–74, 1996, with permission from Elsevier Science, Oxford.

The parakoniocortex has been called area 42 by Brodmann and TB by von Economo. It was subdivided by Galaburda and Sanides into three regions: (1) a rostral area, PaAr (rostral auditory parakoniocortex) on the anterior aspect of the superior temporal plane; (2) a lateral area, PaAi (internal auditory parakoniocortex) that lies lateral to koniocortex and extends a short distance onto the superficial aspect of the superior temporal gyrus; and (3) a caudal area, PaAc (caudal auditory parakoniocortex) that covers the caudal portion of the superior temporal plane and extends around the insula to the parietal operculum (Fig. 27.26). The parakoniocortex is surrounded, in turn, by an extensive area of auditory cortex that covers the remainder of the superior temporal plane and the lateral surface of the superior temporal gyrus, with the exception of its rostral pole. This region was designated area 22 by Brodmann, TA by von Economo, and PaAe (external auditory parakoniocortex) by Galaburda and Sanides. Its cytoarchitecture is characterized by very well developed layers III and V, and by

column formation that extends from layer II through layer V.

Auditory cortical areas peripheral to the core cortex have also been identified in other species of primates. Anatomical and physiological studies define a belt area surrounding the core medially, rostrally, laterally and caudally (Pandya and Sanides, 1973; Imig *et al.*, 1977; Galaburda and Pandya, 1983; Morel and Kaas, 1992; Morel *et al.*, 1993; Hackett *et al.*, 1998a). The area rostral and lateral to the belt, on the anterior superior temporal plane and lateral surface of the superior temporal gyrus, has been called Ts2 and Ts3 (Pandya and Sanides, 1973) and more recently, parabelt (Morel *et al.*, 1993; Hackett *et al.*, 1998a). Both belt and parabelt cortex differ significantly from the core area in their pattern of thalamic input. Tracer injections into the macaque belt area label cells only in the medial and dorsal divisions of the medial geniculate (Rauschecker *et al.*, 1997). Thalamic input into the parabelt cortex also comes only from the dorsal and medial nuclei of the medial geniculate, and in addition, from the medial division of the pulvinar (Trojanowski and Jacobsen, 1975; Burton and Jones, 1976; Hackett *et al.*, 1998b; Fig. 34.45). Ablation of the core area of macaque auditory cortex eliminates responses to auditory stimuli in the adjacent belt region (Rauschecker *et al.*, 1997), which suggests that input from the medial and dorsal geniculate nuclei is not sufficient to support auditory processing in the absence of direct projections from the ventral medial geniculate. Instead, information processing in the secondary auditory cortical areas appears to depend on transcortical projections that pass successively from core to belt to parabelt cortex. Short association projections from the core to the belt have been demonstrated by older degeneration studies (Jones and Powell, 1970; Forbes and Moskowitz, 1977; Selzer and Pandya, 1978) and more recently by use of neuronal tracers (Fitzpatrick and Imig, 1980; Aitkin *et al.*, 1988: Luethke *et al.*, 1989; Morel and Kaas, 1992; Morel *et al.*, 1993). A second set of short association projections connects the belt to parabelt cortex (Morel and Kaas, 1992; Hackett *et al.*, 1998a).

Direct recordings of evoked activity support the idea that transcortical passage of information occurs also in human auditory cortex. Electrical stimulation of the transverse temporal gyrus results in short latency evoked potentials in the lateral superior temporal area, indicating transcortical passage of excitation (Liégeois-Chauvel *et al.*, 1994; Howard *et al.*, 2000). When the generation sites of evoked potentials were located by identification of the point of wave inversion (polarity reversal), the sources of the N/P 16 and N/P 30 potentials (waves following the stimulus by 16 and 30 msec) were located in the most medial part of the transverse temporal gyrus (Fig. 34.28). The generation site of the N/P 50 response was found more lateral in the transverse gyrus, and the N/P 60-75 was localized to the lateral end of the gyrus. The medial to lateral sequence of these evoked potentials may correspond to sequential activity in koniocortex, parakoniocortex and association cortex.

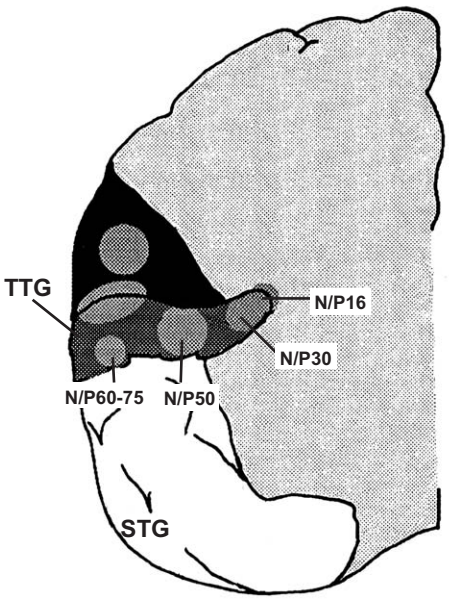

FIGURE 34.28 Diagrammatic representation of suface recordings made from human auditory cortex during surgery. Light circles indicate the polarity inversion sites of the earliest components of the auditory evoked response on the transverse temporal gyrus (TTG). N/P16, N/P30, N/P50, and N/P60-75 are potentials recorded subsequent to a transient stimulus. STG, superior temporal gyrus. Adapted from *EEG and Clinical Neurophysiology* **92,** C. Liegeois-Chauvel, A. Musolino, J.M. Badier, P. Marquis, and P. Chauvel, figure 8, Evoked potentials recorded from the auditory cortex in man, pp. 79–92, 1994, with permission from Elsevier Science, Oxford.

In addition to the connections from core to belt to parabelt within one hemisphere, monkey auditory cortex shows strong linkages between the two hemispheres. Lesions in the core, belt or parabelt result in degenerating axons and terminals in homologous areas in the contralateral hemisphere (Pandya and Sanides, 1973; Forbes and Moskowitz, 1977; Seltzer and Pandya, 1978; Aitkin *et al.*, 1988; Luethke *et al.*, 1989; Morel *et al.*, 1993; Pandya and Rosene, 1993; Hackett *et al.*, 1999). Callosal connections are largely between areas of like frequency, but may spread to adjoining fields. Like the thalamocortical projection, callosal axons end in spatially separated and irregular patches. Unlike thalamocortical axons, the commissural projection does not end primarily in layer IV. Instead it forms a double layer of terminals in layers V and II-III (Pandya and Rosene, 1993).

Functional Imaging of Auditory Cortex

The general function of auditory cortex can be deduced from cases of large lesions that destroy extensive areas of superior temporal cortex bilaterally. Subjects with such lesions suffer from cortical deafness (Hood *et al.,* 1994; Kaga *et al.,* 1997; Garde and Cowey, 2000), but they are not deaf in the same sense as persons who have disorders of the auditory periphery. Instead they retain normal peripheral hearing sensitivity, respond reflexively to sounds, detect and localize environmental sounds, judge loudness and pitch of tones, and can even discriminate monosyllables. Presumably processing of sound at a brain stem level allows this detection and identification of stimulus characteristics. However, these subjects suffer from auditory agnosia, in that they are unaware of the significance of auditory stimuli, including environmental sounds, speech and music. These findings suggest that the basic functional role of auditory cortex is to ascribe meaning to sounds that are processed at lower levels of the auditory system. It is difficult to obtain a more detailed view of the function of human auditory cortex from restricted cortical lesions because of problems in determining the exact extent and effect of the lesions. Alternatively, function of specific areas of human auditory cortex can be revealed by functional imaging, including, both PET and fMRI studies.

In imaging studies, simple auditory tasks, such as passive listening to white noise bursts, tones or CV (consonant-vowel) speech syllables, result in activation that is restricted to areas within the lateral fissure, on the superior temporal plane (Price *et al.,* 1992; Zatorre *et al.,* 1992, 1994; Binder *et al.,* 1994, 1997, 2000; Huckins *et al.,* 1998; Fig. 34.29A). The extent of the activation varies from subject to subject, and may spread anteriorly or posteriorly on the superior temporal plane, or occasionally onto the inferior surface of the parietal lobe. There is a tendency for activation to tones or syllables to spread further laterally than that from white noise bursts. The area of activation is generally within and around the transverse temporal gyrus, and probably includes the anatomically defined areas of koniocortex and parakoniocortex, but it is more variable in extent than the cytoarchitectural zones. With exposure of subjects to more complex stimuli, i.e., passive listening to tone patterns, single words, pseudowords or narrative text, activity is still present in the cortex of the superior temporal plane, but now foci of activation appear on the lateral aspect of the superior temporal gyrus, i.e., in area 22/TA/PaAe (Fig. 34.29B). Considerable intersubject variation is observed in the location of foci, but it is generally true that speech stimuli activate a more extensive region of the temporal lobe than does unmodulated noise. However, different speech stimuli (words, pseudowords, text) produce similar or identical activations. Overall, imaging of the response to auditory stimuli shows a spread of activity, beginning with activation by simple stimuli of a limited region of the superior temporal plane, and expanding with more complex stimuli to the surface of the superior temporal gyrus.

With higher level language processing, activation sometimes spreads ventrally into the superior temporal sulcus. The basis for this spread is likely to be projections from cortex of the superior temporal gyrus into the upper bank of the sulcus, as shown in monkeys (Seltzer and Pandya, 1978, 1994). The upper bank of the sulcus has been described as a voice-selective region because it shows greater neuronal activity when subjects listen to vocal sounds, either speech or nonspeech, rather than to nonvocal environmental sounds, scrambled voices, or amplitude-modulated noise (Mummery *et al.,* 1999; Binder *et al.,* 1994, 1997, 2000; Belin *et al.,* 2000). The posterior part of the superior temporal sulcus is more active during listening to sentences in a familiar language than to acoustically matched sentences in an unfamiliar language (Schlosser *et al.,* 1998; Fig. 34.29D). The posterior superior temporal sulcus has also been described as a face-selective area, showing activity when subjects view faces with moving eyes and mouth (Puce *et al.,* 1998). Finally, there is evidence suggesting that the sulcus is an integrative area for visual and auditory aspects of speech, in that activity spreads from visual cortex along the superior temporal sulcus during lip reading, i.e., perception of language from a moving face (Auer *et al.,* 2001).

The imaging studies note that activation is generally bilaterally equal, i.e., there is a similar amount of activity in the right and left hemispheres. However, with complex stimuli, particularly language, the question arises as to whether there is a right-left asymmetry in the response. Because handedness influences hemispheric lateralization, imaging studies of speech processing are normally restricted to neurologically normal right-handed persons. In right-handers, there is a tendency for greater activation of the left hemisphere during tasks that depend on word meaning, in that the total area of activity is greater on the left. The regions of asymmetry generally lie at the periphery of the active region. One such region is the cortex of the temporoparietal junction (Brodmann area 39), which may be equivalent to the area identified by Wernicke (1908) as a site where lesions can cause a sensory (receptive) aphasia. However, it is clear that this is not an area that processes speech in isolation, but rather a higher level of transcortical processing that begins in the primary auditory cortex. Left lateralization for speech characterizes both males and

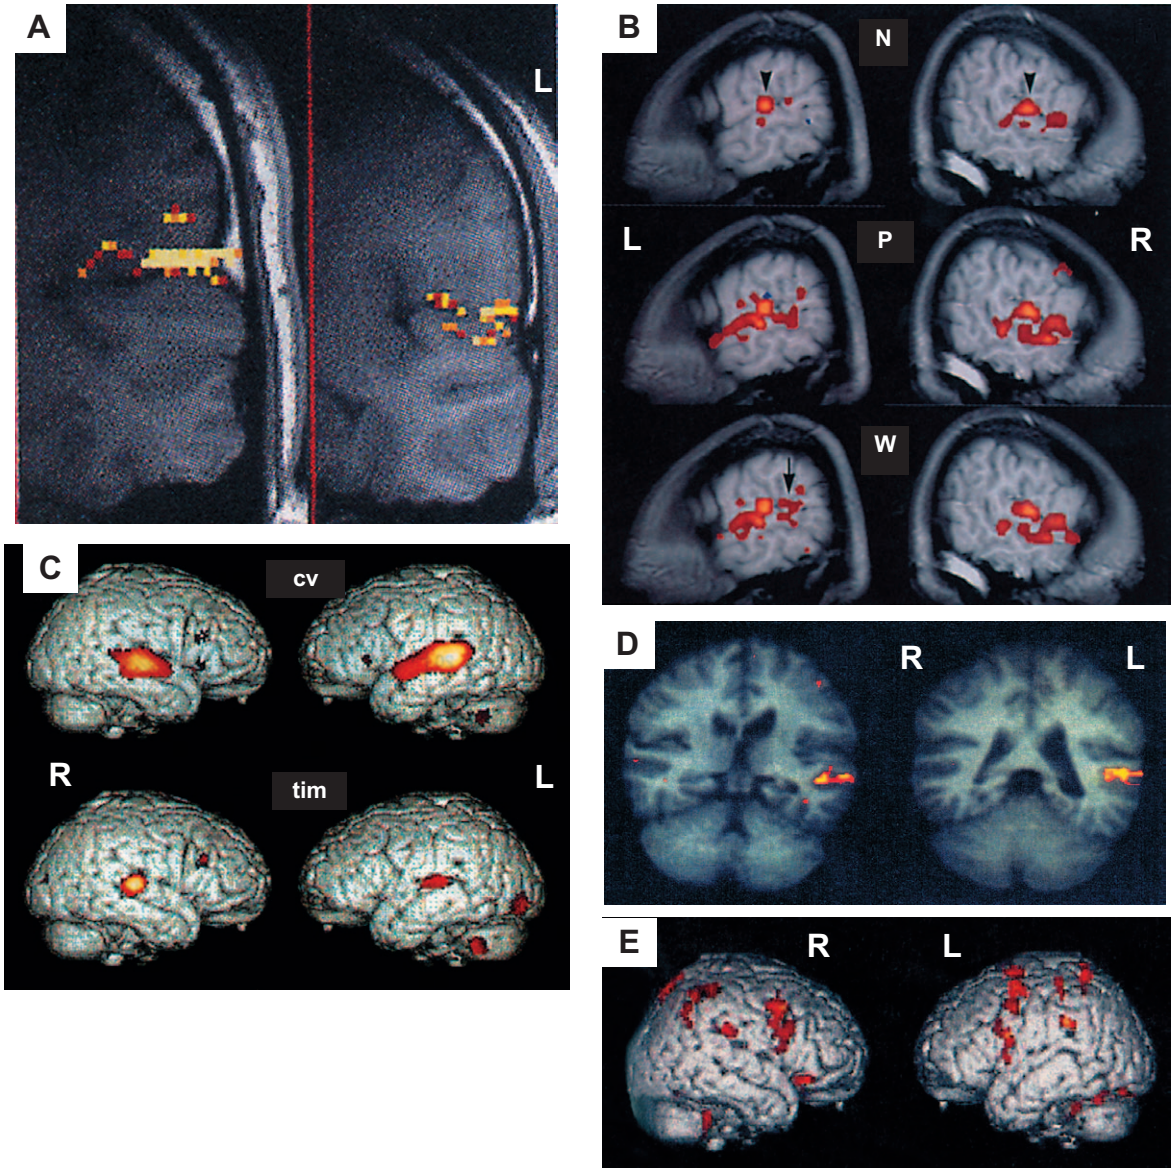

FIGURE 34.29 Functional imaging of human auditory cortex. females (Frost *et al.*, 1999), but this left dominance is not absolute across subjects. In one fMRI study of a task dependent on word meaning, 94% of the right-handed subjects were left hemisphere dominant and 6% had bilaterally equal language representation (Springer *et al.*, 1999). Occasionally a reversed, or "mirror image", representation of language in the right hemisphere of a right-handed person is observed (Chee *et al.*, 1998). The functional significance of greater left hemisphere activity is implied by imaging studies of stroke patients after infarctions of the left posterior perisylvian area (Weiller *et al.*, 1995; Heiss *et al.*, 1997; Mummery *et al.*, 1999). Subjects who showed good recovery of speech perception had increasing activation of left temporal lobe cortex surrounding the infarct. Subjects with recruitment of additional cortex only in the right hemisphere showed single word comprehension, but continued impaired understanding of fluent speech. Like the results of the imaging studies of normal subjects, these findings suggest bilateral temporal lobe involvement in speech processing, with a final level of processing generally present (in right-handers) in the left hemisphere.

Some indications of an opposite asymmetry in processing musical stimuli come from cases of pathology. A patient with a right thalamic tumor experienced distorted perception of music but not of voices (Roeser and Daly, 1974). Cortical activity has been demonstrated in the right superior temporal lobe during musical hallucinations (Kasai *et al.*, 1999). A case of amusia, a form of auditory agnosia, was seen after an infarction involving the right insula (Griffiths *et al.*, 1997b). In this patient, a battery of tests confirmed a dissociated receptive musical deficit in the presence of normal appreciation of environmental sounds and speech. In imaging studies, listening to tone patterns or melodies causes foci of activity in the right temporal and parietal lobes (Roland *et al.*, 1981; Zattore *et al.*, 1994). However, the side of greatest activation can be influenced by the analysis strategy of the subject. Musically naive subjects show greater temporal and frontal lobe activity on the right side, whereas musically sophisticated subjects who visualize musical scores may have greater left-sided activity (Mazziota *et al.*, 1982). In discrimination of musical timbre (harpsichord/guitar/organ), the peak of activity in the superior temporal gyrus is larger on the right (Hugdahl *et al.*, 1999) (Fig. 34.29C), and right temporal lobe lesions create a significant deficit in timbre discrimination (Samson and Zatorre, 1994). However, different components of musical analysis do not always activate the same areas. One study has shown separate cortical areas for tasks involving attending to pitch, melodic interval, melodic contour, meter, and rhythm

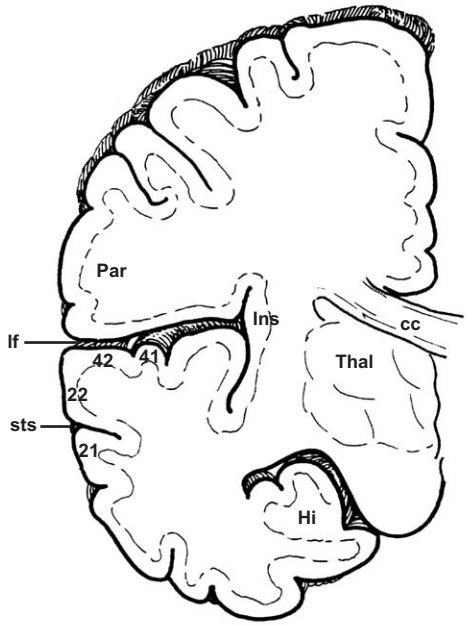

FIGURE 34.30 Cross section through one hemisphere of the human forebrain. The "what" pathway passes laterally and ventrally from area 41 across areas 42, 22, and 21. The "where" pathway passes medially and dorsally through the insula and into parietal cortex (Par). cc, corpus callosum; Hi, hippocampus; Ins, insula; lf, lateral fissure; sts, superior temporal sulcus; Thal, thalamus.

(Liégois-Chauvel *et al.*, 1998). In most of these tasks, there is greater right-sided activity, but melodic interval appears to be processed in the left hemisphere. Thus, analysis of music, like that of speech, is a complex process involving interaction of the two hemispheres, with some hemispheric specialization at the highest levels of analysis.

It is a commonly accepted view that auditory cortex is mainly confined to the temporal lobe, with activation spreading laterally and ventrally from the koniocortex. However, there is increasing evidence for a pathway responding to position and motion of auditory stimuli that extends medially and dorsally into the parietal lobe (Fig. 34.30). The idea of a "two stream" organization of sensory cortex originated in the visual system. In monkey and human visual cortex, information processing flows from the primary visual area in two broad functional streams (Goodale *et al.*, 1994). The ventral visual stream, known as the "what" pathway, leads to the inferior temporal region and is concerned with perceptual features of a visual stimulus. The dorsal stream, referred to as the "where" pathway, leads to the parietal region and is concerned with perception of an object's location and motion. A similar two-stream organization may exist in human auditory cortex. The right insula is activated by a moving sound image

(Griffiths *et al.*, 1994), and, conversely, a patient with a right hemisphere stroke causing atrophy of the right insula was unable to detect sound source movement by either phase or loudness cues (Griffiths *et al.*, 1996). Subjects listening to stimulus movement simulated by changes in binaural timing show maximal activity in the inferior parietal area, particularly on the right side (Griffiths *et al.*, 1998; Weeks *et al.*, 1999) (Fig. 34.29E). These findings suggest that there is transcortical passage of information from auditory koniocortex posteriorly and medially, across the insula and into the parietal lobe, during processing of information on sound source position and motion. They also suggest a dominant functional role of the right hemisphere in sound localization.

THE DESCENDING AUDITORY SYSTEM

Descending Projections from Cortex

The descending projections from auditory cortex to the thalamus are reciprocal, in the sense that cortical regions project back to the thalamic areas that are the source of their afferent input. Injection of neuronal tracers into the primary auditory cortex of the marmoset and macaque demonstrates a dense projection to the ventral medial geniculate and a much lighter projection to the medial and dorsal nuclei (Aitkin *et al.*, 1988; Pandya *et al.*, 1994). These descending projections originate mainly from pyramidal cells of layer VI, with some contributions from cells of layer V. In contrast, when tracer injections are made into the parabelt or into the cortex of the upper bank of the superior temporal sulcus, the descending axons end only in the medial and dorsal nuclei of the medial geniculate and in the medial pulvinar (Yeterian and Pandya, 1991; Pandya *et al.*, 1994; Hackett *et al.*, 1998b; Guteirrez *et al.*, 2000). Because there are few descending connections from the thalamus, these corticothalamic pathways form feedback loops that can allow reverberant activity of the thalamus and cortex.

Many of the axons descending from cortex bypass the thalamus and travel to the tectum, where they end in the inferior colliculus. Anterograde transport of tracers shows that the termination of these axonal projections is primarily in the caudal half of the pericentral colliculus, i.e., in the dorsocaudal cortex (squirrel monkey, FitzPatrick and Imig, 1978; marmoset, Luethke *et al.*, 1989). The dorsocaudal cortex is a multilayered structure, with neurons segregated into several layers and cells becoming progressively larger in the deeper layers. This cortical cytoarchitecture in monkey

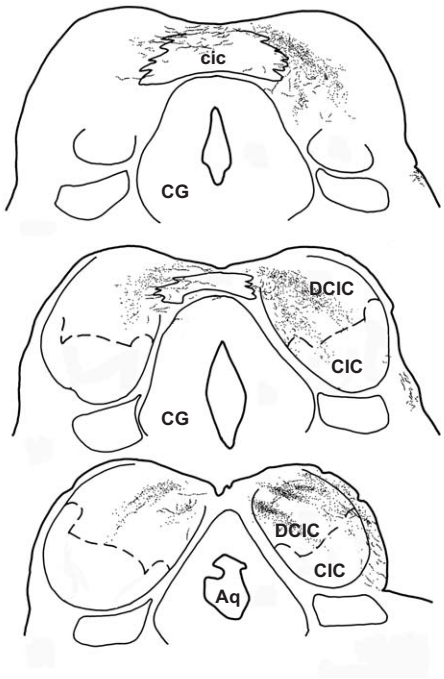

FIGURE 34.31 Following tracer injection into the auditory cortex of the marmoset, labeled bands of axons are present in the dorsocaudal cortex of the inferior colliculus (DCIC). Few degenerating axons enter the central nucleus of the inferior colliculus (CIC). Some degenerating axons cross in the commissure of the colliculus (cic) to end in the dorsocaudal cortex on the opposite side. Aq, aqueduct; CG, central gray. Adapted from *Journal of Comparative Neurology* **285,** L.E. Luethke, L.A. Krubitzer, and J.H. Kaas, figure 14, Connections of primary auditory cortex in the New World monkey, *Saguinus,* pp. 487–513, 1989, with permission from Wiley-Liss, a subsidiary of John Wiley & Sons, Inc., New York.

(FitzPatrick, 1975) and man (Geniec and Morest, 1971) is similar to that of nonprimate species. Within the dorsocaudal cortex, the descending cortical axons form bands oriented from dorsomedial to ventrolateral (Fig. 34.31). A smaller number of axons cross the midline in the commissure of the inferior colliculus and terminate in the dorsocaudal region of the colliculus on the opposite side. Because it is the primary target of corticofugal axons, the dorsocaudal cortex appears to be an important relay in the descending auditory pathway.

Descending Projections from Inferior Colliculus

Descending projections from the inferior colliculus originate predominantly from its dorsocaudal cortex (Moore and Goldberg, 1966). The descending axons run along the surface of the brain stem adjacent to the lateral lemniscus and terminate mainly in the region of the superior olivary complex. As in nonprimate

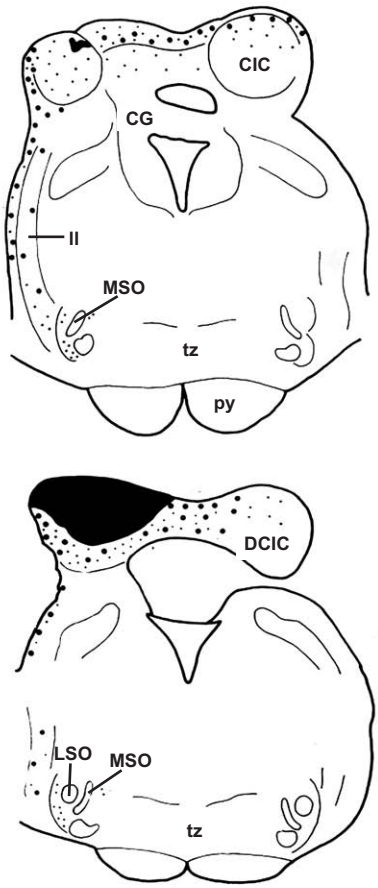

FIGURE 34.32 A lesion *(shaded black)* confined mainly to the dorsocaudal cortex of the inferior colliculus (DCIC) in the macaque results in degenerating axons *(large dots)* descending superficial to the lateral lemnisus (ll). Degenerating terminals (*small dots)* are present in the periolivary region (PO) of the superior olivary complex. Adapted from *Experimental Neurology* **14,** R.Y. Moore and J.M. Goldberg, figure 1, Projections of the inferior colliculus in the monkey, pp. 429–438, 1966, with permission of Harcourt Brace, a subsidiary of Academic Press.

mammals, terminals are found throughout the periolivary region, but not in relation to the medial and lateral olivary nuclei (Fig. 34.32). The density of terminals is greater ipsilaterally and is heaviest in the ventral periolivary cell groups.

Descending Projections from Periolivary Region

Descending projections from the superior olivary complex arise exclusively from periolivary cells. In nonprimate mammals, a sizable projection from periolivary cells terminates in the cochlear nuclei (Covey *et al.,* 1984; Spangler *et al.,* 1987). In the guinea pig, most of the descending axons have been shown to contain GABA or glycine, or to colocalize both inhibitory substances (Kolston *et al.,* 1992; Ostapoff *et al.,* 1997). The GABA- and glycine-immunostained axons run in the trapezoid body to the ventral cochlear nucleus, and many continue into the dorsal cochlear nucleus as the centrifugal bundle of Lorente de No. In the baboon, however, only scattered GABA- and glycine-immunoreactive axons are present in the trapezoid body and acoustic striae. In addition, the centrifugal bundle of Lorente de No cannot be identified in the human cochlear nuclear complex (Moore and Osen, 1979). Thus, the possibility must be considered that this part of the descending system is poorly developed in higher primates.

Periolivary neurons also form an efferent projection to the organ of Corti that is termed the olivocochlear pathway. Early demonstrations of olivocochlear neurons in mammals were done on the basis of their content of acetylcholinesterase (AChE), the degradative enzyme for acetylcholine (Brown and Howlett, 1972; Warr, 1975; Osen *et al.,* 1984). In the human brain stem, AChE-positive olivocochlear axons were traced dorsally from the human superior olivary complex and into the vestibular nerve (Moore and Osen, 1979). Antibodies to choline acetyltransferase (ChAT), the synthesizing enzyme of acetylcholine, have also been used to identify olivocochlear neurons in the periolivary region in the squirrel monkey (Thompson and Thompson, 1986), macaque (Carpenter *et al.,* 1987), and man (Moore *et al.,* 1999) (Fig. 34.33, ChAT).

In nonprimate mammals, two subdivisions of the olivocochlear system can be demonstrated by anterograde and retrograde transport of neuronal tracers (Warr and Guinan, 1979; Guinan *et al.,* 1983). In the lateral subdivision, axons of cells associated with the lateral olivary nucleus form synaptic terminals contacting afferent fibers from inner hair cells and, in some cases, inner hair cell somata. In the medial subdivision, axons of cells located throughout the periolivary region form synaptic terminals contacting outer hair cells and, occasionally, their afferent fibers. The two systems also differ in their chemical characteristics in that lateral olivocochlear neurons colocalize a variety of neuropeptides with the cholinergic enzymes. One of these peptides is calcitonin gene–related peptide (CGRP). In the human superior olivary complex, a cluster of mostly small oval cells that are both ChAT and CGRP positive is located adjacent to and surrounding the lateral olivary nucleus (Moore *et al.,* 1999) (Fig. 34.33, CGRP). It is likely these neurons are homologous to the mammalian lateral olivocochlear system. The remainder of the population, which is immunopositive only for ChAT, consists predominantly of larger multipolar cells distributed throughout the periolivary

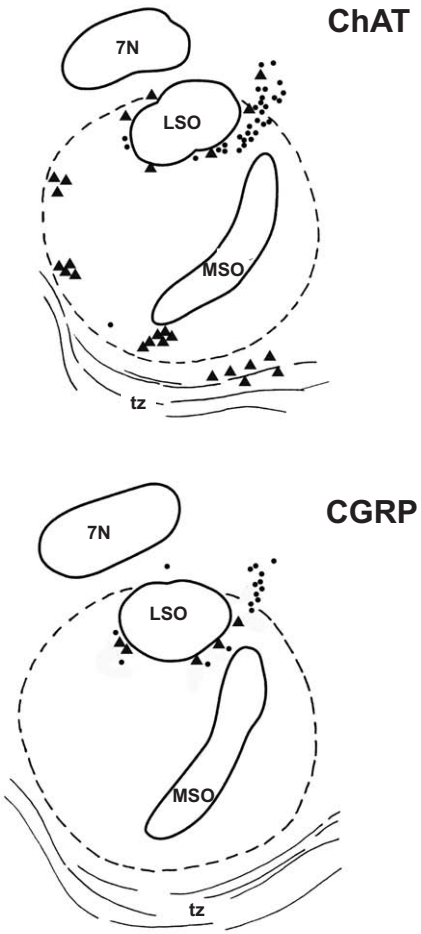

FIGURE 34.33 Distribution of immunoreactive neurons in the human superior olivary complex, including both large cells (▲) and small cells (✳). Immunostaining for choline acetyltransferase (ChAT) demonstrates the entire population of efferent neurons, including both the medial and lateral subsystems. Immunostaining for calcitonin gene–related peptide (CGRP) demonstrates only the lateral efferent neurons. Simmons, and Y.-L. Guan, figure 5, The human olivocochlear system: organization and development, pp. 311–325, 1999, with permission from Karger AG, Basel.

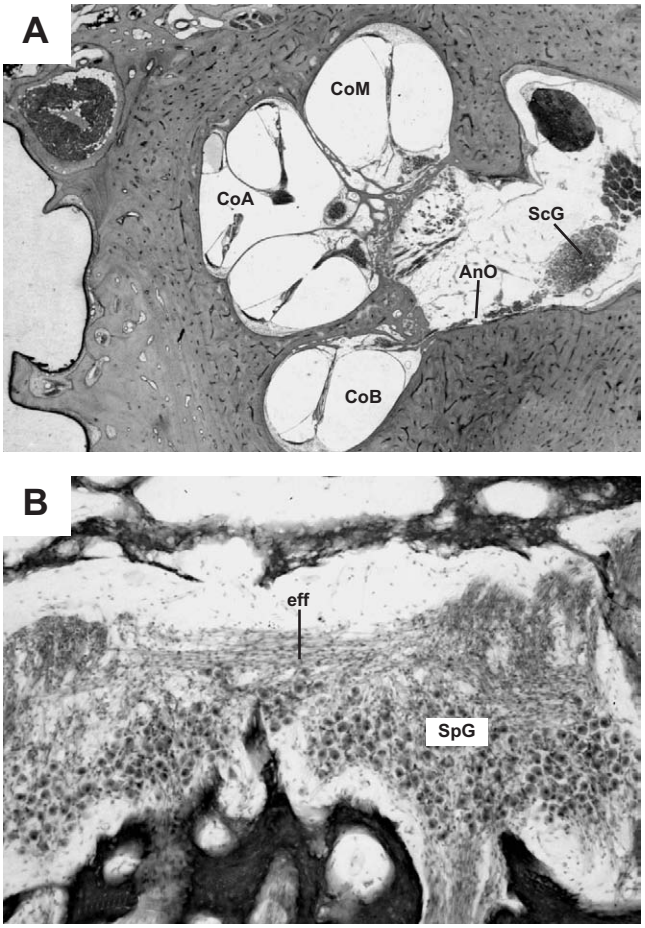

FIGURE 34.34 **(A)** Vertical section through the cochlea and internal auditory canal showing the vestibulocochlear anastomosis of Oört (AnO) passing from Scarpa's ganglion (ScG) of the inferior vestibular nerve into the basal turn of the cochlea (CoB). CoA, apical turn, CoM. middle turn. **(B)** A horizontal section through the cochlea illustrates the intraganglionic efferent bundle (eff) on the surface of the basal segment of the spiral ganglion (SpG). Celloidin sections, hematoxylin & eosin.

region (Fig. 34.33, ChAT). These cells are most heavily concentrated ventrally but are also scattered along the dorsal, medial, lateral, and rostral boundaries of the olivary complex. Because of their size and distribution, it seems likely that the cells are homologous to the medial olivocochlear system in nonprimate species.

Efferent Innervation of the Cochlea

Olivocochlear axons leave the brain stem in the vestibular nerve, traverse its inferior branch, and pass through the vestibulocochlear anastomosis or nerve of Oört (Oört, 1917) (Fig. 34.34A) to enter the basal turn of the cochlea. The bundle of efferent axons passes toward the apex of the cochlea in the lateral aspect of Rosenthal's canal. Early investigations demonstrated efferent axons and terminals within the human cochlea by their content of AChE (Schuknecht *et al.*, 1959; Ishi *et al.*, 1967). Some of the fibers, the thin axons of lateral efferent neurons, pass into the organ of Corti and run toward the apex of the cochlea as the inner spiral bundle. These efferent axons form synaptic terminals on the afferent axons of inner hair cells and, occasionally, on the inner hair cell bodies themselves.

Other efferent fibers, the thicker axons of the medial efferent neurons, traverse the tunnel of Corti as the tunnel-crossing fibers (Fig. 34.5B). They then form the outer spiral bundle whose fibers branch to synapse on the bases of outer hair cells. In the human cochlea, as in other mammalian species, efferent terminals are most numerous in relation to outer hair cells. In recent years, the efferent nature of axons in the inner spiral bundle, tunnel-crossing fibers, and terminals at the base of outer hair cells has been confirmed by immunostaining for ChAT (Schrott-Fischer *et al.*, 1994).

Because the principal neurotransmitter of the olivocochlear system is acetylcholine, its activity might be expected to affect the actin-based system of outer hair cell motility. In fact, experiments on outer hair cells isolated from guinea pig cochleas have shown that application of acetylcholine affects the electromotile responses of these cells (Slepecky *et al.*, 1988; Dallos *et al.*, 1997). The cells exposed to acetylcholine show increased motility, but the response occurs much more slowly than the rapid response to electrical and acoustic stimulation. In human subjects, stimulation of the olivocochlear pathway by acoustic input to the opposite ear causes suppression of spontaneous and evoked otoacoustic emissions (Mott *et al.*, 1989; Khalfa and Collet, 1996; Veuillet *et al.*, 1996; Hood *et al.*, 1996). This effect is believed to be due to the outer hair cell response to acetylcholine and to be mediated mainly by medial olivocochlear neurons.

Behavioral effects have also been demonstrated from activation of the olivocochlear system by contralateral ear stimulation. In functional studies of normal human subjects, these behavioral effects include enhancement of selective attention (Puel *et al.*, 988; Giard *et al.*, 1994; Scharf *et al.*, 1997) and improved processing of complex signals in noise (Giraud *et al.*, 1997). The idea that the behavioral changes are the results of olivocochlear system activity is supported by observations in subjects who have undergone vestibular neurectomy. These subjects, whose efferent pathway has been disrupted by severing the vestibular nerve, have no detectable change in hearing in quiet. In the presence of noise, however, there is increased subjective loudness and worsened intensity discrimination in the operated ear (Zeng *et al.*, 2000). It is true that the physiological and perceptual effects of efferent system activity have been demonstrated by artificial stimulation or disruption of the descending auditory system at a level only one neuron above the cochlea. Nonetheless, the continuity of the descending system from cortex to cochlea provides a potential route for the highest levels of auditory processing to bias the activity of the peripheral receptor.

