Preface

Neuroscience comprises increasingly diverse fields ranging from molecular genetics to neurophilosophy. The common thread between all these fields is the structure of the human nervous system. Knowledge on the structure, connections and function of the brain of experimental animals is readily available. On the other hand the structure of the human brain was studied by the classical anatomists and their work is difficult to retrieve. With the current intense interest in the structure of the human brain engendered particularly by imaging studies, groups of scientists familiar with the classical works, but who are also versed in modern neuroscience technologies, have commenced human brain studies.

The present book gives an authoritative account of the structure of the human brain tempered by functional considerations. The task of describing all parts of the nervous system in the context of modern hypotheses of structural and functional organization would be overwhelming for a single individual. We have, therefore, asked scientists with knowledge and affection for their research areas to contribute to this edited volume. We trust that the combined effort of contributors to The Human Nervous System 2e will do justice to the data and concepts available in our field while stimulating the readers' brains, arousing curiosity and providing a framework for thinking.

CHAPTER

1

Brain Evolution

GEORG F. STRIEDTER
Department of Neurobiology and Behavior
University of California at Irvine
Irvine, California, USA

"The route to an understanding of humans leads just as surely through an understanding of animals, as the evolutionary pathway of humans has led through animal precursors."—*Konrad Lorenz*, "The Russian Manuscript," p. xxvii

The question of how the brain of *Homo sapiens* differs from that of chimpanzees, gorillas, and other animals was intensely debated by Richard Owen and T. H. Huxley around the time that Darwin published his *Origin of Species*. Owen had been Britain's most prominent comparative anatomist and he vigorously opposed the very idea of biological evolution. Regarding the possibility that humans might have evolved from apes, Owen argued that the overall pattern of morphological development differs so dramatically between apes and humans that it is difficult to see how one could have been transformed into the other. Owen also noted that human brains are significantly larger than chimpanzee or gorilla brains, both absolutely and relative to body size, and that this size difference arises because human brains continue to grow for a much longer postnatal period (Owen, 1859). Moreover, Owen described three anatomical features that supposedly distinguish human brains from those of apes, namely, a posterior cerebral lobe, a posterior horn of the lateral ventricle, and the hippocampus minor, a ridge in the floor of the posterior horn of the lateral ventricle (Owen, 1857). Owen later conceded that these three structures might not be strictly unique to humans, but he continued to insist that these three human brain structures differ markedly from their homologues in apes (Owen, 1859). In Owen's view, these neuroanatomical differences were important because they could, in large measure, account for the enormous mental and behavioral differences between humans and apes. In fact, Owen argued that the neuroanatomical differences between apes and humans were so great that they warranted the placement of humans into their own taxonomic subclass, the Archencephala or "ruling brains" (Owen, 1857).

T. H. Huxley, in contrast, argued that humans differ anatomically from apes no more than apes differ from one another and that man must, therefore, "take his place in the same order with them" (Huxley, 1863, p. 86). In a very famous and rather vicious attack, Huxley assailed Owen's 1857 claim that the posterior lobe, posterior horn, and hippocampus minor are unique to humans (Huxley, 1863; Cosans, 1994; Desmond, 1994).[1] Specifically, Huxley argued that many well-respected neuroanatomists had already observed homologues of these three structures in chimpanzees and other apes and that Owen, who must have known about these

[1]It is worth noting that Huxley's attack on Owen was not quite fair, since Huxley (1863) never bothered to rebut Owen's 1859 argument that human brains differ from those of apes primarily in how they have modified homologous brain structures. Instead, Huxley continued to attack Owen's 1857 statement that humans possess some brain structures that have no homologues in apes (Cosans, 1994).

prior findings, was severely biased, if not dishonest, in his analysis. Huxley conceded that "there is a very striking difference in absolute mass and weight between the lowest human brain and that of the highest ape," but he claimed that "the difference in weight of brain between the highest and the lowest men is far greater, absolutely and relatively, than that between the lowest man and the highest ape" (Huxley, 1863, pp. 120–122). Therefore, Huxley contended, the brains of humans and other apes are really quite similar in terms of anatomical detail and overall size. This conclusion, in turn, led Huxley to suggest that the "vast intellectual chasm" between humans and other apes is due primarily to nonneural differences, specifically to the possession of articulate speech, which he considered to be "the grand distinctive character of man (whether it be absolutely peculiar to him or not)" (p. 122). Ironically, then, Huxley's attack on Owen's position narrowed the "zoological gulf" between man and ape but failed to provide a biological explanation of the "intellectual chasm" between them. Therefore, it is not surprising to discover that Huxley was a great admirer of Descartes, did not believe in physiological explanations of human intelligence, and ultimately abandoned faith not only in God (he coined the word *agnostic*) but also in the possibility of obtaining a scientific account of human consciousness (Cosans, 1994; Desmond, 1994).

My rationale for beginning this essay on brain evolution with a recounting of the old Owen–Huxley debate is that many of the issues raised in their quarrel remain of interest even today. For instance, how significant is the difference in overall brain size between humans and other primates, and what is its relationship to the differences in their mental abilities? Do human brains possess any truly unique features or brain areas? What is the relationship of language to the human brain and does human language have homologues in other species? And how can our ideas about God and consciousness be reconciled with Darwin's ideas about evolution and, more generally, with the search for biological explanations of the human mind? These are tough questions and, despite considerable effort, they remain largely unresolved (Preuss, 1995; Deacon, 1997; Miller, 1999). Nor do I pretend to have definitive answers. I will, however, attempt here to show that evolutionary neurobiology has progressed considerably since Darwin's days, that many of the old ideas about brain evolution have been replaced by better theories (Striedter, 1998a), and that it is time to reapproach some of the questions that intrigued Owen and Huxley.

Specifically, I review below what we now know about the historical pattern of vertebrate brain evolution. Next, I discuss the relationship between brain development and evolution, emphasizing how phylogenetic transformations may be explained in terms of changing developmental mechanisms. In the final section, I take up the questions of how the human brain differs from that of other primates and how a knowledge of these neuroanatomical differences might help us to understand exactly what it is that sets humans apart from other animals. My general thesis is that the insights gained during the last century, particularly during the last 20 years, by evolutionary neurobiologists studying nonhuman brains can now be used to remove at least some of the mystery, and often outright confusion, that has traditionally surrounded the problem of human brain evolution. It is in this sense that I agree with Lorenz, quoted above, that a full understanding of human nature requires insights gained from the study of animals (Lorenz, 1996).

HISTORICAL PATTERN OF VERTEBRATE BRAIN EVOLUTION

The most insidious idea in the study of brain evolution is the very old notion that biological evolution proceeded in a linear and progressive manner, from lower to higher forms of organization and with *Homo sapiens* at the very top of the so-called phylogenetic scale. The belief that all living creatures can be arranged in a linear sequence had its origin in the theological and decidedly nonevolutionary concept of a *scala naturae*, with archangels at the top and sponges near the bottom, but continued to thrive in the minds of most post-Darwinian thinkers (Hodos and Campbell, 1969; Bowler, 1988). For example, Huxley himself wrote, in what might well be the first explicit account of brain evolution:

> The brain of a fish is very small,… In Reptiles, the mass of the brain, relatively to the spinal cord, increases and the cerebral hemispheres begin to dominate over the older parts; while in Birds this predominance is still more marked. The brain of the lowest Mammals, such as the duck-billed Platypus and the Opossums and Kangaroos, exhibits a still more definite advance in the same direction. The cerebral hemispheres have now so much increased in size as, more or less, to hide the representatives of the optic lobes, which remain comparatively small.… A step higher in the scale, among the placental Mammals, the structure of the brain acquires a vast modification.…
> The appearance of the "corpus callosum" in the

> placental mammals is the greatest and most sudden modification exhibited by the brain in the whole series of vertebrated animals.… In the lower and smaller forms of placental Mammals the surface of the cerebral hemispheres is either smooth or evenly rounded, or exhibits a very few grooves.… But in the higher orders, the grooves, or sulci, become extremely numerous, and the intermediate convolutions proportionately more complicated in their meanderings, until, in the Elephant, the Porpoise, the higher Apes, and Man, the cerebral surface appears a perfect labyrinth of tortuous foldings. (Huxley, 1863, pp. 112–114).

This linear and progressive view of brain evolution dominated evolutionary neurobiology throughout the 19th and most of the 20th century (Edinger, 1908; Kappers *et al.*, 1936; Herrick, 1948). Over the years, several specific hypotheses were proposed to explain how brains became more complex as they "ascended" the phylogenetic scale, e.g., by the addition of phylogenetically new brain parts to older brains or by an increase in the histological differentiation of ancestral brain regions (e.g., MacLean, 1990; Ebbesson, 1984). These theories were well publicized and influential within the neuroscience community, where terms such as "subhuman primates" and "lower vertebrates" are still commonly used. However, most evolutionary neurobiologists now consider these theories to be patently false or, at least, distressingly incomplete. Because the *scala naturae* way of thinking is so well entrenched among medically oriented neuroscientists, psychologists, and anthropologists (Cartmill, 1990; Campbell and Hodos, 1991), I will expend some effort here to review why the strictly linear view of brain evolution is untenable and what alternative view has taken its place.

Perhaps the most obvious difficulty with the *scala naturae* view of evolution is that different authors generally have different ideas about how to rank different species along the phylogenetic scale. Dolphins and other toothed whales, for example, are sometimes considered high on the phylogenetic scale because they are capable of complex vocal behaviors, have remarkably large brains for their body size, and display highly convoluted cerebral and cerebellar cortices (Fig. 1.1); (Ridgway, 1986; McCowan and Reiss, 1997; Marino, 1998; Janik, 2000). However, other authors have deemed dolphin brains to be quite primitive because their cerebral cortex is relatively thin, represents a relatively small fraction of total brain volume, exhibits little areal differentiation, and is poorly laminated (Fig. 1.1); (Glezer *et al.*, 1988; see Deacon, 1990a). The perceived position of dolphins on the phylogenetic scale therefore

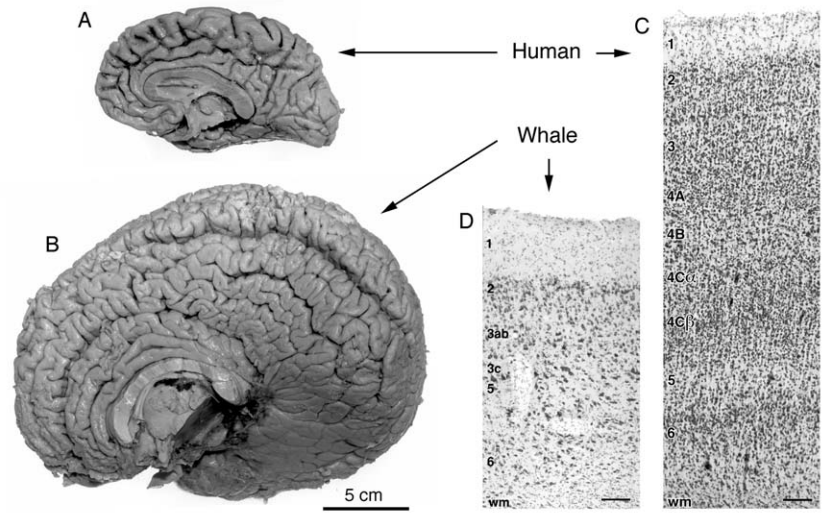

FIGURE 1.1 The brain of a human **(A)** is smaller and less convoluted than that of a killer whale **(B),** but the neocortex is thicker and more highly laminated in a human **(C)** than in a pygmy sperm whale **(D);** shown here are sections through primary visual cortex. In addition, one can note that the corpus callosum is proportionately smaller in the whale than in the human brain. Both brains are shown at the same scale and from a medial view. The scale bars for the neocortical sections both equal 150 μm. Abbreviations: 1, 2, 3, 4A, 4B, 4C, 5, and 6, neocortical layers; wm, white matter. Panels A and B are reproduced from Ridgway (1986) with permission of Sam Ridgway and Lawrence Erlbaum Associates. The photographs of the neocortical sections are reproduced from Preuss (2001) with the permission of Todd Preuss, Patrick Hof, and Cambridge University Press.

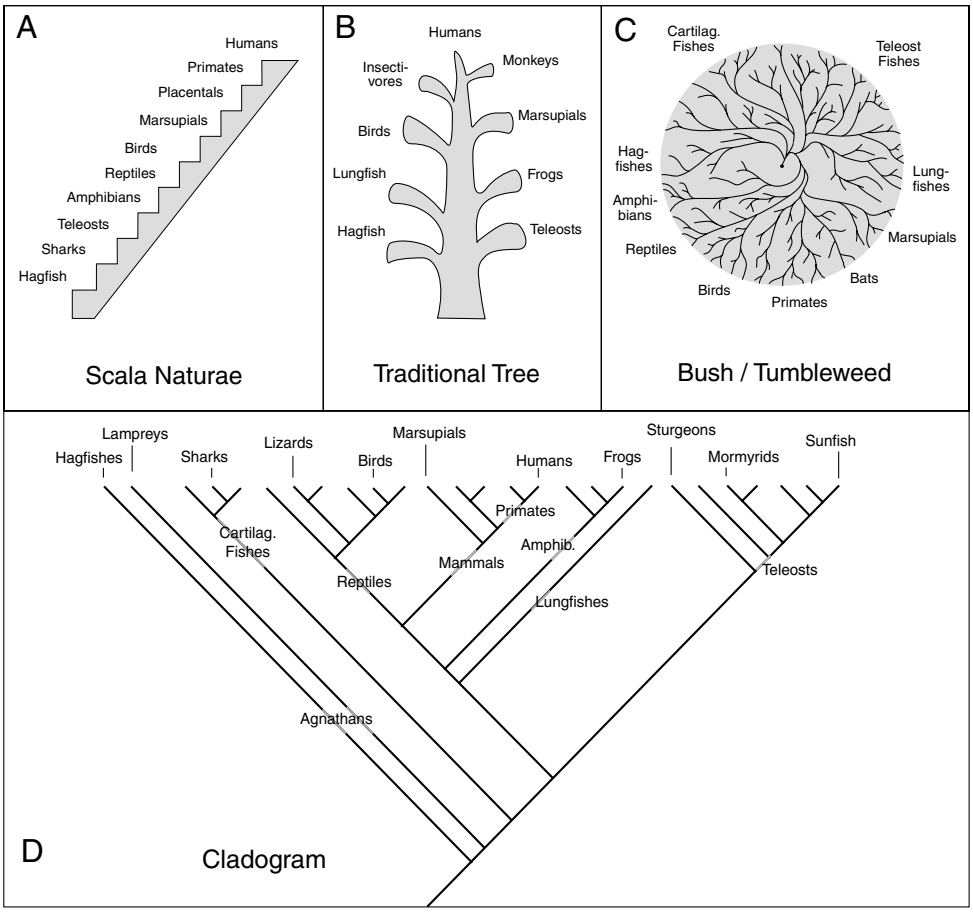

FIGURE 1.2 Vertebrate phylogeny has been depicted in a variety of ways. According to the deeply entrenched *scala naturae* view of evolution, vertebrates can be arranged along a linear phylogenetic scale **(A).** Phylogenetic trees, in contrast, have a branched topology. Traditionally, most phylogenetic trees place humans at the top and represent other taxa as side branches off the main trunk **(B).** More accurately, however, vertebrate phylogeny would be represented as a severely pruned bush, or tumbleweed, with extant taxa occupying only the tips of the outermost branches **(C).** In practice, most evolutionary biologists work with dichotomously branching "cladograms" **(D),** which represent both extant and extinct species along the top of the diagram.

depends on which characters are being considered. Nor are dolphins the only thorn in the side of the phylogenetic scale. Monotremes, for example, are often considered to be quite primitive in the sense that they are the oldest surviving order of mammals, but echidnas (spiny anteaters) actually have quite large and convoluted brains (Rowe, 1990). Similarly, birds and bony fishes are often judged to be "lower vertebrates," but parrots are capable of cognitive feats that put many mammals to shame (Pepperberg, 1990; Hile *et al.*, 2000), and mormyrid electric fish have exceptionally large brains that consume an astonishing 60% of the body's oxygen, compared to about 20% in humans and 2% to 8% in most other vertebrates (Nilsson, 1996). Even the "lowly" hagfish, one of the jawless vertebrates, does not contain the simple nervous system one might have expected, but instead displays a bulky and highly differentiated brain that includes a five-layered telencephalic region (Wicht and Northcutt, 1992; Wicht and Nieuwenhuys, 1998).

Instead of a linear phylogenetic scale, then, vertebrate species form a phylogenetic tree, bush, or tumbleweed that has been severely pruned by extinction events (Fig. 1.2). Nonhuman lineages do not represent "blind alleys" explored by evolution in its quest for *Homo sapiens* (Huxley, 1942); (Fig. 1.2B) but rather the outcome of divergent and opportunistic descent with modification (Darwin, 1859). Moreover, the currently living species represent only the outermost terminal branchlets of the phylogenetic tumbleweed, which means that they are unlikely to represent the transitional forms or "missing links" of evolutionary lore. There are,

of course, some "living fossils" that have changed very little over many millions of years, but even these often exhibit unique specializations that disqualify them as strictly transitional forms. For example, the coelacanth *Latimeria chalumnae,* is probably a representative of the extinct rhipidistians that gave rise to tetrapods, but it also exhibits several peculiar nonancestral (i.e., derived) features, including ovoviviparity, a huge and mysterious "rostral organ" that is probably used to detect electrical signals emitted by prey, and an odd telencephalon with "rostral bodies" that are not found in any other vertebrates (Nieuwenhuys, 1998a). Even with bona fide (i.e., dead) fossils it is generally difficult, and some would argue impossible, to determine whether a specimen is "the" sought-after ancestor or merely an independent offshoot from the lineage of interest (Eldredge and Cracraft, 1980; Wolpoff, 1999). Regardless of one's position on this point, the controversy is largely moot for evolutionary neurobiologists since brains generally do not fossilize and skull endocasts provide minimal information about the structural organization of extinct brains (Rogers, 1998). In sum, the brains available for comparative study are scattered across the outer surface of the phylogenetic tumbleweed, and each is likely to be a mosaic of both primitive and uniquely derived features. If this is so, then how can evolutionary neurobiologists hope to reconstruct the course of brain evolution?