Visual System

RAINER GOEBEL,[1] LARS MUCKLI,[2] and DAE-SHIK KIM[3]

[1]*Department of Neurocognition, Faculty of Psychology, Universiteit Maastricht, Maastricht, The Netherlands*

[2]*Department of Neurophysiology, Max-Planck Institute of Brain Research, Frankfurt, Germany*

[3]*Center for Magnetic Resonance Research, University of Minnesota, Minneapolis, MN, USA*

In neuroscience we know more about vision than any other system. This knowledge is derived from a rich diversity of methodological approaches. The advanced state of the neuroscientific research of the visual system is important in itself but may also serve as a model system for understanding general principles about how the brain processes information. In the following, basic anatomical and functional properties of the visual nervous system will be described. First, the early stages of visual processing in the eye and the pathways from the retina to the visual cortex are presented. This is followed by a detailed description of the remarkable organization of primary visual cortex. Then the anatomical and functional properties of areas are described, which are located in extrastriate cortex, the visually responsive cortex outside the primary visual area. Finally, general theoretical approaches are discussed in an attempt to explain how the visual system integrates processing in various specialized areas so as to construct a vivid representation of the visual world.

CENTRAL VISUAL PATHWAY

Anatomy of the Central Visual Pathway

Eye

The structure of the eye (Fig. 35.1) serves various functions that contribute to the formation of a clear image on the retina. In many aspects the human eye can be compared to a camera (Wurtz and Kandel, 2000). However, the optical qualities of the eyes are surprisingly poor in comparison with those of a regular camera. If, for example, the retina were replaced by a color film, we would receive pictures of deficient quality. Nevertheless, the visual system of humans is the most sophisticated visual system in nature. Before we turn to the question of how the visual system generates its amazing precision, we take a quick look at the structure of the eye (Tripathi and Tripathi, 1984).

The human eye is an approximately spherical ball of 24 mm diameter, surrounded by white, tough fibrous tissue—the sclera. The anterior segment of this tissue, the cornea, is avascular, transparent, and more highly curved. In its way from the outside world to the retina, light passes through the conjunctiva—a delicate membrane covering the cornea—through the cornea, the anterior chamber (aqueous humor), the lens, and the vitreal chamber (vitreous humor) until it enters the ganglion cell layers of the retina. In this way light is refracted by a power of about 43 diopters (dpt) at the

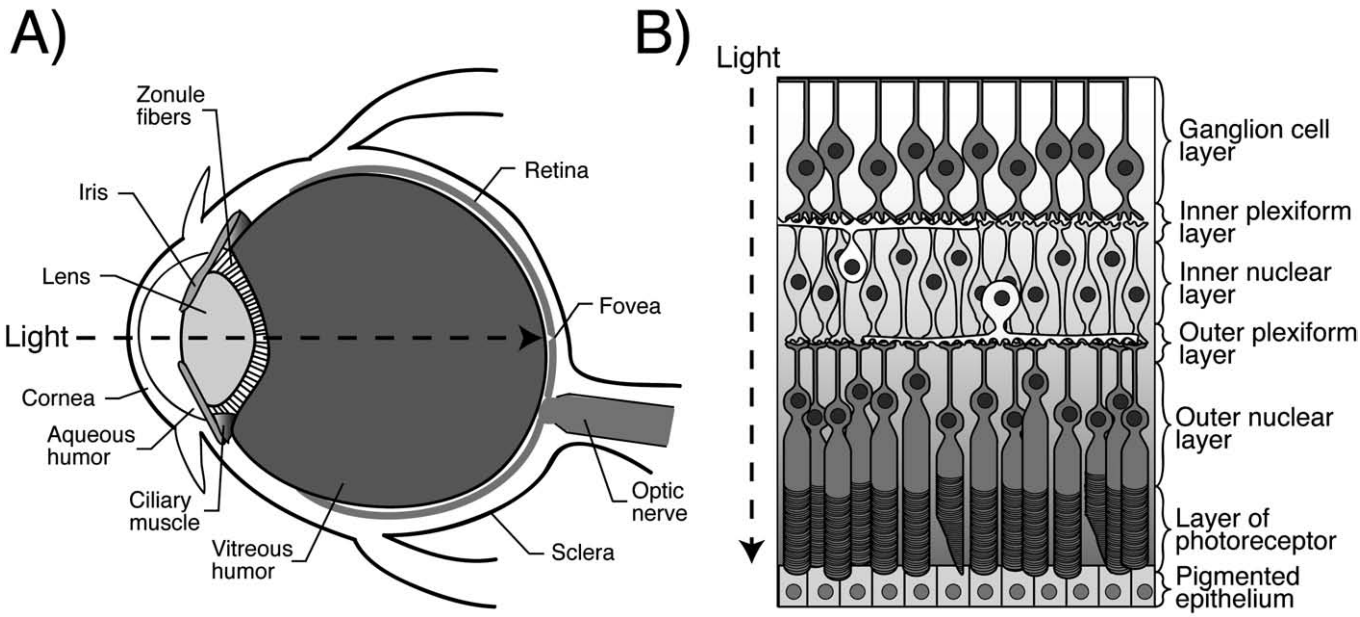

FIGURE 35.1 (A) The eye in cross section. (Adapted from Bear, Connor & Paradiso, 1996, p. 216). (B) The laminar structure of the retina, showing its five layers. Note that light must pass through these layers to reach the photoreceptors, which are situated at the back of the retina. (Adapted from Bear, Connor & Paradiso, 1996, p. 222).

cornea and about 20 dpt at the relaxed lens. Altogether 60 dpt refers to a focal point of 17 mm (1/60 m) after the lens.

The ***lens*** is an elastic body that is suspended by annular ligaments (zonule fibers), which originate in the ciliary muscle. The pressure of the inner eye tightens the lens through the annular ligaments. If the ciliary muscle, on which the annular ligaments are attached, contracts, the tension on the lens is relieved and the elastic lenses bend outward. A camera lens can be adjusted to focus on distant as well as on nearby objects by varying the distance between lens and projection plane. In the eyes, the refraction power is increased by flexion of the lenses. In the relaxed condition, the lenses are far-adjusted (10 m and above). In order to accommodate for nearby objects, the ciliary muscle is contracted so that the lenses can bend outward. Depending on the elasticity of the lenses, this can lead to a power of up to 8 dpt. The elasticity of the lens decreases with age, which leads to age-related farsightedness (presbyopia) (Bron *et al.*, 2000).

Farsightedness (hyperopia) also exists, independent of age, if the eyeball is too short and the refraction power is therefore not strong enough. In contrast, elongated eyeballs cause nearsightedness (myopia). At hyperopia the eyes try to compensate the missing refractory power by constant contraction of the ciliary muscle, but this compensation strategy becomes insufficient for near vision. In addition, ciliary muscle contraction leads automatically to an inward turning of the eyes, which is a useful mechanism for normal vision, allowing both eyes to fixate on an object even at close distances. In hyperopia, however, this mechanism misaligns the visual axes and leads to strabismus and double images. One strategy of the visual system to prevent double images is by constantly suppressing the information of one eye, which can eventually lead to amblyopia (Moore *et al.*, 1999; Sireteanu, 2000).

In front of the lens, there is another smooth muscle, the ***iris***, which has a function similar to that of the diaphragm of a camera in controlling the amount of light that enters the pupil. In this way the iris can quickly adjust to changing light intensities, the more effective but slower mechanism for light adaptation can be found in the section on Photoreceptors.

If the iris and the ciliary muscle are paralyzed, e.g., following application of atropine to the eyes, the iris will stay open and cause increased light irritability, and the ciliary muscle will remain relaxed, thus causing difficulties for near accommodation.

Retina

The main contribution of the eyes to vision is to project a picture from the external world onto the retina, upside down and focused, as in a camera. The retina's contribution, on the other hand, is much more complicated (Masland and Raviola, 2000). It transposes light into neuronal code (transduction) and processes

important features of the visual input (Meister and Berry, 1999). Right from the first synapse, the retina thereby feeds into parallel processing streams that are specialized for different visual features, such as contrasts, motion, or color, and that are kept in parallel for many processing steps until an undivided conscious percept is recovered somewhere in the neocortex (Wässle, 2002).

Some peculiarities of the retina are so distinct from other sensory organs that the retina is regarded as a peripheral part of the brain rather than a normal sensory organ. For one, the embryological development of the retina derives from a portion of the same neural ectoderm that gives rise to the rest of the brain (Graw, 1996). During the course of embryological development, the retina migrates to the periphery and then extends connecting links back to the rest of the brain. Moreover, the synaptic organization of the retina is similar to that of other regions of the brain.

The retina is structured into five layers named with reference to the center of the eyeball: outer nuclear layer, outer plexiform layer, inner nuclear layer, inner plexiform layer, and ganglion cell layer. Interestingly, light has to travel through all these layers until it reaches the photoreceptors—a fact that contributes to the relatively poor optical properties of the eyes mentioned earlier.

The fovea centralis—the region of best vision—is the only part of the retina at which the neuronal and vascular circuitry bends sideward, so that light reaches the photoreceptors directly. This part of the retina appears yellow—also referred to as yellow spot. Here single cones innervate distinct ganglion cells unlike in other regions of the retina where many photoreceptors converge to a few ganglion cells.

The retina itself is a thin layer about 2 mm thick and 270 mm wide. It contains about 120 million neurons. The pigmented epithelium at the outer end of the eyes (at the bottom of Fig. 35.1) assures that any remaining photons are absorbed if they have not been absorbed by the photoreceptors that are emedded in the epithelium.

Photoreceptors (Outer Nuclear Layer)

There are two main categories of photoreceptors in the outer nuclear layer: rods and cones (Schultze, 1866; Boycott and Wässle, 1999). The general structure of the 120 million rods and the 6 million cones is similar. They are composed of four parts: an outer segment containing the photosensitive substance (pigment), an inner segment, a cell body, and a synaptic terminal (pedicle). Human rods and cones are typical of a fairly general vertebrate pattern. Rods are more sensitive to dim light but not to color. Peripheral vision depends almost exclusively on rods, central vision on cones. At light intensities below the sensitivity of cones vision depends solely on rods (scotopic vision) and color processing is not possible. We become aware of our missing rod receptors in the fovea if we try to fixate a small light source, such as a star on a starry sky. Whenever we fixate that light source precisely it disappears and reappears only if we focus nearby (von Kries, 1896). Cones are less sensitive to dim light, but they are sensitive to color. In fact, there are three different kinds of cones in humans: S cones, which are maximally sensitive to short wavelength (420 nm, blue); M cones, sensitive to middle wavelength (531 nm; green); and L cones, sensitive to long wavelength (559 nm; red). Some birds and fishes have more then two cones; among mammals, only humans and some monkeys are trichromates (Jacobs, 1993, 2002; Wässle, 2002).

The wavelength to which the rods and cones are most sensitive depends on the absorption characteristics of the visual pigment it contains (rhodopsin; or one of three different cone opsins; Wurtz and Kandel, 2000). Visual pigment is a molecule found in the outer segment of photoreceptors, where thousands of lamellated membrane infoldings (cones) or free-floating membrane disks (rods) are tightly packed. Visual pigments consist of a large protein opsin and a small light-absorbing compound, retinal, which changes its configuration when activated by a specific wavelength of light and triggers a cascade of events that eventually lead to a hyperpolarization of the membrane potential. In darkness the concentration of the second-messenger molecule cGMP (cyclic guanosine 3′,5′-monophosphate) is high and opens cGMP-gated ion channels allowing a constant inward current that keeps the cell depolarized at –40 mV (dark current).

Light transduction leads to a reduction of cGMP and hence to hyperpolarization of the cell. Photoreceptors are sensitive to small changes in the illumination. Prolonged or slow changes of the illumination lead to light adaptation that is regulated by Ca^{2+} concentration changes. Dark-adapted rods are so light sensitive that they can detect a single photon. Upon the detection of a photon, the membrane potential hyperpolarizes, and increasing the release of glutamate at its synapses.

Until recently, it had been thought that the transformation of light to neuronal code is exclusively performed in rods and cones. Now, a retinal ganglion cell type has been found to contain a newly discovered light-responsive protein (melanopsin; Provencio *et al.*, 2000, 2002). These ganglion cells project primarily to the suprachiasmatic nucleus and are relevant for the control of the circadian clock (Hattar *et al.*, 2002).

Neuronal Processing (Inner to Outer Plexiform Layer)

The first neuronal computation that processes light information and extracts different features, which are

then processed in parallel (Stone, 1983) and projected from the retina toward the brain, is performed by four main cell types of neurons: ***horizontal cells***, ***bipolar cells***, ***amacrine cells***, and, finally, ***ganglion cells***. These cells collaborate on modulating the synapses between photoreceptors and bipolar cells, in the outer plexiform layer, and the synapses between bipolar cells and the ganglion cells, in the inner plexiform layer (cone pathway). It is the task of the bipolar cells to project the neural code forward to the ganglion cells. Horizontal cells have a modulatory influence at the photoreceptor synapse (outer plexiform layer). Amacrine cells have a modulatory influence at the ganglion cell synapse (inner plexiform layer). In the rod pathway there are A-II amacrine cells interposed between rod bipolar cells and ganglion cells (Kolb and Famiglietti, 1974). In this way, cells in the retina process the signals of one or many photoreceptors resulting in small or huge receptive fields. A receptive field corresponds to the region in space in which a light stimulus can induce a neuronal response, which can be either an enhancement (on cells) or a reduction (off cells) of activity.

Photopic Pathway The cone photoreceptors release the transmitter glutamate at their synaptic terminal, the cone pedicles, which inhibits off bipolar cells, and excites on bipolar and horizontal cells (Dogiel, 1891; Polyak, 1941; Boycott and Dowling, 1969; Kolb *et al.*, 1980; Boycott *et al.*, 1987). Horizontal cells, in turn, release the inhibitory transmitter γ-aminobutyric acid (GABA) at their termination zone, which is again at the cone pedicles. This synaptic arrangement has been named a triad (Missotten, 1965; Stell, 1965; Kolb, 1970; Boycott and Kolb, 1973). About 10 morphologically different types of bipolar cells project from the cone synapse to the inner plexiform layer (Boycott and Wässle, 1999). Four of them are off bipolar cell types; they respond more strongly if the stimulus is darker than the background, and six of them are on bipolar cell types, responding more strongly if the stimulus is brighter than the background. Two cone bipolar cell types, one on and one off bipolar, are especially sensitive to contrast information, another two are responsible for the red–green portion of light, and one is devoted to blue light (Dacey and Lee, 1994; Calkins *et al.*, 1998; Ghosh *et al.*, 1997). Furthermore, there are three cone bipolar cell types that specialize in detecting directional information, i.e., retinal drift or motion (Berry *et al.*, 1999). In the photopic pathway, cone bipolar cells synapse at dyads onto ganglion and amacrine cell dendrites.

Rod Pathway Rods are connected to rod bipolar cells (Boycott and Dowling, 1969; Kolb, 1970). These do not synapse directly onto ganglion cells but onto two kinds of amacrine cells, one of them being the all-amacrine cell (Wässle *et al.*, 1995). AII-amacrine cells make inhibitory synapses with off cone bipolar and off ganglion cells and contact on cone bipolar cells via large gap junctions. In this way, they are "through-conducting neurons" (Masland, 1986) that produce signals of opposite polarity in on and off ganglion cells.

Amacrine Cells Morphologically, there are 30–40 different types of these "axonless" amacrine cells (Masland and Raviola, 2000). Relatively little is known about the specific signal-processing properties of these different amacrine cells. One exception is the cholinergic starburst cell (Famiglietti, 1992), which has recently been shown to play an important role in the extraction of direction-selective information, which is fed forward to direction-selective ganglion cells. Direction-selective ganglion cells (Kuffler, 1953) respond to stimuli that are moving in one, but not in the opposite, direction. Yoshida *et al.* (2001) selectively eliminated the starburst amacrine cells in mice, which abolished direction selectivity in ganglion cells and the optokinetic eye reflex. This indicates that starburst cells are crucial for detecting the direction of movement in mice.

Ganglion Cells The retinal ganglion cells have their dendrites in the inner plexiform layer and their cell bodies in the ganglion cell layer. Retinal ganglion cells project their axons across the inner surface of the retina toward the optic disk, where the optic nerve is formed. The different response patterns of ganglion cells can be identified by microelectrode recordings (Kuffler, 1953). Ganglion cells either have on or off center response characteristics (see below; cf. Fig. 35.2B). Within each subgroup there are five to seven additional cell types. Their properties vary with respect to temporal dynamics (tonic or phasic), size of the receptive field, contrast sensitivity, and, as mentioned before, their capability to detect the direction of movement. Another ganglion cell type is devoted to the control of iris contraction (Berson *et al.*, 2002; Lucas *et al.*, 2001). Furthermore, there are ganglion cell types responding to red, green, or blue yellow light (color vision; Dacey, 1999).

The input from the photoreceptors (outer plexiform layer) to the ganglion cells arrives through bipolar and amacrine cells' synapses at the ganglion cells, dendrites in the inner plexiform layer. The inner plexiform layer is precisely organized into on and off layers, from which the respective on and off center ganglion cell dendrites originate.

Optic Nerve, Chiasm, Optic Tract

The axons of the retinal ganglion cells form the optic nerves, optic chiasm, and optic tracts. The optic nerves leave the retina at the optic disk and penetrate

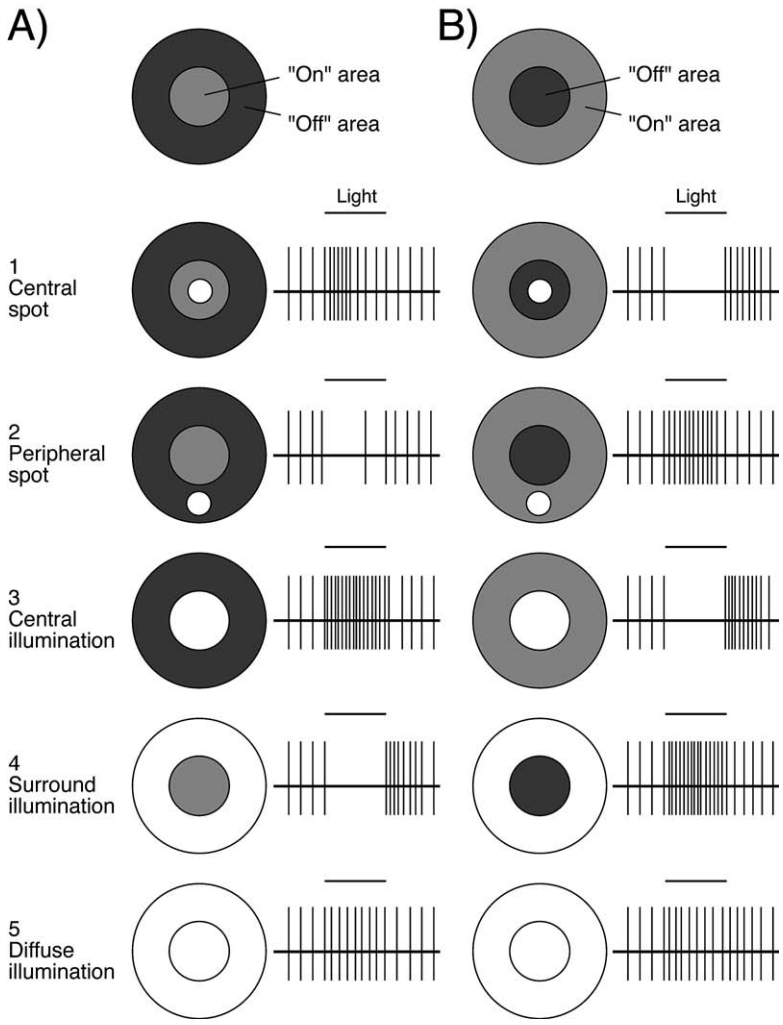

FIGURE 35.2 Retinal ganglion cells have circular receptive fields divided into a center and a surround. ON-center/OFF-surround cells are excited when illuminated in their center and inhibited when illuminated in their surround. OFF-center/ON-surround cells exhibit the opposite pattern. (A) ON-center cells respond maximally when (3) the center is illuminated and the surround is not and minimally in (4) the opposite illumination condition. Partial illumination of (1) center or (2) surround results in brief excitation and inhibition, respectively. Diffuse illumination (5) or darkness (not shown) results in a weak level of excitation because the center and surround tend to cancel each other's effects. (B) The activity of OFF-center cells is inhibited when (1, 3) their center is illuminated and excited when (2, 4) their surround is illuminated. As in the ON-center cells, opposing effects on center and surround caused by diffuse illumination (5) and darkness (not shown) produce weak levels of excitation. (Adapted from Kandel *et al.*, 1995, p. 418).

the lamina cribrosa. The area where the ganglion cell axons leave the retina does not have any photoreceptors; therefore, no visual information is detected in this region, which results in a blind spot in our visual field. This blind spot is easy to demonstrate; however, under normal circumstances the blind spot is not perceived but filled in. The optic nerve consists of about 1.5 million axons only. Most of them are 1 µm in diameter, about 10% of them are 2–10 µm, and all together a nerve fiber is 3–4 mm thick. Compared to the 120 million photoreceptors in the retina the signal has massively converged.

The neuronal circuitry in the retina has filtered and condensed the incoming information into 1 million specialized projections to the brain. About 5 cm after leaving the retina, the two optic nerves intermingle at the optic chiasm, where the containing axons are sorted into two optic tracts. In humans, about 50% of the axons cross the hemispheres. The distribution of fibers from one optic nerve into two optic tracts relates, in general, to the amount of binocularity. Thus, because in fish the eyes are placed far laterally, there is no overlap in the visual fields, and all the axons cross at the chiasm into the opposite optic tract. In animals in

which the eyes are set further forward, and thus the visual fields of the eyes overlap, the fibers cross only partially. This configuration is necessary to enable fusion of the corresponding retinal images. This principle was correctly deduced from optical considerations by Isaac Newton (Brewster, 1855), later by von Gudden (1874) and confirmed by von Monakow (1883). After crossing of the ganglion cells that originate in the nasal part of the retina, each optic tract contains always exclusively the information of the contralateral visual field. The nasal retinal ganglion cells process information from the lateral visual field. The retinal ganglion cells end mostly in the lateral geniculate nucleus (LGN) of the thalamus. In addition, right after the optic chiasm, there are a few other projections to midbrain structures (discussed below).

Lateral Geniculate Nucleus

In a cross section (Fig. 35.3) the lateral geniculate nucleus (LGN) appears somewhat like a bent knee, hence, the term geniculate, from the Latin for "knee." The LGN can be divided into six clearly visible layers, labeled 1–6 from ventral to dorsal. As mentioned above, 10% of the retinal ganglion cells are thicker in diameter. These belong to the heavily myelinated magnocellular system (M-type ganglion cells) and terminate in the lower layers 1 and 2 of the LGN. These layers consist of relatively large neurons and are called ***magnocellular layers***. Layers 3–6 contain small cells and are termed the ***parvocellular layers***, in which the P-type ganglion cells terminate. Crossed and uncrossed retinal fibers terminate in different laminae of the LGN; layers 1, 4, and 6 receive axons from the contralateral eye and 2, 3, and 5 from the ipsilateral eye. The cells of each layer constitute a ***retinotopic representation*** of the hemiretina that innervates it. The upper visual field projects inferior laterally in the LGN and the lower field superior medially (Connolly and Van Essen, 1984; Kaas *et al*., 1972; Malpeli and Baker, 1975). The maps of the six layers are precisely in register. The fovea projects to the posterior pole of the LGN and receives a disproportionately large representation (magnification factor).

Neurons in the magnocellular LGN (layers 1 and 2) are more sensitive to contrast, respond strongly to movement, but are insensitive to wavelength. In contrast, the majorities of parvocellular neurons respond weakly to movement but are color-opponent cells (concentric single opponent, concentric broadband opponent, and coextensive single opponent).

Optic Radiation

Four major projection streams project from the LGN to the visual cortex, two from the magnocellular layers of the LGN and two from the parvocellular layers. They form the optic radiation, which starts to bend slightly anteriorly and laterally before it swings posteriorly in the walls of the lateral ventricle to enter the white matter of the occipital pole. Their retinotopic structure is maintained throughout the projection from the LGN toward the visual cortex. Axons of the magnocellular layers synapse in layer IVCα, whereas parvocellular layers synapse in the neighboring but separate IVCβ.

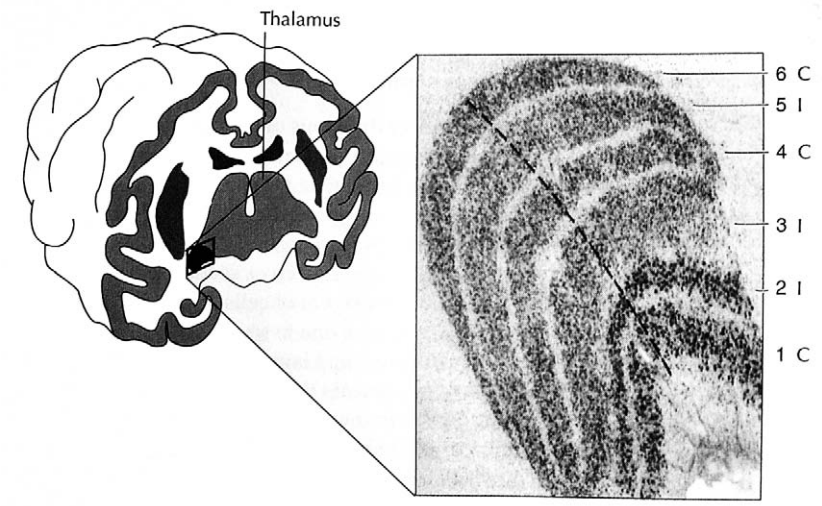

FIGURE 35.3 The lateral geniculate nucleus of the macaque monkey. The tissue has been stained to show cell bodies and reveals the LGN's six-layered organization, with the two ventral layers (magno-cellular layers) composed of larger cells than the other four layers (parvocellular layers). Each layer receives input exclusively from either the contralateral (C) or ipsilateral (I) eye. (Adapted from Bear, Connor & Paradiso, 1996, p. 249).

Retinotectal and Other Projections

The great majority—about 90%—of retinofugal projections terminate in the LGN (see above) Another eight different projection routes leave the retina to terminate in nuclei of the thalamus, the hypothalamus, or the brain stem.

Just below the optic chiasm is the termination region of the hypothalamus, the ***suprachiasmatic nucleus,*** which is important for the generation of the circadian rhythms (Moore, 1973).

Soon after, the optic chiasm projections branch off to ***pretectal*** nuclei (olivary nucleus) and to the ***superior colliculus***. The superficial layers of the colliculus receive input from the retina and V1; the deeper layers also receive inputs from other sensory systems. The major output of these laminae is to those deeper regions of the midbrain and the brain stem that are concerned with the generation of eye movements.

In addition, the pretectal nuclei and the ***ventral LGN*** control the pupillar contraction and also contribute to the control of eye movements. The ***accessory optic tract*** (dorsal, medial, and lateral accessory optic nucleus; Giolli, 1963) and the pretectal nuclei contribute to the detection of self-motion and the initiation of compensatory body movements (Weiskrantz, 1990). Among some smaller projection routes are those to the ***inferior pulvinar*** and the ventral LGN, and to the hypothalamus (suprachiasmatic nucleus).

Functional Aspects and Pathology of the Central Visual Pathway

Neural Processing in the Retina

As mentioned before, the eye is often compared to a camera and the retina to the film in the camera. However, the neuronal processing in the retina, is much more effective. It results in the output of 12–15 functionally distinct ganglion cell types, which can be regarded as 12–15 separate films that have been exposed with different temporal resolution, with different light sensitivity, and different spatial resolution, in addition to one separate film devoted to the recording of moving pictures. The massive parallel processing that is realized by the retina enables such an outstanding performance (Hubel and Wiesel, 1979).

An important feature of retinal ganglion cells is their divided antagonistic center-surround receptive field. The circular receptive fields have either an on center/off surround (often called on center) or an off center/on surround (off center). The antagonistic relationship of center and surround means that if the center and surround are illuminated simultaneously, the firing rate of the neuron will be relatively low (see Figs. 35.1 and 35.2). The same is true if both zones are not illuminated. The antagonistic nature of the receptive fields serves important functions for the visual system; it fosters ***contrast enhancement*** and contributes to ***lightness constancy***. In contrast enhancement, a darker area that is next to a lighter area appears to have an even darker band along the common boarder, whereas the lighter area appears to have an even lighter band along the common boarder (as can be illustrated by Mach bands). This process sharpens vision by exaggerating differences in lightness. The visual system is specialized to detect contours rather then absolute level of luminance. If the overall level of luminance increases, the center and the surround input of a ganglion cell is enhanced. Due to the antagonistic nature the net effect is constant firing across different intensities of illumination.

Visual Deficits Induced by Lesions to the Central Visual Pathway

The nature of the visual impairments seen after damage to different parts of the visual pathways reflects the anatomical relationships in the central visual pathway (Fig. 35.4). In the optic tract, the nasal half of each retina crosses over to the other side of the brain, whereas the fibers from the two temporal hemiretinas do not cross over. Each optic tract carries information from the ipsilateral temporal hemiretina and the contralateral nasal hemiretina, which means that each optic tract conveys the visual information of the contralateral visual field. Thus, damage to optic fibers anterior to the optic chiasm affects vision in one eye. Damage to the optic chiasm itself most often results in damage to its medial portions, causing bitemporal hemianopia.

PRIMARY VISUAL CORTEX

Anatomy and Lamination

The primary visual cortex is commonly known as area V1, or area 17 according to Brodmann (Brodmann, 1909), or area OC according to von Economo (Von Economo and Koskinas, 1925). The primary visual cortex is the first cortical area in which the visual data converge after their initial separate processing in the retina and subcortical nuclei, in particular LGN and superior colliculus. It is believed that the unity of the information needed for a complete reconstruction for the visual world is still preserved in this first processing stage of the cortical visual pathway. Beyond area V1, different features of the visual world are processed in separate cortical areas in a massively parallel manner

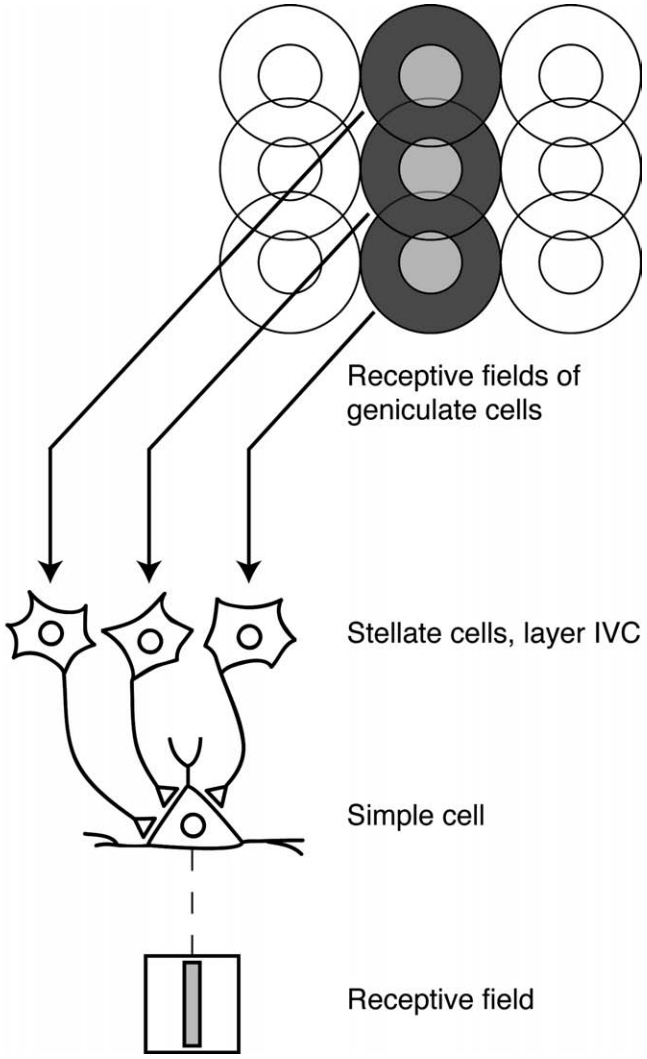

FIGURE 35.4 The mechanism by which the output of LGN cells with center-surround receptive fields is transformed into the elongated receptive fields of simple cortical cells is unknown. One hypothesis is that the simple cortical cell's receptive field is generated by the converging input of three or more ON-center LGN cells whose centers define its location and orientation. (Adapted from Kandel *et al.*, 1995, p. 435).

(Felleman and Van Essen, 1991; Ungerleider and Haxby, 1994). In other words, V1 might be assumed to be the gateway to the higher visual areas, and as such it has attracted a great deal of investigation in the past. While most of our knowledge about the structure and function of V1 originates from studies in nonhuman primates, in particular that of Old World monkeys (Felleman and Van Essen, 1991), the basic scaffold of the functional architecture in humans is generally assumed to be homologous to that of other primates.

In humans, much of area V1 lies on the medial surface of the respective hemispheres, surrounding the calcarine fissure in the occipital lobe (Bolton, 1900; Brodmann, 1909; Zilles, 1990). Rostrally and posterolaterally area V1 is bordered by the lunate and inferior occipital sulci, respectively. In adult macaque monkeys, 1 mm^3 of V1 tissue contains approximately 4700 neurons, 2900 microglia, 3400 oligodendrocytes, and 49,000 astrocytes (O'Kusky and Colonnier, 1982). The cell densities in human striate cortex might be considered to be around the same order of magnitude.

The primary visual cortex consists of a wide variety of cells (Lund, 1988; Peters and Jones, 1984). Traditionally, the cells in V1 have been classified into two morphologically and functionally distinct types: excitatory pyramidal and a wide variety of nonpyramidal cells (Peters and Jones, 1984). The axons of pyramidal cells provide the feedforward and feedback projects to the other cortical areas and subcortical structures, respectively (Lund, 1988; Rockland and Lund, 1983; Yoshitaka *et al.*, 1996). The axons of nonpyramidal cells are confined within the primary visual cortex (Callaway, 1998; Lund, 1988).

Around 80% of cells in the primary visual cortex are pyramidal (Callaway, 1998; Lund, 1988; Peters and Jones, 1984; Yoshitaka *et al.*, 1996). Their cell bodies are shaped like pyramids, and they have apical dendrites that extend toward the white matter. The dendrites are covered with numerous spines, thus identifying themselves as excitatory neurons. Most pyramidal cells can be found in the cortical layers II/III and V/VI (Callaway, 1998; Lund, 1988). Among the nonpyramidal cells, the stellate cells are the most ubiquitous ones. Stellate cells are generally smaller than pyramidal cells and their cell bodies are star shaped. Stellate cells are present in two variations: spiny and smooth (nonspiny). The spiny stellate cells are excitatory, whereas the smooth ones are inhibitory. Both the pyramidal and the spiny stellate neurons use mostly glutamate or aspartate as their neurotransmitter. The smooth, inhibitory stellate cells use mainly γ-aminobutyric acid (GABA) as their neurotransmitter (Fitzpatrick *et al.*, 1987).

Besides the pyramidal and the stellate cells, the primary visual cortex contains a large number of other, relatively low-density cells. While the exact number of different cell types in V1 will depend on the methodological criteria and taxonomical definitions applied, more than 40 types of cells have been identified based on cell morphology, dendritic arborization, physiology, and immunostainings (Lund, 1988; Peters and Jones, 1984). Some of the more prominent of these low-density cells are as follows:

1. *Inhibitory basket cells.* Basket cells have relatively large cell bodies with myelinated axonal branch extending laterally for a great distance; Their axonal

collaterals terminate on pyramidal cell bodies and dendrites in a manner resembling a basket.
2. *Chandelier cells* are inhibitory cells, with axons displaying characteristic branching into vertical sections.
3. *Inhibitory double-bouquet cells.* Double-bouquet cells have axon collaterals and dendrites extending vertically in a tight bundle.
4. *Neurogliaform cells.* These are inhibitory neurons resembling glial cells. Their axon and dendrites branch but mostly remain in the vicinity of the soma giving rise to a dense spherical region of fibers.
5. *Cajal–Retzius cells.* These inhibitory cells are one of the very few types found in layer I of the primary visual cortex. Cajal–Retzius cells are found predominantly in the neonatal brains. Although most Cajal–Retzius cells disappear during the postnatal development, some may survive into the adulthood.

Like other cortical areas, V1 consists of a laminated sheet of cells arranged in six main layers (most dorsal layer I through most ventral layer VI) with the full thickness from pia to the white matter of about 2 mm (O'Kusky and Colonnier, 1982). The laminated anatomical segregation and the unique pattern of connectivity between the laminae throughout V1 suggest a division of computational labor between the different laminae (Hubel and Wiesel, 1972; Lund, 1988; Rockland and Lund, 1983). Most commonly, the six layers of the primary visual cortex are subdivided into nine distinct layers of neurons: layers I, II, III, IVA, IVB, IVCα, IVCβ, V, and VI. There is a great variability of cell types, density, and pattern of connectivity from layer to layer.

Layer I is nearly devoid of neurons and is composed predominantly of dendritic and axonal connections (Lund and Wu, 1997). The apical dendrites from layers II–VB pyramidal cells form a dense network of synapses with axonal inputs from LGN, the pulvinar, feedback pathways from extrastriate areas, nonspecific thalamic nuclei, and other subcortical regions. Thus, while layer I contains few neurons, it is a networking layer that has a direct concerted effect on the firing properties of pyramidal cells in deeper layers.