For most contemporary evolutionary neurobiologists the answer to this question is "cladistics," a formal and widely applicable method for taxonomic classification and phylogenetic reconstruction (Hennig, 1966; Kirsch and Johnson, 1983; Northcutt, 1985a; Northcutt and Wullimann, 1988; Nieuwenhuys, 1994). Cladistics (also termed phylogenetic systematics) was created primarily to aid in the classification of organisms; however, once a classification has been established, the method can also be used to distinguish between homologous[2] and homoplasous (i.e., independently evolved) features and to reconstruct when in phylogeny a particular feature evolved (Eldredge and Cracraft, 1980; Ridley, 1986). Consider, for example, the corpus callosum. This great commissure, coursing between the cerebral hemispheres of all placental mammals, is not found in any marsupials or monotremes, and is likewise lacking in all nonmammalian vertebrates (Owen, 1857; Elliot Smith, 1910). This phylogenetic distribution strongly suggests that the corpus callosum evolved with the origin of placental mammals because all alternative scenarios would be significantly less parsimonious, involving multiple phylogenetic losses and/or gains. Consider further the observation that the corpus callosum is significantly smaller (relative to total brain weight) in toothed whales than in other large-brained placental mammals (Fig. 1.1); (Rilling and Insel, 1999a). This phylogenetic distribution makes it most parsimonious to conclude that the corpus callosum shrank in size, relative to the rest of the brain, with the origin of toothed whales (also known as the Odontoceti). Interestingly, the phylogenetic shrinkage of the corpus callosum in toothed whales was apparently accompanied by a phylogenetic decrease in the relative thickness and volume of the neocortex (Ridgway and Wood, 1988).[3] Cladistics is, of course, more complicated than is apparent from these examples, and its practical and logical limitations are severe when one attempts to analyze characters that evolve readily, and hence repeatedly, in different lineages. Nonetheless, cladistics is the best available method for reconstructing the phylogeny of neural characters, and it has met with considerable success in that capacity (e.g., Northcutt, 1985a, b, 1995; Butler and Hodos, 1996; Nieuwenhuys *et al.,* 1998).

Perhaps the most important finding to have emerged from the modern cladistic analyses of brain evolution is that relative brain size increased independently in most major vertebrate lineages (Northcutt, 1981, 1985a). Manta rays, for example, have brains that are almost 40 times larger than the brains of other cartilaginous fishes with similar body weights (R. G. Northcutt, personal communication). Among bony fishes, relative brain size increased significantly in the lineage leading to teleosts, the most speciose class of vertebrates (Lauder and Liem, 1983), and within teleosts brain size increased again several times, most notably in the above-mentioned mormyrids (Nilsson, 1996) and in some coral reef and pelagic fishes (Bauchot *et al.,* 1989). In sauropsids (i.e., reptiles and birds), relative brain size increased significantly in the lineage leading to modern birds and, within birds, in parrots, corvids (e.g., ravens), and owls (Stingelin, 1958; Portmann and Stingelin, 1961). Among mammals, relatively large brains evolved in primates, toothed whales, and elephants.

[2]Many different definitions of homology have been proposed over the years (see Hall, 1994). In my view, it is best to say simply that features in two or more different species (or larger taxonomic groups) are homologous if, and only if, (1) they are similar enough to be identified as "the same character" and (2) they originated just once, in a common ancestor of the taxa being considered, and were then retained with a continuous history in the descendent lineages under consideration (see Striedter and Northcutt, 1991; Striedter, 1998b, 1999).

[3]It may also account for the unusual ability of dolphins to sleep with one cerebral hemisphere at a time (Ridgway, 1986).

One frequently neglected aspect of these phylogenetic increases in brain size is that they are accompanied by major changes in brain organization. Simply put, the phylogenetically enlarged brains are not isometrically scaled-up versions of their smaller cousins, for different brain regions generally increase at different rates (i.e., allometrically) as overall brain size increases (Deacon, 1990a; Finlay and Darlington, 1995). Largely because of this allometric scaling, the neocortex, for example, occupies a far greater percentage of the whole brain in large mammals than in small ones. Moreover, larger brains generally exhibit a greater degree of cytoarchitectural complexity (i.e., a greater number of distinct, nonidentical cellular aggregates) than do smaller brains. Consistent with this general principle are the findings that (1) mormyrids have one of the most complex telencephalons among teleost fishes (Nieuwenhuys and Meek, 1990), (2) the forebrain of birds is more complex than that of reptiles (Nieuwenhuys *et al.*, 1998), and (3) primates have a greater number of distinct neocortical areas than do other mammals (Brodmann, 1909; Kaas, 1987). Thus, both brain size and brain complexity have increased several times independently in diverse branches of the phylogenetic tumbleweed.

Although brain size and complexity have tended to increase, rather than decrease, during vertebrate evolution, there are several lineages in which relative brain size and complexity have been reduced. Specifically, some lungfishes (i.e., the South American and African genera) and the urodele amphibians (i.e., salamanders) have unexpectedly small and simple brains, with extremely small cerebella and few distinct cell groups (Northcutt, 1986; Roth *et al.*, 1997; Nieuwenhuys, 1998b). Although these lungfishes and salamanders have manifestly similar brains, they do not constitute adjacent branches of the phylogenetic tree and are separated, phylogenetically speaking, by several taxa with larger and more complicated brains (e.g., the Australian lungfishes and anuran amphibians). Therefore, it is most parsimonious to conclude that small and simple brains evolved independently in these two lineages, probably as a result of pedomorphosis—the general retention of juvenile characteristics (Gould, 1977; Bemis, 1984). If this is true, then it is misguided to assume that the brain of a modern salamander can, on account of its general simplicity, be a good model for "the" primitive vertebrate brain (Herrick, 1948). Instead, the features of the most ancestral vertebrate brain must be discovered by a complex phylogenetic analysis to determine, character by character, which neural features are primitive and which derived. To the inevitable frustration of those in search of truly primitive brains, this collection of primitive features, i.e., the vertebrate morphotype, is unlikely to exist in any species living today (Northcutt, 1985b, 1995; Wicht and Nieuwenhuys, 1998). An analogous dilemma exists for those interested in "the" primitive mammalian brain. Hedgehogs, tenrecs, and other "basal insectivores" (Stephan, 1967), for example, have relatively simple brains with very little neocortex, but they are a rather heterogeneous assemblage of taxa (Eisenberg, 1981), and their simplicity may be derived rather than primitive (Kirsch *et al.*, 1983). Even monotremes and marsupials, the two earliest branches of the mammalian radiation, are quite diverse in brain structure and far from uniformly primitive (Rowe, 1990). Therefore, those who seek to establish the ancestral pattern of mammalian brain organization must sample broadly and proceed cautiously.

The traditional explanation of how brains increased (or decreased) in complexity during the course of evolution is that brain regions were successively added to (or lost from) ancestral brains (Edinger, 1908; MacLean, 1990). According to this view, brains evolve in a manner analogous to the transformation of a medieval fortress into a king's palace by the successive addition of new structures (think, for example, of the Louvre in Paris). This additive view of brain evolution was enormously influential, as evidenced by the prevalence of the prefixes "neo," "archi," and "paleo" in the neuroanatomical nomenclature. It is unlikely to be correct, however, at least as a general theory, because most of the supposedly "added" brain divisions have now been identified, albeit in modified form, also in those taxa that were supposedly lacking them (Karten, 1969; Northcutt, 1981; Reiner *et al.*, 1984; Butler and Hodos, 1996). A homologue of mammalian neocortex, for example, has been identified in virtually all nonmammalian vertebrates (although its extent and composition is still debated; Northcutt, 1995; Striedter, 1997; Puelles *et al.*, 2000). Therefore, it appears that most major brain divisions are conserved across vertebrates and that phylogenetic differences in complexity arise because these conserved brain regions diverge in their embryonic development in such a way that they become subdivided to varying degrees and/or, occasionally, in fundamentally different ways (Striedter, 1999). Phylogenetically new structures therefore can and do arise in brain evolution, but they cannot be thought of as simple additions to adult ancestral brains. Returning to the architectural analogy, it is better to compare brain evolution to the history of ancient Troy, which was destroyed and rebuilt many times, doubtlessly retaining some major features across each iteration but also varying in countless details (Schliemann, 1875). Viewed from this perspective, one must marvel at the fact that brains are "rebuilt" so faithfully across each

generation and that a considerable number of features are conserved across millions of years (Striedter, 1998b). One may also begin to wonder what role the mechanisms and rules of neural development have in guiding the course of brain evolution, and whether it might not be possible to understand the process of brain evolution in terms of the developmental transformations which it depends.

DEVELOPMENTAL MECHANISMS UNDERLYING BRAIN EVOLUTION

The relationship between development and evolution has long held great fascination for comparative biologists. According to Haeckel's famous biogenetic law, phylogenetic change causes additional stages to be appended to an organism's ontogeny, which therefore comes to "recapitulate" the organism's phylogenetic history. In Haeckel's view, then, phylogeny is the mechanism that underlies ontogenetic change (Haeckel, 1889). This idea was turned on its head by Garstang and others who argued instead that ontogenetic changes are the driving force behind phylogenetic change and that ontogenies may change in a variety of different ways, including nonterminal addition of stages, deletion of stages, and divergence of ontogenetic trajectories (Garstang, 1922; de Beer, 1958; Alberch, 1980). Garstang's anti-Haeckelian view of development and evolution has now become widely accepted, partly because it fits better with the comparative embryological data (von Baer, 1828), but also because the *scala naturae* view of evolution, which is complexly intertwined with Haeckel's ideas on recapitulation, has generally fallen out of favor (Gould, 1977). In addition, Garstang's approach allows comparative embryologists to go beyond the reconstruction of phylogenetic history and to create developmental explanations for why particular phylogenetic changes have occurred (or did not occur). The phylogenetic loss of lateral line organs in direct-developing frogs, for example, can be explained by a loss of ectodermal competence for lateral line placode induction (Schlosser *et al.*, 1999). Such mechanistic explanations for phylogenetic change are more difficult to attain when it comes to brain evolution, but there are several areas of developmental neurobiology that can already be discussed with this goal in mind. Below, I briefly review (1) the implication of finding highly conserved embryonic regions in vertebrate brains, (2) the correlation between when a brain region is "born" and how much its size tends to change during phylogeny, and (3) the data on how changes in one brain region affect the development of other brain regions.

Shortly after neurulation, when vertebrate embryos reach the so-called phylotypic stage of development (Richardson *et al.*, 1997), the brain is quite similar (though not identical) across the major vertebrate taxa (Bergquist and Källén, 1954). Most conserved across species is the embryonic hindbrain which is, at that age, divided into a series of segments, or neuromeres (Fig. 1.3), each of which constitutes a lineage restriction domain and expresses a unique combination of transcription factors (Fraser *et al.*, 1990; Gilland and Baker, 1993; Lumsden and Krumlauf, 1996). The discovery of these highly conserved hindbrain neuromeres has revitalized the field of comparative neuroembryology and stimulated many investigators to look for conserved neuromeres also at more rostral levels of the neuraxis. This search has yielded a great deal of data but little consensus, particularly about whether the forebrain is segmentally organized (Figdor and Stern, 1993; Puelles and Rubenstein, 1993; Alvarez-Bolado *et al.*, 1995; Guthrie, 1995; Shimamura *et al.*, 1997; Smith Fernandez *et al.*, 1998; Nieuwenhuys, 1998c; Striedter *et al.*, 1998; Striedter and Keefer, 2000; Puelles *et al.*, 2000). At this point, it seems most prudent to conclude simply that there are at least some lineage restriction compartments in the embryonic forebrain and that some of these coincide with spatially restricted patterns of gene expression. More detailed studies will be needed to determine the exact number of these compartments, their orientation with respect to the brain's long axis (Puelles *et al.*, 1987), and the details of how gene expression is related to lineage restriction. It also remains to be seen exactly how well conserved the forebrain's compartmental organization is between taxa (Wullimann and Puelles, 1999). Nonetheless, the modern cellular and molecular studies have confirmed that vertebrate brains are far more similar to one another at embryonic stages than later on (Bergquist and Källén, 1954).

Less certain is how the phylogenetic conservation of embryonic brain regions is reflected in the organization of adult brains. For example, the hindbrain neuromeres are somewhat ephemeral structures, bearing little obvious relation to adult morphology or function. Recent fate-mapping studies have shown that some embryonic neuromere boundaries later become coincident with the rostrocaudal boundaries of adult cell groups (Marín and Puelles, 1995; Díaz *et al.*, 1998), but it remains difficult, if not impossible, to identify any adult structural or functional features that are uniquely shared by the adult derivatives of a particular neuromere (Bass and Baker, 1997). This suggests that the hindbrain neuromeres are conserved not for their

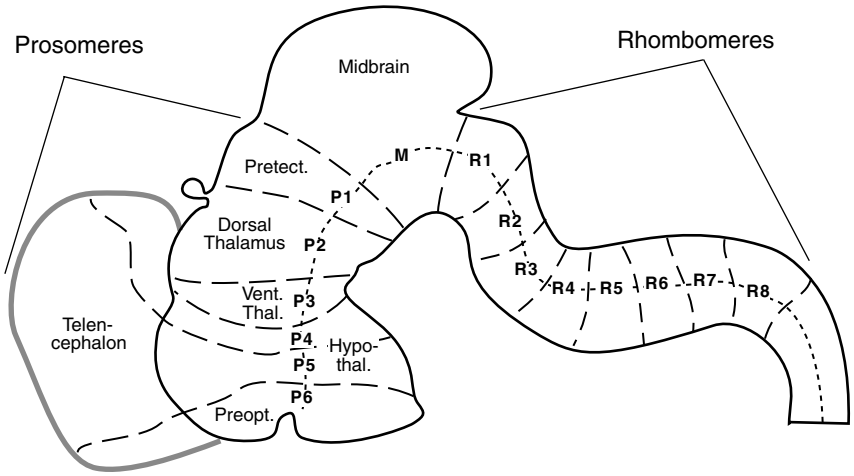

FIGURE 1.3 Schematic diagram of the neuromeric model of embryonic vertebrate brain organization (see Rubenstein *et al.*, 1994). Each neuromere can be thought of as a doughnut-shaped ring around the brain's longitudinal axis *(fine dotted line)*. The borders between adjacent neuromeres *(heavy dotted lines)* are thought to be sites of cell lineage restriction and correspond to the boundaries of some regulatory gene expression domains. The neuromeric model of brain organization conflicts with other models of brain organization (such as Herrick's four-tiered model of diencephalic organization), but several classically recognized brain divisions, such as the dorsal and ventral thalami, correspond quite well to the dorsal or ventral portions of one or more neuromeres. Hypothal, hypothalamus; M, mesomeres; P1 to P6, prosomeres; Preopt., preoptic area; Pretect., pretectum; R1 to R8, rhombomeres; Vent. Thal., ventral thalamus.

adult function but because they play an important role in hindbrain morphogenesis, possibly setting the stage for the later formation of other developmental compartments (see Davenne *et al.*, 1999). Indeed, a steadily growing amount of information indicate that brain compartmentalization is an ongoing process, generating successively smaller compartments and ultimately leading to the formation of functionally coherent adult cell groups (Redies and Takeichi, 1996; Redies, 2000). If this is correct, then a phylogenetic change in the development of early embryonic brain compartments may divert the course of subsequent morphogenesis in such a way that it leads to the phylogenetic repatterning of a major brain region in the adult. Such early developmental changes may, for example, underlie the radically divergent nature of telencephalic organization in teleost fishes, where the telencephalon everts rather than evaginates (Nieuwenhuys and Meek, 1990), and in sauropsids, where telencephalic development is dominated by the formation of several intraventricular ridges (Striedter, 1997). Moreover, whenever development diverges so dramatically, it may well be impossible to homologize the individual adult cell groups across the divergent taxa (Striedter, 1999). Finally, to the extent that early embryonic brain regions impart on their adult derivatives some shared adult features, one may be able to homologize higher level adult brain regions, e.g., the mammalian neocortex, even when it is not possible to homologize many of the constituent lower level characters, e.g., the individual neocortical areas (Northcutt and Kaas, 1995).

A second major approach to the study of brain development and evolution consists of trying to explain phylogenetic changes in the size of the adult brain, or of specific adult brain areas, in terms of phylogenetic changes in the dynamics of cell proliferation and neurogenesis. It is likely, for example, that phylogenetic differences in the onset and duration of neurogenesis (and hence in the amount of time during which neuronal precursors multiply exponentially; Caviness *et al.*, 1995; Takahashi *et al.*, 1997; Kornack and Rakic, 1998) can, in large measure, account for the enormous differences in adult brain size between small and large mammals (Stephan *et al.*, 1981). Moreover, the time of peak neurogenesis for any particular brain area is remarkably well correlated with the degree to which that brain area enlarges phylogenetically as overall brain size increases (Finlay and Darlington, 1995). This finding has led to the hypothesis that, as brain development is prolonged and overall brain size enlarged, the brain regions with relatively late neuronal "birthdates" (and hence relatively protracted periods of precursor proliferation) are constrained to enlarge much more than brain regions with relatively early neuronal birthdates (Finlay and Darlington, 1995). For example, since the most anterior and dorsal portions

of the embryonic brain are "born" after most of the other brain areas, the brain regions derived from these anterior dorsal portions of the neural tube should exhibit the proportionately greatest enlargement as overall brain size increases. Consistent with this hypothesis, mammalian neocortex derives from the most anterior and dorsal region of the embryonic brain, exhibits a relatively late and prolonged period of neurogenesis, and is enlarged disproportionately as overall brain size increases phylogenetically (Hofman, 1989; Finlay and Darlington, 1995; Finlay *et al.*, 1998). Finlay and Darlington's general theory is thus consistent with an impressive amount of correlative data, but many questions remain about the cellular mechanisms that control overall brain size and regional variations in the timing of neurogenesis.