Layers II/III (also called "supragranular" layers) consist of many somata and dendrites of excitatory pyramidal cells (Lund, 1988; Lund and Wu, 1997; Rockland and Lund, 1983). While layer II/III neurons receive only few thalamic inputs [with the exception of cells inside cytochrome oxidase (CO) blobs], they receive massive inputs from layer IVC neurons (directly from IVCβ and indirectly from IVCα through IVB). Layers II/III neurons are also connected through reciprocal projections with layer V neurons. Excitatory pyramidal cells in II/III project extensively to extrastriate cortical regions such as V2, V3, V4, and V5 (human homolog of primate MT). In addition, through a plexus of long-range horizontal connections, layer II/III excitatory pyramidal cells are interlinked with other pyramidal cells sharing similar receptive field properties (Lund, 1988; Malach *et al.*, 1993; Ts'o *et al.*, 1986). Such long-range horizontal connections can extend for up to several millimeters. About 20% cells in layers II/III are GABAergic and hence presumably inhibitory interneurons that do not project axons outside these layers. While their precise computational role remains elusive, it is generally believed that these interneurons perform dynamic gain control of cortical activity (Fitzpatrick *et al.*, 1987).

Layer IV (the "granular" layer) is divided into four horizontal sublayers: IVA, IVB, IVCα, and IVCβ. Layers IVCα and IVCβ are the major recipients of dorsal LGN (LGNd) innervation (Hubel and Wiesel, 1972; Lund, 1988). The LGNd magnocellular (M) and parvocellular (P) layers project to IVCα and the IVCβ, respectively [axons from interlaminar zones in LGNd (I) project to CO blobs neurons in II/III; see below]. Thus, the M and P streams remain segregated at this stage. Layer IVCα and IVCβ receive vertical inputs from layer VI neurons. Layer IVA shows up in the Nissl stain as a dark band of small granule-like cells. This and the lack of pyramidal cells differentiate this layer from layer IIIB. Layer IVB is a low-cell-density layer that contains a low-density arrangement of pyramidal cells. However, IVB plays a significant role in conveying the M-pathway information through two principal projections: (1) after receiving M-path way information from IVCα, IVB projects to CO blobs in II/III; and (2) layer IVB also provides direct projections to area V5 as well as the superior colliculus.

Layer V is subdivided into VA and VB (Lund, 1988; Lund and Yoshitaka, 1991; Rockland and Lund, 1983). Layer VA neurons do not project to IVB and only weakly innervate IVCβ. They innervate all other layers. VA neurons appear to project primarily to IIIB. Pyramidal neurons in VB send recurrent axons to layer IIIA. Meynert cells at the V/VI border and within layer VI project to both MT and SC. Layer V receives feedback projections from II/III neurons, and they provides strong feedback projections to layer VI neurons. Furthermore, layer V neurons provide corticofugal backprojections to subcortical nuclei such as superior colliculus (SC), pulvinar, and pons.

Layer VI neurons are known to send recurrent axons into IVCα and IVCβ (Lund, 1988). Other neurons (or possibly even the same ones) project axons back to the LGNd. While layer VI neurons receive most input

from layer V neurons, they also receive a direct input from the LGNd. Layer VI provide massive corticofugal projections to LGNd and claustrum.

Cytochrome oxidase (CO) blobs are regions of high staining for the metabolic enzyme cytochrome oxidase (Wong-Riley, 1989). CO blobs and the interleaved "interblob" regions form discrete organizing structures in cortical layers II/III and V/VI. Layer II/III neurons in the CO blob region receive direct input from the interlaminar cells of LGNd (I pathway), thus bypassing the vertical information processing in the primary visual cortex (Horton, 1984; Horton *et al.*, 1990). While the CO blobs have been speculated to be associated with information processing other than the parvo (P) and magno (M) pathways, their exact contribution for visual information processing remains elusive.

The overall flow of the information to and from the primary visual cortex provides the redistribution and recurrent projections of the M, P, and I visual information (Lund, 1988; Rockland and Lund, 1983). The M input from LGNd projects to IVCα and IVB, and then subsequently to V2, V3, V4, and V5. The P input to IVCβ from LGNd projects to the CO blob regions in II/III and then subsequently to the extrastriate areas. The CO interblob zones contain a mixture of M+P inputs conveyed through collective inputs from mid-IVC. Finally, the I path bypasses the aforementioned intracortical processing by providing direct inputs to the CO blob neurons. The recurrent projects are provided by II/III neurons that are projecting back to layers V and VI. Layer VI in its turn projects to layers IVCα and IVCβ, thus closing the computational loop.

Receptive Field Properties in V1

Given the complexity of the cell types and circuitry in V1, one might expect receptive field properties far beyond the simple center/surround types encountered in retina and LGN. In fact, it was found early on that the small spots of light that were found to be so effective in activating the LGN neurons were effective only in the layer IVC neurons, which receive direct inputs from LGN (Hubel and Wiesel, 1968; Kuffler, 1973). Neurons in most other layers responded vigorously only if the light stimulus provided linear properties, such as lines, slits, or bars (Hubel and Wiesel, 1968, 1977). Furthermore, V1 neurons were found to possess a preference with respect to the angle of those lines and bars with respect to their receptive fields (Hubel and Wiesel, 1974). Thus, we speak of "orientation selectivity" of V1 cells (Fig. 35.4). Orientation-selective cells in V1 are either of "simple" or "complex" type (Hubel and Wiesel, 1968). Simple cells respond best to a stationary light bar of certain orientation. To this end, their receptive field is subdivided into excitatory and inhibitory zones. If light falls on the excitatory zone, the spike rate increases, whereas light on inhibitory zone decreases the spike rate. The anatomical substrate of this orientation selectivity remains not completely understood. A parsimonious but increasingly accepted idea hypothesizes that this excitatory linear zone is made up of multiple, overlapping center/surround type of LGN inputs terminating within the same V1 cell's receptive field (Hubel and Wiesel, 1977). When first proposed by Hubel and Wiesel more than 40 years ago, this "feed-forward" model was met with skepticism, as it would require an exceedingly precise projection geometry of the thalamocortical projections. However, numerous correlation and pharmacological studies suggest the tentative validity of this simple model (Chapman *et al.*, 1991; Ferster, 1987; Reid and Alonso, 1995; Tanaka, 1983).

While the simple cells prefer stationary subdivision of their receptive fields into excitatory on and inhibitory off regions, respectively, the complex cells' response properties are invariant of the exact position of the light bars, as long as it has the correct orientation (Hubel and Wiesel, 1968, 1977). Complex cells also possess a larger receptive field than simple cells. A particularly effective stimulus for complex cells is a light bar of correct orientation moving across the receptive field. The anatomical correlate of complex cells remains elusive.

Despite an overwhelming number of experimental details, the overall function of the orientation selective simple and complex cells (and also that of more exotic hypercomplex and end stop cells) in V1 remains unknown. In fact, the overall function of V1 itself is still unknown. In any regard, it is surprising that the most favorite stimulus feature to activate V1 cells is that of line segments. Line segments can carry information about edges, or the contour of a perceived object, whereas they cannot code for a monotonous interior or background of an object.

Columnar Organization of Computational Modules in V1

It was found early on that the neurons in V1 are spatially organized according to their receptive field properties (Hubel and Wiesel, 1969). If one inserts a recording electrode vertically into the cortical plate, the measured receptive field properties of the neurons from pia to the white matter will be similar to each other. Thus, the primary visual cortex is parceled into narrow columns of cells sharing similar receptive field properties. Such clusters of isoreceptive field properties

are called "cortical columns" (Hubel and Wiesel, 1977). Cortical columns represent one of the most ubiquitous organizing principles of the cortical organization. Such columnar organization has been found across all cortical areas, ranging from somatosensory to auditory cortices.

In the primary visual cortex, the structure, layout, and function of the columnar layout have been particularly well studied using a variety of techniques in the past (Figs. 35.5 and 35.6). These include the single and multiunit recording techniques (Hubel and Wiesel, 1968), the 2-deoxyglucose technique (Hubel

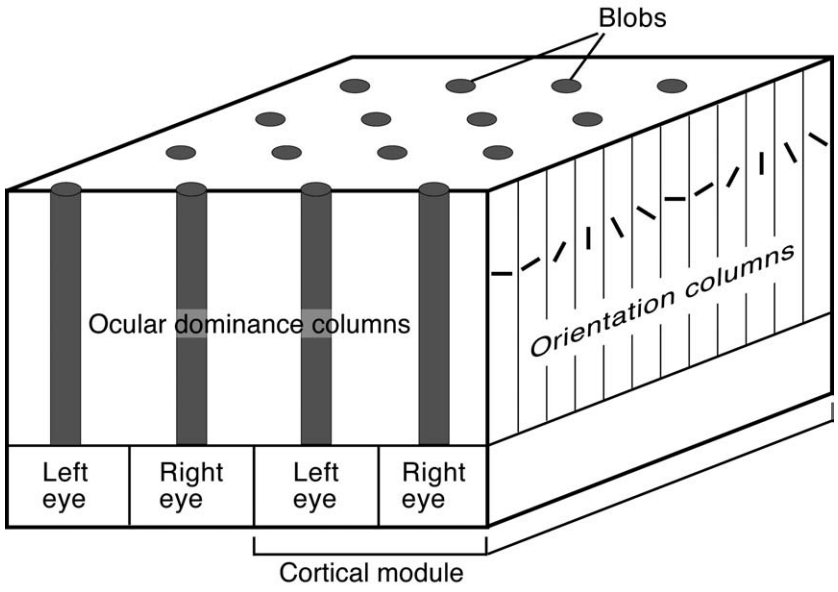

FIGURE 35.5 Schematic drawing of a cortical module. The primary visual cortex is organized into cortical modules, each consisting of a set of orientation columns crossed with ocular dominance columns. Within a cortical module, all cells have similar receptive fields (respond to the same small part of the visual field), but vary in terms of input source (left or right eye), orientation sensitivity, color sensitivity (Blobs), and size sensitivity (not shown). (Adapted from Bear, Connor & Paradiso, 1996).

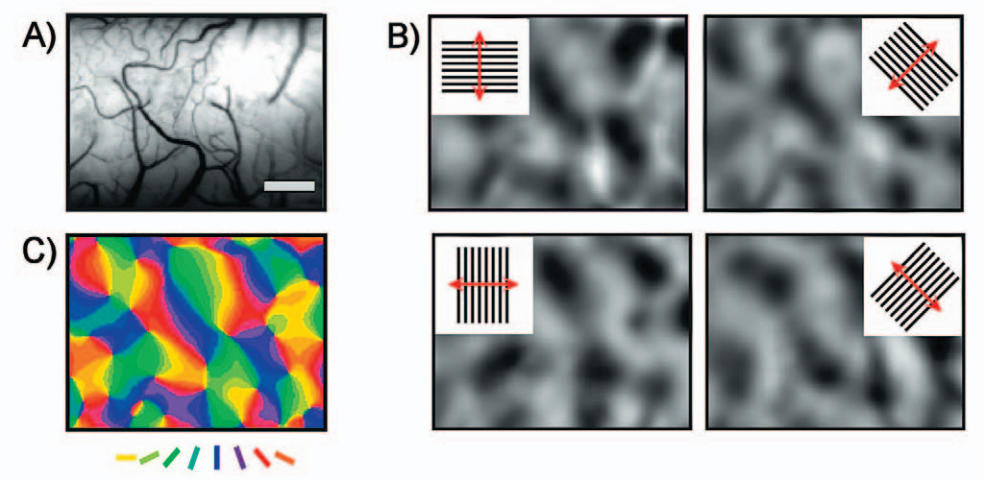

FIGURE 35.6 Details about the structure and function of cortical maps in the mammalian visual cortex have been revealed by the invasive technique of optical imaging of intrinsic signals (for details, see text). (A) Video image of exposed cat visual cortex (scale bar = 1mm). (B) Single condition maps obtained by stimulating the visual cortex with a large field of gratings. In each condition, gratings are presented in a different (fixed) orientation. To obtain strong responses, the gratings are moved forward and backward in directions orthogonal to the selected orientation. (C) Angle map obtained by integrating the results from the single condition maps. As indicated below the panel, colors code for the orientation yielding the maximal response at a given cortical patch.

et al., 1978), and the technique of optical imaging (using the intrinsic or voltage-sensitive dye signals) (Fig. 35.7) (Blasdel, 1992; Blasdel and Salama, 1986; Obermayer and Blasdel, 1993; Ts'o *et al.*, 1990). In particular, the recently developed "optical imaging of intrinsic signals" (Malonek and Grinvald, 1996; Ts'o *et al.*, 1990) provided a great deal of novel information about the details of the structure and function of the cortical maps in mammalian visual cortex. Optical imaging of intrinsic signals is based on the fact that following the onset of, for example, visual stimulation, cerebral metabolic rate of oxygen ($CMRO_2$) is increased rapidly without a commensurate elevation of cerebral blood flow (CBF) and cerebral blood volume (CBV), resulting in a net increase of deoxyhemoglobin around the microvasculature in active cortical regions. Utilizing the fact that gray matter tissues dominated by deoxyhemoglobin absorb relatively more light at near-infrared wavelength (605 ± 10 nm), one can discern the "active" areas of the cortex by shining a light on the exposed cortical surface (Malonek and Grinvald, 1996). The ability of optical imaging to resolve individual columns is assumed to be based on the facts that (1) individual neurons in mammalian cortex are never more than

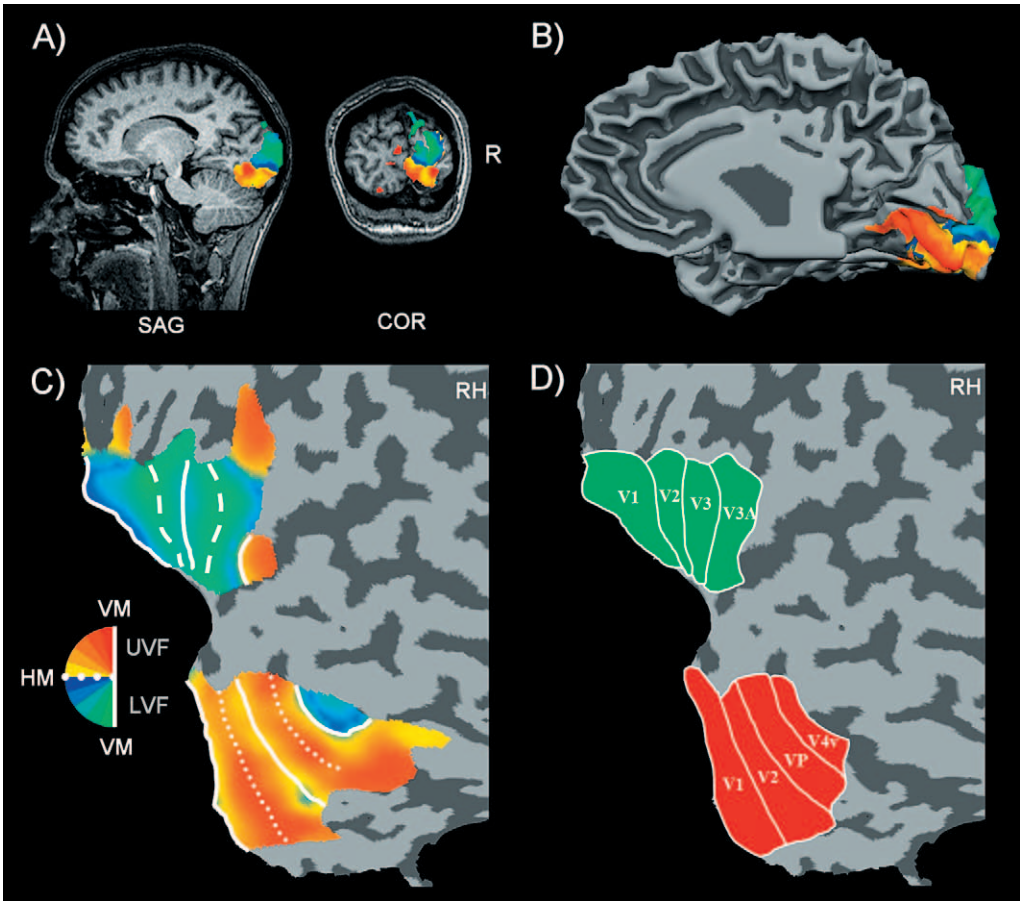

FIGURE 35.7 Details about the organization of human visual cortex have been revealed by the non-invasive technique of functional magnetic resonance imaging (fMRI). The figure shows a particular application of fMRI, the retinotopic mapping of early visual areas (for details, see text). (A) Result of a "polar mapping" experiment visualized on a sagittal and coronal anatomical slice. In a polar mapping experiment, a half-ray is slowly rotated around a central point, which the subject fixates. The ray, thus, stimulates different parts of the visual field at different moments in time (i.e. first the upper vertical meridian, then the left horizontal meridian, then the lower vertical meridian and so on). Different colors correspond to the position of the ray at which the maximal response within a cortical voxel is obtained (see legend in C). (B) The result of the same experiment visualized on a medial three-dimensional view of the right hemisphere of the scanned subject. (C) The same result visualized on a flattened representation of the right hemisphere. Note that such a "flat map" is ideally suited to visualize topologically organized information. (D) The "stripes" revealed on the flattened representation from the polar mapping experiment (see C) demarcate the borders of early visual areas (for details, see text).

20–30 μm away from a microcapillary (Pawlik *et al.*, 1981); and (2) mammalian neurons are spatially grouped according to their functional specificity (Hubel *et al.*, 1978). Good correlation between electrical activity and intrinsic signals has been observed (Crair *et al.*, 1998; Shmuel and Grinvald, 1996). However, this technique provides only very limited depth information, since only signals from the superficial 300–500 μm can be accessed. Furthermore, optical imaging is an invasive technique requiring a large craniotomy to allow for the light of specific wavelength to be illuminated on the cortical surface.

While invasive techniques such as optical imaging and single-unit recording have been used primarily to elucidate the layout of the cortical maps in mammalian brains other than humans (however, single/multiple techniques and optical imaging have been used to map the layout of the cortical maps in the human primary visual cortex during or before neurosurgical operations), there is no reason to believe that the human visual cortex will not follow this general scheme of the columnar parcellation of the brain. Indeed, recent advances in noninvasive functional magnetic resonance imaging (fMRI) based on blood oxygenation level dependent (BOLD) signals demonstrate the parsimonious validity of the columnar organization also in the human striate cortex (Cheng *et al.*, 2001; Dechent and Frahm, 2000; Goodyear and Menon, 2001).

Another important organizing principle in the primary visual cortex is that of maps (Swindale, 2001). This refers to the fact that as one moves tangentially from one cortical column to the next (with a step size of about 30–100 μm), there is a progressive change in the respective receptive field property (Hubel and Wiesel, 1968). Therefore, neighboring columns in V1 code for "neighboring" properties of the stimulus environment. The primary visual cortex contains therefore a topographic "map" of the respective stimulus parameter (Swindale, 2001). The most prominent of these cortical maps in V1 is the map of retinotopy. This map is based on topography-preserving projections from the retina to the LGN layers and from the LGN layers to area V1 (for details, see "Retinotopic Mapping of Early Visual Areas"). Besides the retinotopic map, the primary visual cortex contains a number of additional topographic maps (Bartfeld and Grinvald, 1992; Swindale, 2000). In the primary visual cortex of nonhuman primates, "columns" and "maps" have been reported for orientation, ocular dominance, direction, spatial frequency, and disparity. In humans, maps for retinotopy (Engel *et al.*, 1994; Sereno *et al.*, 1995) and ocular dominance (Cheng *et al.*, 2001; Goodyear and Menon, 2001) have been reported, and there is no reason to believe that the human primary visual cortex contains fewer cortical maps than that in primates or felines. The total number of cortical maps in the primary visual cortex is unknown, and likewise, it is not known whether there is a maximal number of cortical maps that can be represented in the primary visual cortex (Swindale, 2000). Theoretical considerations suggest this to be the case, as an ever increasing number of cortical maps should make it more and more difficult for the individual maps to maintain the topographic representation of their respective stimulus feature (Swindale, 2001; Swindale, 2000; Swindale *et al.*, 2000).

While each of the cortical maps displays a unique topological arrangement, recent studies using multielectrode and optical imaging techniques have uncovered a number of highly consistent geometrical features among multiple cortical maps (Bartfeld and Grinvald, 1992; Hubener *et al.*, 1997; Kim *et al.*, 1999; Swindale *et al.*, 2000).

The overall geometry of the maps tends to mirror the characteristic features of the respective receptive field property: binary properties, such as ocular dominance, are represented as an approximated binary map in the cortex (Hubel and Wiesel, 1969; Hubener *et al.*, 1997; Kim *et al.*, 1999). Isofunctional domains representing circular parameters, such as orientation, are arranged in a circular manner around particular foci in the cortex [termed "pinwheel centers" (Bonhoeffer and Grinvald, 1991)]. The complete sequence of the orientations appears only once around such foci, thereby giving rise to two types of pinwheel centers, distinguished by their chirality (Bonhoeffer and Grinvald, 1991). Finally, the direction of stimulus motion, which is invariant under 360° rotation, is represented continuously everywhere across the cortical surface, except around pinwheel centers. Here, only half of the full range of directions of motion can be represented, as the orientation is invariant under 180° rotation, resulting in "direction discontinuity lines," across which the preferred direction changes by 180° (Shmuel and Grinvald, 1996).

The layout of the multiple cortical maps are highly intercorrelated. A number of robust geometrical relationships among multiple maps tangential to the cortical plate have been described in mammalian visual cortices (Bartfeld and Grinvald, 1992; Hubener *et al.*, 1997; Kim *et al.*, 1999; Swindale *et al.*, 2000): (1) Orientation domains and ocular dominance borders tend to intersect at right angles. (2) Centers of pinwheel tend to coincide with the centers of ocular dominance columns and furthermore with CO blobs. This tendency is arguably stronger in macaques than in cats, where conflicting results exist. (3) Orientation singularities of opposite chiralities are connected always by an odd number of directional line discontinuities, where

the preferred direction of motion changes rapidly. (4) Isodirection domains tend to intersect ocular dominance borders at a right angle.

The tangential layouts of additional cortical maps (e.g., spatial frequency and disparity) and their geometrical relationships to the aforementioned columnar structures remain elusive (Issa *et al*., 2000; Shoham *et al*., 1997; Swindale, 2000). Notably, the functional architecture of the spatial frequency representation in the primary visual cortex has caused substantial controversy in recent years. Although some investigators argued that all spatial frequencies are represented continuously over the cortical surface (Tootell *et al*., 1981), recent evidence suggests that the primary visual cortex is rather parceled into two complementary domains—one for low spatial frequencies, and the other for high spatial frequencies (Shoham *et al*., 1997). The reason for this discrepancy remains unknown. Likewise, the origin and function of the geometrical relationships among multiple cortical maps remain—despite many speculations—elusive.

EXTRASTRIATE CORTEX

Anatomical and functional discoveries since the early 1970s in the monkey and human brain have caused a radical revision of theories of how the visual system is organized in the *extrastriate cortex*, the visually responsive cortex outside striate area 17 or V1. The most important of these discoveries is that many cortical regions outside primary visual cortex are specialized for the processing of specific aspects of vision, such as color, motion, and form. This specialization of function along relatively elementary dimensions was unexpected because that cortex was thought to be reserved for "associative" functions, including perception and object recognition. Instead of an expected large region of undifferentiated higher functioning, this *visual association cortex* [Brodmann areas (Bas) 18 and 19] consists of cytoarchitectonically distinct areas that subserve specific visual functions (Zeki, 1978; Zilles and Clarke, 1997; see chapter by Zilles, this volume). In addition, it is now known that the visual cortex extends into the temporal and parietal lobes (Felleman and Van Essen, 1991). Based mainly on vast anatomical data of monkey visual cortex (*Macaca mulatta*), the picture of a highly diverse yet hierarchically structured organization of the visual system has emerged (Felleman and Van Essen, 1991; DeYoe *et al*., 1994). Van Essen and colleagues identified 32 areas and 305 connections among these areas organized in a hierarchy of 10 cortical stages. Recently, our understanding of the functional organization of the human brain has greatly expanded due to the availability of functional neuroimaging techniques that allow direct noninvasive observation of brain activity. Results obtained with these techniques, most notably fMRI, suggest that the general organization of the extrastriate cortex is similar in monkey and man (Van Essen, 2002).

Occipital Visual Areas

The visual cortex in the occipital lobe outside V1 contains areas V2, V3, V3A, and V4v (Fig. 35.8). There are numerous additional areas located at the borders between the occipital lobe and the temporal and parietal lobes, including MT/V5, V3B/V7/KO, LOC, and V4/V8.

V2

Within area V2, subregions have been defined by the same method for cytochrome oxidase staining as described earlier for V1 (see "Anatomy and Lamination"). In the case of V2, the subareas are called *thin stripes*, *thick stripes*, and *interstripes*. Neurons originating in the blob areas of V1 project to the thin stripes of V2. Neurons within the thin stripes are wavelength sensitive, and many are also double opponent. They generally have larger receptive fields than the double-opponent cells of V1. Neurons in the thin-stripe regions of V2 project to V4. In addition, there are direct connections from the blob areas of V1 to V4.

Neurons in the interblob regions of V1 project to the interstripe regions of V2. Neurons within the interstripe regions have larger receptive fields but similar receptive field characteristics to those in the interblob V1 regions, i.e., the majority of cells are not wavelength but orientation selective. Neurons in the interstripe region of V2 project to V4. There are also direct connections from the interblob regions of V1 to V4.

Neurons in layer IVB of V1 project to the thick stripes of V2. As with the projections of the two parvocellular channels from V1, the most striking elaboration of this magnocellular projection is an increase in the size of receptive fields. The cells in the thick-stripe regions are orientation selective as well as direction selective, i.e., they fire when a stimulus moves in a particular direction. In addition, the cells are also sensitive to binocular disparity, which allows them to code depth information. From V2 there are projections to V3 and V5. There are also direct projections from layer IVB of V1 to these areas.

V3, VP, V3A

Area V3 receives input from layer IVB of V1 and from the thick stripes of V2. V3 represents the lower

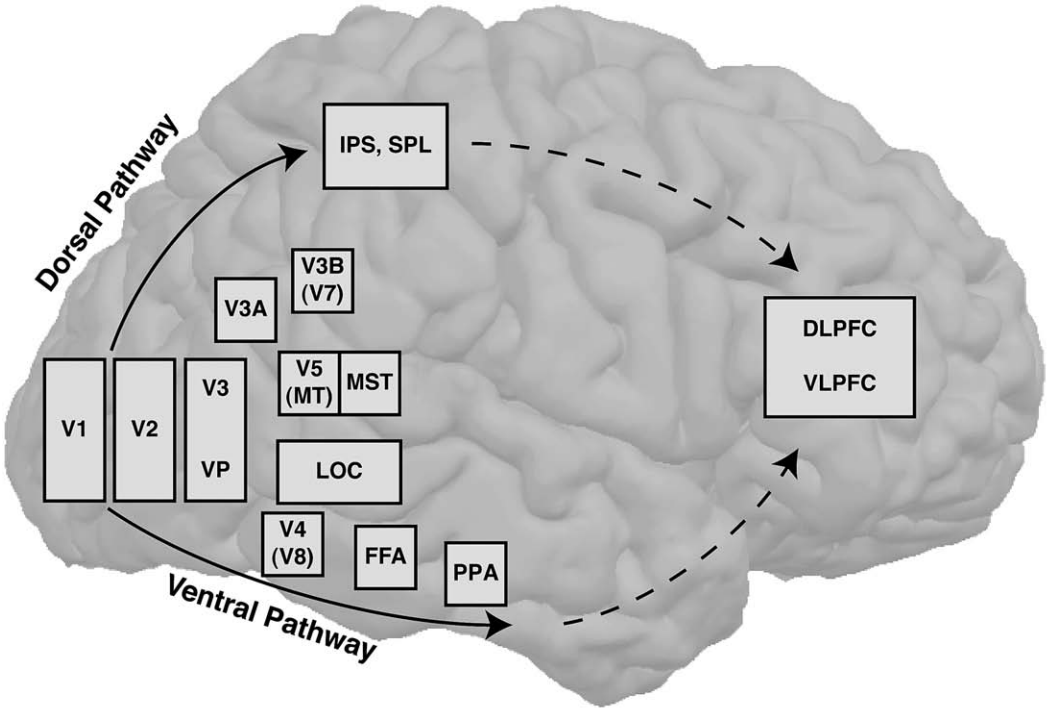

FIGURE 35.8 Prominent cortical visual areas as revealed by functional magnetic resonance imaging of the human visual cortex. As in monkey cortex, visual areas in the human brain are assumed to be organized in a dorsal (occipito-parietal) and ventral (occipito-temporal) pathway indicated by solid lines (for details, see text). Both pathways are assumed to extend into prefrontal cortex (dashed lines). Note that the two "pathways" consist not only of feedforward but also of massive feedback connections. MT, human homologue of monkey middle temporal area; MST, human homologue of monkey medial superior-temporal area; LOC, lateral occipital cortex; FFA, fusiform face area; PPA, parahippocampal place area; IPS, intra-parietal sulcus; SPL, superior parietal lobule; DLPFC, dorso-lateral prefrontal cortex; VLPFC, ventro-lateral prefrontal cortex.

visual field, and the majority of its neurons are orientation selective and exhibit high contrast selectivity. Many cells are both orientation and motion selective. Functional imaging has revealed that motion selectivity is stronger in adjacent area V3A than in V3 in humans while the opposite pattern has been observed for the homolog areas in the monkey (Tootell *et al.*, 1997). Area VP lies anterior to V2v representing the upper visual field. While areas V3 and VP have been considered to be separate areas (Burkhalter and Van Essen, 1986), it has recently been argued that VP is simply the ventral portion of V3 (Zeki, 2003).

V3B/V7/KO

Anterior to V3A, another area called KO has been described, which seems to be specialized for the processing of kinetic contours (Van Oostende *et al.*, 1997). Since this area appears to respond preferably to motion boundaries, it might play an important role for linking motion- and shape-related representations. However, a recent study, has shown that this area is active when subjects view simple shapes, whether derived by motion boundaries or other cues, such as luminance or color differences (Zeki *et al.*, 2003). The authors of this study further argue that area KO is not a new area but belongs to the "V3 family of areas." More specifically, they use the term V3B (following Smith *et al.*, 1998) to denote this area and specify its location in the lateral occipital cortex, posterior to V5 and in close proximity to the V3 complex. They also argue that V3B in each hemisphere represents both quadrants of the contralateral visual field. According to Tootell and colleagues, this region is also labeled as area V7.

V4

Area V4 contains many wavelength-selective cells. There are also cells whose receptive field properties correspond to a particular perceived *color*, i.e., these cells might mediate color constancy (Heywood and Cowey, 1987). In the human brain, a color-selective region has been located in the region of the lingual and posterior fusiform gyri (Lueck *et al.*, 1989; Hadjikhani *et al.*, 1998). Lesions in this region often cause *achromatopsia* (central color blindness; Meadows, 1974). This region is referred to as human V4 (McKeefry

and Zeki, 1997; Zeki *et al.*, 1998) or V8 (Hadjikhani *et al.*, 1998). As mentioned above, V4 receives input not only from the blob regions of V1 and the thin-stripe regions of V2 but also from the interblob regions of V1 and the interstripe regions of V2. These inputs to V4 suggest that this area is not involved only with color processing. Although the majority of cells in V4 are wavelength and some color selective, many are orientation selective and some are both color and orientation selective. It appears, therefore, that area V4 is involved in both color and form processing (see Cowey and Heywood, 1995, for a review).

MT/V5, MST, FST

In monkey cortex, the motion selective area MT (middle temporal area) is located in the middle temporal sulcus, close to the junction of the occipital, temporal, and parietal lobes (Van Essen *et al.*, 1981). As area V3, area MT receives direct input from layer IVB of V1 and from the thick stripes of V2, thus forming a second magnocellular channel. Its cells are responsive to the direction and speed of moving stimuli (Snowden *et al.*, 1992) and their inactivation causes deficiencies in motion direction discrimination. MT neurons have large receptive fields, which might provide a basis for determining whether a number of points (parts of an object) are moving together. Area MT is easily identified in histological sections because of its high myelination, and it is surrounded by several other specialized areas including MST (medial superior temporal area) and FST (fundus of the superior temporal area). These "satellites" of MT process higher order aspects of stimulus motion. The human visual cortex contains an area that is likely to correspond to monkey area MT and is located in the occipito temporo parietal pit. Bilateral lesions that include this area cause a severe impairment in detecting the movement of objects (cortical *akinetopsia*; see Zeki, 1991). Human imaging studies have shown that metabolism and blood flow in that region increase more in response to moving than to stationary stimuli, indicating preferential involvement of this area in the processing of motion information (e.g., Watson *et al.*, 1993; Tootell *et al.*, 1995; Goebel *et al.*, 1998). As functional imaging studies have not yet convincingly differentiated between the human homolog of area MT and its satellites, this motion selective region is often referred to as the *human motion complex* (hMT+) or V5.

Retinotopic-Mapping of Early Visual Areas

Using fMRI and appropriate visual stimuli, the described early visual areas can be charted in individual human brains (Sereno *et al.*, 1995). This is possible because the mapping from the retina to the primary visual cortex is topographical and because other early visual areas retain this retinal topography, but represent the visual field in either a mirrored or nonmirrored two-dimensional layout. In a topographical mapping, neighboring regions in one area (retina) project to neighboring regions in another area (primary visual cortex). Since this mapping is preserved also at the next cortical stages (V2, V3/VP, V3A, V4), neighboring positions in the visual field tend to be represented by groups of neurons that are adjacent but laterally displaced within the cortical gray matter of these areas. This transformation preserves the qualitative spatial relations of the retina but exhibits systematic distortions, i.e., there is much more cortical tissue devoted to foveal regions than peripheral regions of the visual field (cortical magnification). A successful delineation of the early visual areas with fMRI exploits the fact that successive visual areas alternate with a mirror or nonmirror representation of the visual field. Multiple horizontal and vertical meridian representations across the visual cortex, thus, indicate the transitions between early visual areas. With appropriate visual stimuli, fMRI studies have successfully been used to reveal multiple meridian representations arranged in approximately parallel bands along the flattened cortical surface (Sereno *et al.*, 1995). fMRI-based retinotopic mapping has quickly become an important tool to noninvasively define the borders of early visual areas (e.g., Tootell *et al.*, 1996, 1997; Goebel *et al.*, 1998, 2001; see Fig. 35.8).

In V1, the representation of the horizontal meridian is contained within the calcarine sulcus, such that the upper (dorsal) bank contains the lower visual field representation, and the lower (ventral) bank contains the upper visual field representation of the contralateral visual hemifield. The border between V1 and dorsal V2 (V2d) is identified by the first vertical meridian representation of the lower visual field. Similarly, the border between V1 and ventral V2 (V2v) is identified by the first vertical meridian representation of the upper visual field. Note that there are four spatially separated subparts of V2 (V2v and V2d in the left and right hemisphere), each representing one quadrant of the visual field (Fig. 35.8). In the dorsal part of the cuneus, the border between V2d and V3 is identified by the second horizontal meridian representation in each hemisphere. In a complementary fashion, the border between V2v and VP in the ventral cortex is identified by the second horizontal meridian representation in each hemisphere. V3 and VP in one hemisphere represent the contralateral visual hemifield and—combined across hemispheres—these areas provide a complete third representation of the visual field. The next retinotopically organized areas in the dorsal part are V3A and V7 (or V3B; see below), which, unlike V3,

contain a complete representation of the contralateral visual hemifield. The next retinotopically organized area in ventral visual cortex has been termed V4v, which is demarcated by another upper vertical meridian representation. The functional organization and naming convention in this region is currently debated (Hadjikhani *et al.*, 1998; Zeki, 2003). On the one hand, it has been suggested that there is one larger area, V4, consisting of a complete hemifield representation complementary to the representation in V3A in the dorsal cortex. On the other hand, an additional area beyond V4v has been suggested and termed "V8" containing an additional hemifield representation. Because of this debate, this region is at present often referred to as V4/V8.

In higher visual areas in the temporal and parietal lobes, it becomes increasingly difficult to show a retinotopic organization. One reason for this is that higher visual areas are much smaller than early visual areas, which makes it difficult to resolve the intra-areal layout with fMRI. Another reason might be that the spatial layout within these areas becomes less dominated by retinotopic but more complex organizational principles.

Two Main Cortical Pathways

Ungerleider and Mishkin (1982; Mishkin *et al.*, 1983) proposed that the extrastriate visual areas are organized into two hierarchically, functionally specialized, processing pathways (Fig. 35.9): an occipitotemporal pathway or "ventral stream" for object recognition and an occipitoparietal pathway or "dorsal stream" for spatial vision and visually guided actions. Areas along both pathways are organized hierarchically such that low-level inputs are transformed into more complex representations through successive stages of processing. The ventral stream or "what" system is supposed to perform a fine-grained analysis of the visual scene, including processing of color and shape (see "Ventral Visual Areas"). The dorsal stream or "where" system processes spatial characteristics of the visual scene (see "Parietal Visual Areas"). Emphasizing that the latter pathway is also involved in visuomotor transformations, Milner and Goodale (1995) proposed to distinguish between *vision for perception* (ventral pathway) and *vision for action* (dorsal pathway).

The two pathways have been originally described for nonhuman primates. They originate in areas V1 and V2 and extend into the temporal ("what" system) and parietal ("where" system) lobe, respectively. The ventral stream consists of the areas V1–V4, which belong to the occipital lobe, and the areas PIT (posterior IT) and AIT (anterior IT). This pathway is assumed to be mainly driven by the parvocellular system. The dorsal stream consists of the areas V1, V2, dorsal V3 (V3d) and MT/V5, MST, LIP, and VIP (lateral and ventral intraparietal area) and 7a. This pathway is assumed to be mainly driven by the magnocellular system.

With brain imaging techniques, the two major processing pathways have been convincingly demonstrated in the normal human brain (e.g., Haxby *et al.*, 1991), and several specialized areas have been identified on the basis of their stimulus preference profiles (see "Ventral Visual Areas").