The finding that brain areas enlarge in a rather predictable manner as overall brain size increases (Fig. 1.4) may mean that brain evolution is governed by developmental constraints that prevent brain regions from varying in size independently of one another (Finlay and Darlington, 1995). This "developmental constraint" hypothesis receives some support from the finding that, across 22 species of mammals, the area of neocortex devoted to corticospinal projections correlates more strongly with total neocortical area than with a variety of behavioral and ecological measures, including digital dexterity and hand–eye coordination (Nudo and Masterton, 1990a). On the other hand, the same data also reveal several important, and allometrically poorly predicted, species differences in areal distribution, density, and size of the corticospinal neurons (Nudo and Masterton, 1990a, b; Nudo *et al.*, 1995). Moreover, even in the dataset used by Finlay and Darlington, the sizes of the olfactory bulb and olfactory cortex are poorly correlated with overall brain size (Sacher, 1970; Gould, 1975; Stephan *et al.*, 1981). In fact, the developmental constraint hypothesis predicts the size of individual brain regions at best to within a factor of 2.5, which still leaves room for impressive regional differences in size.[4] Thus, the finding that the cerebellum is 45% larger than expected in apes than in monkeys (Rilling and Insel, 1998b) is consistent with the developmental constraint hypothesis, but it nonetheless suggests that the cerebellum develops and evolves somewhat independently of other brain regions. Finally, it remains unclear how well the developmental constraint hypothesis applies to nonmammals. For

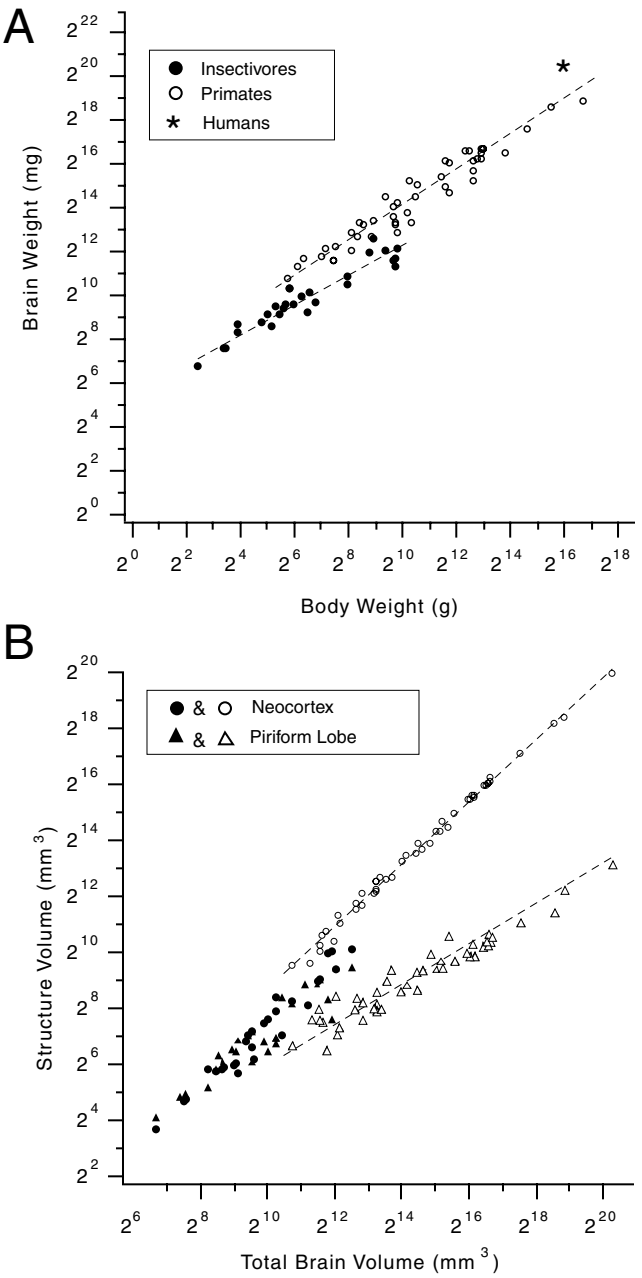

FIGURE 1.4 **(A)** Brain and body weight plotted for 27 insectivores and 47 primates on a log-log plot. The slopes of the regression lines are slightly less than 1, which means that relative brain weight decreases as body weight increases (i.e., negative allometry). It is interesting to note that primate brains are approximately twice as large as insectivore brains of equal body size and that human brains are approximately three times as large as would be expected for a typical primate of the same body size. **(B)** A log-log plot showing that the neocortex expands more quickly than the piriform lobe as total brain size increases, which means that large brains have proportionately more neocortex. As in (A), the solid symbols refer to data from insectivores while the open symbols are primate data points. The data used to generate both graphs were taken from Stephan *et al.* (1981).

[4]This expected range of size differences is based on Finlay and Darlington's two-factor model, considering both overall brain size and the size of the main olfactory bulb. The range would be even larger if overall brain size is used as the only factor in predicting the size of a specific brain region.

example, the cerebellar valvula in mormyrid teleosts is clearly expanded beyond any allometric expectations (Nieuwenhuys and Nicholson, 1969). In summary, then, developmental constraints can account reasonably well for phylogenetic changes in the relative size of many brain regions, particularly for mammals of vastly different body sizes, but they leave plenty of room for mosaic brain evolution, i.e., for changes in the size of individual brain regions that are relatively independent of changes in overall brain size.

A third major area of research into brain evolution and development consists of attempts to explain the evolution of neuronal circuits in terms of changes in axonal development and axon-mediated developmental interactions. It has been proposed, for example, that some phylogenetically new connections in adult animals (e.g., the postmammillary fornix projections in adult cats, rabbits, and, probably, elephants) may have evolved because axon collaterals that were developmentally transient in the ancestral condition became permanent during the course of evolution (Stanfield *et al.*, 1987). In addition, species differences in the adult size of some cell groups may be due to phylogenetic changes in the amount of naturally occurring developmental cell death, which in turn may be regulated by axon-mediated trophic interactions with other brain areas (Katz, 1982). Phylogenetic increases in the size of a particular muscle, for example, are likely to cause a phylogenetic increase in the size of the motor neuron population innervating that muscle by reducing the amount of naturally occurring, trophic factor–dependent cell death among those motor neurons (Holliday and Hamburger, 1976). Such trophic interactions might cascade throughout large portions of the nervous system (Wilczynski, 1984) but are likely to be buffered out quickly whenever neurons can derive trophic support from multiple sources, i.e., whenever neural connections diverge or converge (Finlay *et al.*, 1987). Finally, it is important to note that trophic cascades are affected by the phenomenon of compensatory innervation, in which a reduction in the size of one afferent projection causes a compensatory (and probably trophic factor–mediated) increase in the size of another projection or, in some cases, the sprouting of previously nonexistent projections (Katz *et al.*, 1981). Large neonatal midbrain lesions in hamsters or ferrets, for example, cause the sprouting of compensatory projections from the retina to auditory or somatosensory thalamic nuclei that were partially denervated by the lesions (Schneider, 1973; Frost, 1981; Sur *et al.*, 1988). This rerouting of visual information to normally nonvisual thalamic nuclei, in turn, leads to developmental changes in some (but not all) thalamocortical and intracortical connections (Pallas *et al.*, 1990; Gao and Pallas, 1999).

Most of what we know about how changes in development can alter adult brain organization comes from experimental lesion or transplantation studies, but there is some evidence that similar phenomena also occur naturally. The dorsal lateral geniculate nucleus of congenitally eyeless mice, for example, receives ascending somatosensory projections (Asanuma and Stanfield, 1990) and contains some types of synapses (Katz *et al.*, 1981) that are not usually found in normal mice, strongly suggesting that some kind of compensatory innervation has take place. Similar compensatory changes may have taken place also in blind mole rats (Heil *et al.*, 1991), but this remains controversial. According to the best available evidence, it appears that the enormous decrease in the size of the retina in blind mole rats is associated with a dramatic reduction in the size of the lateral geniculate nucleus, an elimination of the typically precise topography of the thalamocortical visual projection, and an expansion of the normal auditory and/or somatosensory thalamocortical systems (Necker *et al.*, 1992; Cooper *et al.*, 1993a; Rehkämper *et al.*, 1994). These differences in adult organization might have been predicted from what we know about trophic interactions between interconnected cell groups (Oppenheim, 1981), the activity-dependent fine tuning of topographical projections (Meyer, 1983), and cross-modal competitive interactions and compensation (Rauschecker *et al.*, 1992). Unexpectedly, however, the suprachiasmatic nucleus, which receives retinal input and controls the timing of circadian rhythms in most mammals, has remained relatively large in blind mole rats (Cooper *et al.*, 1993b). This fact is only surprising, however, if one assumes (1) that blind mole rats are truly blind, which is not true since they have rudimentary retinas that are required for the photic entrainment of their circadian rhythms (Pevet *et al.*, 1984), and (2) that the suprachiasmatic nucleus depends on its retinal input for trophic support, which is also likely to be incorrect because transplanted suprachiasmatic nucleus cells can survive even if they do not receive retinal afferents (Lehman *et al.*, 1995). Thus, the available data suggest that many of the neural features that distinguish blind mole rats from other, sighted rodents can be explained as secondary developmental consequences of an early embryonic reduction in retinal size.