Ventral Visual Areas

In the macaque monkey, cortex ventral to area MT and anterior to V4 is generally considered part of the ventral processing stream (see below). This region includes a cluster of inferotemporal areas that are implicated mainly in pattern recognition and form analysis (e.g., Tanaka, 1996, 2001). Electrophysiological studies in primates identified remarkable selectivities of IT cells for specified categories of complex stimuli such as faces or spatial layouts (Perrett *et al.*, 1982, 1985; Gross, 1992; Tanaka, 1996, 2001; Logothetis, 2000; Kreiman *et al.*, 2000). Another cluster of areas within the ventral superior temporal sulcus (ventral STS) includes polysensory regions and regions involved in both form and motion processing (Oram and Perrett, 1997). With human neuroimaging, specialized areas located in close proximity to area V4/V8 have been characterized, including the lateral occipital complex (LOC), the fusiform face area (FFA; Kanwisher *et al.*, 1997), the parahippocampal place area (PPA), and several overlapping regions sensitive to different object categories (e.g., Ishai *et al.*, 1999).

LOC

Several human imaging studies have shown that a region in the lateral occipital cortex extending anterior in the temporal cortex is involved in shape processing, responding strongly to images of objects but not to scrambled control stimuli. It has been further conjectured that this region, called LOC (lateral occipital complex; Malach *et al.*, 1995; Grill-Spector *et al.*, 2001; Malach *et al.*, 2002), represents perceived object shape (Kourtzi and Kanwisher, 2001). Studies using event-related potentials recorded from electrodes placed in the LOC region on the cortical surface of patients prior to surgery found object-specific waveforms that show stronger activation for a variety of objects (cars, flowers, hands, butterflies, and letters) than to scrambled control stimuli. In addition, lesion studies have revealed that damage to the fusiform and occipitotemporal junction results in a variety of recognition deficits. These findings suggest that LOC may

be necessary for object recognition containing most likely important midlevel representations of shape features. The LOC is largely nonretinotopic and is activated by both contralateral and ipsilateral visual fields. It contains at least two spatially segregated subdivisions, a dorsal caudal subdivision LO and a ventral anterior subdivision at the posterior aspect of the fusiform gyrus called pFs (postfusiform) or VOT (ventral occipitotemporal cortex; Malach *et al*., 2002; Grill-Spector, 2003). LO is situated posterior to MT in the lateral occipital sulcus and extends into the posterior inferior temporal sulcus. VOT/pFs is located bilaterally in the fusiform gyrus and occipito temporal sulcus (Grill-Spector, 2003; Malach *et al*., 2002). Each of these subdivisions contains a separate foveal representation. The fovea of LO is connected to the confluence of fovea of early visual areas, whereas pFs contains a separate foveal representation that is located on the lateral bank of the collateral sulcus extending into the fusiform gyrus. The anterior subregion of LOC has been shown to respond more invariantly to position, size, and small orientation changes than the posterior subregion (Grill-Spector *et al*., 2000). Anterior to LOC, several areas have been suggested as modules for representing and perceiving specific object categories, such as faces and places.

FFA

One of the most extensively studied areas in recent years is the fusiform face area (FFA). The FFA responds much more strongly to a wide variety of face stimuli (e.g., front view photographs of faces, line drawings of faces, cartoon faces, and upside-down faces) than to various nonface control stimuli (e.g., cars, scrambled faces, houses, hands). It has been proposed that the FFA is not specialized for face processing per se but is specialized for making any discriminations for which substantial *expertise* has been gained (Gauthier *et al*., 1999). Besides the FFA, there are other regions responding more to faces than to other object categories, which are located in a more posterior occipital region partially overlapping LO, and in a region near the posterior end of the superior temporal sulcus.

PPA

Another well-studied category-selective region of cortex is the parahippocampal place area (PPA; Epstein and Kanwisher, 1998) responding strongly to a wide variety of stimuli depicting places and/or scenes (e.g., outdoor and indoor scenes and houses) compared to various control stimuli (e.g., faces or scrambled scenes).

The description of areas FFA and PPA raises the question how many category-selective regions of cortex exist in the human visual system, and, more generally, how the ventral temporal cortex is organized. Hypotheses range from the assumption that there are a few specialized processing modules, i.e., for faces, places, letters, and human body parts (Puce *et al*., 1995, 1996; Kanwisher *et al*., 1997, 1999; Epstein and Kanwisher, 1998; Epstein *et al*., 1999; Polk *et al*., 2002; Downing *et al*., 2001) up to the proposal of widely distributed and overlapping cortical object representations (Ishai *et al*., 1999, 2000; Haxby *et al*., 2001). Effects of category-related expertise (Gauthier *et al*., 1999; Gauthier and Nelson, 2001) and, more recently, different category-related resolution needs (Levy *et al*., 2001; Hasson *et al*., 2002; Malach *et al*., 2002) have also been proposed to explain the topology of the human what pathway. Further insights into the question how objects are represented in ventral visual cortex might come from functional imaging studies investigating *within-category response*s, e.g., by comparing responses to single-object images, such as two different faces or two different houses (Kriegeskorte *et al*., 2003). It has also been proposed that the eccentricity gradient observed in early visual areas continues into the ventral visual cortex (Malach *et al*., 2002). For example, regions selective to faces (FFA) overlap with the representation of the fovea, whereas regions selective to houses (PPA) overlap with a peripheral visual representation located in the collateral sulcus. These findings suggest that the entire ventral visual cortex may be organized along an eccentricity axis (Fig. 35.10).

Parietal Visual Areas

Regions of the parietal cortex are thought to be involved fundamentally in spatial processing and the control of action. The parietal lobe also contains somatosensory regions, which are, not discussed here. In the monkey, the posterior parietal visual cortex includes several areas in and near the intraparietal sulcus (IPS), plus additional areas in more posterior regions. The most fine-grained parcellation of this region (Lewis and Van Essen, 2000) is based on immunohistochemical as well as cyto- and myeloarchitecture and includes seven distinct areas [7a, LIPd, LIPv (dorsal and ventral portion of lateral intraparietal), VIP (ventral intraparietal), MIP (medial intraparietal), MDP (mediodorsal parietal), and DP (dorsal parietal)] plus additional architectonic zones. Unfortunately, the terminology of parietal areas is somewhat confusing: area VIP of Ungerleider and Desimone (1986) corresponds to LIPv (ventral LIP) of Lewis and Van Essen (2000); areas LIP and VIP of Felleman and Van Essen (1991) correspond to LIPd (dorsal LIP) and LIPv/VIPl [ventral intraparietal (lateral)], respectively, of Lewis and Van Essen (2000). A second group of areas, near the posterior end of the intraparietal sulcus, includes areas MDP, MIP,

and DP, plus zone LOP (lateral occipitoparietal). Area MDP corresponds to V6A of Galletti *et al.* (1999). Zone LOP may correspond to the caudal subdivision of the IPS (cIPS or CIP; Taira *et al.*, 2000). Monkey neurophysiology has characterized many areas in the intraparietal sulcus that respond during specific visuomotor processes. These include areas specialized for saccades (LIP, Colby *et al.*, 1996), reaching (parietal reach region, PRR, which includes both area V6A and MIP; Galletti *et al.*, 1997; Snyder *et al.*, 1997), grasping [anterior intraparietal area (AIP), Taira *et al.*, 1990], processing of shape and orientation (cIPS, Sakata *et al.*, 1997), and movements towards and contact with the mouth and head (VIP, Colby *et al.*, 1993). These areas have been shown to code space in a variety of coordinate frames, including eye-centered (LIP), head-centered (VIP, V6), and body-centered (area 5, MIP) coordinates, and many are modulated by factors such as eye position.

In the human, the intraparietal sulcus separates the superior parietal lobe (BAs 5 and 7) and the inferior parietal lobe. The inferior parietal lobe contains BA 39, corresponding roughly to the angular gyrus, and BA 40, corresponding roughly to the supramarginal gyrus. Neuroimaging studies have revealed that human parietal cortex consists of numerous specialized subregions similar to those described for nonhuman primates (for a review, see Culham and Kanwisher, 2001). However, the detailed mapping of the human parietal cortex presents a challenge for current research because of the wide variety of tasks associated with the parietal lobe, including sensorimotor mapping, spatial visual attention, mental imagery, spatial working memory, and motion processing. This variety of functions is also evident from patients with lesions in the parietal lobe causing many cognitive deficits including attentional disorders, such as hemispatial *neglect* and *simultanagnosia*, spatial localization disorders, and sensorimotor coordination problems. There is increasing evidence that the activity in several parietal areas modulates activity in other visual areas within the occipital and temporal lobe. Since parietal activity may precede target stimuli in attention tasks and is often stronger than in earlier visual areas (e.g., Corbetta *et al.*, 2000), the parietal lobe is considered to be the source of attentional control signals (see next section).

Theoretical Perspectives and Outstanding Questions

The previous sections have described many specialized areas in the visual cortex devoted to specific aspects of vision. The functional properties of these areas have been revealed by numerous factors, including the physiological characteristics of single neurons, anatomical inputs and outputs, metabolic microarchitecture, effect of lesions, and an increasing number of noninvasive neuroimaging studies. Taken together, these findings are the reason why we know more details about the visual cortex than about any other cortical system. This advanced level of understanding brings with it profound problems that have yet to emerge in the study of other cortical areas. Knowing more details about a complex structure leads to a clearer view of the deeper questions. Two of the major questions arising are why these specialized areas exist and how the different aspects of the visual world processed in these separate areas of cortex are integrated into a unified representation of the world. At present, these questions cannot be answered satisfactorily, but the following sections present major theoretical perspectives on how the visual system as a whole processes information.

Bottom-up and Top-down Processing in the Visual Hierarchy

Felleman and Van Essen (1991) noted that the hierarchy of processing levels in the visual system consists not only of feedforward but also of massive feedback connections. The classical view of the visual system largely neglected these feedback connections and summarized its operation with a few general principles. First, processing as revealed by neuronal receptive fields is hierarchical, beginning with the simple and complex cells described by Hubel and Wiesel (1968; see "Receptive Field Properties in V1"). Neurons in higher cortical areas represent increasingly complex characteristics of images, objects, and categories (Maunsell and Newsome, 1987; Vogels and Orban, 1996). Higher neurons are also less dependent on coincidental spatial features, such as precise location, retinal size, viewpoint, lighting, and color. Another principle of the classical view is the presence of multiple areas belonging to parallel pathways, such as the dorsal and ventral streams (Ungerleider and Mishkin, 1982; Livingstone and Hubel, 1988; Goodale and Milner, 1992, see "Parietal Visual Areas"). Specialized areas and pathways are assumed to exist because of the need to solve difficult computational problems for different aspects of the visual world that require highly specialized neuronal organizations. Another principle of the classical view states that high-level processing such as learning (i.e., experience) and attention (i.e., context) occurs only in high cortical areas in the ventral and dorsal pathway (e.g., Bushnell *et al.*, 1981; Moran and Desimone, 1985; Malach *et al.*, 1995). Although it was known that feedback connections reach areas as low as V1 and even the LGN, their function was largely ignored.

Despite the fact that the precise functional roles and cognitive consequences of the feedback connections are still unknown, the feedback connections play a key role in recent theories of the visual system (e.g., Zeki, 1993; Tononi and Edelman, 1998; Singer, 1999; Hochstein and Ahissar, 2003) extending the classical view. These theories suggest a variety of functions for the recurrent connections between V1 and higher visual areas. Higher areas might send feedback signals to confirm the reliability of the information they receive from V1 or to modulate V1 activity on the basis of top-down knowledge, perceptual grouping, or attentional selection. Recent physiological and functional MRI studies have now confirmed strong top-down effects of learning and visual attention in V1 (e.g., Ahissar and Hochstein, 1997; Roelfsema *et al.*, 1998; Brefczynski and DeYoe, 1999; Somers *et al.*, 1999) and even in the LGN (O'Connor *et al.*, 2002). Multiple recordings of intracortical event-related potentials support the view that the observed modulations in early visual areas are indeed top-down effects by revealing that attentional modulation effects occur well after the initial transient response in V1 and that attentional effects in V4 and inferotemporal cortex precede those in V1 (Mehta *et al.*, 2000). Another important role that has been proposed for the recurrent connections is to integrate processing occurring in multiple specialized brain areas.

Unified Representations of the Visual World and the Binding Problem

According to the classical view focusing on feedforward processing, an integrated visual representation of the visual world should be accomplished by a master area on top of the hierarchy to which all of the specialized areas report. There are serious problems with this solution, however, both on conceptual and empirical grounds (e.g., Zeki, 1993; Singer, 1999; von der Malsburg, 1999). Conceptually, such a master map would presumably contain cells with highly specific receptive fields (conjunction units or "grandmother cells"; Barlow, 1995) that represent the culmination of the hierarchical integrative processes of the system. The conjunction neurons would respond only to specific combinations of features, such as shape, orientation, color, texture, motion, and position in space. Conceptually, it is difficult to imagine how there could be a sufficient number of conjunction neurons to represent uniquely all intra- and interareal feature constellations of real-world objects. In addition, it is hard to see how novel objects with entirely new relations among features could be represented in such a system. The master area hypothesis also has serious problems on empirical grounds. First, although there is good evidence of a hierarchical organization of the visual system, there is no anatomical evidence that the specialized visual areas all converge on one area (Felleman and Van Essen, 1992). The numerous forward and backward connections between areas at different stages of the hierarchy suggest that processing is not strictly hierarchical but highly interactive. Second, despite the fact that neurons have been found that respond selectively to hands or faces, these cells are not selective for a *specific* hand or face but are coarsely tuned to a broad spectrum of exemplars of the relevant category. Thus, it is more likely that individual objects are represented uniquely only by distributed representations or cell assemblies spread within and across numerous brain areas (Hebb, 1949).

The conceptual and empirical problems with the master area solution have stimulated alternative theories of integrative processing in which the massive feedback projections play an important role. In this view, reentrant connections from higher visual areas to V1 and V2 are assumed to provide the basis for integrating specialized processing occurring in higher visual areas (e.g., Zeki, 1993). Because V1 contains a high-resolution map of almost all relevant feature information and forms well-organized connections with retinotopic extrastriate areas, it could function as the central location to integrate perceptual information across multiple areas. This view puts the "master map" at the bottom instead at the top of the visual hierarchy. As an example, reentrant connections from V4 to V2 project not only back to the thin stripes and interstripes (V4's major input sources from V2), but also to the thick stripes of V2, which project to V3 and V5. This could represent a mechanism for integrating processing concerned with form and color—mediated by parvocellular channels—with the processing of form and motion mediated by magnocellular channels.

If this view of integrative processing is correct, the correlate of coherent percepts would be a distributed representation spread within and across many brain areas. Since in the real world many objects have to be represented at the same time, the question arises how such distributed representations could be tagged as related, i.e., how neurons could be linked together when participating in the representation of the same object and how they could be kept apart when participating in the representation of different objects. This problem of tagging belongingness is often referred to as the *binding problem*. The binding problem should be solved rather early in the visual hierarchy in order to assure that the responses of the neurons that constitute an assembly are processed and evaluated together at subsequent processing stages and are not confounded with other, unrelated responses. Several mechanisms to solve the binding problem have been proposed,

including suppression, enhancement, and temporal synchrony, which are assumed to occur during visual processes such as perceptual organization and selective visual attention. Suppression refers to the inhibition of unrelated responses excluding them from further processing. Enhancement refers to increasing the firing rates of the relevant neurons. Temporal synchrony refers to effects that increase the likelihood that relevant cells discharge in precise temporal synchrony. All three mechanisms enhance the relative impact of the selected responses and can therefore be used to tag them as related. There is empirical evidence that all three mechanisms play a crucial role in the selection and grouping of responses (e.g., Roelfsema *et al.*, 2002; Fries *et al.*, 2001). The temporal synchrony mechanism appears conceptually more flexible than the other mechanisms because it permits specification of relations independently of firing rate. This property is especially beneficial when multiple visual objects have to be represented simultaneously across potentially overlapping neuronal populations in early visual areas.

Visual Awareness

As outlined above, early visual areas play an essential role in recent theories of the visual system because they assume that V1 and V2 integrate the results of specialized processing occurring in higher visual areas (e.g., Zeki, 1993; Lamme and Roelfsema, 2000; Bullier, 2001). Because of the assumed essential role in integrative processing and feature binding, the question arises whether primary visual cortex contributes directly to conscious perception (Tong, 2003) despite the fact that V1 is located at the lowest level of the cortical visual hierarchy. Lesion studies indicate that V1 is necessary for normal visual function and awareness. Small lesions in V1 lead to scotomas or phenomenal blindness restricted to corresponding regions of the visual field as expected from the retinotopic organization of V1 (reviewed in Inouye, 2000). However, these findings do not answer the question whether V1 itself is important for visual awareness because the lesions disrupt the flow of information from V1 to higher visual areas. While proponents of the integrative role of primary visual cortex propose that V1 directly contributes to visual awareness (Zeki, 1993; Lamme and Roelfsema, 2000; Bullier, 2001), other researchers have proposed that only higher level extrastriate areas are directly involved in conscious perception (Crick and Koch, 1995; Rees *et al.*, 2002). In addition, they argue that only extrastriate areas that project directly to prefrontal cortex can directly contribute to consciousness, on the assumption that all conscious experiences must be reported and capable of directly generating a motor act. Because V1 lacks direct projections to prefrontal cortex, this theory assumes that V1 cannot directly contribute to visual awareness. More recent variants of this proposal assume that both frontal and parietal attention related areas are important for conscious perception, and that top-down signals from these areas to the extrastriate cortex might be important for selecting specific visual representations for awareness (Leopold and Logothetis, 1999). Proponents of the integrative role of V1 assume on the contrary that sustained activity between a given extrastriate area and V1 is necessary to maintain a visual representation in awareness. This means that V1, despite its lack of direct feedforward connections with the prefrontal cortex, can determine what extrastriate information reaches prefrontal areas by supporting or failing to support the information represented in intermediate extrastriate areas.

Evidence from neuroimaging studies indicate that V1 activity is tightly correlated with awareness under various conditions, such as binocular rivalry (Polonsky *et al.*, 2000; Tong and Engel, 2001) and near-threshold visual detection (Ress *et al.*, 2000). There are, however, other studies that show that V1 activity might be necessary but is not sufficient for perceptual awareness. For example, the responses of V1 neurons can follow flickering color gratings at temporal rates that are too fast to be received (Gur and Snodderly, 1997). According to current evidence from lesion studies, neither activity in V1 nor in higher visual areas is sufficient for awareness. A recent study of blindsight patients has shown that in the absence of V1 visual signals can still reach many extrastriate areas via subcortical projections but that activity in the extrastriate areas seems incapable of generating normal conscious experiences (Goebel *et al.*, 2001). It might be that the relationship between activity in certain visual areas and awareness is flexible and situation dependent rather than hard wired. Perhaps the information in V1 is necessary only for certain types of awareness, such as perception during focal attention or the perception of low-level features. Along these lines, a recent theory proposes that different areas contribute to visual awareness in two operational modes of the visual system, *vision at a glance* and *vision with scrutiny* (Hochstein and Ahissar, 2002). According to this theory, conscious perception begins at the top of the visual hierarchy, gradually returning downward as needed. The initial conscious percept, vision at a glance, matches a high-level, generalized, categorical scene interpretation. For later vision with scrutiny, *reverse hierarchy routines* focus attention to specific, active, low-level units, incorporating into conscious perception detailed information available from areas as low as V1.

Acknowledgments

This work was supported by the Human Frontiers Science Program (DSK, RG) and the Max Planck Society (LM). The authors are grateful to Bettina Sorger and Stefan Kiess for helpful comments on the manuscript, to Ralph Galluske for providing Fig. 35.6 and to Jens Schwarzbach for providing Fig. 35.7.

Emotional Motor System

GERT G. HOLSTEGE, LEONORA J. MOUTON, and PETER O. GERRITS

Department of Anatomy and Embryology, Faculty of Medical Sciences
University of Groningen, Groningen, The Netherlands

For most clinical neurologists the motor system consists of the corticospinal or pyramidal tract, originating from the motor or premotor cortex and terminating in the brainstem and spinal cord. The reason is simple. Partial interruption of the pyramidal tract leads to inability to move particular parts of the body and complete unilateral interruption to hemiplegia.

However, many findings in mammals, including humans, point to the existence of a different motor system, called the "emotional motor system" (Holstege, 1992). An example are the patients with a central paresis of the lower face caused by an interruption of motor cortical fibers innervating the motoneurons of the face musculature. These patients are not able to use their oral muscles voluntarily on the contralateral side of the lesion (Fig. 36.1, left). Yet, when they enjoy a funny story or a joke, they suddenly smile and use these muscles on both sides of the face (Holstege, 2002; Fig. 36.1, right). Both, the somatic or voluntary (Fig. 36.2, left) and the emotional motor system (Fig. 36.2, right) make use of the same motoneurons and premotor interneurons. These inter- and motoneurons represent the basic motor system.

Although this chapter focuses on the emotional motor system, the basic and the somatic motor systems will be discussed shortly in order to point out the similarities and differences between the two systems.

BASIC MOTOR SYSTEM

Somatic and Autonomic Motoneurons

Movements are the result of contractions of striated and smooth muscles that are controlled by somatic and autonomic motoneurons, respectively. The motoneurons, in turn, are controlled by nearby or distant premotor interneurons.

Somatic motoneurons are located in various brainstem nuclei and in the ventral horn throughout the length of the spinal cord. They innervate striated muscles. In the spinal cord, motoneurons innervating distal limb muscles, such as those of the hand, arm,

FIGURE 36.1 A patient suffering from a lesion in the white matter nearby the the face area of the primary and premotor cortex. The patient is not able to show her teeth on the contralateral side of the lesion *(left)*, but on the same side she is able to smile *(right)*.

foot, and leg, are located in the lateral and dorsal parts of the ventral horn. Those innervating the most distal muscles, such as the digits, are found in the most dorsal parts (VanderHorst and Holstege, 1997b). On the other hand, motoneurons innervating the muscles between the trunk and limb and those innervating axial muscles lie ventrally and medially in the ventral horn, respectively.

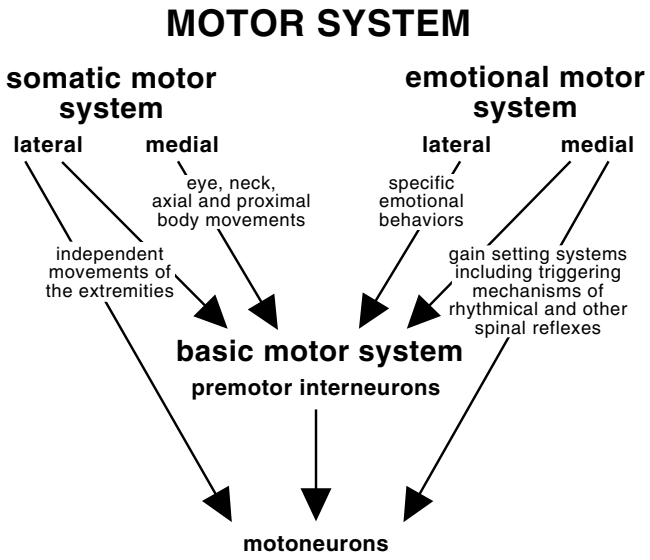

FIGURE 36.2 Scheme of the motor system consisting of a voluntary and an emotional motor component.

Autonomic (sympathetic and parasympathetic) motoneurons innervate glands and smooth muscles of viscera and blood vessels. There are preganglionic and postganglionic motoneurons, of which the preganglionics are located in the brainstem or spinal cord. Their axons run through a peripheral nerve and synapse on a postganglionic motoneuron in a peripheral ganglion. The sympathetic preganglionic motoneurons are active during basic survival behavior (fright, flight and fight), and are located in the intermediolateral cell column of the T1-L3 spinal segments. Each sympathetic preganglionic motoneuron controls about 30 postganglionic motoneurons.

The parasympathetic autonomic motoneurons, on the other hand, are especially active during rest and digest. They are located in the brainstem and in the intermediolateral cell column of the S2-S4 segments of the spinal cord. Each of these parasympathetic preganglionic motoneurons controls about two postganglionic motoneurons, located in so-called terminal ganglia in or close to the target organ.

Although the preganglionic and postganglionic sympathetic and parasympathetic motoneurons belong to the so-called autonomic system, they are not "autonomous" at all, but are under strong control of especially the emotional motor system.

Premotor Interneurons

Premotor interneurons project to somatic motoneurons or to preganglionic autonomic motoneurons. Premotor interneurons play a role not only in relatively simple motor activities such as reflexes but also in more complex motor activities. Many premotor interneurons lie in the intermediate zone near their target motoneurons, but in some cases they are located far from them (e.g., in respiration and micturition control systems).

Premotor interneurons projecting to distal muscle motoneurons innervating muscles of hip or shoulder, centrally; and those projecting to the trunk and axial motoneurons, medially in the intermediate zone (Fig. 36.3). The last projections are bilateral because of the bilateral function of the axial muscles. These interneuronal– motoneuronal projections belong to the so-called propriospinal pathways.

The motoneuronal cell groups (e.g., the motor trigeminal, facial, ambiguus, and the hypoglossal nuclei) in the caudal brainstem also receive many afferents from the premotor interneurons, the so-called propriobulbar pathways. These interneurons are located in the lateral tegmental field of the caudal pons and medulla oblongata as defined by Holstege *et. al.* (1977). The lateral tegmental field can be considered as the rostral extension of the intermediate zone of the spinal cord (Fig. 36.4).

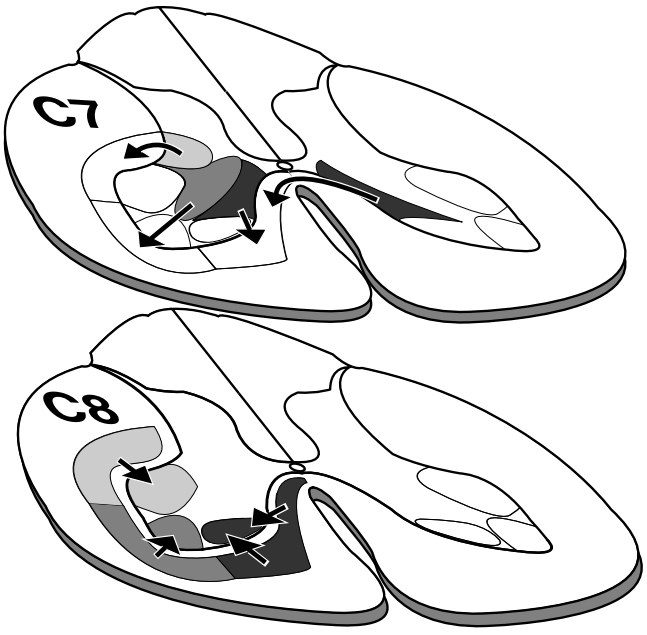

FIGURE 36.3 Schematic illustration of the projections from interneurons in the C7 intermediate zone (laminae V-VII) via the propriospinal pathways to the motoneurons at the C8 level.

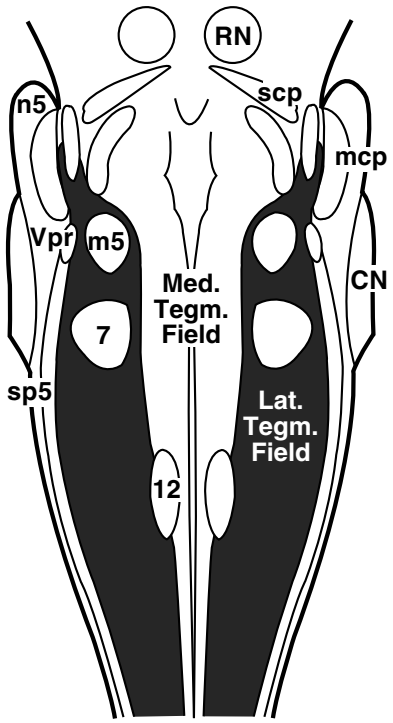

FIGURE 36.4 Schematic horizontal section through the brainstem. The lateral tegmental field is indicated in black.

Specific Premotor Interneuronal Systems Between Brainstem and Spinal Cord

Some premotor interneuronal projections to motoneurons are rather long. An example is the premotor projections to motoneurons involved in respiration. These motoneurons lie in the C4-C6 (phrenic nucleus motoneurons innervating the diaphragm) and the T1-L3 spinal cord (motoneurons innervating the intercostal and abdominal muscles). Their premotor interneurons are not located in the spinal cord because the respiratory afferents enter the central nervous system in the caudal. The inspiratory premotor interneurons innervating the phrenic and external intercostal motoneurons are located in the lateral solitary nucleus and rostral nucleus retroambiguus. The expiratory premotor interneurons innervating the abdominal and internal intercostal motoneurons are found in the caudal nucleus retroambiguus (Fig. 36.5). The abdominal muscles play an important role in postural control also, and the premotor interneurons for this function are located in the spinal cord near the abdominal motoneurons themselves. Another example of long basic system projections are the brainstem–spinal pathways involved in micturition (see "Pathways Involved in Micturition").

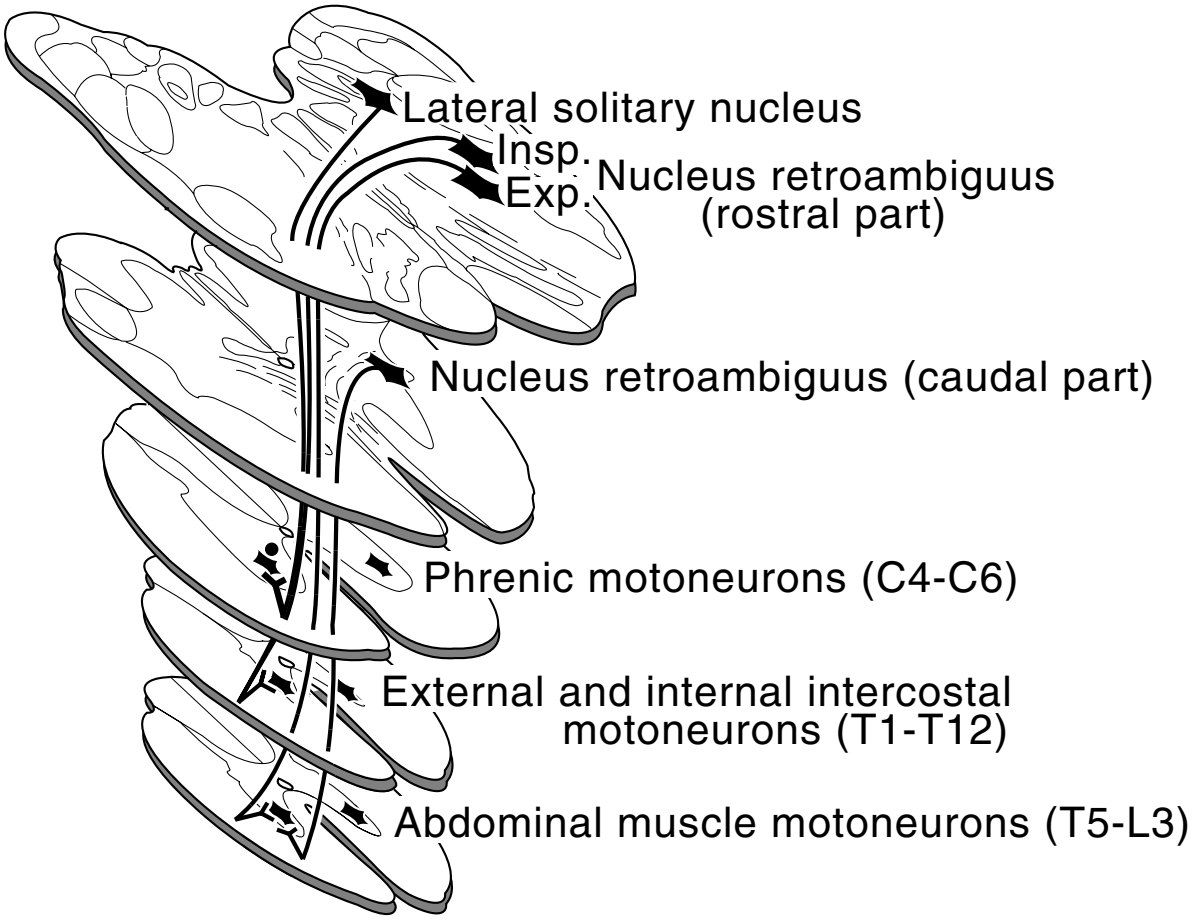

FIGURE 36.5 Schematic overview of the pathways controlling respiration and abdominal pressure. For the sake of clarity only the contralaterally descending pathways are indicated, although there exist to a limited extent some ipsilateral ones also.

SOMATIC MOTOR SYSTEM

The somatic motor system enables the individual to react voluntarily to events in its surrounding. As pointed out by Kuypers (1981), the somatic motor system consists of a medial and a lateral component controlling proximal and distal musculature, respectively.

Medial Component of the Somatic Motor System

The medial component represents a phylogenetically old supraspinal motor control system and is involved in maintenance of erect posture (antigravity movements), integration of body and limbs, synergy of the whole limb, and orientation of body and head. It controls the skeletal muscles of the neck, trunk, shoulders, and hip as well as the extrinsic eye muscles in the orbit.

Brainstem pathways belonging to the medial component of the somatic motor system are the interstitiospinal, vestibulospinal (Fig. 36.6, right), tectospinal, and reticulospinal tracts (Fig. 36.6, left). These pathways terminate mainly on premotor interneurons in the medial half of the ventral horn; in turn, the interneurons project to axial and proximal muscle motoneurons on both sides of the spinal cord.

There is also a corticospinal projection belonging to the medial component of the somatic motor system. It originates in the trunk, back, and neck representations of the primary motor and premotor cortex and descends bilaterally through the medial part of the ventral funiculus (Fig. 36.7, right). Similar to the brainstem–spinal fiber tracts, these corticospinal fibers terminate mainly on medially located premotor interneurons and not on motoneurons.

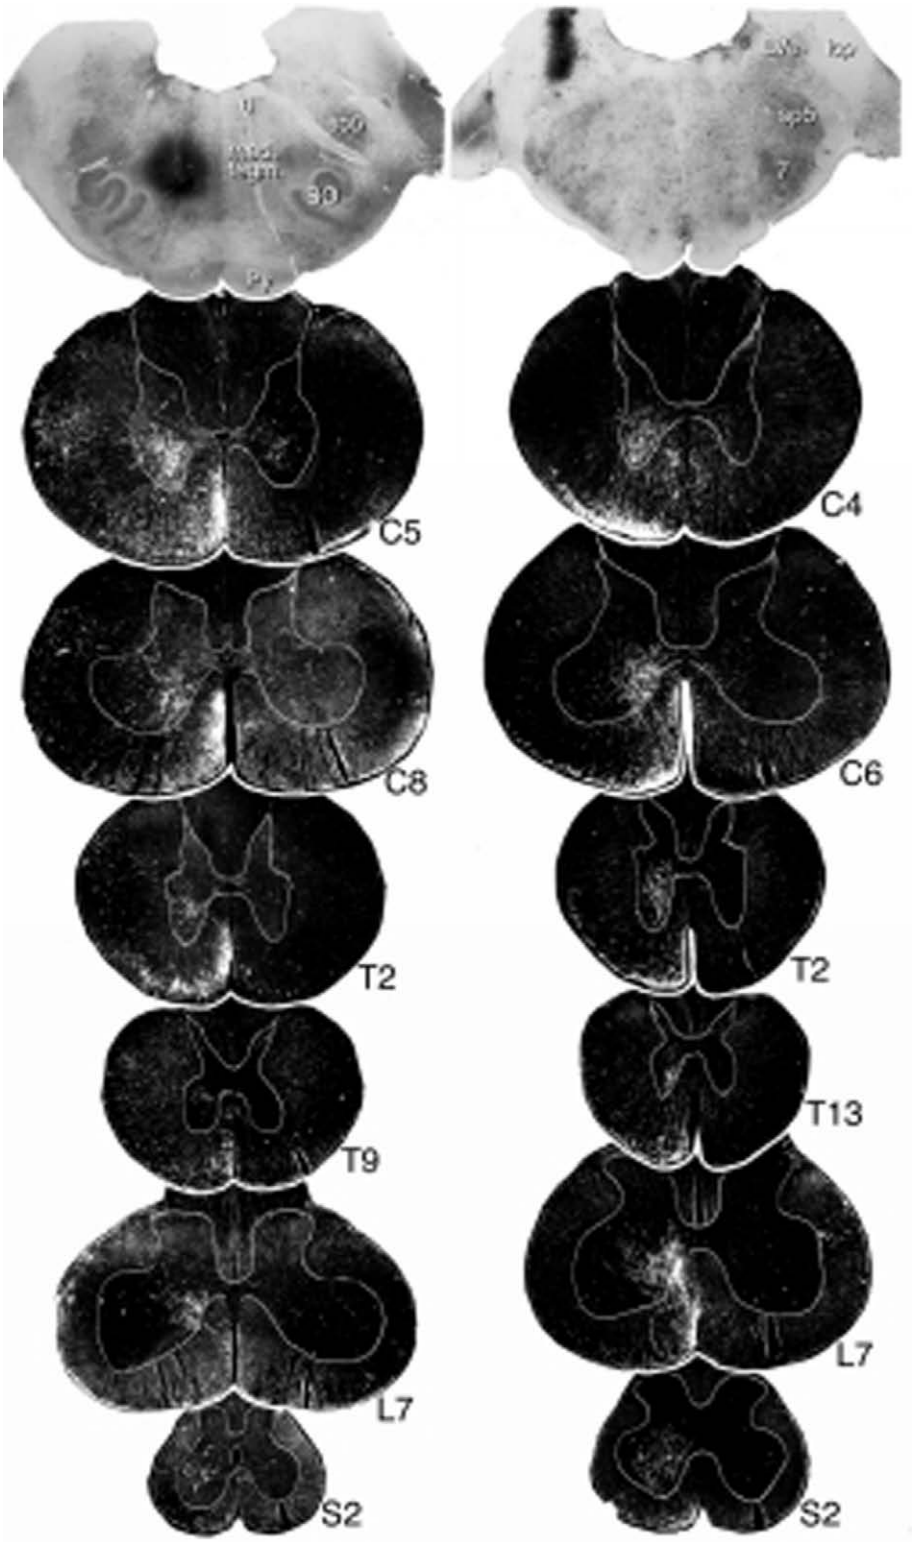

FIGURE 36.6 Brightfield photomicrographs of tritiated leucine injection sites in the medial reticular formation at the pontomedullary transition area *(left)* or in the vestibular complex *(right)*. Darkfield photomicrographs show the descending fibers and termination areas in the medial ventral horn in both cases.