Although a full synthesis of the developmental and phylogenetic data on brain organization has not yet been achieved, the examples reviewed above demonstrate that it is already possible to sketch out some mechanistic developmental explanations for at least some phylogenetic changes in brain organization. In addition, one can begin to discern a few fairly general rules about how brain development and evolution

relate to one another. For example, neuronal cell groups that receive trophic support via a limited set of axonal connections should be more phylogenetically labile than those that either do not depend on other cell groups for trophic support or have a large number of different inputs and outputs (Finlay *et al.*, 1987; Striedter, 1990a, b). Furthermore, as brain size increases phylogenetically, the proportions of the various brain regions to one another should change dramatically (largely in accordance with allometric predictions) and this, in turn, should alter the outcome of at least some competitive interactions during axonal development, thereby leading to potentially major phylogenetic changes in neural circuitry (Deacon, 1990a). More generally, this realization implies that neural connections should be more phylogenetically labile than the cell groups they interconnect (Striedter, 1992) and that superficially similar brains, which appear in Nissl stains to differ only in the relative size of homologous cell groups, may nonetheless differ significantly in terms of neural circuitry and functional organization. Armed with these insights, and with the tools of modern evolutionary neurobiology for reconstructing phylogenetic change, one can again approach the question originally posed by Owen and Huxley: how did human brains change during the course of hominid evolution?

EVOLUTION OF UNIQUELY HUMAN BRAINS

Comparisons between humans and other animals always involve both similarities and differences. Among evolutionary biologists interested in behavior, there is a long tradition of highlighting the similarities between human and animal behavior (Romanes, 1881; Wilson, 1975), but many differences also stand out. Clearly, only humans sit around the fire (or dinner table) to tell each other jokes and stories about past glories or future plans, and only a human would eagerly read what Owen wrote about primate brains 140 years ago. Moreover, only humans use general engineering skills to overcome environmental challenges that other animals can solve solely through evolution by natural selection. These are, of course, merely some of the major differences between human and animal behavior, but they suffice to pique one's interest in the general question of how human brains differ from those of other animals and how these neuroanatomical differences might relate to the known differences in behavior. In the following paragraphs I will review some of what we know about (1) phylogenetic size increases in human brains, (2) the existence of uniquely human neuroanatomical features, (3) phylogenetic changes in the relative proportions of various brain areas in primates, and (4) the possibility of major connectional and functional changes in human brain evolution. Given the limitations of space and my own expertise, I offer not a complete review of the relevant literature but merely an outline of how one might begin to untangle the mysteries of human brain evolution. I have also omitted from this discussion any speculations about the selective pressures or chance events that might explain *why* human brains evolved their particular anatomical or behavioral features (Gould and Lewontin, 1979; Lauder, 1996).

Although it is generally accepted that humans have the largest brains among vertebrates, absolute brain size is actually much greater in elephants and many whales than it is in humans (5–10 kg for whales and elephants, 1.4 kg on average for humans; van Dongen, 1998). Even relative to overall body size, human brains do not come out at the "top of the scale" because the brain comprises only about 2% of the body's weight in adult modern humans, but more than 3% in mormyrid teleosts and nearly 10% in adult mice (Stephan *et al.*, 1981; Nilsson, 1996). Indeed, the only way to become convinced that humans have uniquely enlarged brains is to plot brain size versus body size for a large number of species, to realize that relative brain size decreases predictably as body size increases, and then to note that the relative brain size of humans significantly exceeds the value predicted from that negative allometric relationship (Fig. 1.5A). Using this kind of allometric analysis, it becomes apparent that the brain is approximately twice as large in primates as in other mammals of similar body size and that the brain of modern humans is roughly three times larger than expected from an analysis of other primates (Passingham, 1982). Human brains should really be housed in bodies the size of King Kong (Deacon, 1990a). Analysis of the hominid fossil record indicates that relative brain size increased rather late in hominid evolution (approximately 2–3 million years ago) and that this increase was not due to a phylogenetic reduction of body size, which actually increased considerably during hominid evolution (Tobias, 1973; Hofman, 1983; Wolpoff, 1999). In developmental terms, the phylogenetic increase in human brain size is due primarily to the fact that in humans the brain grows at the high (primate typical) fetal growth rate for a much longer time than it does in other primates (Fig. 1.5B; Count, 1947; Passingham, 1985; Deacon, 1990c). Thus, Owen's original hypothesis that human brains are larger than those of apes because they grow for a longer period (Owen, 1859) has been substantiated by modern research. It is likely, however, that additional mechanisms also contribute to the

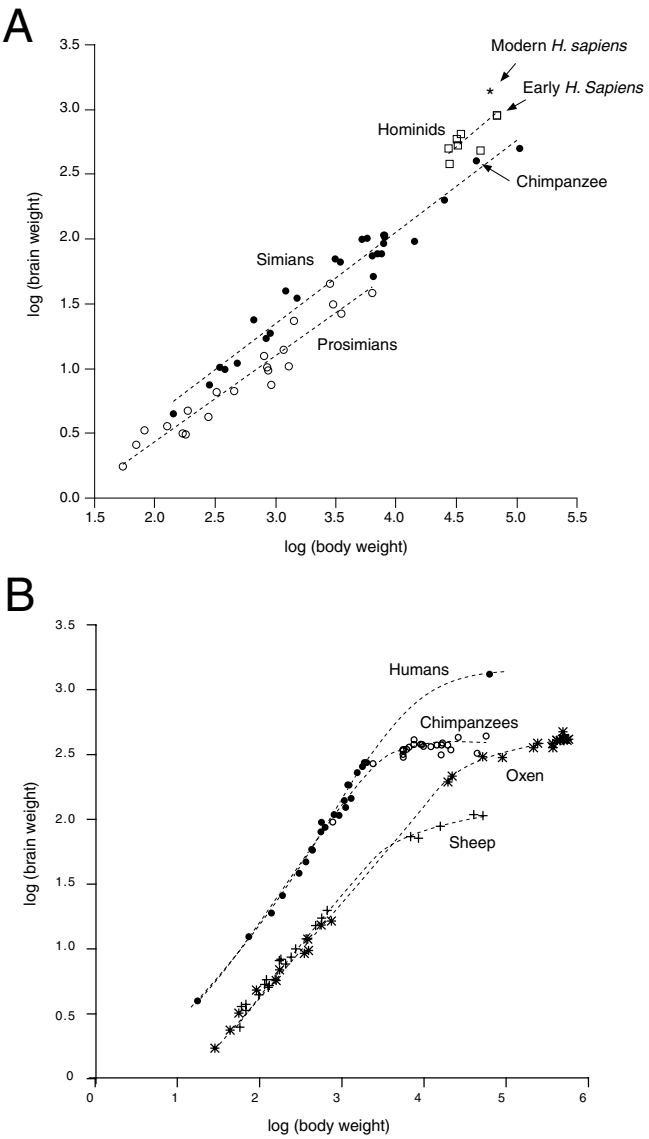

FIGURE 1.5 **(A)** Log-log plot of brain versus body weight for various primates, showing that simians (monkeys and apes) tend to have larger brains than prosimians of similar body weight, that hominids tend to have larger brains than simians, and that relative brain size has increased again in modern *Homo sapiens*. The data used to generate this plot were taken from Stephan et al. (1981) and Wolpoff (1999). **(B)** An analysis of brain development reveals that human brains grow at the nearly exponential rate typical of fetal brain growth for a longer period of time than do chimpanzee brains. The data also show that primate brains are already significantly larger than sheep or ox brains at very early stages of embryonic development. These data are from Count (1947).

phylogenetic increase in human brain size, for brain cell density appears to be higher in humans than in macaques at early embryonic stages (Widdowson, 1981).

Given that human brains have increased in terms of both absolute and relative size, many investigators have wondered whether human brains possess some regions or features that are not found in smaller brains. The classic comparative cytoarchitectonic studies of Brodmann and others (e.g., Brodmann, 1909; see Chapter 27) already suggested that primates have a greater number of distinct neocortical areas than most nonprimates, and this has been confirmed in modern studies. Specifically, it appears that the principal sensory and motor areas are highly conserved across mammals, but that many higher order cortical areas are more difficult to homologize between primates and other mammals (Kaas, 1987). The developmental mechanisms underlying this phylogenetic increase in the number of cortical areas remain controversial, but probably involve interactions between dorsal thalamic afferents, intracortical axons, and enlarged cortical precursor regions that cause embryonic regions to differentiate into a greater number of adult cortical areas than were present in the ancestral condition (Kaas, 1989; Killackey, 1990; Krubitzer, 1995; Striedter, 1998b). Whatever the mechanistic details, it is clear that many neocortical areas cannot be homologized in a one-for-one manner between primates and other mammals (Kaas, 1983), particularly when one compares primates and cats, which have independently evolved elaborate visual systems with many neocortical areas (Sereno and Allman, 1991). Turning to comparisons between humans and other primates, Brodmann and others identified several cortical areas in the human frontal, temporal, and parietal lobes, including the famous "language areas" of Broca and Wernicke, that did not appear to have homologues in nonhuman primates (Brodmann, 1909). However, these claims were gradually eroded by later investigators who showed that homologues of the human language areas probably do exist in at least some nonhuman primates (Deacon, 1992; Aboitiz and Garciá, 1997) and, more generally, that human and anthropoid monkey cortices are remarkably similar to one another in terms of cytoarchitectural organization (Galaburda and Pandya, 1983; Petrides and Pandya, 1999; to see how similar prefrontal cortex is between rhesus monkeys and humans, refer to Chapter 25). The currently available data therefore suggest that the phylogenetic increase in overall brain size during hominid evolution was not associated with a dramatic increase in the number of distinct brain regions.

Although humans probably evolved very few truly "new" brain areas (or neuronal cell types, but see Nimchinsky *et al.*, 1999; Preuss *et al.*, 1999), several regions in the human brain clearly differ from their ape homologues in terms of relative size. Most strikingly, human brains contain 15–24% more neocortical gray matter (and 22% more neocortical white matter) than would be expected for nonhuman primate brains of

equal size (Rilling and Insel, 1999b). Interestingly, this phylogenetic size increase affects some neocortical regions more than others. For example, primary visual cortex, constitutes an unexpectedly small percentage of the human neocortex (although it is roughly as large as would be expected given human body and retinal size; Passingham, 1973; Holloway, 1979). Prefrontal cortex, on the other hand, is enlarged significantly in human brains. This finding has been challenged repeatedly (Uylings and van Eden, 1990; Semendeferi et al., 1997), but a careful application of allometric techniques and cytoarchitectonic criteria suggests that, indeed, prefrontal cortex is approximately twice as large in humans as would be expected for nonhuman primates with a neocortex of equal size (Passingham, 1973; Deacon, 1997). This interpretation is further supported by the finding that human prefrontal cortex is significantly more complexly folded than would be expected from the study of nonhuman primates (Zilles *et al.*, 1989; Rilling and Insel, 1999b). In addition, it is likely that some portions of the parietal and temporal lobes, several dorsal thalamic nuclei, the cerebellar hemispheres, and several brain regions directly connected to the cerebellum are also unexpectedly large in humans (Holloway, 1972; Passingham, 1973; Armstrong, 1982; Rilling and Insel, 1998b). Many of these conclusions remain debatable, however, due to a dearth of quantitative data and/or difficulties associated with the allometric analyses (Deacon, 1990b, c). Finally, it may be noted that one supposed hallmark of human brain organization, namely, the bilateral asymmetry in the size of the language-related planum temporale, has now been observed also in the brains of chimpanzees and other great apes (Gannon *et al.*, 1998; Hopkins *et al.*, 1998).

The observed changes in the relative sizes of homologous brain areas between humans and other primates may seem to be of minor importance, given that new brain areas have evolved repeatedly during vertebrate evolution, but they are likely to be associated with functionally significant changes in neuronal connectivity. It has been argued, for example, that the phylogenetic expansion of neocortex inevitably leads to a reduction in the degree of neocortical interconnectedness (Frahm *et al.*, 1982; Stevens, 1989; Deacon, 1990a; Ringo, 1991), a hypothesis that is supported by the finding that during primate evolution increases in neocortical white matter outpace increases in gray matter much less than would be expected if interconnectedness remained constant (Frahm *et al.*, 1982; Rilling and Insel, 1999a, b). In addition, changes in the relative size of brain areas are likely to be associated with changes in the size of the related afferent and efferent pathways, and changes in the relative sizes of these pathways are likely to (1) alter the balance of functional interactions between adult brain areas, leading to changes in the relative importance of particular brain areas for some behaviors, and (2) bias the outcome of competitive interactions during axonal development in such a way that some connections are completely lost while others appear *de novo* (Deacon, 1990a). These hypotheses are supported by the observation that the enlarged prefrontal cortex in humans probably has connections that are not present in other primates, including important connections to the midbrain and medullary vocal control areas (Deacon, 1989, 1992). Just as the prefrontal cortex thus appears to have become "co-opted" into the machinery for vocal communication in humans, so other neocortical areas in humans may have become necessary for the performance of behaviors that are less dependent on the neocortex in other mammals. However, such apparent shifts in neural function toward the neocortex, sometimes referred to as "neocorticalization," remain poorly understood. Perhaps the best studied case of neocorticalization involves the corticospinal tract, which projects more strongly to spinal motor neurons in primates than in other mammals (Heffner and Masterton, 1975) and is both larger and functionally more important in humans than in other primates (Lawrence and Kuypers, 1968; Heffner and Masterton, 1983). Interestingly, this increase in the functional importance of the corticospinal tract in humans appears to be accompanied by the phylogenetic elimination of the rubrospinal tract, which is prominent and important for motor control in most other mammals (Voogd *et al.*, 1990, and Voogd, Chapter 11).

The behavioral correlates of the neuroanatomical differences between humans and apes are difficult to assess with rigor. The phylogenetic enlargement of the human brain has frequently been interpreted as an indication of increased intelligence (Jerison, 1973), but this hypothesis has been difficult to confirm in detail (Holloway, 1974), largely because it is so difficult (if not impossible) to define "general intelligence" (Macphail, 1982). Overall brain size has also been linked to life span (Sacher, 1973; Allman *et al.*, 1993), metabolic rate (Armstrong, 1985), social complexity (Byrne and Whiten, 1988), diet and home range (Clutton-Brock and Harvey, 1980). Unfortunately, all of these interpretations involve at least some questionable assumptions and are difficult to separate (van Dongen, 1998). Some of these difficulties may be avoided by searching for more specific correlations between structure and function. It is likely, for example, that the fine digital dexterity and power grip of humans are due to specific phylogenetic changes in the human corticospinal tract (Heffner and Masterton, 1983). Similarly, the phylogenetic co-option

of prefrontal cortex into the vocal control system probably facilitated the emergence of symbolic language during hominid evolution (Deacon, 1997). More generally, it seems reasonable to speculate that the phylogenetic enlargement of the prefrontal cortex in modern humans has enhanced their ability to inhibit automatic responses, form symbolic representations of external objects, monitor the contents of working memory, and plan future courses of action (see Owen *et al.*, 1996, 1999; Deacon, 1997). Clearly, however, even these conjectures will have to be made more specific in terms of both anatomical and behavioral differences or similarities. To this end, it will be important to perform comparable functional imaging studies in both humans and apes and to develop ever better methods for tracing neuronal pathways in human brains (e.g., Conturo *et al.*, 1999).

CONCLUSIONS

Students of brain evolution have traditionally emphasized either the discontinuity between brains of different species or their fundamental similarities in structural organization. Thus, the early, pseudo-Darwinian view that brain evolution proceeds linearly along a phylogenetic scale (Bowler ,1988), driven by the steady accretion of novel parts, gradually gave way to the view that all vertebrate brains are constructed according to a common plan, implying that vertebrate brains consist mostly of homologous parts (Kuhlenbeck, 1967–77; Northcutt, 1981; Butler and Hodos, 1996; Nieuwenhuys *et al.*, 1998). Faith in the conservative nature of brain evolution should not be carried too far, however, because many adult brain structures cannot be homologized across all vertebrates and telencephalic organization, in particular, differs dramatically between major taxa (Northcutt, 1981; Striedter, 1997, 1999). In mammals, the neocortex does exhibit some highly conserved anatomical features (Rockel *et al.*, 1980; but see Skoglund *et al.*, 1996). However, new neocortical areas and features have evolved in several mammalian lineages, and it is probably wishful thinking to argue that rat neocortex is a good model for most aspects of human neocortical structure or function (Kolb and Tees, 1990; see Preuss, 1995). In contrast, the brains of apes, seem remarkably similar to human brains in terms of gross structure and cytoarchitectural organization. For example, the rhesus monkey atlas of Paxinos *et al.* (2000) displays the same prefrontal cortical areas as can be found in human brain maps. Yet it is important to remember that we still know relatively little about the details of human (or, for that matter, ape) neuroanatomy (see Preuss, 1995, in press) and that some of the relative size differences between human and ape brains are probably associated with significant, and as yet unknown, phylogenetic changes in neuronal connections and functional organization.

In summary, it seems fair to say that the goal of explaining human uniqueness in terms of species differences in brain development and adult structure appears increasingly attainable, particularly as new data emerge on human and primate brain organization (e.g., Rilling and Insel, 1999a, b). It is appropriate, therefore, to close this chapter with a quote from the much maligned, yet rarely read, Owen, who clearly shared this ambition when he wrote:

> The long-continued growth and superior size of the human brain, more especially the superior relative size of the cerebral hemispheres and their numerous deep and complex convolutions, are associated with psychical powers, compensating for and permitting the absence of natural weapons of offence and defence; they are corelated with those modifications of the lower limbs which free the upper ones from any call to serve the body in the way of moving and supporting it, and leave them at the command of the intellect, for such purposes, in the fabrication of clothing, weapons, etc., as it may energize upon according to its measure of activity in the individual.
> (Owen, 1859, p. 270).

CHAPTER

2

Embryonic Development of the Central Nervous System

FABIOLA MÜLLER and RONAN O'RAHILLY
University of California School of Medicine
Davis, California, USA

This account of the development of the human nervous system during the embryonic period is based largely on the authors' investigations, particularly on a series of 14 articles (O'Rahilly and Müller, 1981, 1990; Müller and O'Rahilly, 1983–1990c) and on a book, "The Embryonic Human Brain" (O'Rahilly and Müller, 1999a), in which many additional details and an extensive bibliography can be found. The references provided in this chapter relate to mammals and are mostly concerned with humans unless otherwise indicated. All 16 tables are based on the authors' research.

The following points emphasize the importance of studying the development of the nervous system, in particular the embryonic human brain.