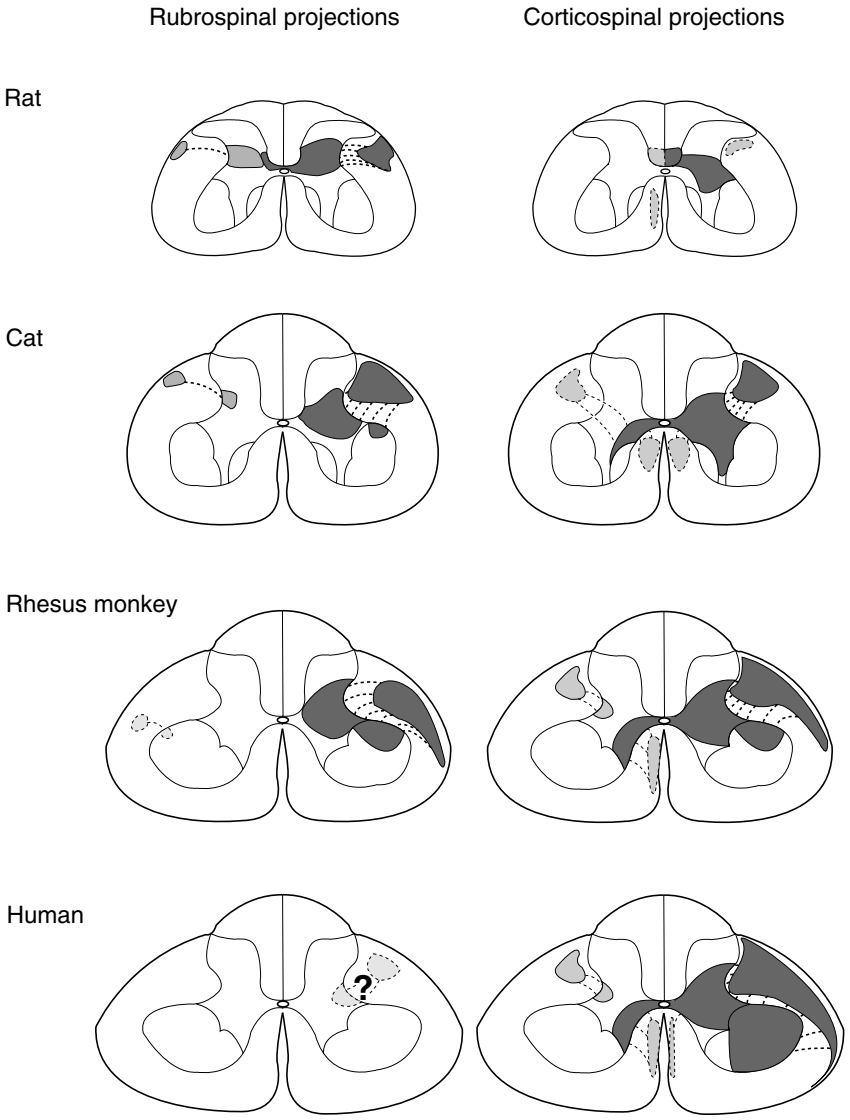

FIGURE 36.7 Schematic representation of the rubrospinal and corticospinal projections in rat, cat, rhesus monkey, and human at the level of C8. The gray areas in the white matter represent the descending pathways; those in the gray matter represent termination zones. Dark gray areas represent strong projections; lighter gray areas represent light projections.

Lateral Component of the Somatic Motor System

The lateral component of the somatic motor system controls the premotor interneurons and motoneurons of the distal muscles. This component consists of two pathways—the lateral corticospinal and the rubrospinal pathways. In humans, the lateral corticospinal pathway subserves the control of the independent movements of the extremities. It controls the motoneurons via direct projections as well as indirectly via strong projections to the laterally located premotor interneurons. The motoneurons innervating the muscles of the distal limbs receive the strongest direct projections from the motor cortex. This descending system enables humans to make most refined and extremely complex movements, such as independent finger movements and speech, the most complicated motor performance. In most mammals, both the lateral corticospinal and the rubrospinal pathways are important, but in humans the rubrospinal pathway seems to be irrelevant (Fig. 36.7).

The question is what drives the somatic motor system. The prefrontal cortex might play an essential role in deciding whether or not a motor activity is necessary to react to a certain situation. Since the

prefrontal cortex receives many afferents from limbic brain structures involved in emotional activity, one might argue that the somatic motor system is also a tool for the emotional brain to satisfy its needs.

EMOTIONAL MOTOR SYSTEM

Similar to the somatic motor system, the emotional motor system has a medial and a lateral component, each subserving different functions.

Medial Component of the Emotional Motor System

The medial component (Fig. 36.8) represents descending projections from the medial parts of the preoptic region, dorsal hypothalamus, and from the periaqueductal gray (PAG) to the caudal pontine and medullary ventromedial tegmental field. This region contains the caudal raphe magnus (RMg), pallidus (RPa), and obscurus nuclei (ROb), but the bulk of the neurons is located laterally adjoining the raphe nuclei. Neurons in the medullary ventromedial tegmental field give rise to descending pathways that terminate among almost all parts of the spinal gray matter, including the dorsal horn and the autonomic and somatic motoneuronal cell groups (Fig. 36.9, right). These projection systems are so diffuse that one particular ventromedial tegmental neuron sends axon collaterals to the caudal spinal trigeminal nucleus, to the cervical, and to the lumbosacral portions of the spinal cord (Martin *et. al.,* 1981; Hayes and Rustioni, 1981; Huisman *et. al.,* 1982; Lovick and Robinson, 1983). They do not produce specific movements, but act as "level setting" systems.

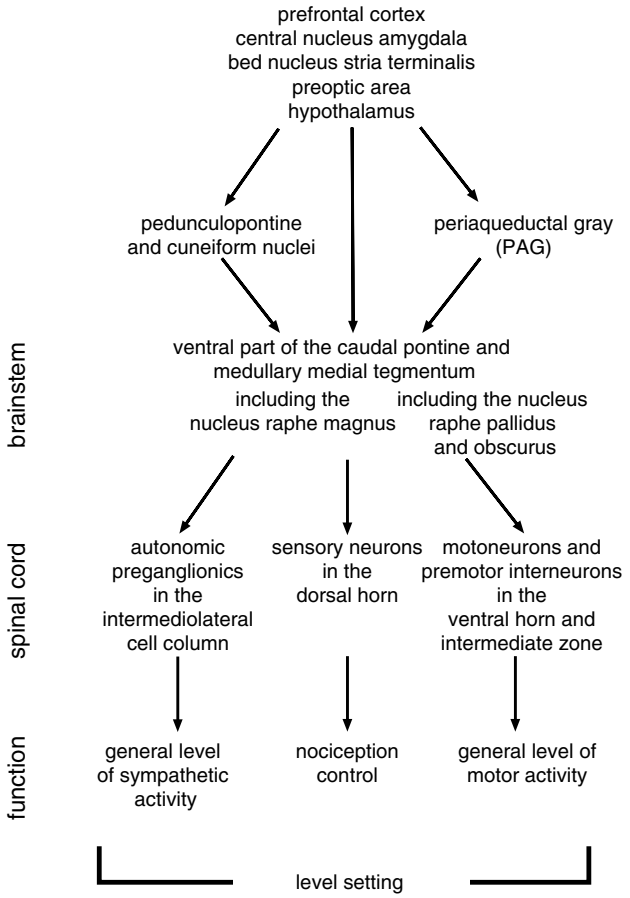

FIGURE 36.8 Schematic overview of the structures involved in the medial component of the emotional motor system.

Many different neurotransmitter substances exist in neurons in the medullary ventral tegmental field, of which serotonin (5HT) is the best known. Serotonin enhances the excitability of the motoneurons for inputs from other sources as the somatic motor system or the basic motor system (e.g., respiratory control systems). Several peptides are also present in the spinally projecting neurons in the ventromedial medulla and RPa and ROb. Many neurons contain substance P, thyrotropin-releasing hormone, somatostatin, and methionine- and leucine-enkephalin, and a few neurons contain vasoactive intestinal peptide and cholecystokinin. Most of these peptides coexist to a variable extent with serotonin in the same neuron. Most of the diffuse descending pathways to the spinal cord are not derived from serotonergic neurons. Possible neurotransmitter candidates for these pathways are acetylcholine and somatostatin and γ-aminobutyric acid (GABA). Even colocalization of serotonin and GABA in spinal cord-projecting neurons in the ventral medulla in the rat has been demonstrated. This means that some terminals taking part in this diffuse descending system may have inhibitory as well as facilitatory effects on the postsynaptic element (e.g., a motoneuron), although the majority is probably either facilitatory or inhibitory. Spinal motoneurons display a bistable behavior and can switch back and forth to a higher or lower excitable level. Bistable behavior disappears after spinal transection but reappears after subsequent intravenous injection of the serotonin precursor 5-hydroxytryptophan. Thus, intact descending pathways are essential for this bistable behavior of motoneurons, and serotonin is one of the neurotransmitters involved in switching to a higher level of excitation. GABA may possibly be involved in switching to a lower level of excitation (see Holstege, 1991, and Rekling *et. al.,* 2000, for reviews).

In summary, when the facilitory part of the diffuse system is active, less energy is needed by the somatic

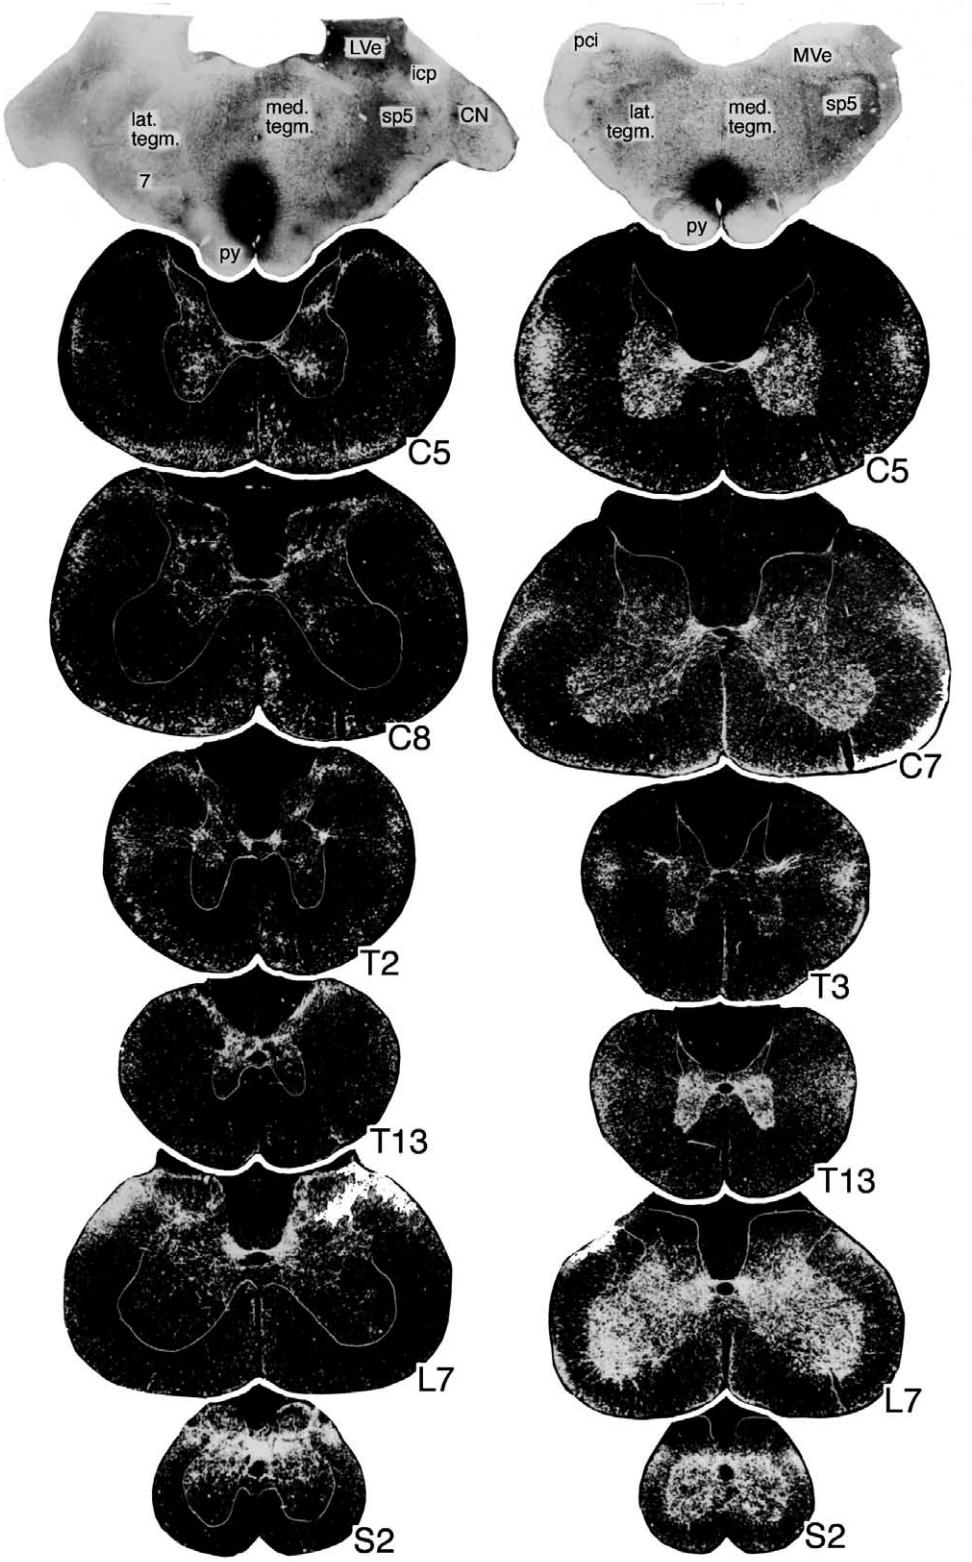

FIGURE 36.9 Brightfield photomicrographs of autoradiographs showing tritiated leucine injection sites in the ventral part of the medial tegmental field including the RMg *(left)* and Rpa *(right)*. Darkfield photomicrographs on the left show the distribution of the labeled fibers mainly to the dorsal horn (laminae I, the upper part of II and V), the intermediate zone, and the autonomic motoneuronal cell groups. On the right, the labeled fibers are distributed to the ventral horn (intermediate zone and autonomic and somatic motoneuronal cell groups).

motor system to "activate" specific premotor interneurons and motoneurons to produce a certain movement. Conversely, when the inhibitory part of the diffuse system is active, the somatic motor system needs more energy to produce the same effect. Possibly, the latter situation is predominant in patients suffering from depression causing the feeling that every movement requires "much more energy than normal."

The Medial Component and Nociception

The neurons in the ventromedial tegmentum have a great impact not only on the motor but also on the sensory system. The rostral medullary medial tegmentum including the RMg targets mainly laminae I and V neurons in the dorsal horn throughout the length of the spinal cord (Fig. 36.9, left). These pathways represent direct inhibitory connections with neurons in turn projecting to supraspinal levels (Antal *et. al.*, 1996; Light *et. al.*, 1986). Correspondingly, stimulation in the rostral ventromedial tegmentum produces an inhibition of the activity level of lamina I and V neurons, resulting in a strong inhibition of nociception (see Fields *et. al.*, 1991, for review).

Control of the Diffuse Pathways

Another question is which brain regions control the ventromedial medullary tegmentum, that gives rise to the diffusely projecting fiber systems? Perhaps the most important of these regions are the periaqueductal gray and the surrounding mesencephalic tegmentum (Fig. 36.10, left), but further rostrally the medial hypothalamus and medial preoptic region also project to the ventromedial tegmentum (Fig. 36.10, right). The caudal hypothalamus projects mainly to the caudal half of the ventromedial tegmentum including the RPa (i.e., to the "motor" part of the diffuse descending pathways), while more rostral regions of the medial hypothalamus and the preoptic region project to the RMg and adjacent regions, giving rise to diffuse projections to the dorsal horn (i.e., to the "somatosensory or nociceptive" part of the diffuse descending pathways; Holstege, 1987). Another projection originates from lateral limbic regions, such as the central nucleus of the amygdala, the lateral bed nucleus of the stria terminalis (Fig. 36.10, middle) and the lateral hypothalamus. Their main projections are to the lateral tegmental field of caudal pons and medulla, but there is a separate projection to the rostral (the somatosensory or nociceptive) part of the medullary medial tegmentum.

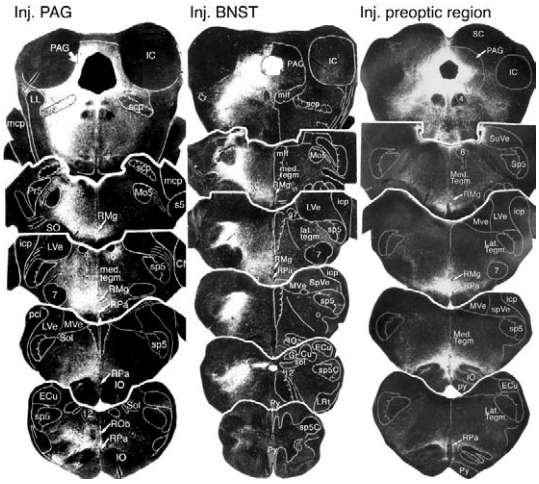

FIGURE 36.10 Three cases with injections in the periaqueductal gray (left), the bed nucleus of the stria terminalis (middle), and the preoptic region at the level of the anterior commissure (right). Note that in all three cases there is strong projection to the ventromedial tegmentum at the level of caudal pons and rostral medulla. In the PAG and BNST cases, these fibers come from lateral; the preoptic area sends its fibers to the ventromedial tegmentum via a medially descending fiber stream. Note also the differences with respect to the projections to the caudal ventromedial medullary tegmentum between the cases, and the strong projections to the lateral tegmentum in the BNST case.

In general terms, stimulation in the PAG in animals produces behavior associated with the direct survival, such as arousal, aggressive, or defensive behaviors accompanied by a strong inhibition of nociception. Because of this strong antinociceptive effect, in patients suffering from untreatable severe pains, neurosurgeons stimulated the PAG to see whether a similar antinociceptive effect could be achieved. However, at least in more caudal parts of the PAG, such stimulation resulted in fear and panic-like emotions such as anxiety, terror, and even feelings of imminent death.

Another well-known example in humans that arousal of the motor system coincides with inhibition of nociception has been described by doctors working in field hospitals in the First World War. In that war, soldiers were fighting in trenches against "the enemy" a few hundred yards away. There are several reports that soldiers had not felt that they were shot in the foot or leg. Their level setting system was functioning at a maximum, the motor system was maximally aroused, and nociception was maximally inhibited.

Lateral Component of the Emotional Motor System

The lateral component of the emotional motor system consists of pathways that subserve specific

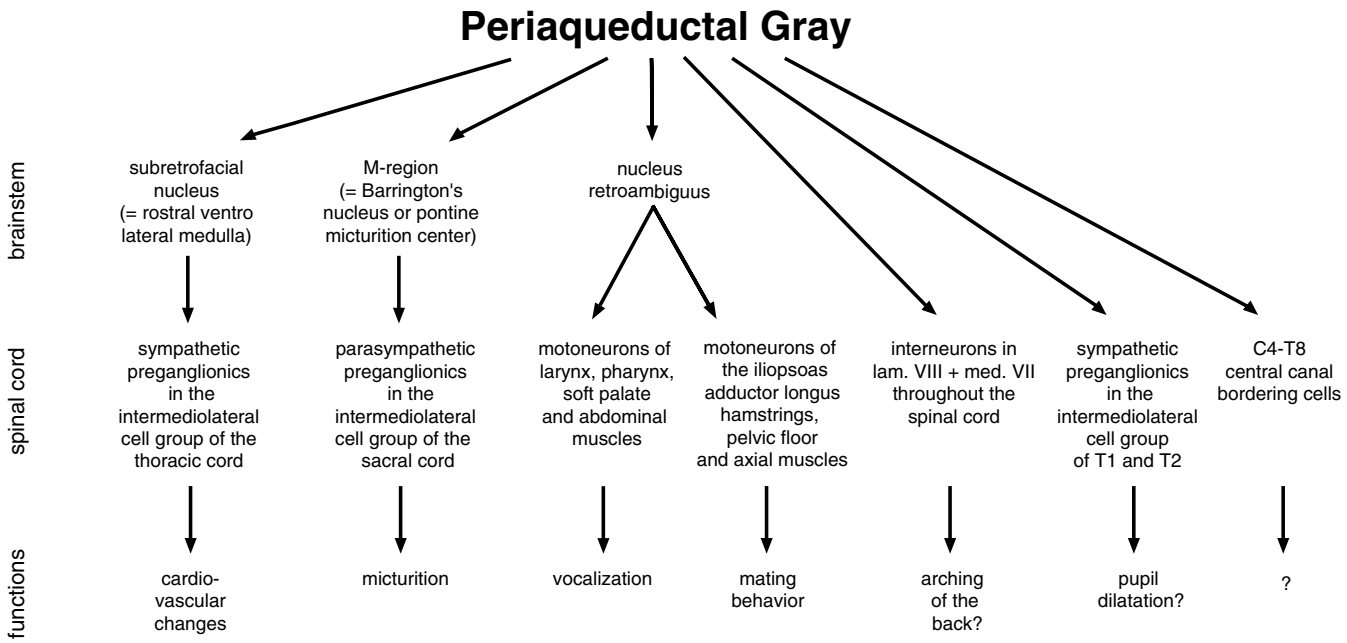

FIGURE 36.11 Schematic overview of some of the motor output systems of the PAG. All these motor systems are directly involved in basic survival behavior.

motor functions, in contrast to the unspecific diffuse pathways of the medial component. Examples of the specific functions are cardiovascular regulation, vocalization (= the production of sound), mating behavior, and micturition (Fig. 36.11). Pathways belonging to the lateral component originate in the PAG, lateral hypothalamus, central nucleus of the amygdala, and lateral part of the bed nucleus of the stria terminalis (Fig. 36.10, middle). The PAG sends projections to specific groups of interneurons in the caudal brainstem and spinal cord (Fig. 36.11), the lateral hypothalamus, central nucleus of the amygdala, and lateral part of the bed nucleus of the stria terminalis project to the lateral tegmentum (Figs. 36.4 and 36.10, middle), containing premotor interneurons to the somatic and preganglionic motoneurons in the caudal brainstem. An overview will be given of three projection systems, that for vocalization, mating behavior, and micturition.

Pathways Involved in Vocalization

Vocalization can be defined as the nonverbal production of sound and requires coordination between the activity of abdominal and expiratory intercostal muscles and muscles of the larynx, pharynx, and soft palate. Most animals use vocalization as an important tool for survival. Vocalization should not be confused with speech, the production of vowels and consonants in humans. Proper combination of vowels and consonants form words and sentences.

In animals as diverse as leopard frogs and chimpanzees, vocalization is brought about by different parts of the limbic system, but specifically by the PAG (see Holstege, 1989, for review). Stimulation in the caudal PAG results in vocalization, and bilateral PAG lesions completely abolish it, leading to mutism (Adametz and O'Leary, 1959). Also in humans a few clinical cases are known in which lesions in the PAG led to mutism (Botez and Barbeau, 1971; Esposito *et. al.*, 1999). The pathways involved originate in the PAG and descend to terminate in neurons in the nucleus retroambiguus (NRA) and on neurons in the adjoining caudal medullary lateral tegmental field. The latter neurons, in all likelihood, serve as a relay for the PAG to reach the motoneurons innervating lower mouth muscles and the muscles of the mouth opening and tongue. The NRA neurons project to the motoneurons in the nucleus ambiguus innervating pharynx and larynx, and to the motoneurons of the intercostal and abdominal muscles in the spinal cord.

In our concept, speech is the (pre-) motor cortex modulation of vocalization (Holstege and Ehling, 1996; Fig. 36.12). The cortical modulation is brought about by an enormous number of "memory" neurons in the premotor cortical regions that project to the motor cortex, which in turn has direct access to mouth, pharynx, and larynx muscle motoneurons. Only the human cortex contains such a large amount of motor memory (area of Broca), which makes humans the only species that is able to use speech for commu-

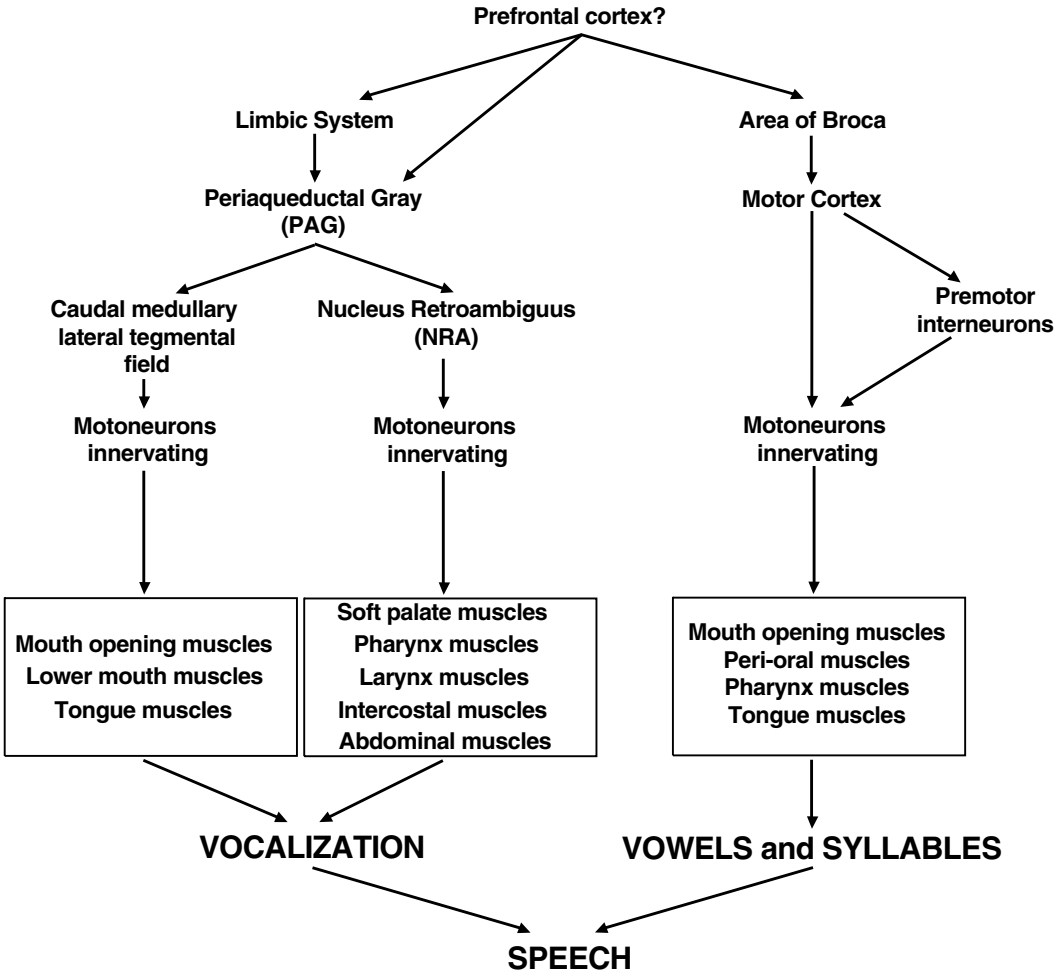

FIGURE 36.12 Schematic overview of the pathways possibly involved in the production of speech.

nication. Patients with damage of the area of Broca suffer from motor aphasia, but they still can vocalize (i.e., produce sounds) similar to animals. This is consistent with the concept that the motor output components of vocalization, possibly the PAG-NRA-motoneuronal pathways, are still intact in these patients.

Pathways Involved in Mating Behavior

Mating Behavior in Animals

The survival of the species depends on successful mating behavior. Although the behavioral aspects of mating are extensively studied, only little is known about the precise anatomical organization of the motor output systems of mating.

For example, in the rat, lesions in the preoptic region, lateral central tegmental field, or PAG cause problems with mating, but whether these regions have any connections with the motoneurons involved in mating behavior is not known. A first step in understanding this system are the studies in cat that show a direct pathway from the sacral cord to the PAG (Fig. 36.13), and from the PAG to the NRA in the caudal medulla. The NRA, in turn, projects to those motoneurons in the lumbosacral cord that produce the mating posture (Fig. 36.14). In normal estrous cats as well as in ovariectomized cats with subcutaneously administered estrogen, this hormone elicits so-called growth cones (Fig. 36.15) in the NRA fibers terminating on lumbar motoneurons. These growth cones produce an almost nine times increase of excitatory boutons with synapses on the dendrites of the lumbosacral mating motoneurons (VanderHorst and Holstege 1997; Fig. 36.16).

In male cats, the number of NRA terminals on "mating" motoneurons was about half of that found in estrous, which is still substantially more than in nonestrous females. Also the distribution pattern of

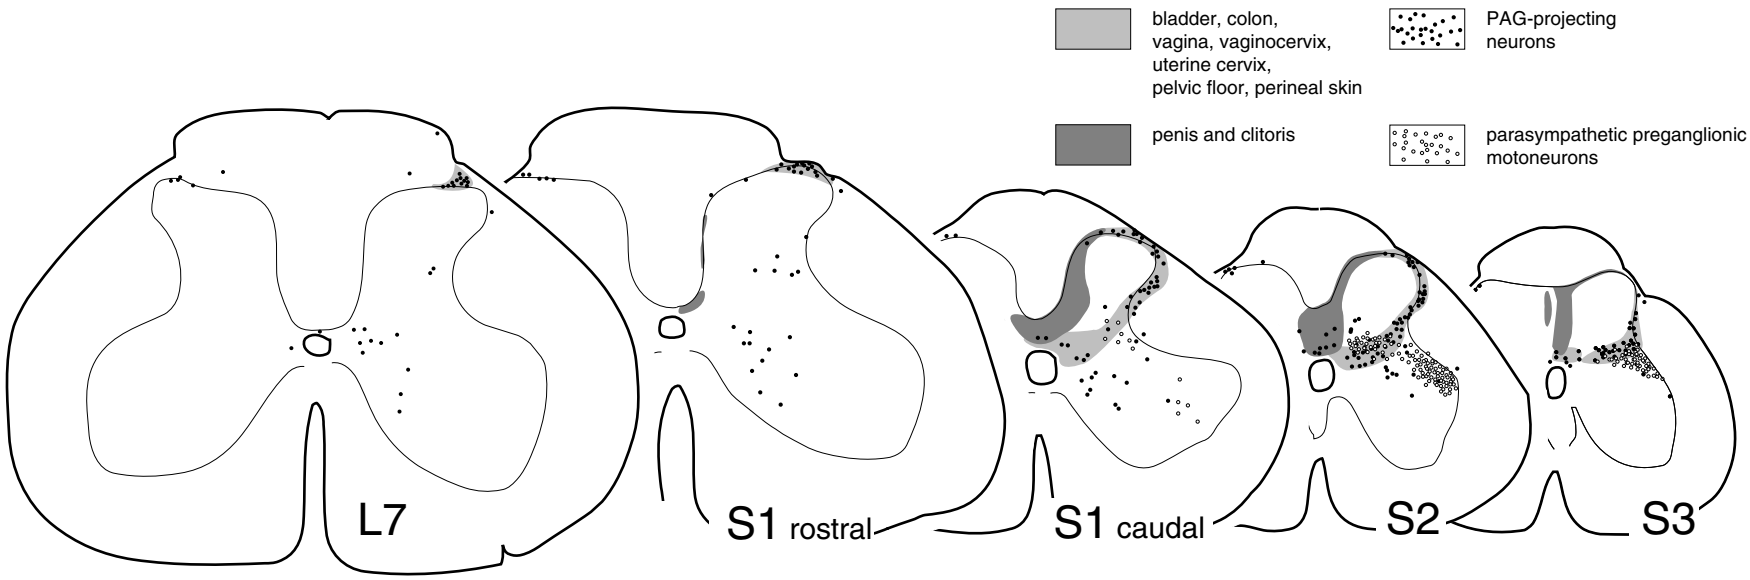

FIGURE 36.13 Schematic overview of where the urogenital afferent projections terminate in the sacral cord and where the neurons are located that project to the PAG.

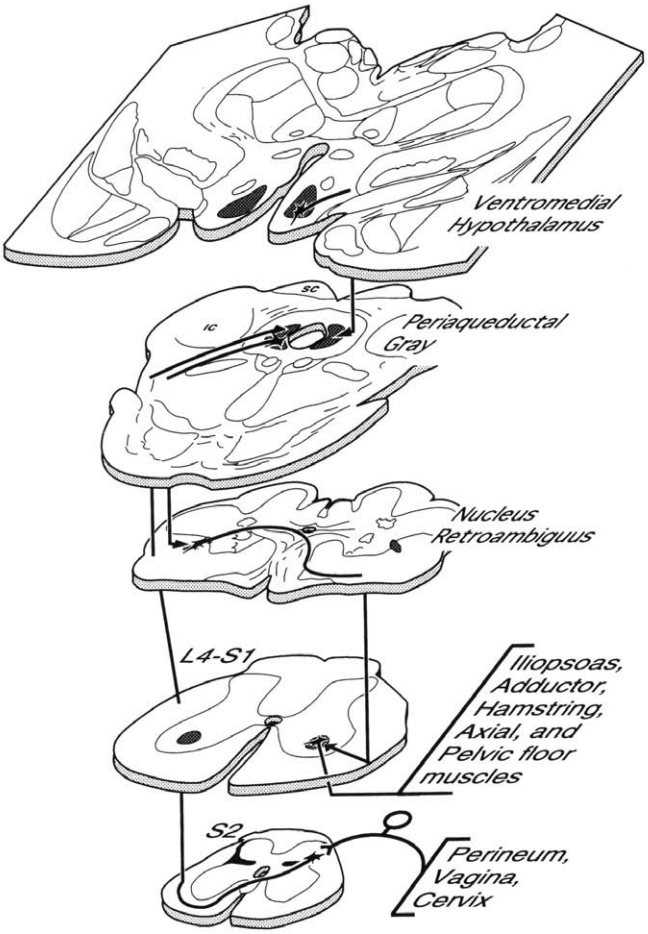

FIGURE 36.14 Schematic overview of the ascending and descending pathways that play a role in the mating reflex circuit in cats.

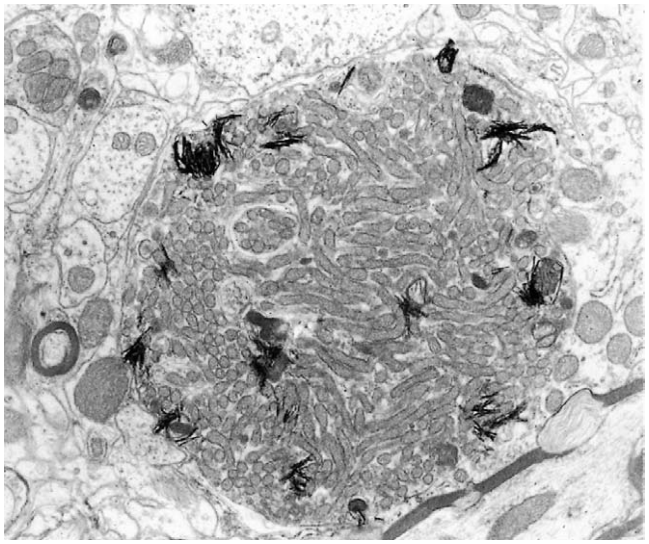

FIGURE 36.15 Electronmicrograph representing a labeled growth cone in the semimembranosus motoneuronal cell group in the sixth lumbar spinal segment of an estrous cat with an injection of wheatgerm agglutinin horseradish peroxidase (WGA-HRP) in the NRA. Note the tetramethylbenzidine (TMB) reaction products in mainly the peripheral parts of the cone.

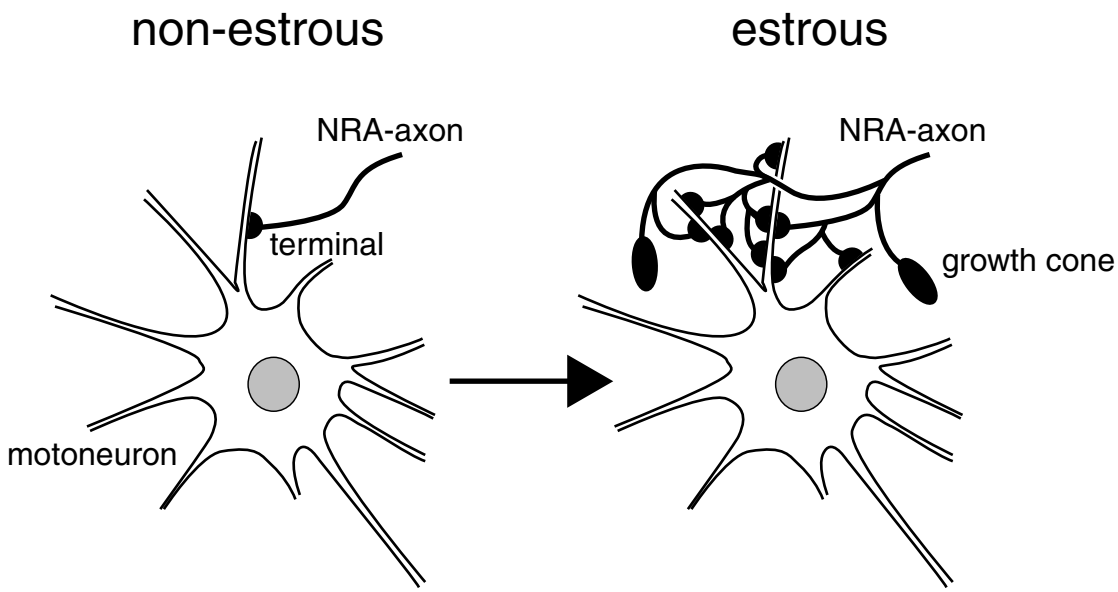

FIGURE 36.16 Schematic illiustration of the estrogen-induced axonal sprouting of NRA fibers to lumbosacral (semimembranosus) motoneurons.

the NRA terminals was slightly different in males than in females. Although further behavioral studies are needed to confirm this hypothesis, it seems likely that in cats the PAG-NRA-mating motoneuronal pathway generates the posture necessary for mating. Also in the female hamster, which shows a less complicated but very outspoken mating or lordosis posture, a similar PAG-NRA-axial muscle motoneuronal pathway seems to exist, possibly involved in lordosis (Gerrits and Holstege, 1999).

Mating Behavior in Humans

A largely unresolved matter is how mating is organized in humans. This species does not have a very distinct mating posture as in cat and hamster, but one might assume that also in humans the motor output related to mating depends on specific descending pathways. Although the techniques used in animals to investigate these pathways are not applicable to humans, modern neuroimaging techniques make it possible to reveal the human brain structures involved in mating and especially ejaculation and orgasm.

A Positron Emission Tomography (PET) study (Holstege *et. al.*, 2003a) was done in which male and female volunteers were asked to have an ejaculation or orgasm, brought about by manual stimulation of their female/male partner. The PET technique using radioactive water ($H_2{}^{15}O$) shows increases or decreases in blood flow in distinct parts of the brain, representing increases or decreases of activation of neurons in these areas. Although the resolution of PET is relatively limited, the results of the ejaculation/orgasm studies were remarkable. The strongest activation was in the so-called mesodiencephalic region, with structures such as the ventral tegmental area (VTA; known as the "reward" area), the subparafascicular nucleus, the ventromedial posterior thalamic nucleus, the intralaminar nuclei, and, especially in men, the lateral central tegmental field (Figs. 36.17 and 36.19). A similar region in the mesodiencephalic transition zone was activated during cocaine (Breiter *et. al.*, 1997) and especially heroin rush (Sell *et. al.*, 1999), suggesting that these experiences are similar to sexual orgasm. It might also explain why substances such as cocaine and heroin are so addictive.

Other findings in the ejaculation/orgasm studies are the increased activation of the lateral putamen (Fig. 36.18), certain parts of the prefrontal, temporal, parietal, and insular cortex and a very strong activation of the cerebellum (Fig. 36.19). In the study of men, strong activation was also found in the medial pontine tegmentum (Figs. 36.18 and 36.19). In correspondence with the findings in the cat in women increased activation was found in the PAG (Holstege *et. al.*, 2003b). Surprisingly, activation was not found in the hypothalamus or preoptic area in men or women (Fig. 36.18). One might speculate that these regions play a role in creating the conditions in which mating can take place (e.g., estrous versus nonestrous), but that they are not involved in the motor act itself.

An important decrease of activation was also found. The medial parts of the amygdalar regions (Fig. 36.20) were deactivated, not only during ejaculation or orgasm, but also during sexual stimulation and erection. A similar decrease of amygdalar activity was found during romantic love (Bartels and Zeki, 2000).

An active amygdala is crucial for individual survival by constantly monitoring environmental stimuli. In the case of possibly hazardous events, the amygdala elicits a fear response to protect the organism from harm. However, in the context of sexual behavior, such vigilance could easily block the sexual act, leading to unsuccessful reproduction. One might hypothesize that, in order to prevent such a disruption, brain structures involved in sexual behavior decrease vigilance by inhibiting amygdalar activity. Although deactivation of the amygdala may make the organism less concerned with potential danger, it enhances the odds

FIGURE 36.17 PET-scan results showing activations in the mesodiencephalic transition zone, comparing ejaculation with stimulation. In (a) increased activation is present in the area of the ventral tegmental area (vta), intralaminar and ventroposterior thalamic nuclei, sunparafascicular nucleus, and lateral part of the central tegmental field (lctf). The red lines on the glass brains (SPM's) indicate how the sections were made. The activations (ejaculation minus stimulation, $p < .01$, corrected for multiple comparisons) are superimposed on the average T1 weighted MRI of the subjects.

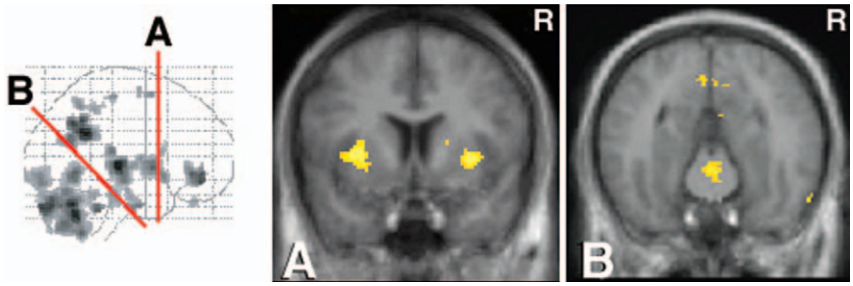

FIGURE 36.18 PET-scan results showing activations in ventrolateral putamen and adjoining parts of the claustrum and insula **(A)** and pontine medial tegmentum **(B)**, comparing ejaculation with stimulation. Note in A the absence of activity in the medial preoptic area, hypothalamus, and amygdala.

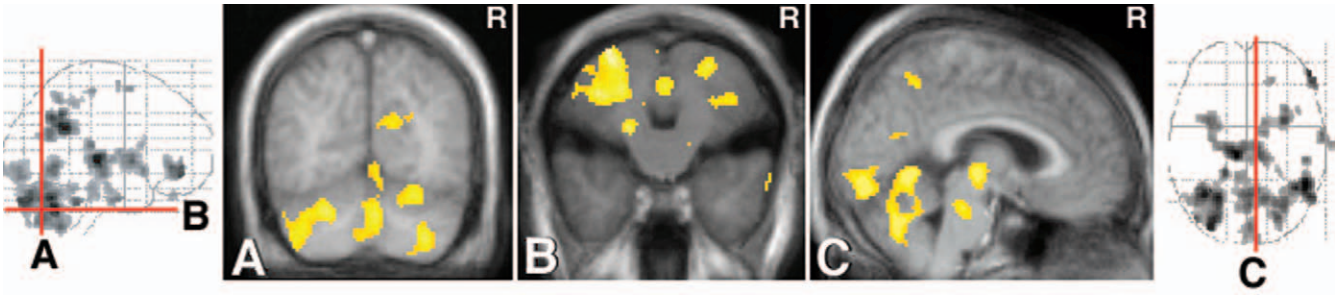

FIGURE 36.19 Frontal **(A),** horizontal **(B)** and sagittal sections show the strong activation in the cerebellum and area 18 of the cortex (A and C). Note in C also the activation in the mesodiencephalic region and the medial pontine tegmentum. The red lines on the glass brains (SPM's) indicate how the sections were made. The activations (ejaculation minus stimulation, p < .01, corrected for multiple comparisons) are superimposed on the average T1 weighted MRI of the subjects.

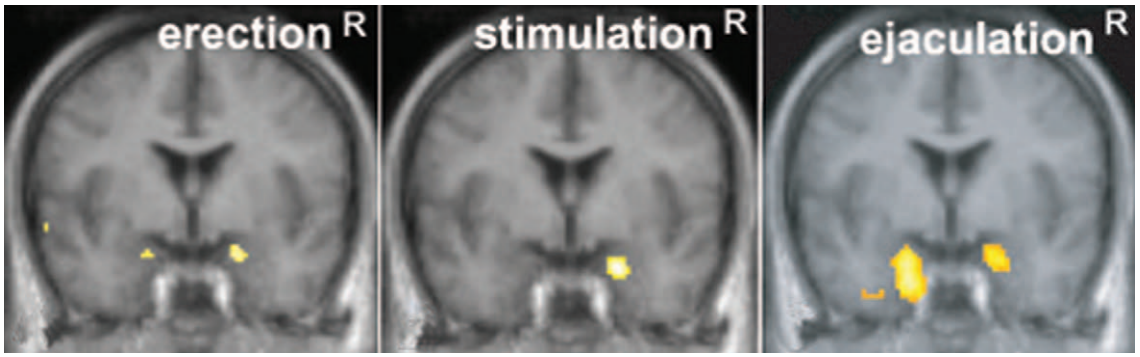

FIGURE 36.20 PET-scan results showing significant amygdala deactivations ($p < .001$, uncorrected; extent: 8 voxels), during erection *(left)*, during sexual stimulation *(middle)*, and during ejaculation *(right)*, all compared with a rest condition. The results were superimposed on the volunteers' averaged MRI. After small volume correction (height: $p < .05$), all amygdala deactivations survived multiple comparisons correction.

of species survival because reproduction is more likely to succeed.

Pathways Involved in Micturition

Micturition is the process of emptying the bladder when it is full. Because during micturition the individual is relatively vulnerable, it needs a "safe" surrounding. Thus, the micturition control centers in the central nervous system need information not only about bladder filling but also about the safety of the environment. They receive afferents concerning bladder filling via the lumbosacral cord and information concerning the safety of the individual from various limbic system regions.

Micturition itself is a coordinated action between the urinary bladder and the external urethral sphincter muscle, which takes part in the pelvic floor.

Pelvic Floor Motoneurons

The external urethral sphincter muscle and the external anal sphincter belong to the pelvic floor, all muscles of which are innervated by the pudendal nerve. In cat, dog, rhesus monkey, and humans, the motoneurons of the pelvic floor muscle are located in the so-called nucleus of Onuf, after Onufrowicz (1899). Onuf's nucleus is located on the ventrolateral border of the ventral horn in the sacral segments S1-S3. In the cat, the external urethral sphincter muscle motoneurons are located in the ventrolateral and the external anal sphincter motoneurons in the dorsomedial part.

Onuf nucleus motoneurons occupy a separate position between somatic and autonomic motoneurons. Arguments in favor of the Onuf motoneurons being somatic are that they (1) innervate striated muscles and (2) are under voluntary control. Arguments that favor Onuf's nucleus containing autonomic motoneurons are that (1) cytoarchitectonically they resemble autonomic motoneurons; (2) they have an intimate relationship with sacral parasympathetic motoneurons; (3) unlike all other somatic motoneurons, but similar to autonomic motoneurons, they receive direct hypothalamic afferents; (4) their neuropeptide and transmitter input resemble that of the sacral autonomic neurons; (5) together with the sacral autonomic (parasympathetic) motoneurons they are well preserved in the spinal cord of patients who have died from amyotrophic lateral sclerosis (ALS) and poliovirus infection, which explains why bladder and sphincter function remain intact until the last stages of ALS; and (6) they are affected in the Shy-Drager syndrome, which is characterized by loss of autonomic motoneurons. The conclusion must be that Onuf motoneurons represent a separate class of motoneurons (see Blok and Holstege, 1998 for review; see Chapter 6).

Bladder Motoneurons

The detrusor muscle of the bladder is a smooth muscle innervated by parasympathetic and sympathetic motoneurons. The parasympathetic postganglionic bladder motoneurons are located in the bladder wall. The parasympathetic preganglionic motoneurons lie in the intermediolateral cell column of the sacral spinal cord, and their axons reach the bladder via the pelvic nerve.

The sympathetic preganglionic motoneurons of the bladder are located in the intermediolateral cell group of the thoracolumbar cord (in the rat T11-L2). They send their axons to the sympathetic postganglionic cells in the sympathetic chain T12-L6, the inferior mesenteric ganglia and the major pelvic ganglia. Sympathetic postganglionic fibers run via the pelvic and hypogastric nerves to the bladder.

Micturition

More than 75 years ago, Barrington (1925) showed that normal micturition in adult cats depends on an intact spinal cord. He also showed that the dorsal tegmentum of the pons is crucial for the coordination of bladder contraction and sphincter relaxation during micturition. That is also the case in humans because patients with a transection of the spinal cord have great difficulty in emptying the bladder. When their detrusor muscle of the bladder contracts, the sphincter contracts also, which results in a so-called dyssynergic micturition.

Later physiological and anatomical work has demonstrated that the M-(medial)region or pontine micturition center or Barrington's nucleus has direct excitatory connections with the parasympathetic bladder motoneurons. Moreover, this same cell group, and possibly the same cells, has similar direct excitatory projections to the GABA-ergic and glycinergic neurons in the intermediomedial sacral cell group, which cells, in turn, inhibit the motoneurons in Onuf's nucleus. This way the pontine micturition center excites the bladder motoneurons leading to bladder contraction and at the same time inhibits the bladder sphincter allowing the urine to pass the urethra (Fig. 36.21).

As pointed out earlier, micturition is under strong emotional control, which explains why the afferent sources to the pontine micturition center originate from limbic regions (i.e., the PAG; Blok and Holstege, 1994; Taniguchi *et. al.*, 2002, and the preoptic region, Holstege, 1987). Neuroimaging studies in men and women (Blok *et. al.*, 1997, Blok and Holstege, 1998) suggest that the previously described system, based on cat experiments, is also present in humans (Fig. 36.22).

With respect to the basic scheme (Fig. 36.2), the descending projections from the pontine micturition center to the sacral cord belong to the basic motor system, and the afferent projections to the pontine micturition center belong to the lateral component of the emotional motor system.

Continence

During storage of urine, the detrusor muscle is relaxed and the external urethral sphincter muscle is activated. Because sympathetic fibers have an indirect inhibitory effect on the detrusor muscle and an excitatory effect on the smooth musculature of the urethra and base of the bladder, they are thought to promote continence during the storage phase. In fact, there exists a specific projection from the lateral pontine tegmentum, the so-called L= (lateral)-region, to Onuf's nucleus, which might also play a role in continence. This idea is corroborated by the finding that neuroimaging studies in men and women have revealed hyperactivity in the lateral pons when the

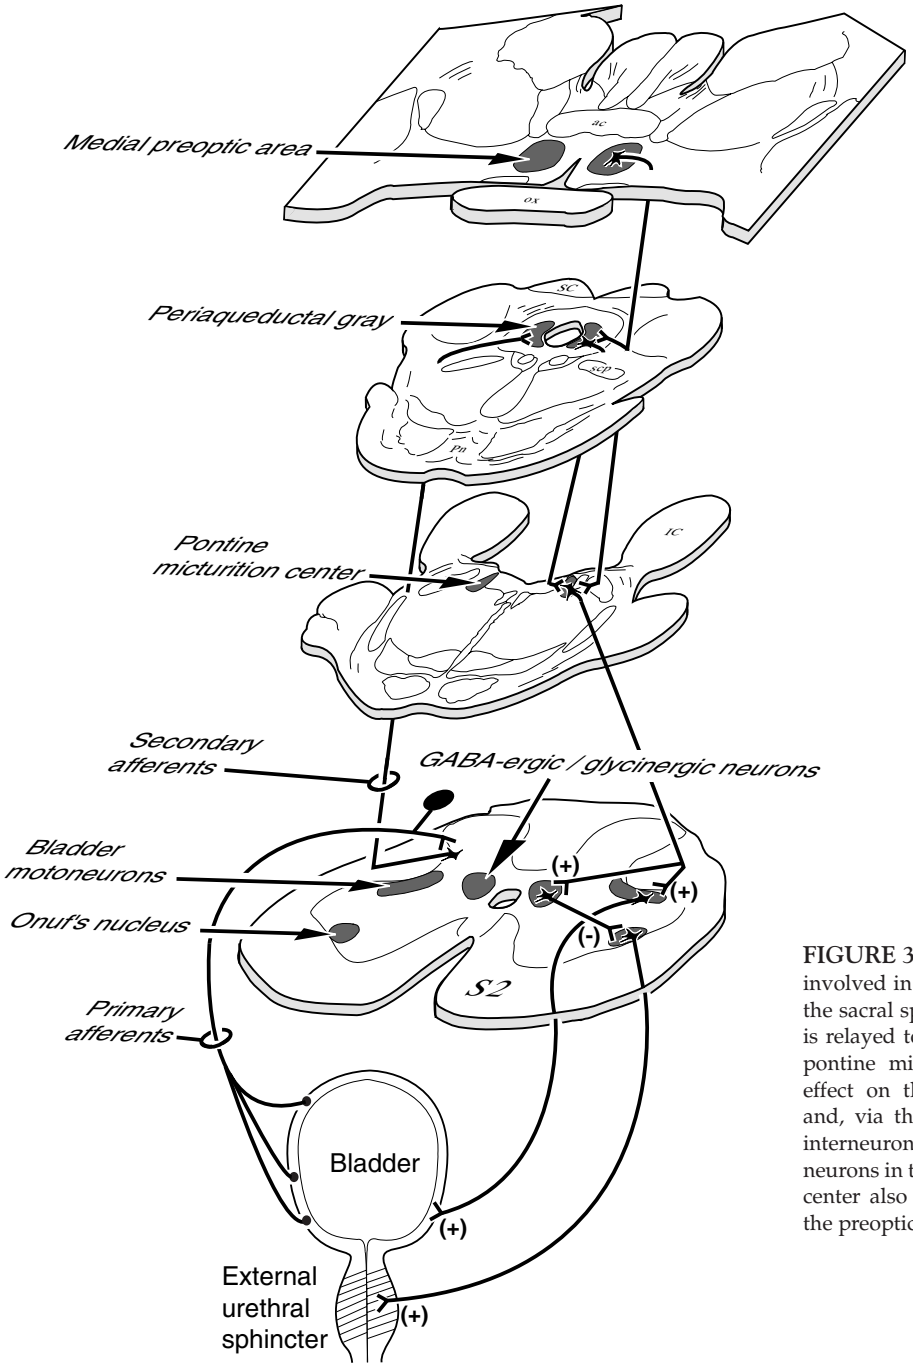

FIGURE 36.21 Schematic overview of the pathways involved in micturition control. Bladder afferents enter the sacral spinal cord, from where bladder information is relayed to the PAG. The PAG in turn projects to the pontine micturition center, which has an excitatory effect on the parasympathetic bladder motoneurons and, via the sacral GABA- and glycinergic premotor interneurons, an inhibitory effect on the sphincter motoneurons in the nucleus of Onuf. The pontine micturition center also receives specific afferent connections from the preoptic region.

volunteers involuntarily kept their pelvic floor strongly contracted for emotional reasons, (Blok and Holstege, 1997; Fig. 36.23).

The Emotional Motor System and the Cortex

Although the motor and premotor cortex with their descending projections are the best examples of the somatic motor system, it would be a misunderstanding that no part of the emotional motor system originates from the cortex. The prefrontal cortex contains many regions that have direct access to the PAG, caudal brainstem, and even spinal cord. Another cerebral cortex part that might play a role is the cingulate gyrus, which receives strong afferent connections from many parts of the limbic system, (Chapter 24). Its rostral part may play an important role in micturition control (Fig. 36.24), and its caudal part, in the emotional motor control of the face. Morecraft *et. al.* (2001) have demonstrated in monkey that the caudal cingulate gyrus, which they call the M4 (fourth motor) region, projects directly to motoneurons, especially those of the upper mouth muscles. Although this projection is

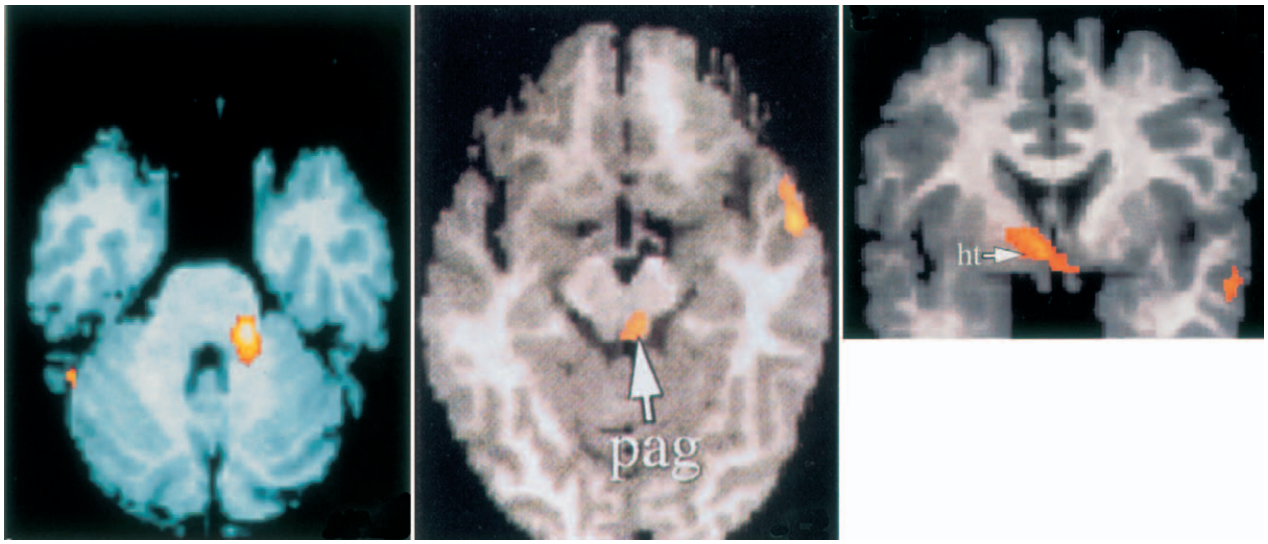

FIGURE 36.22 PET-scan results showing regions with significantly higher regional cerebral blood flow (rCBF; $p < .002$) comparing successful micturition with withholding of urine. Note the activation in the area of the pontine micturition center on the left, in the PAG in the middle, and in the hypothalamus on the right (see further Blok *et al.*, 1997).

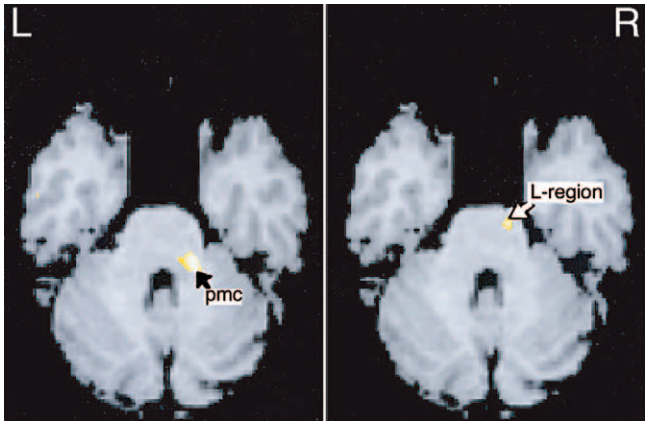

FIGURE 36.23 *Left:* PET-scan results showing significant differences in rCBF in the region of the pontine micturition center comparing successful micturition with withholding of urine. *Right:* Significant differences in rCBF in the region of the so-called L-region comparing unsuccessful micturition with with an empty bladder (uncorrected threshold of p < .002).

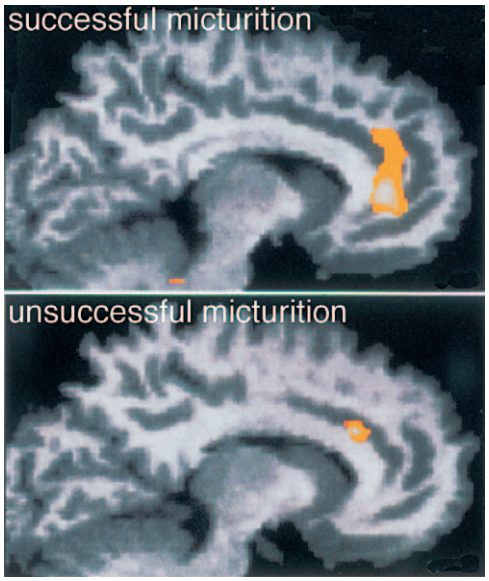

FIGURE 36.24 *Top:* PET-scan results showing significant differences in regional cerebral blood flow in the anterior cingulate gyrus, comparing sucessful micturition with voluntary withholding of urine. *Bottom:* PET-scan results comparing unsuccessful micturition with voluntary withholding of urine (uncorrected threshold $p < .001$). Note that a diiferent part of the cingulate gyrus is active during both activities.

much weaker than the projections originating in the motor and premotor cortex, it might play a role in the face movements of emotional expression (Fig. 36.1).

CONCLUDING REMARKS

The idea of the existence of an emotional motor system is primarily based on anatomical organization. The pathways of the somatic and emotional motor system are always separate until their termination on premotor interneurons or motoneurons. Also the function of the pathways is different. The emotional motor pathways play a role in basic survival behavior. The somatic or voluntary motor system, and especially its cortical parts, start operating only after a relatively long time of processing environmental data, combined with information from the extensive (visual, auditory, motor, sensory, and emotional) memory banks in the

various regions around the primary cortices. It is not so that the two components of the motor system exclude each other. Usually, they are active at the same time, and sometimes even within the framework of the same motor activity (e.g., human speech).

The behavioral differences between animals and humans are not located in the emotional, but in the somatic motor system, which, as pointed out earlier, is nothing more than a tool of the emotional or limbic system to fulfill its needs. In that respect, humans differ only slightly from other animals.

Cerebral Vascular System

OSCAR U. SCREMIN
Department of Veterans Affairs
Greater Los Angeles Healthcare System
Los Angeles, California, USA

Cerebral blood vessels were central to the ancient ideas of brain function embodied in the dogmas of antiquity. The rete mirabilis, an intricate system of branching arteries, usually intermingled with veins or sinuses, so delicate that in the words of Galen "no threads produced by the hand of man can compare with them in delicacy of composition or density of network" (Clarke and O'Malley, 1968) was one of the sites where in his conception the "vital spirits," in the blood transformed into the "animals spirits" which were the mediators of all movement and sensation. We recognize today that circulation of blood through the brain is needed for "all movement and sensation" not because it carries the "vital spirits" but the brain energy substrates instead. The "transformation" does not occur in the rete mirabilis, which exists in birds, cats, sheep, calf, and swine, although not in primates (Daniel *et al.*, 1953; Baker, 1982), but in the cerebral tissue itself. After all, brain function can proceed only for a few seconds after the flow of blood has been interrupted (Rossen *et al.*, 1943). The capillary network is that sector of the cerebral vasculature where those energy substrates are transferred and where blood flow materializes control of the neuronal microenvironment. The capillary network was only discovered in 1661 by Marcello Malpighi of Bologna (Young, 1929). It is interesting to note that the contemporary imaging techniques that have revolutionized the study of brain function are mostly based on blood flow–related variables. If Galen were to be resurrected almost two millenia later, although ignoring the details, he would not be a bit surprised.

The brain vascular system is both unique and heterogenous in terms of structure, microvascular organization, and function. Cerebral capillary abundance ranges from 260 mm/mm^3 (average of cerebrum white matter) to 2000 mm/mm^3 in the paraventricular and supraoptic nuclei of the hypothalamus (Zeman and Innes, 1963). In addition to these quantitative differences, which reflect variations in metabolic rate as well as the existence of specialized endocrine secretory mechanisms, there are also wide variations in capillary structure. Most vessels in the nervous system possess endothelial cell tight junctions that provide a seal and prevent or considerably hinder the passage of water-soluble molecules unless they interact with specialized

transport systems (Davson *et al.*, 1987). This phenomenon was first recognized in 1885 by Paul Ehrlich, who observed that coerulein sulphite, an acidic dye, stained all organs except the brain when injected systemically (Ehrlich, 1885). Capillaries in certain areas, however, are considerably more permeable and thus create microenvironments within brain tissue where many more blood constituents are accessible to nerve cells (Pardridge, 1988; Davson *et al.*, 1987; Gross *et al.*, 1986).

Another unique aspect of the brain circulation is the absence of a lymphatic system as known in most other organs. Although materials deposited in brain tissue or subarachnoid space can be recovered in the lymph nodes, this phenomenon is believed to be the result of transfer from cerebrospinal fluid to extracranial extracellular fluid through the cribriform plate and the spaces around the trunks of the emerging cranial and spinal nerves (Davson *et al.*, 1987).

In primates, as in all placental mammals, cerebral arteries and veins almost never run in pairs, even though they connect through a complex network of capillaries. In the brains of marsupials in contrast, arteries and veins meet at the surface of the brain, penetrate the brain tissue together, and remain paired throughout to the end of the terminal loop of capillaries (Wislocki and Campbell, 1937; Scharrer, 1962). Another important characteristic of the human cerebral vascular system, shared by most species, is the lack of direct communications between arteries and veins (arteriovenous anastomoses or A-V shunts).

For many years it was believed that the microvascular organization of the brain was dominated by terminal (nonanastomosing) arteries, an idea pioneered by Conheim who, based on the discrete distribution of infarcts after embolic occlusion of single vessels, coined the term "end arteries" (Conheim, 1872). It was not until the detailed anatomical work of Pfeiffer (1928) that the concept of brain blood vessels integrating into an almost uninterrupted vascular network was established. In addition, the existence of numerous interarterial and intervenous anastomoses create considerable redundancy and make it almost impossible to produce complete localized cessation of blood flow in the brain by selective occlusion of single blood vessels. However, occlusion of a single artery may produce a distinct area of necrosis when the perfusion pressure in its territory of distribution drops below the level required to maintain blood flow above a critical threshold of tissue viability. The existence of a continuous vascular network also explains the decrease of blood flow in areas surrounding an infarct, termed the "ischemic penumbra." and provides the basis for therapeutic interventions aimed at enhancing perfusion by collateral circulation in this zone.

ANATOMY OF CEREBRAL BLOOD VESSELS

Arteries

Extracranial Origins

Four arteries supply almost exclusively the brain: two internal carotids (ictd) and two vertebrals (vert). The contributions of blood flow to the brain of these systems in the adult human brain is approximately three fourths of the total for the carotids, and one fourth for the vertebrals (Scheel *et al.*, 2000). These vessels originate from branches stemming out of the aortic arch (ao). Phylogenetically, six branchial arches are recognized, of which in mammals the fourth gives origin to the aortic arch on the left and the subclavian artery (sbcl) on the right. The third branchial arch and the remnants of the primitive dorsal aorta originate the internal carotid, while the remnants of the primitive ventral aorta turn into the external carotid artery (ectd). A brachiocephalic trunk (bcph) originates from the convexity of the aorta and gives origin to the right subclavian and right common carotid artery (cctd). On the left side, the common carotid and subclavian arteries originate separately from the aorta, to the left of the brachiocephalic trunk origin. The vertebral arteries originate from the subclavians and run dorsally and medially to reach the transverse foramen of the sixth cervical vertebra (C6). They continue rostrally within the transverse canal, formed by the superposition of the transverse foraminae of the cervical vertebrae [Mai *et al.*, 1997, from here on referred to as "Atlas" (Coronal Section 9a)]. Inside the canal, the vertebral arteries give off radicular arteries that feed into the ventral and dorsal spinal arteries (Fig. 37.13) as well as numerous branches directed to the neck musculature. After it goes through the transverse foramen of the atlas, situated laterally to that of the axis, they turn anteromedially perforating the atlantooccipital membrane and dura (Atlas Coronal Section 10a and Sagittal Section 5p).

The forebrain (telencephalon and diencephalon) receives its arterial supply from the internal carotids, which divide intracranially into the anterior (acer) and middle (mcer) cerebral arteries (Atlas Coronal Section 8a; Fig. 37.1), and the anterior choroidal artery. The hindbrain (metencephalon and myelencephalon) as well as the mesencephalon receive their arterial supply from the vertebral arteries (Fig. 37.2; Atlas Coronal Section 10a), which join to form the basilar artery (Figs. 37.2 and 37.3; Atlas Coronal Section 9a). This vessel in turn divides into the two posterior cerebral arteries (Figs. 37.2 and 37.3; Atlas Horizontal Section 8p). The carotid and the vertebrobasilar system are precariously

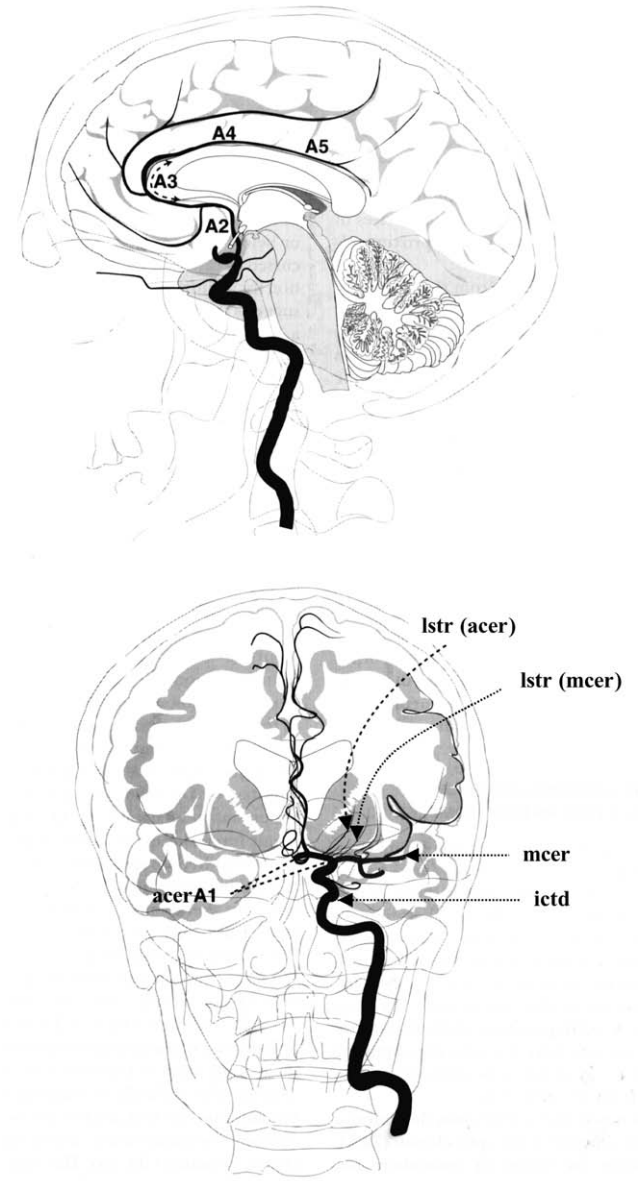

FIGURE 37.1 Segmental anatomy of the anterior cerebral artery in sagittal *(top)* and coronal *(bottom)* projections. The segments of this artery are defined thus: A1 from the internal carotid artery bifurcation to the anterior communicating, A2 to the junction of genu and rostrum of the corpus callosum, A3 around the genu, A4 to the plane of the coronal suture, and A5 from the coronal suture to the terminal branches. lstr, lenticulo striate arteries from anterior cerebral (acer) and middle cerebral (mcer); ictd, internal carotid artery. connected by a pair of posterior communicating arteries (pcoma) (Fig. 37.3; Atlas Horizontal Section 8p).

The Carotid System

The common carotid bifurcates into an external and an internal carotid at or slightly below the level of the hyoid bone, on the projection of the C3-C4 or C4-C5 vertebrae (Atlas Horizontal Section 16a). The internal carotid then courses in a cephalad direction, medial to the internal jugular vein, with the vagus nerve interposed between the two vessels (Atlas Horizontal Sections 13–15). The common carotid usually gives no branches proximal to its bifurcation, except for occasionally the superior thyroid or its laryngeal branch, the ascending pharyngeal, the inferior thyroid or, exceptionally, the vertebral artery.

The internal carotid artery lies first posterolaterally (Atlas Horizontal Sections 16a, 15p) and then medially (Atlas Horizontal Sections 13a, 14p) to the external carotid artery. It gives no significant branches on its cervical trajectory. In about 5–15% of subjects, tortuosity or kinking of this portion of the artery can be observed in angiograms (Osborn and Maack, 1980). In rare cases, this anomaly can induce occlusion of the vessel. Rarely this artery may be absent or hypoplastic. It enters the carotid canal at the base of the skull, just medial and rostral to the jugular foramen (Atlas Horizontal Section 11a). Inside the petrous bone it may give off two small branches—the vidian and the caroticotympanic arteries. Two intracavernous branches of the internal carotid artery deserve mention: the meningohypophyseal trunk, supplying the tentorium, the meninges, and the pituitary gland, and the artery of

the inferior cavernous sinus, which anastomoses with the external carotid artery territory via a branch traversing the foramen rotundum. It is noteworthy that the internal carotid artery lies inside a major sinus (cavernous), which drains blood from the orbit and nasal cavities. This arrangement creates the opportunity for heat exchange between the arterial input to the brain, bringing warm blood from the body core, and the cooler venous output from the nasal cavities, which are normally cooled by evaporation of water induced by the respiratory air stream. In animals with a carotid rete mirabilis, in which the exchange surface between arterial and venous components of this structure is quite extensive, this phenomenon affords protection of the brain from hyperthermia during exercise (Baker, 1982). Whether the same protective mechanism exists in humans, in which the rete is absent and the exchange surfaces are consequently limited, is a matter of controversy (Cabanac, 1986; Deklunder *et al.*, 1991).

After the internal carotid artery exits the cavernous sinus, it gives off the ophthalmic artery (oph), which provides the main arterial supply to the eye and the orbital contents. The oph anastomoses extensively with the territory of the external carotid artery and is a potential source of collateral circulation to the brain in cases of occlusion of the internal carotid artery below the origin of the oph. In fact, studies with transcranial Doppler sonography (TCD) indicate that when the internal carotid artery is occluded, the blood flow direction in the oph reverses (Rutgers *et al.*, 2000), providing the intracranial structures with blood from the external carotid artery. A recent evaluation using TCD and near infrared spectroscopy to measure regional cerebral oxygen saturation concluded that the external carotid artery contributes significantly to intracranial circulation in cases of severe internal carotid artery stenosis (Fearn *et al.*, 2000)

In the early stages of human development (35 day, 12–14 mm embryo), the internal carotid artery divides intracranially into four vessels: anterior, middle, and posterior cerebral (pcer), and anterior choroidal (ach) arteries (Kaplan and Ford, 1966) (Fig. 37.4). The posterior cerebral arteries anastomose caudally with the two terminal branches of the basilar artery, which supply the ventral mesencephalon, and continue beyond that point to supply the dorsal mesencephalon and caudal portion of the diencephalon. As the telencephalon develops, the posterior cerebral artery also supplies its caudal portion. Up until birth, the entire territory of the posterior cerebral artery appears to be supplied from the internal carotid artery. At later stages, however, the proximal portion of the artery (which is named posterior communicating artery in the adult) thins out, and the two terminal branches of the basilar (named the P1 or precommunicating segments of the posterior cerebral artery in the adult) take over the supply of the distal posterior cerebral artery (named the postcommunicating or P2 and P3 portions of the posterior cerebral artery). Thus in the most common adult configuration, the vertebrobasilar system supplies the mesencephalon and caudal forebrain via the posterior cerebral artery. In some cases, however, these brain areas are supplied by the internal carotid artery in the adult, when the fetal configuration persists, and the pcoma, P2, and P3 portions of the posterior cerebral artery appear as a single vessel of uniform size, while the posterior cerebral artery P1 segments become hypoplastic. This anomaly is called the "fetal" variant of the posterior cerebral artery (Padget, 1944).

Between the origin of the oph and the emergence of the pcoma, the internal carotid emits a number of small vessels that supply the anterior portion of the infundibulum, and the superior and inferior hypophyseal arteries that form an anastomotic circle with their symmetrical vessels to supply the infundibulum, pituitary stalk, and neurohypohysis (see Chapter 19). The hypophyseal arteries could also originate from the anterior portion of the pcoma.

The anterior cerebral artery is one of the terminal branches of the internal carotid artery. It courses rostromedially, dorsal to the optic nerve (Atlas Coronal Section 8a), to reach the interhemispheric fissure (Atlas Horizontal Section 8a, and Coronal Section 7a). At the midline, it anastomoses with its contralateral homonymous vessel through the anterior communicating artery (acom) (Fig. 37.3). Numerous variations in the shape and magnitude of this anastomosis have been described, including absence, duplication, and triplication of the acom. Along its precommunicating segment (A1), the anterior cerebral artery supplies perforator branches to the septal nuclei, the anterior portion of the hypothalamus, including the supraoptic nuclei, and the anterior portion of the striatum (lenticulostriate arteries, lstr) (Fig. 37.1). The recurrent artery of Heubner originates from the acer at or close to the anterior communicating artery, coursing caudally alongside the anterior cerebral artery. It provides a number of perforators just rostral to the similar branches of the middle cerebral artery, entering the lateral part of the anterior perforated substance. The terminal extra- and intraparenchymal arborizations of this vessel anastomose with branches of the middle cerebral artery and may provide collateral blood flow to the basal ganglia in cases of middle cerebral artery occlusion (Morris, 1997). Occasionally it also irrigates the orbital surface of the frontal lobe. This artery

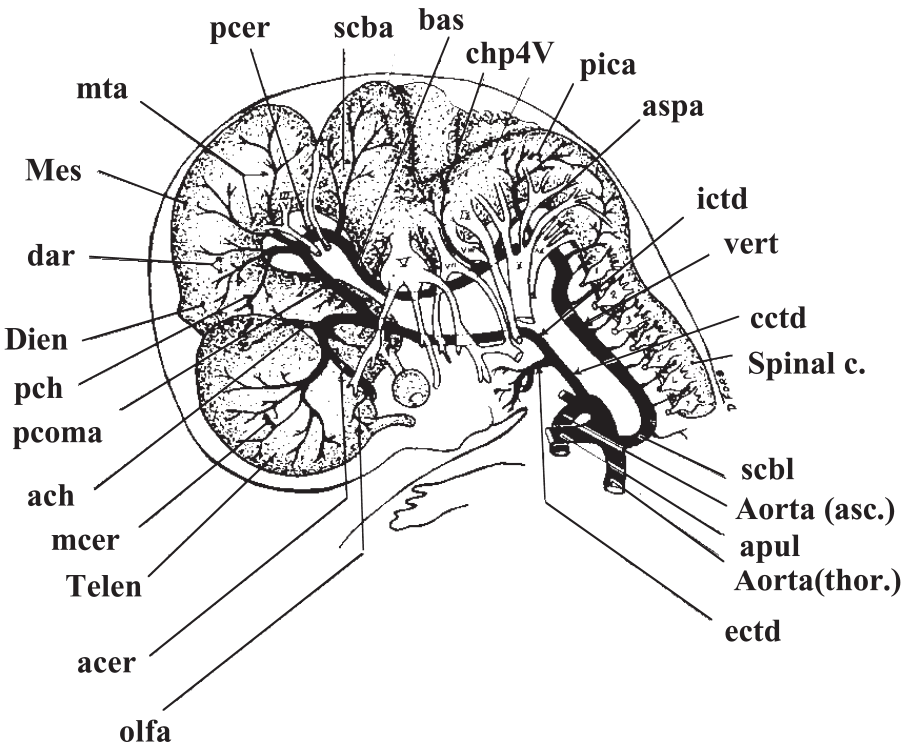

FIGURE 37.4 Continuity of the great anastomotic arch between common carotid and subclavian arteries is well established in the human embryo, shown in this semischematic representation at 35 days of age. supplies the anterior limb of the internal capsule, the anterior putamen, and reaches the inferior portion of the caudate.

The anterior cerebral artery continues rostrodorsally, curves around the genu of the corpus callosum (Atlas Coronal Section 7a), and, as the pericallosal artery, supplies the medial aspect of the frontal lobe (Fig. 37.1) through the internal frontal branches (anterior, middle, and posterior) as well as the corpus callosum, its adjacent cortex, septum pellucidum, anterior pillars of the fornix, and the anterior commissure. Its largest branch, the callosomarginal artery, courses laterally into the cingulate sulcus. The terminal portion of the anterior cerebral artery branches anastomose with the cortical and perisplenial branches of the posterior cerebral artery. These channels may become important in cases of occlusion of the anterior cerebral artery, when some of its territory may become covered by the posterior cerebral artery and viceversa (Morris, 1997).

The medial aspects of both hemispheres could be irrigated from a single anterior cerebral artery, when a pericallosal artery provides branches to the contralateral side, or even more completely when an azygos (unpaired) anterior cerebral artery is present.

The middle cerebral artery is considered the continuation, or the main terminal branch, of the internal carotid. It is a vessel of paramount functional significance since in its territory are found the cortical representations of motor, somatosensory, language, and higher cognitive functions. It also provides irrigation to most of the striatum and long ascending and descending tracts. This artery originates from the internal carotid artery just lateral to the optic chiasm (Atlas Coronal Section 8a), and then it proceeds laterally, ventral to the olfactory trigone to enter the Sylvian fissure. Along the middle cerebral artery proximal trajectory, a variable number of perforators arise from its dorsal aspect and penetrate the base of the brain through the anterior perforated substance (Fig. 37.1). Two groups of these vessels are described as medial or lateral lenticulostriate arteries depending of whether they are situated medial or lateral to a parasagittal plane passing through the olfactory tract. These lenticulostriate arteries irrigate the lateral

portion of the rostral two thirds of the caudate nucleus and putamen. The anterior medial portion of these nuclei is irrigated by the lstr arteries from the anterior cerebral and recurrent artery of Heubner (Fig. 37.1).

The middle cerebral artery divides into its cortical branches generally at the level of the limen insulae, dorsal to the temporal pole (Atlas Coronal Section 8a). This division may take place, however, anywhere between 1 and 4 cm from its origin from the internal carotid artery, and this point may be different on each hemisphere of the same brain (Kaplan and Ford, 1966). The pattern of arborization of this artery on the cortical surface consists of a bifurcation (78% of hemispheres), trifurcation (12%), or division into multiple trunks (10%) (Gibo *et al.*, 1981). Although branching of the middle cerebral artery is variable, a description of the most commonly found named vessels is given, according to Morris (1997). The anterior temporal branch irrigates the temporal pole and a variable extent of the lateral temporal lobe. It originates as part of a trifurcation of the middle cerebral artery or in a common trunk with the orbitofrontal artery that distributes over the inferior and middle frontal gyri and the orbital surface of the frontal lobe. The prefrontal and precentral arteries cover two triangular-shaped areas of the frontal lobe with vertices toward the temporal pole, situated between the frontal pole and the precentral gyrus. The rolandic arteries supply the precentral and postcentral gyri. The angular artery runs caudally over the superior temporal gyrus and reaches the occipital lobe. Between this artery and the rolandic artery are several parietal branches.

The cortical branches of the middle cerebral artery anastomose with branches of the anterior cerebral artery and posterior cerebral artery (Fig. 37.5). The region over which these anastomosis occur has been diagramatically represented as a large diameter circle. This area is considered of clinical significance because it appears to be the site of "watershed" infarctions (Zülch, 1985).

The anterior choroidal artery (ach) branches out of the posterior wall of the internal carotid artery proximal to the origin of the middle cerebral artery and anterior cerebral artery, and distal to the posterior cerebral-internal carotid anastomosis (Fig. 37.3). The first branches from this vessel supply the amygdala and the rostral hippocampus. The anterior choroidal then continues caudally giving branches that irrigate the rest of the hippocampus, optic tract, the tail of the nucleus caudatus, medial pallidum, ventral thalamus, the posterior limb of the internal capsule, and lateral geniculate. The vessel then proceeds caudolaterally giving numerous branches to the choroid plexus of the temporal horn of the lateral ventricle. The anterior choroidal artery anastomoses with branches of the anterior cerebral artery, posterior cerebral artery, and middle cerebral artery. Occlusion of the anterior choroidal artery may be associated with contralateral hemiplegia (posterior limb of the internal capsule), hemianesthesia (thalamocortical tracts), hemianopsia (lateral geniculate), and memory loss (hippocampus) (Cooper, 1954).

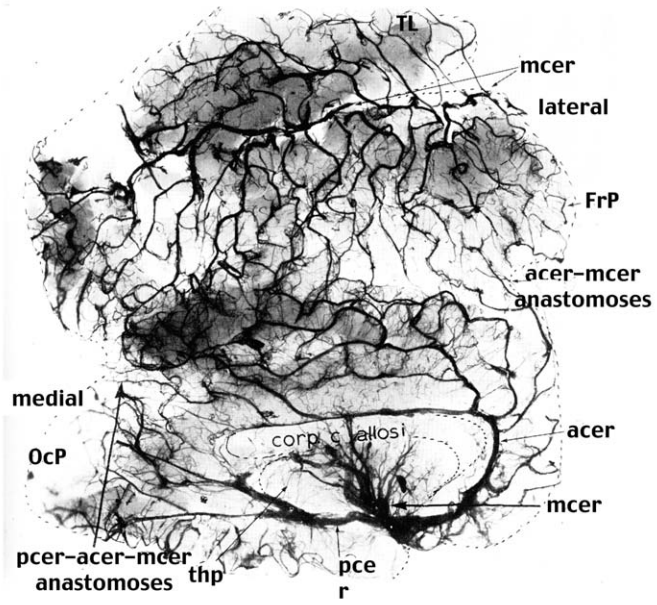

FIGURE 37.5 Postmortem angiogram in which the entire cerebral cortex has been flattened to show the multiple anastomoses between the territories of the anterior (acer), middle (mcer), and posterior (pcer) cerebral arteries. The thalamo-perforating branches (thp) are also shown. The corpus calllosum is outlined for reference. OcP, occipital pole; FrP, frontal pole; TL, temporal lobe. Vertebrobasilar System

The vertebral arteries fuse to form the basilar artery (Fig. 37.3), which starts its course over the ventral portion of the medulla, usually at or a few millimeters below the inferior border of the clivus (Atlas Horizontal Section 10p). The anterior spinal artery (aspa) originates from both vertebral arteries, close to the point where they join, or occasionally from only one of them (Fig. 37.3). The remaining medial branches of the intracranial portion of the vertebral artery supply the anterior medulla and pyramids. The lateral branches of this portion include the posterior inferior cerebellar artery (pica) and branches to the inferior cerebellar peduncle, lateral medulla, and the inferior olive and associated structures (Fig. 37.2). The pica, which may alternatively originate from the basilar or from the extracranial

portion of the vertebral, irrigates the inferolateral cerebellar hemisphere (Fig. 37.2). The extent of the cerebellar distribution of the pica is variable and inversely related to the size of the territory covered by the anterior inferior cerebellar artery (aica), a branch of the basilar artery. Cases in which the pica originates from the internal carotid artery or branches of the external carotid artery have been described but are rare (Morris, 1997). On its course toward the cerebellum, the pica gives branches to the lower medulla and fourth ventricle. Proximal occlusion of the pica gives rise to the Wallenberg's syndrome, with homolateral cerebellar symptoms and trigeminal sensory deficits, and contralateral hemiplegia associated with deficits of pain and thermal sensations.

Blood flow in the basilar artery is laminar, as in practically all normal arteries in the body with the possible exception of the root of the aorta during the ejection phase (Fung, 1984). It is then conceivable that the streams of blood originating in both vertebral arteries may not mix along the course of the basilar. This phenomenon was first documented by McDonald using dye injections and direct observation of the exposed artery in rabbits (McDonald and Potter, 1951). It is also an observation of human intraarterial angiography (IAA) that in cases of low injection rates of contrast medium into the vertebral artery, a cerebellar artery or posterior cerebral artery contralateral to the site of injection may not fill simply because it is being perfused by nonopacified blood from the homolateral (noninjected) vertebral artery, and this should not be interpreted as a vessel occlusion (Morris, 1997). The same phenomenon has been demonstrated with selective saturation pulses on magnetic resonance angiography (MRA) (Smith and Bellon, 1995).

Numerous branches, called perforator arteries because they penetrate the substance of the brainstem, originate from the basilar artery along its course (Figs. 37.6 and 37.7). Median perforators (mper) originate from the posterior wall of the basilar and penetrate the pons and midbrain to irrigate structures adjacent to the midline, reaching the floor of the fourth ventricle. Branches destined to lateral structures, named circumflex (circ) or transverse, encircle the brainstem and penetrate its substance at variable distances from their origin. There are numerous anastomoses among the finer intraparenchymal branches of these vessels, although their distribution remains essentially unilateral.

The aica originates from the basilar as a single vessel or as several smaller twigs (Fig. 37.2). It courses caudolaterally and provides several perforators to

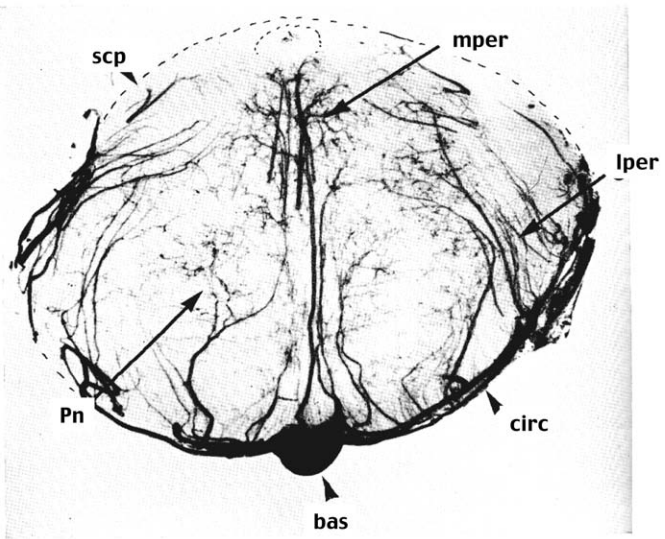

FIGURE 37.6 Angiography of the pons (rostral end) shown in a coronal section. Pn, pontine nucleus; scp, superior cerebellar peduncle. the pons before it reaches the inferior surface of the cerebellar hemisphere (Fig. 37.8). Its area of distribution, as stated previously, depends on the size of the territory of the pica. Occasionally, when the pica is absent, the aica covers the territory of both arteries (aica–pica complex). These vessels contribute to the formation of the choroid plexus of the fourth ventricle. The labyrinthine artery, which arises commonly from the aica and occasionally from the basilar, accompanies the VII and VIII nerves into the internal acoustic meatus to reach the inner ear.

The superior cerebellar artery (scba) arises at or just caudal to the rostral division of the basilar into the two posterior cerebral arteries (Fig. 37.2). A large perforator arises from this artery at its origin or sometimes from the basilar, and a number of smaller perforators originate from the superior cerebellar artery and distribute to the pontine lateral tegmental region. There are usually three cerebellar branches of the scba: the medial, distributing mostly over the vermis, and the intermediate and lateral, over the cerebellar hemispheres (Fig. 37.8). There are numerous anastomoses on the surface of the cerebellum between branches of these vessels and those of the interfolial arteries that originate from them and course between the cerebellar folia (Fig. 37.8).

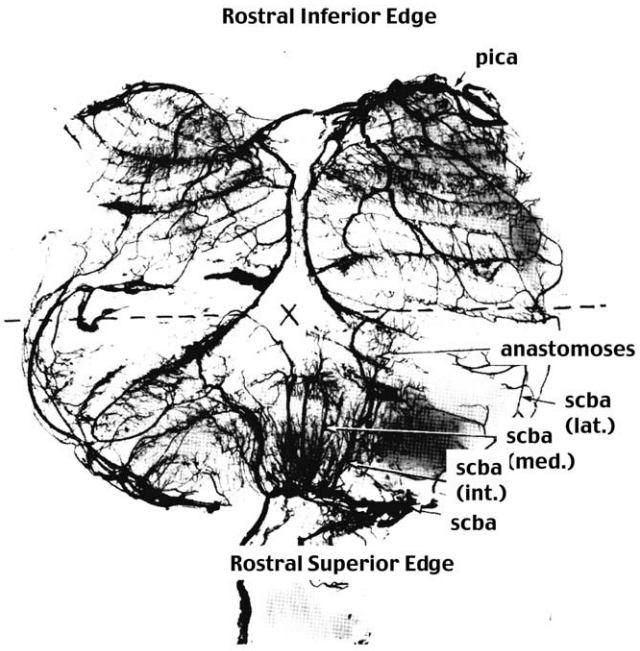

FIGURE 37.8 Postmortem angiogram in which the entire cerebellar cortex has been flattened to show the multiple anastomoses between the territories of the superior cerebellar (scba) and the posterior inferior cerebellar (pica) arteries. The lateral (lat.), intermediate (int.), and medial (med.) branches of the scba are shown. The rostral inferior edge of the cerebellum is at the top and the rostral superior edge at the bottom of the figure. The line labeled "X" represents the most caudal edge of the cerebellar cortex. From Kaplan and Ford (1966), *The brain vascular system*, Elsevier, Amsterdam, by permission of the author.

The basilar artery terminates dividing into two posterior cerebral arteries, which connect with the posterior communicating arteries (pcoma) (Fig. 37.3) and then curve around the midbrain. At this level, their position is usually superomedial to the tentorium (Atlas Coronal Section 10a), and they terminate in a number of cortical vessels over the calcarine fissure. In cases of supratentorial mass–occupying lesions or herniation of the temporal lobe, the brainstem may be compressed against the tentorium with the posterior cerebral artery or some of its branches becoming occluded or stretched resulting in severe ischemia and/or hemorrhage. Depending on the branching pattern of the posterior cerebral artery, the main trunk of the artery (in distal division patterns) or some of the branches (in the proximal division pattern) may be affected, with variable functional consequences (Ono *et al.*, 1984).

Three segments are commonly described in the posterior cerebral artery: P1 from its origin until the anastomosis with the posterior communicating, P2 from the end of P1 to the back of the midbrain, and P3 as the segment running through the lateral portion of the quadrigeminal cistern (Morris, 1997). A large number of perforating vessels arise from the P1 segment and are directed toward the peduncle and brainstem (peduncular perforating branches) and superiorly to irrigate the thalamus (thalamoperforator arteries), (see Chapter 20). Peduncular perforating branches also originate from the P2 segment. There are also circumflex branches that run parallel to the posterior cerebral artery before penetrating the thalamus or mesencephalon. The medial posterior choroidal artery (Fig. 37.2) originates from the P2 segment and courses around the brainstem giving off branches contributing to the irrigation of the midbrain, tectal plate, pineal gland, posterior thalamus, habenula, and medial geniculate body (Morris, 1997). It also supplies the homolateral choroid plexus of the third ventricle. Lateral to the medial posterior choroidal artery originate a number of lateral posterior choroidal arteries, up to nine per side. These vessels supply parts of the midbrain crus, the pineal body, splenium, posterior commissure, tail of the caudate nucleus, thalamus, and fornix. They enter the lateral ventricle where they supply the choroid plexus and then enter the foramen of Monro to anastomose with the medial posterior choroidal arteries (Morris, 1997).

The cortical branches of the posterior cerebral artery are the more distal to the origin of this artery and

distribute to the inferior and medial surface of the temporal lobe (anterior and posterior temporal branches) and to the medial aspect of the occipital lobe and posterior parietal lobe (calcarine and parietooccipital branches). Arteries at the edge of the posterior cerebral artery territory anastomose with the terminal arborizations of the middle cerebral and anterior cerebral arteries (Fig. 37.5). The overlapping of these territories is believed to establish efficient collateral circulation in cases of occlusion of the posterior cerebral artery, preventing extensive infarction and producing a spare of the macular territory (Strong and Elwyn, 1953).

The Arterial Circle

One of the notable characteristics of cerebrovascular anatomy is the abundance of anastomoses between large arteries, extracranially (angular to ophthalmic arteries) and intracranially (the arterial circle at the base of the brain) as well as between small arteries on the surface of the brain (the leptomeningeal plexus) (Fig. 37.9). Knowledge of these features dates back to Gabriel Fallopius (1523–1562) a disciple of Vesalius, who appears to be the first anatomist to mention the existence of an anastomotic circle of arteries at the base of the brain. The first illustration of this anatomical feature was provided by Guilio Casserio (1545–1605), one of William Harvey's professors at Padua (Fig. 37.3, top left) (Casserio, 1632). Interestingly enough this is an incomplete circle with one of the posterior communicating arteries either absent or considerably hypoplastic. Anomalies of this communicating vessel are known today to be present in approximately 40% of cases (Riggs and Rupp, 1963). Johan Vesling (1595–1649), from the School of Padua, and the Swiss anatomist Johan Wepfer (1620–1695) also described the arterial circle (Clarke and O'Malley, 1968). Thomas Willis, Sedleian Professor of Natural Philosophy at Oxford, was also aware of this feature and asked his friend Christopher Wren, the architect of Canterbury Cathedral, to illustrate the arterial circle which he did masterfully (Willis, 1664). The image is somewhat idealized (Fig. 37.3, top right) because all vessels appear symmetrical and with almost the same diameter, a condition that is indeed rare in the adult human brain. However, the name of Willis remains attached to this anatomical circle on account of his insight into its possible function. After observing autopsy material with a completely occluded carotid artery in patients with no symptoms, he reasoned that the circle served to provide collateral circulation from other supplying arteries. Willis also performed animal experiments such as the ligation of both carotid arteries in a dog. In the words of his assistant Richard Lower, "the animal was not altered … [such] that within a quarter of an hour after, he got loose and followed the doctor [Willis] into town, as he visited his patients" (Tower, 1991). However the success of this experiment probably related more to the notorious abundance of anastomoses among intra- and extracranial vessels in dogs (Sagawa and Guyton, 1961) and in particular to the existence of the anastomotic artery, a large vessel communicating the external carotid artery and the arterial circle in this animal.

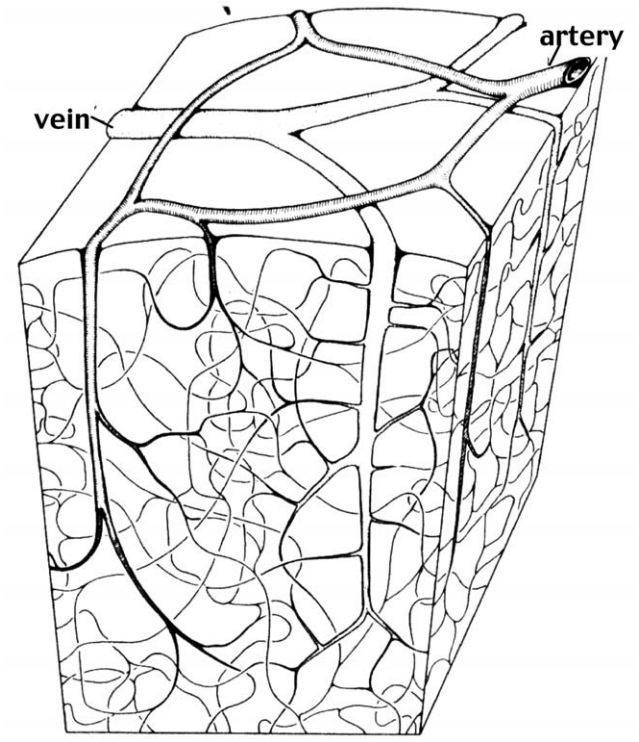

FIGURE 37.9 Schematic three-dimensional representation of the cerebral cortex vascular architecture. Arteries and veins run at a distance and connect at all levels through capillary loops inside the cortex. Small arterial circles join the cortical arteries and give origin to multiple perforators. From Scharrer, E. (1940). Arteries and veins in the mammalian brain. Anat. Rec. 78, 173–196. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

Understanding of the considerable amount of variability in the arterial circle composition was gained through exhaustive anatomical studies. The importance of these anomalies goes beyond the mere academic interest because they are very frequent (50–80% of cases depending on the authors), and they are associated with an increased risk of stroke (Hedera *et al.*, 1998; Schomer *et al.*, 1994). In 1947, Padget (1944) summarized the findings of a large number of anatomical specimens reported in the literature at the time. Starting with a "typical" circle with the anterior communicating as half to two thirds the size of the anterior cerebral, in turn half the size of the internal carotid, and the pcoma with half the size of the posterior cerebral, in turn

half the size of the basilar, agreement of the posterior portion of the circle (posterior communicating and posterior cerebral arteries) with this pattern was found in less than 50% of 1033 cases. The anterior portion of the circle (anterior cerebral and anterior communicating arteries) was considered to be more dependable than the posterior one as a source of collateral circulation, although no quantitative data was presented to support this statement.

Quantitative estimates of the prevalence of circle anomalies in 994 specimens (Riggs and Rupp, 1963) indicate that a complete "typical" circle is found in only 20% of cases. Anomalies included absence or hypoplasia of the anterior communicating artery (20%), posterior communicating arteries on one or both sides (38%), and proximal anterior cerebral artery (12%). The rest of the anomalies were represented by hypoplasia of the divisional branches of the basilar artery. When the latter were added to defects in the posterior communicating arteries, 48% of specimens had the carotids supplying all or a larger than expected portion of the hemispheres, with absent or limited capacity of the posterior circulation to compensate for deficits in carotid blood flow.

A serious limitation of the anatomical studies is that although they can identify cases of anatomical compromise of collateral circulation through the arterial circle when some of its component vessels are severely hypoplastic or absent, they cannot ascertain whether a vessel of "normal" caliber would be able to sustain a significant amount of additional blood flow to compensate for stenosis or occlusion of one or more of the circle-supplying vessels. The ability of the posterior communicating artery to supply collateral blood flow, for instance, has been found to depend not only on its diameter but also on the resistance of its afferent and efferent vessels (Hillen *et al.*, 1982). These variables in turn cannot be evaluated without blood flow and blood pressure data.

IAA and MRA can provide information on direction of flow in the component vessels of the circle in addition to the anatomical information (Hoksbergen *et al.*, 2000a). However, the transcranial color-coded duplex ultrasonography technique (TCCD) can provide currently the most accurate information regarding blood velocity (although not volumetric blood flow due to lack of vessel cross-sectional area information) in the blood vessels that supply the brain. Compression of one carotid artery in the neck in a subject with an anatomically complete circle, is associated with increased blood velocity in the contralateral precommunicating segment (A1) of the anterior cerebral artery, reversal of blood flow in the homolateral A1, and increased blood velocity in the homolateral precommunicating segment (P1) of the posterior cerebral artery (Hoksbergen *et al.*, 2000b). In a series of 76 subjects without cerebrovascular symptoms, Hoksbergen *et al.* found that only 29% of them responded with blood flow changes described previously as characteristic of a complete arterial circle, and 45% of the hemispheres examined had anomalies of the posterior part of the arterial circle that impaired collateral blood flow from the basilar to the internal carotid artery (Hoksbergen *et al.*, 2000b). Within the last group, they included cases in which posterior communicating artery blood velocity decreased (revealing an internal carotid origin of flow in the vessel) or failed to increase over 20% of baseline. Cross flow through the anterior part of the circle was not found in only 5% of the subjects. The higher prevalence of functional insufficiency in the posterior versus anterior communicating arteries is in general agreement with the anatomical information given earlier.

It is important to note that in the presence of an anatomically complete arterial circle, blood velocity in the homolateral middle cerebral artery decreased between 25% and 67% during brief unilateral carotid compression. In the hemispheres with nonfunctional pcoma, this range was 27–88% (Hoksbergen *et al.*, 1999). Thus it is obvious that even in the relatively small proportion of individuals with an anatomically "typical" arterial circle, this structure cannot provide complete compensation by collateral blood flow following sudden occlusion of one of the four vessels supplying the brain. In this context, it is important to note that failure of adequate collateral blood flow compensation during sudden unilateral internal carotid occlusion, defined as a decrease of middle cerebral artery blood velocity > 40%, has been reported to be followed by hemodynamic cerebral infarction if the occlusion becomes permanent (Sorteberg *et al.*, 1999).

The question of whether the vessels in the arterial circle are capable of remodeling over time after a permanent occlusion, or perhaps in response to slowly developing stenosis of one of its supplying arteries has been answered affirmatively by the work of Coyle and co-workers (Coyle and Panzenbeck, 1990), who showed hypertrophy of the posterior cerebral artery of rats following ligation of the common carotid artery. In humans it has been demonstrated that the vessels supplying a high flow arteriovenous malformation undergo a so-called angiomatous change, which is not considered to be part of the malformation but to represent adaptive remodeling owing to high flow conditions (Morris, 1997). The modest changes in collateral blood flow that take place in the arterial circle after occlusion of one of its afferent vessels may not be sufficient to generate remodeling in humans,

however. In an MRA study, Rutgers *et al.* (2000) have followed patients with uni- or bilateral occlusion of the internal carotid over 1.5 years and found no improvement in the patterns of collateral blood flow over time.

Microvascular Anatomy

The arteries on the surface of the human brain were described in the early work of Duret and Heubner (Duret, 1874; Heubner, 1874). The last author recognized the existence of numerous interarterial anastomoses between vessels of variable caliber. This arrangement is also found in other animals and has been described in great detail by several authors (Bar, 1980; Duvernoy *et al.*, 1981; Eecken, 1959; Mchedlishvili and Kuridze, 1984).

The diagram shown in Figure 37.9, which we owe to Scharrer (1940), illustrates the existence of a network of anastomosing pial arteries (the leptomeningeal plexus) from which penetrating vessels emerge at right angles, capillarize, and drain into collecting veins that course to the pial surface widely separated from the supplying arteries. The detailed anatomy of the intervening capillary plexus is extremely complex and highly dependent on the neuronal anatomy, to the extent that observation of the blood vessel network allows sometimes to recognize the underlying neuronal substrate. A striking example is observed in Figure 37.10, where the inferior olive and corticospinal tract precise structural limits can be followed in a specimen in which only the blood vessels have been made visible.

Detailed analysis of the intracortical vascular network reveals arterioles that traverse all cortical layers with minimal or no branching to reach the deeper layers and the subcortical white matter, where they give off capillaries that orient themselves in compliance with the general trajectories of nerve fibers (Fig. 37.11, A6). Other groups of arteries give branches to subcortical and cortical levels (Fig. 37.11, A5), all cortical levels (Fig. 37.11, A4), or restricted cortical layers (Fig. 37.11, A1-A3). In most areas of the cortex, many arteries converge over a single intracortical vein that are less numerous than arteries, and of a larger caliber, with their afferent vessels joining at right angles (Fig. 37.11, V4-V5).

Vascular Territories

A large number of descriptions of the territories covered by the various cerebral arteries are available in the literature (see review by van der Zwan *et al.*, 1992). Delineations of these territories are shown in the Atlas for horizontal and coronal brain sections. It is important to recognize that these limits are quite

FIGURE 37.10 Transverse section of medulla oblongata of a specimen injected with India ink/gelatin solution and cleared with the Spalteholtz technique. Contrast is provided by the microvascular density, which is much greater for gray than for white matter structures. variable, on account of anatomical and hemodynamic factors. The line of separation between the territories of the anterior cerebral artery, middle cerebral artery, and posterior cerebral artery, for instance, depend on the hemodynamic conditions in each territory that determine the extent to which the three main supplying vessels contribute to their irrigation. Thus, proximal occlusion of the middle cerebral artery may induce the anterior cerebral artery and posterior cerebral artery territories to expand over that of the middle cerebral artery. Another condition of a shift in distribution of arterial supply may be found as described earlier with a high-flow arteriovenous malformation that would create a "sump" effect drawing blood from arteries of neighboring territories. A similar situation, generated by the increased collateral blood flow through the acer-mcer anastomoses, has been demonstrated in rats subjected to a middle cerebral artery occlusion (Coyle, 1984).

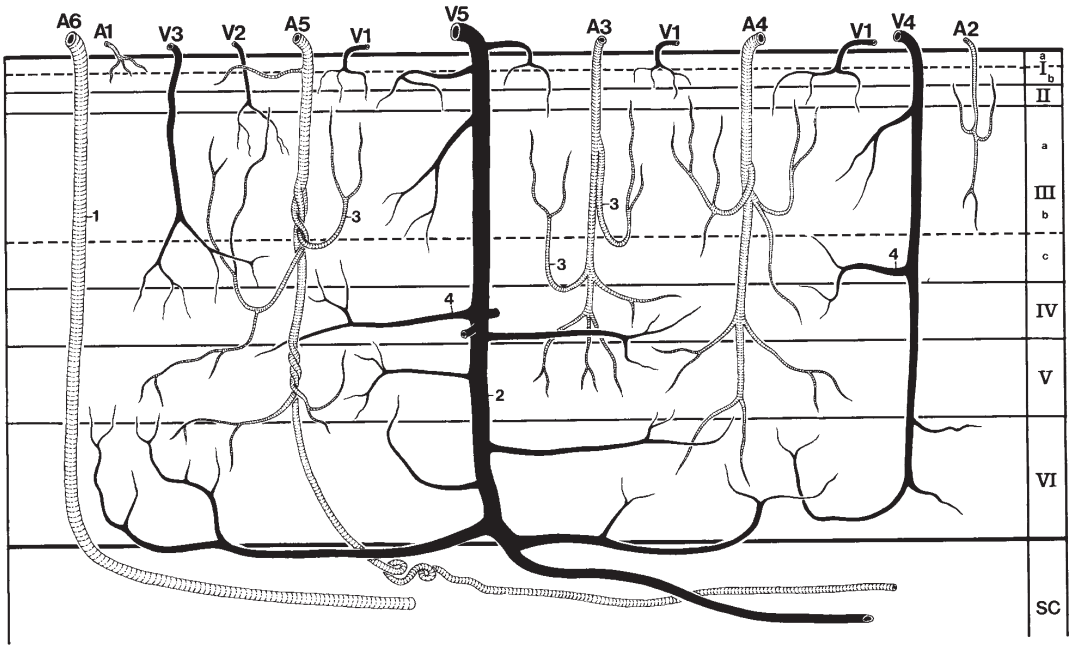

FIGURE 37.11 Schematic two-dimensional representation of the types of arteries and veins found in the human cerebral cortex. Arteries distribute to the superficial layers only (A1, A2), to layers I–V (A3), to all layers (A4, A5), or preferentially to the subjacent white matter (A6). This segmental arrangement creates the anatomical substrate for a differential control of blood flow to cortical layers. Veins (shown in solid black) are usually larger and receive afferent branches at right angles from circumscribed (V1–V3) or wide (V4, V5) distributions. I–VI, cortical layers; SC, subcortical white matter. From Duvernoy, H.M. (1999). *The Human Brain Surface, Three Dimensional Sectional Anatomy with MRI, and Blood Supply.* Springer, New York, by permission of the author and publisher.

Veins

The veins of the brain originate from an interconnecting network of superficial vessels that drain the capillary bed and usually run away from the arteries (Fig. 37.9), with the exception of marsupials and several other vertebrates in which veins and arteries run at close proximity in pairs (Wislocki and Campbell, 1937; Scharrer, 1940). These veins empty into sinuses, with walls formed by endothelium-lined recesses of the duramater, a meningeal layer with little compliance. This structural feature serves to make the volume of the cerebral venous compartment less dependent on variations in venous pressure than most other organs. These sinuses connect with the extracranial venous system of the head through "emissary" vessels. In humans, some of the more constant emissary veins can be found in the parietal (superior sagittal sinus) occipital (torcular), temporal (transverse sinus), and mastoid (transverse sinus) regions (Atlas Coronal Sections 11a, 12a). One of these emissaries, as detailed later, constitutes an important cranial venous outflow channel in most mammals, but the functional significance of emissary veins in humans remains a matter of debate (Deklunder *et al.*, 1991; Cabanac, 1986).

Two venous systems are usually considered (Strong and Elwyn, 1953): (1) an external or superficial system that drains the cerebral cortex and subcortical white matter into the superior sagittal, cavernous, petrosal, and transverse sinuses (Fig. 37.12A, B), and (2) the internal or ventricular system that drains the dorsal diencephalon, basal ganglia, and choroid plexuses into the great cerebral vein of Galen, which joins with the inferior sagittal sinus to form the straight sinus (Fig. 37.12C, D). The vein of Galen originates from the fusion of the two internal cerebral veins (icv; Atlas Coronal Section 11a), and it also receives additional tributaries including the basal vein (vein of Rosenthal), which drains extensive basal cortical areas, and the posterior callosal veins, which drain medial portions of the cortex (Fig. 37.12D). The internal cerebral veins are formed by the confluence of the posterior terminal vein, which runs between the dorsal thalamus and caudate, the anterior terminal vein, which drains the head of the caudate, and the septal and choroidal veins.

The superior sagittal and straight sinuses drain into two transverse sinuses at the torcular Herophilii (confluence of the sinuses) and from there blood flows

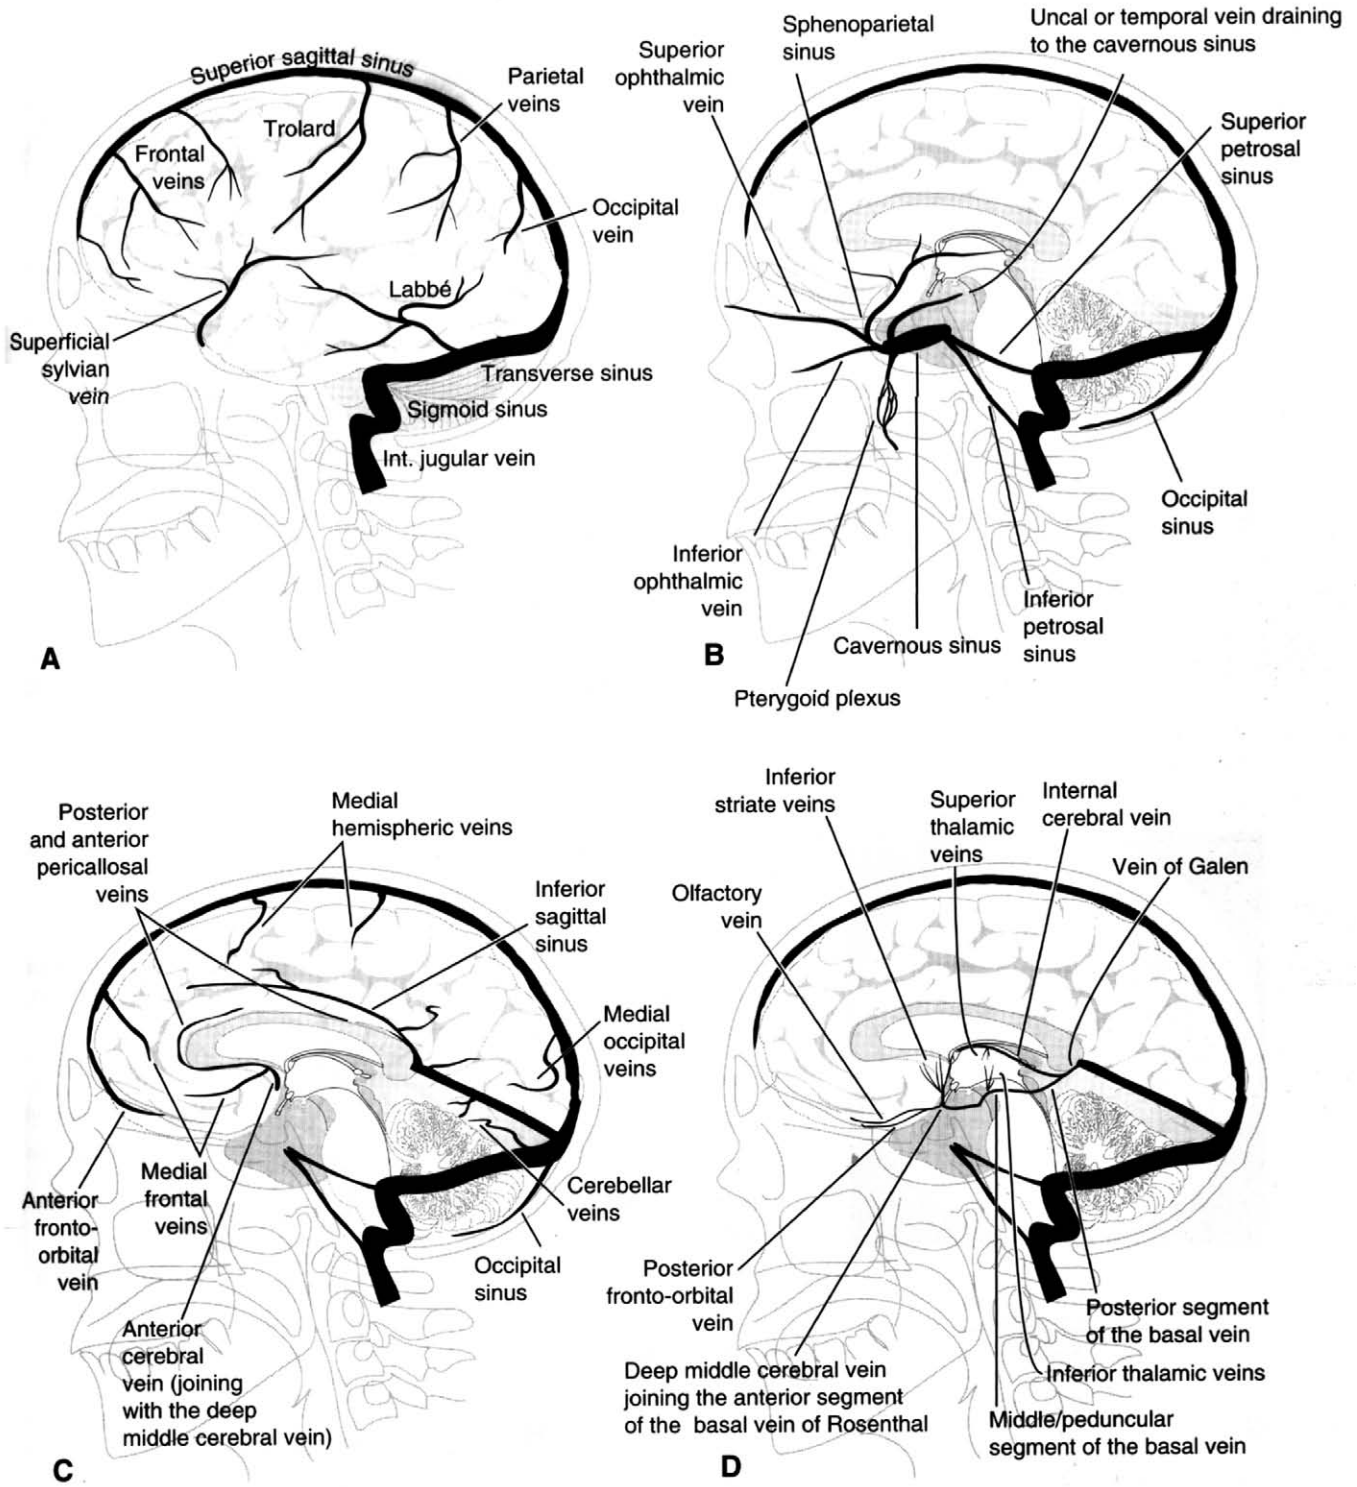

FIGURE 37.12 Anatomy of cerebral veins on a sagittal plane projection. **(A)** The superficial system is shown with the two main anastomotic channels, the veins of Labbé and Trolard and drainage toward the sagittal, transverse, and sigmoid sinuses into the internal jugular vein. **(B)** The anastomoses between the superior sagittal sinus, draining the superficial system, and the cavernous sinus through the superior and inferior petrosal sinuses are shown. The extracranial afferents to the cavernous sinus are also indicated. **(C)** Midline elements of the superficial venous system draining into the superior and inferior sagittal sinuses are shown. **(D)** Components of the deep cerebral venous system draining the diencephalon and striatum, as well as the basal vein carrying blood from the basal portion of the hemisphere into the vein of Galen are illustrated. down into the sigmoid sinus and into the internal jugular veins that exit the cranial cavity through the jugular foramen (Fig. 37.12). This is the main cerebral venous outflow in most primates including humans. In some primates (acrobatus pigmeus and rhesus), and most other mammals (with the notable exceptions of cats and pigs), the internal jugular veins share to a variable degree the venous outflow from the brain with the retroglenoid veins (also called temporal emissaries, dorsal cerebral, or superior cerebral veins; Padget, 1957), which are in essence extensions of the transverse sinuses that exit the cranial cavity through the postglenoid (also called spurious jugular) foraminae. Although blood from the internal jugular in humans and the retroglenoid vein in some well-studied experimental animals may be potentially contaminated by small amounts of blood from extracerebral territories, they constitute reliable sampling sources for the measurement of cerebral blood flow and cerebral uptake or release of gases and other molecules of interest (Kety and Schmidt, 1948; Nilsson and Siesjö, 1983; Scremin and Jenden, 1992).

The configuration of veins on the surface of the brain shows considerable variability. The general pattern observed includes 6 to 15 superior cerebral veins that collect blood from the medial and convex portions of the cortex and empty into the superior sagittal sinus (Atlas Coronal Sections 5–15). The inferior cerebral veins drain the lateral portion of the cortex and the base of the hemispheric surface into the middle cerebral vein, which runs into the Sylvian fissure to reach the cavernous (Atlas Coronal Sections 7a, 8a) or sphenoparietal sinuses. There is usually a large vein (vein of Trolard) that communicates the superior and inferior cerebral veins, establishing an anastomotic channel between the superior sagittal sinus and the middle cerebral vein and, hence, the cavernous sinus (Fig. 37.12A). Similarly, another anastomotic channel (vein of Labbé) communicates the middle cerebral vein with the transverse sinus (Fig. 37.12 A). The basal portion of the brain surface is drained by veins that empty into the transverse and superior petrosal sinuses (tentorial surface), cavernous and sphenoparietal sinuses (temporal surface), rostral portion of the superior and inferior sagittal sinuses (orbital portion), anterior cerebral vein (medial orbital cortex and hypothalamus), and the basal vein (Fig 12D), formed by the confluence of the anterior cerebral and inferior striate veins (medial portion of the temporal lobe and uncus).

The insula is drained by the deep cerebral vein, situated within the Sylvian fissure, and empties into the basal vein at the level of the anterior perforated substance (Fig. 37.12D). The ventral thalamus and hypothalamus are drained by vessels that end into the interpeduncular venous plexus and eventually into the cavernous sinus, sphenoparietal sinus, or basal vein.

The external and internal venous systems are widely interconnected through vessels running on the surface of the hemispheres, the most notable of which are the veins of Trolard and Labbé (Fig. 37.12A), providing communication between the dorsal, lateral, and basal dural sinuses, as well as through the depths of the brain through numerous collaterals joining the superior sagittal sinus and the internal cerebral vein (Fig. 37.12D) to the superficial and deep middle cerebral veins. This redundancy prevents interference with the cerebral circulation of lesions that occlude some of the important veins and sinuses of the brain, provided that the obstruction to blood flow develops gradually.

ANATOMY OF SPINAL CORD BLOOD VESSELS

Arteries

The spinal cord is supplied by three longitudinal anastomotic channels extending along its entire length: one anterior spinal artery (aspa), the largest and more important, found at the entrance of the ventral median fissure, and two posterior spinal arteries located just ventral to the entrance of the dorsal roots (Fig. 37.13). The anterior spinal artery connects rostrally with the two vertebral arteries at the level of the foramen magnum or occasionally at a lower point. The anterior and posterior spinal arteries are joined by transverse anastomoses that may take the form of a well-developed artery (transverse anastomotic circle) or an irregular anastomotic network.

The anterior and posterior spinal arteries are fed by anterior and posterior radicular arteries, respectively. There are 0–6 large (>0.2 mm in diameter) anterior radicular arteries in the cervical, 2–4 in the thoracic, and 1–2 in the lumbar region. Posterior radicular arteries are more numerous but of a smaller caliber. All roots not carrying a large radicular artery may have a small one (<0.2 mm in diameter) that supplies the root itself without reaching the anterior spinal artery (Turnbull, 1972). One anterior radicular artery, the artery of Adamkiewicz or anterior radicularis magna, is larger (1–1.3 mm) than the others (0.2–0.8 mm) and supplies the lumbar cord enlargement, entering most often on the left side with a root between T9 to T12 in 75% of the cases (Adamkiewicz, 1881, 1882; Lazorthes *et al.*, 1966). This vessel acquires importance in cases of obstruction of the aorta or aortic surgery requiring clamping of this artery. If an aortic occlusion or lesion

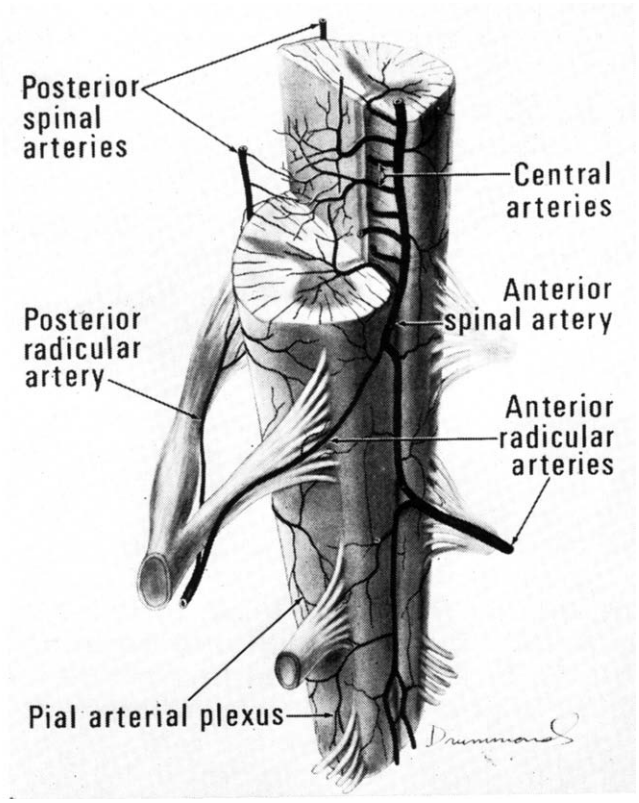

FIGURE 37.13 Arterial supply of the spinal cord. The single anterior spinal artery is shown receiving its supply from the anterior radicular arteries. Central arteries originate from the anterior spinal and distribute primarily to the ventral horns. An extensive pial plexus surrounds the cord and provides irrigation to the anterior and lateral columns. The dorsal horns and columns are supplied predominantly by the posterior spinal arteries. From Turnbull, I.M. (1971). Microvasculature of the Human Spinal Cord. *J Neurosurg* **35,** 141–147, by permission of the author and publisher.

is situated above the emergence of the anterior radicularis magna artery, blood supply of the lumbar cord may be severely compromised because collateral supply from caudal segments to the anterior spinal artery is often insufficient. The thoracic cord is particularly vulnerable to occlusion of a radicular artery leading to spinal cord ischemia because only a few, widely separated radicular arteries are found at this level.

The central (also named sulcal) arteries originate from the anterior spinal artery and run posteriorly to reach the anterior commissure after which they distribute unilaterally within the gray matter of the anterior (ventral) horns and the base of the posterior (dorsal) horns (Fig. 37.13). These vessels are part of the "centrifugal" arterial supply system. The "centripetal" system originates from the surface vessels that supply perforators that tend to converge toward the cord center.

Veins

The distribution and course of spinal veins resembles that of arteries, although they do not necessarily run in close proximity to each other. Radicular veins are more numerous and regular in distribution than their arterial counterparts described previously (Turnbull, 1972). They drain, depending on which level of the cord they are situated, into the vertebral, intercostal, lumbar, or sacral veins.

VASCULAR INNERVATION

Peripheral Autonomic Nerves

The parasympathetic outflow to the head and neck consists of preganglionic fibers from the nuclei of cranial nerves third, seventh, and ninth and postganglionic fibers from the ciliary (third), sphenopalatine (seventh), submaxillary (7th), carotid (7th), and otic (9th) ganglia, as well as from several other microscopic ganglia and scattered cells (Chorobski and Penfield, 1932; Suzuki *et al.*, 1990a, 1990b; Mitchell, 1953). All of these sources contribute nerve fibers to cerebral blood vessels or to the internal carotid plexus, a meshwork of nerve fibers that surrounds the internal carotid arteries.

The sympathetic supply to cerebral vessels originates in preganglionic fibers from neurons in the intermediolateral column of the eighth cervical and upper thoracic nerves and postganglionic fibers from the superior sympathetic ganglion emerging with its largest efferent branch, the carotid nerve which contributes to the carotid plexus (McNaughton, 1938; Falck *et al.*, 1968). Nerve fibers from the stellate ganglion can be traced to the vertebral and basilar arteries (Arbab *et al.*, 1988).

Histochemical studies have revealed that nerve fibers in cerebral blood vessels display immunoreactivity for ACh, and VIP, believed to originate from parasympathetic nerves (Hara *et al.*, 1989; Suzuki *et al.*, 1990b). Norepinephrine (NE), neuropeptide Y, (Edvinsson *et al.*, 1984) and in part 5-HT (Bonvento and Lacombe, 1993) containing fibers in cerebral blood vessels originate in sympathetic nerves.

Nerve fibers from the trigeminal nerve ophthalmic division have been known for a long time to contribute to the carotid plexus (Schumacher *et al.*, 1940; Ray and Wolff, 1940). Substance P and CGRP are found in these fibers (Norregaard and Moskowitz, 1985; Uddman *et al.*, 1985), as well as in those originating in the spinal cord (C2; Arbab *et al.*, 1986; Edvinsson *et al.*, 1989) and small ganglia within the carotid plexus (Suzuki *et al.*, 1989).

In vitro and *in vivo* studies indicate that acetylcholine (ACh), VIP, CGRP, and substance P induce vasodilatation and increase cerebral blood flow (CBF). NE and neuropeptide Y induce vasoconstriction while 5-HT induces vasoconstriction of large blood vessels and both vasodilatation or vasoconstriction in arterioles (Scremin, 1991, 1993; Tuor, 1993; Fahrenkrug, 1993a; Suzuki, 1993; Itakura and Okuno, 1993; Edvinsson *et al.*, 1993). This does not imply that those effects could physiologically be elicited by release from the peripheral innervation described earlier. In the case of the brain, at variance with most other tissues, neurotransmitter substances can originate in the parenchyma and reach blood vessels by diffusion to exert their effects. Furthermore, as reviewed below, many of the transmitters listed above are also found in nerve terminals from intracerebral pathways innervating blood vessels.

Central Pathways

It is believed that the adrenergic fibers making contact with intracerebral (as opposed to pial) microvessels originate in the locus coeruleous (Raichle *et al.*, 1975; Edvinsson *et al.*, 1973; Hartman *et al.*, 1972). Part of the 5-HT immunoreactive fibers found in cerebral blood vessels may originate from neurons in the raphe nucleus (Scheibel *et al.*, 1975; Edvinsson *et al.*, 1983; Bonvento *et al.*, 1990). Although there is morphological evidence for the existence of a central cholinergic innervation of cerebral vessels, its origin is still not clear. A number of stimulation and lesion experiments implicate the nucleus basalis as a source of at least some of the cholinergic innervation of cortical blood vessels. However, other forebrain, brainstem, and cortical sources cannot be discarded (Scremin *et al.*, 1980, 1983; Iadecola *et al.*, 1983; Biesold *et al.*, 1989; Scremin *et al.*, 1991; Dauphin *et al.*, 1991; Waite *et al.*, 1999).

MAPPING CEREBRAL FUNCTION WITH BLOOD FLOW

The existence of a correlation between functional activity of nervous tissue and blood flow had been already established at the beginning of last century by experiments showing an increase in temperature (a blood flow–dependent phenomenon) in the lateral geniculate body (Gerard, 1938) and occipital cortex (Schmidt and Hendrix, 1938) of experimental animals upon illumination of the eyes. An early description of enhancement of blood flow in the visual pathways by photic stimulation was provided by Kety and collaborators using tissue autoradiographic detection of a radioactive blood flow tracer gas (Kety *et al.*, 1955). This methodology was the basis for the development of noninvasive techniques (positron and single photon emission tomography, PET) currently used to image functionally induced changes in cerebral blood flow. In particular, $H_2{}^{15}O$ PET provides quantitative information on CBF (Phelps *et al.*, 1982) with a spatial resolution (full width at half maximum) of 3–4 mm. The short half life of ^{15}O (123 seconds) permits repetition of measurements at intervals of 10 minutes, thus allowing comparisons between different functional states in the same session.

One peculiar characteristic of functional hyperemia in the brain is that the increase in blood flow is in excess of the tissue metabolic requirements, resulting in an "overshoot" of tissue oxygen partial pressure, which translates in enhanced oxygen saturation of cerebral venous blood. The most widely used technique of functional magnetic resonance imaging (fMRI), blood oxygen level dependent (BOLD), detects this phenomenon by exploiting the difference in magnetic susceptibility between deoxygenated and oxygenated hemoglobin (Villringer and Dirnagl, 1995) and thus indicates the localization of the activated areas.

The techniques described here have advanced considerably the description of functional localization in the brain and can produce maps of neuronal activity derived from blood flow–related information. Because of their superior temporal resolution (20–120 seconds for $H_2{}^{15}O$ PET and approximately 2 seconds for BOLD fMRI; Villringer and Dirnagl, 1995), these techniques have largely replaced the estimation of brain glucose utilization by ^{18}F-2-deoxyglucose PET (temporal resolution 30–45 minutes), for functional brain mapping.

The Basic Mechanisms That Couple CBF and Function

The mechanisms that mediate the increase in blood flow associated with neuronal activity are still incompletely understood. It is generally assumed that blood flow is "coupled" to metabolism in the brain (i.e., blood flow changes presumably follow, and are a consequence of, the increase in metabolic activity). The ability of CO_2 to enhance CBF fueled the hypothesis that the metabolic production of this gas would provide an automatic mechanism of adjusting blood flow to metabolism. Many experimental facts challenge this interpretation. It has been shown, for instance, that during the initial phase of convulsive seizures CBF increases several fold, and simultaneous records of tissue pH not only fail to show an error signal

(acidification) but indicate tissue alkalosis instead, due to washout of CO_2 by enhanced circulatory convection (Astrup *et al.*, 1976).

Neuronal activity per se may not be enough to induce functional hyperemia. When spinal motoneurons are activated antidromically at rates of up to 100 Hz, no increase in local blood flow is observed in the ventral horn of the spinal cord, while a large increase in blood flow is found when the same population of cells are stimulated orthodromically (i.e., with intervention of a synapse) at a much lower rate (1 Hz) (Scremin and Decima, 1983). Thus, rather than a feedback mechanism based on a neuronal metabolic error signal, CBF may be controlled by a feedforward mechanism involving synaptically released neurotransmitters acting directly or indirectly on vascular smooth muscle. Such an "anticipatory," primarily vascular mechanism could explain why the increase in CBF observed in functional activation studies is often out of proportion (in excess) of the metabolic requirements, as described in the previous section. Such a mechanism would subserve many functions besides providing adequate supply of oxygen and glucose:

1. *Local temperature regulation.* Heat locally generated by enhanced metabolism in active brain areas needs to be cleared by circulatory convection requiring enhancement of blood flow to avoid a local elevation in temperature. This could maintain the local temperature of the functionally activated region invariant or even decrease it if the temperature of the incoming blood is lower than tissue temperature. Because cooling within a narrow range is associated with enhanced excitation, inhibition, and posttetanic potentiation (Koizumi *et al.*, 1954), an increase in blood flow could result in enhanced synaptic efficacy. Of course, too much brain cooling could be detrimental to neuronal function, and, in that case, an increase in local blood flow (assuming that the body core remains at a higher temperature than the brain) would warm up the area and enhance its function. In some exothermic animals, a mass of thermogenic tissue (brown fat) is juxtaposed to the arteries supplying the brain to warm up the incoming blood (Withers, 1992). The cerebrovascular system then becomes the brain's central heating device. In cold exposed humans, the rate of cooling of the head may be greater than that of the body core, and dangerously low brain temperatures of the centers recruited into function may be avoided, within limits, by functional hyperemia. A similar situation (lower brain than core temperature) may exist in anesthetized animals with open skulls, and this may turn a temperature-sensitive device into a blood flow probe, as in the experiments by Gerard cited.

2. *Termination of transmitter action.* Perfused blood vessels provide a "sink" for the effective dissipation by diffusion of neurotransmitter gradients, thus accelerating the termination of neurotransmitter action.

3. *Control of local PCO_2 and pH.* Given a stable metabolic CO_2 production and arterial PCO_2, local PCO_2 will be controlled by the level of blood flow. Enhanced perfusion in excess of that required to clear any excess production of CO_2 will decrease the local partial pressure of this gas, a phenomenon associated with an increase in synaptic efficacy (Esplin *et al.*, 1973). Thus, an increase in blood flow targeted to a brain region, by adjusting local conditions of the neuronal microenvironment that modulate synaptic transmission, may have an impact on its function beyond the supply of metabolic substrates.

4. *Vascular hydraulic skeleton.* When the brain is taken out of the skull, it collapses and deforms considerably because it lacks structural elements that could conserve its shape. Flotation in the cerebrospinal fluid and enclosure within an almost incompressible cavity contributes to minimizing gravitational effects on its shape *in situ.* However, variations in blood contents and pressure within the vasculature are known to alter the volume of the brain. For example, observation of the microvasculature of the cortex (see Figs. 37.9 and 37.11) indicates a well-oriented architecture with arterial vessels forming rings on the pial surface and a central vein with radiating branches. Expansion of this vascular structure by pressurization and enhanced blood contents in veins (attending effects of vasodilatation) could drag the neural elements attached to the blood vessels and induce changes in the subjacent neural architecture, such as variations in the size of the extracellular space. The functional effects of such mechanical phenomena secondary to a global or regional vasodilatation remain to be explored.

The concepts outlined here give support to the use of blood flow rather than glucose utilization for functional localization, as it may probe a wider spectrum of functions.

Mediators of CBF Control

The role of the synapse in the control of CBF introduced in the previous section suggests that understanding the mechanisms of neurovascular coupling requires knowledge of the effects of neurotransmitter/neuromodulators on CBF. One of the most outstanding examples is provided by acetylcholine. After pharmacologic inhibition of the enzymatic breakdown of ACh, the slope that defines the relationship of CBF to cerebral glucose utilization (CGU) is considerably increased

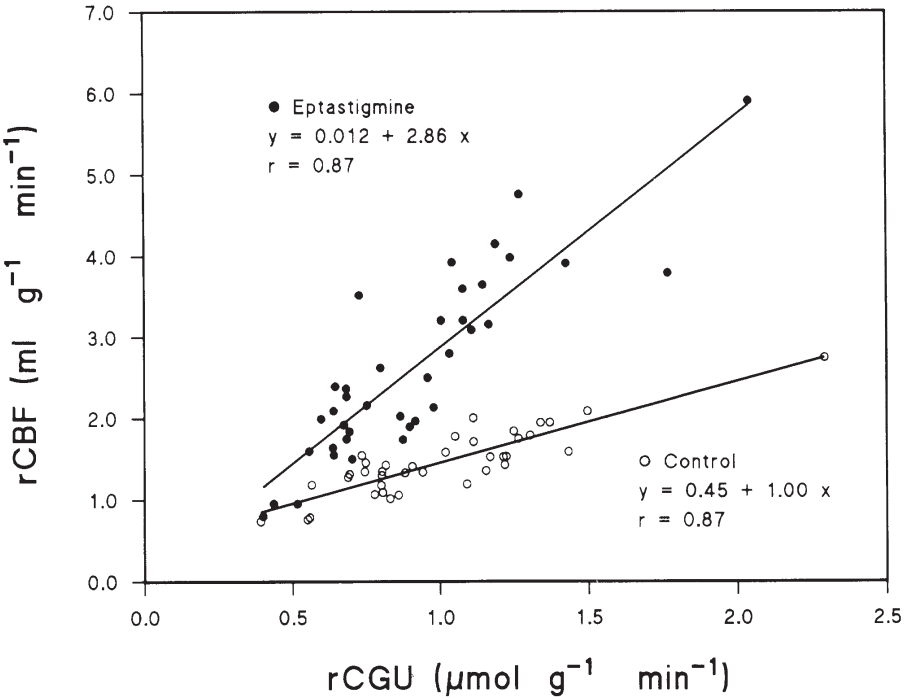

FIGURE 37.14 Scatter plots of paired values of regional cerebral blood flow (rCBF) on regional cerebral glucose utilization (rCGU) for a large number of brain regions in the rat. There is a tight coupling between metabolism and blood flow represented quantitatively by the regression of rCBF on rCGU. This relationship is not fixed however. The large increase in the slope of this relationship by enhancement of cholinergic transmission with the acetylcholinesterase inhibitor epatstigmine suggests a role of acetylcholine in neurovascular coupling. From Scremin, O.U., A.M. E. Scremin, D. Heuser, R. Hudgell, E. Romero, and B. Imbimbo (1993). Prolonged effects of cholinesterase inhibition with eptastigmine on the cerebral blood flow-metabolism ratio of normal rats. *J. Cereb. Blood Flow Metab.* **130,** 702–711, by permission of the authors and publisher

(Fig. 37.14) (Scremin *et al.*, 1993). Under such experimental conditions CBF of most regions increases without a change in glucose utilization. As a consequence, the oxygenation of hemoglobin in cerebral venous blood is enhanced (Scremin *et al.*, 1982), just as observed in the functional activation described previously. The opposite effect is observed with the cholinergic muscarinic blocker scopolamine that induces a decrease in the slope of the regression of CBF on CGU (Scremin and Jenden, 1996). These experiments suggest that ACh may be one of the neurotransmitters that mediate the anticipatory adjustments of CBF associated with synaptic activity inducing the local changes in the neuronal microenvironment discussed in the previous section.

A physiological role of ACh in CBF regulation has been suggested by the fact that the increase in CBF observed during spontaneous cortical arousal or somatosensory stimulation is markedly reduced by cholinergic blockade with atropine or scopolamine, and enhanced by inhibition of acetylcholinesterase with physostigmine (Scremin *et al.*, 1973; Pearce *et al.*, 1981; Tsukada *et al.*, 1997). Moreover, the increase in CBF induced by hypercapnia is enhanced by physostigmine and reduced by atropine or scopolamine (Rovere *et al.*, 1973; Kawamura *et al.*, 1975; Scremin *et al.*, 1978). Both cortical arousal and hypercapnia are known to enhance ACh release at the cerebral cortex (Metz, 1966; Hudson *et al.*, 1985), giving support to a cholinergic mechanism in the mediation of the cerebrovascular effects of both conditions.

ACh is probably one of many neurotransmitters/neuromodulators involved in the control of CBF, a system that might include considerable redundancy. A role has been proposed for NO, which may originate from endothelial cells, macrophages, neurons, or glia (Groves and Wang, 2000). Inhibitors of nitric oxide synthase (NOS), the enzyme that catalyzes the production of NO from arginine, have been reported to induce from 23% (Heinert *et al.*, 1998) to 70% (Harada *et al.*, 1997) inhibition of the hypercapnic hyperemia. The variation in this effect depends on the isoform of NOS predominantly inhibited, the magnitude of the hypercapnic stimulus, and the route of administration

of the inhibitor. Inhibition of the neuronal isoform of the enzyme (nNOS) by systemic rather than by local administration more readily blocks the hypercapnic hyperemia (Fabricius *et al.*, Wang *et al.*, 1995). However, in genetically altered mice lacking nNOS, the hypercapnic hyperemia is not affected (Irikura *et al.*, 1995). Moreover, while NOS inhibition has been shown to reduce the focal increase in CBF induced by somatosensory stimulation (Lindauer *et al.*, 1996), this response remains unaltered in mice lacking eNOS (Ayata *et al.*, 1996) or nNOS (Ma *et al.*, 1996). In these genetically altered animals, the ability of NOS inhibitors to modulate the CBF response to sensory stimulation or hypercapnia is lost. These facts point to the complexity of the role of NO in the control of CBF and to the ability of redundant systems to take over the role of NO when this agent is not present due to loss of synthesis from NOS.

In addition to ACh and NO, other neurotransmitters of widespread distribution within the central nervous system have the capacity to influence the cerebral circulation, and they could also be mediators of neurovascular coupling. Serotonin and phenylethylamine are known to constrict or dilate cerebral blood vessels, depending on the receptors involved and the physiological conditions (Cohen *et al.*, 1996; Scremin *et al.*, 1999; McCulloch and Harper, 1977), while CGRP, VIP, and substance P have been shown to induce vasodilatation (Rosenblum *et al.*, 1993; Juul *et al.*, 1994; Fahrenkrug, 1993b).

GLOBAL RESPONSES OF THE CEREBRAL CIRCULATION

Changes in Arterial Blood Pressure

One of the first observations of Kety and collaborators with the N_2O method of CBF measurement was that the CBF values of hypertensive patients were essentially similar to those of normal controls, in spite of a large difference in perfusion pressure (Kety *et al.*, 1948). This emphazises one of the fundamental characteristics of the cerebral circulation: stability in the face of variations in perfusion pressure. The phenomenon had already been studied by Fog (1937, 1939), who recorded the changes in diameter of pial vessels to oppose variations in arterial blood pressure. The dynamic characteristics of this phenomenon are important. A sudden, sustained rise in arterial blood pressure is followed by an increase in CBF, which over several minutes returns to the level prior to the hypertensive pulse. A similar time course is observed for the CBF and cerebrovascular resistance adjustments when arterial blood pressure is returned to normal (Yoshida *et al.*, 1966). The changes in cerebral vascular resistance that oppose the variations in perfusion pressure develop gradually and do not protect cerebral blood vessels from sudden increases or decreases in arterial pressure. The characteristic plots showing independence of CBF over a range of arterial blood pressure values (approximately between 50 and 150 mm Hg) are constructed by waiting until a new steady state of blood flow is established.

Blood Gases

Asphyxia, the combined occurrence of hypercapnia and hypoxia, was known to dilate cerebral blood vessels since the direct observations on pial blood vessels through skull windows by the dutch physician Franciscus Cornelius Donders published in 1850 (Purves, 1972). Although this phenomenon remained controversial for many years, the introduction of the nitrous oxide technique for the measurement of cerebral blood flow by Kety and Schmidt, and later direct measurements of global CBF from the internal carotid artery of humans with electromagnetic and ultrasound Doppler flow probes established quantitatively the cerebrovascular effects of changes in arterial PCO_2 and PO_2. Although hypercapnia and hypoxia interact in interesting ways, a rational description of their effects on the cerebral circulation is better approached separately.

Carbon Dioxide

The increase in CBF induced by hypercapnia is very rapid, with a time constant of about 20 s (Severinghaus and Lassen, 1967). The hypercapnic cerebral vasodilatation has been extensively studied in animals and humans, in spite of which its understanding remains incomplete. The simple idea of the effect being mediated by a decrease in tissue pH is contradicted by experiments showing blockade of the cerebrovascular action of CO_2 by lesions of the brainstem (Shalit *et al.*, 1967) or decerebration (Seylaz, 1968; Scremin *et al.*, 1978), as well as pharmacological interventions with cholinergic blockers (Rovere *et al.*, 1973; Scremin *et al.*, 1977; Kawamura *et al.*, 1975), and inhibitors of prostaglandin (Pickard and McKenzie, 1973) and NO synthesis (Iadecola, 1992). Blockade of 5-HT receptors or depletion of this transmitter enhance the cerebrovascular effect of CO_2 (Bonvento *et al.*, 1997; Kelly *et al.*, 1995). The magnitude of the CO_2 effect on cerebral blood flow is also dependent on the level and type of anesthesia (Scremin *et al.*, 1978). These facts point to the complex nature of the effect of hypercapnia on cerebral vessels.

Oxygen

The cerebrovascular effect of hypoxia exhibits a threshold around 50 mm Hg PaO_2, close to the point at which hypoxia induces loss of critical judgment (Siesjö, 1984). Below this level, CBF increases as arterial PO_2 decreases (Kogure *et al.*, 1970; Johannsson and Siesjo, 1975; Quint *et al.*, 1980). There is no effect of higher than normal arterial PO_2 except for extremely high levels with a decrease in CBF of 35% at 3.5 atmospheres (Lambertsen *et al.*, 1953).