1. The embryonic period has particular importance in that during its course most major malformations appear, and their origin and timing are related to very early developmental processes.
2. The positions of areas and nuclei in the embryonic brain are frequently quite different from those in the adult, so that their identification depends more on their fiber connections than on their topography.
3. The development of the brain in rodents and even more so in the chick and quail differs appreciably from that in primates, including humans. Indeed, development in primates differs in many respects from the common mammalian pattern.
4. The timing of the appearance of areas and nuclei in the brain bears a relationship to functional considerations and its investigation is necessary for an understanding of early gene expression. Nevertheless, straightforward extrapolation from the chain of events

characteristic of murine ontogeny to that of the human is not permissible (Gérard *et al.*, 1995). Moreover, despite the high degree of sequence conservation of certain genes (Vieille-Grosjean *et al.*, 1997), appreciable differences are being found between the possible effects of human and mouse genomes, so that the mouse may not be a satisfactory model for many aspects of early human development.

5. Studies of the human embryo with the aid of recent methods confirm and further clarify many morphological findings, such as the formation of the neocortical layers published by Müller and O'Rahilly in 1990(a, b). The validity of such comparisons depends on studies being made of the one species, in this instance human, and with the aid of precise staging.

DEVELOPMENTAL STAGES AND AGES

Prenatal life is conveniently divided into the embryonic period, comprising the first eight postfertilizational weeks, and the fetal period, extending thereafter to birth. Within the embryonic period, staging (O'Rahilly and Müller, 1987) is essential for serious work in human embryology. However, it is unfortunate that in the vast majority of studies of other species such as mouse and rat, morphological staging is rarely used, although staging systems are available and have been collected conveniently in an atlas by Butler and Juurlink (1987).

Approximate ages in postfertilizational (or postovulatory) weeks have been assigned to these morphological stages, as listed in Table 2.1. These ages are revised from time to time as new information, e.g., from ultrasonography *in vivo*, becomes available. Although the use of postmenstrual weeks and days is perfectly legitimate in obstetrics, these are not age and should not be so designated. The highly ambiguous term, "gestational weeks" or "gestational age" should be discarded (O'Rahilly and Müller, 2000a).

TABLE 2.1 Initial Appearance of Various Features of the Nervous System

Features	Stage	Weeks[a]
Neural folds and groove	8	
Mesencephalic flexure; primary neuromeres; Rh., M, Pros.	9	
Neural tube begins; Tel. medium and Di.	10	4
Rostral neuropore closes	11	
Caudal neuropore closes; secondary neurulation begins	12	4½
Closed neural tube; cerebellar primordium; isthmus	13	
Pontine flexure; medial ventricular eminence; future cerebral hemispheres; all 16 neuromeres present	14	
Myelencephalon, metencephalon; hippocampal thickening; lateral ventricular eminence	15	5
Epiphysial evagination	15, 16	
Thalamus; all cranial nerves present	16	
Internal and external cerebellar swellings; neurohypophysial evagination; synapses in primordial plexiform layer	17	6
Future corpus striatum; defined interventricular foramina; choroid fissure; dentate nucleus; inferior cerebellar peduncles	18	
Olfactory bulb; insula; choroid plexus of fourth ventricle	19	
Choroid plexus of lateral ventricles	20	7
Cortical plate; anterior and inferior horns of lateral ventricle; circulus arteriosus complete	21	
Internal and external capsules; claustrum	22	
Caudate nucleus and putamen; anterior commissure begins; external germinal layer in cerebellum	23	8

[a]The weeks given are postfertilizational.

AREAS WITH SPECIAL INDUCTIVE INFLUENCE

The prechordal plate (Fig. 2.1A, stippled in the inset) is a multilayered accumulation (up to eight rows) of spherical cells in the human. They resemble endothelial elements but are larger and contain numerous granules (Müller and O'Rahilly, 2003). The dorsal surface of the plate is in close contact with the medial part of the future forebrain, i.e., with the neural groove. The prechordal plate provides a primary signal *(sonic hedgehog, shh)* for the suppression of the medial part of the originally unseparated optic fields, thereby inducing two separate primordia for the future retinae. Lack of this suppression would result in cyclopia.

Later (clearly in stage 10) the areas of the neural plate dorsal to the prechordal plate are the diencephalic region D1 and the future rostral parencephalon with the neurohypophysis. The caudal (epinotochordal) part of the neural plate will develop a floor plate.

The primitive streak (Fig. 2.1B) is the caudal axial structure of the early embryo. It lacks a basement membrane, allowing the emigration of cells, and a high percentage of its cells contribute to the neural plate. Its rostral part contains a proliferative population

that forms the primitive node. The primitive streak gives rise to axial mesoderm, the notochordal process, and foregut endoderm (by way of the notochordal process).

The notochordal process, which becomes the notochordal plate and later the notochord, ends at the oropharyngeal membrane (near the adenohypophysial pouch). It is caudal to the prechordal plate (Fig. 2.1, inset). The notochordal process and the notochord induce the floor plate by means of diffusible factors. The floor plate is a specialized group of median neuroepithelial cells that appear to regulate differentiation of motor neurons and axonal growth, and that also synthesize shh, as does the notochord.

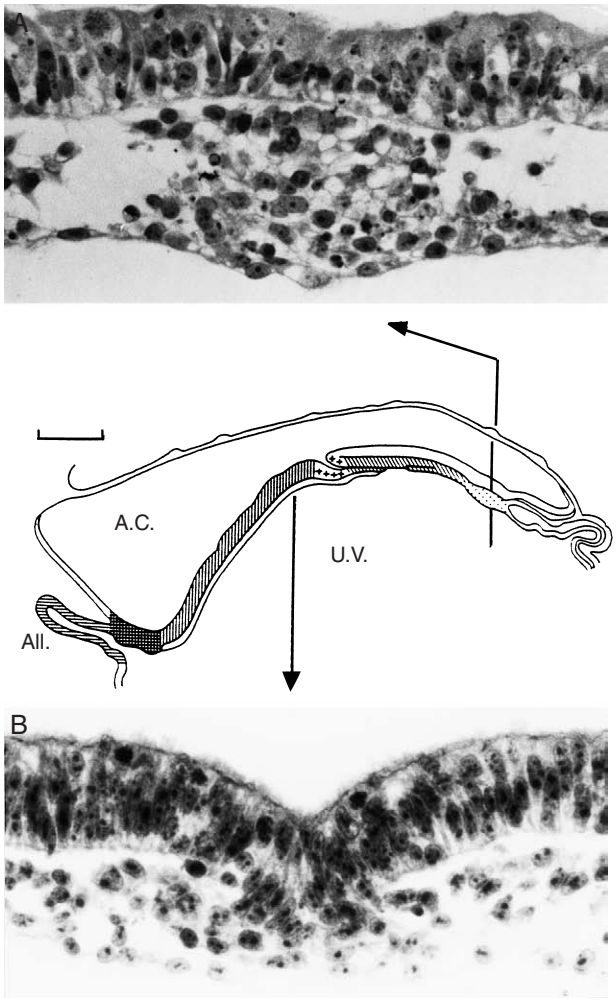

FIGURE 2.1 Areas with special inductive functions. **(A)** Cross-section of the prechordal plate (stage 8a), separated by a basement membrane from the neural ectoderm, which possesses two to three rows of cells. Above the neural ectoderm is the amniotic cavity; below the prechordal plate is the umbilical vesicle. Loose mesenchyme is visible on both sides of the prechordal plate. **(B)** Cross-section of the primitive streak, from which cells can move readily ventrally and ventrolaterally in the absence of a basement membrane. The key is a median reconstruction (stage 8b) showing the levels of sections A and B, as well as the primitive node and neurenteric canal. The notochordal process is shown in oblique hatching and the prechordal plate is stippled. A.C., amniotic cavity; All., allantoic diverticulum; U.V., umbilical vesicle. The bar represents 0.23 mm. A is from R. O'Rahilly and F. Müller, "The Embryonic Human Brain," 2nd Ed. Copyright ©, 1999, Wiley-Liss. B is from R. O'Rahilly and F. Müller, "Human Embryology and Teratology," 3rd Ed. Copyright ©, 2000, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

NEURULATION

Although it is generally maintained that neural induction requires a positive signal from the "organizer," an alternative view is that "neuralization" of the epiblast occurs when the cells do not receive signals that induce them to form epidermis, mesoderm, or endoderm (Hemmati-Brivanlou and Melton, 1997, in a study of amphibia).

Neurulation is the formation of the neural tube and it involves two different processes, termed primary and secondary.

Primary Neurulation

This process extends from the appearance of the neural plate and neural groove to the formation of the neural tube (Fig. 2.2). The closure of the neural folds to constitute the neural tube involves fusion of neural

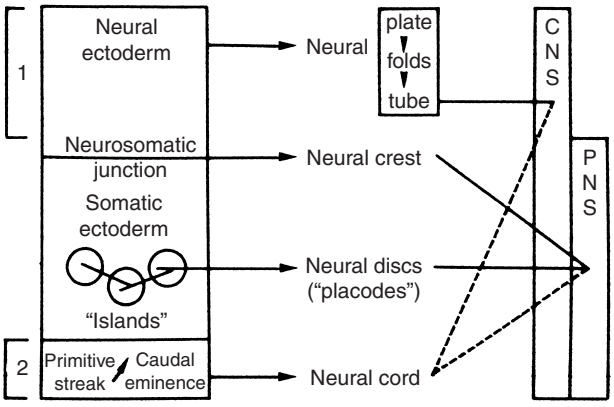

FIGURE 2.2 The origin of the nervous system. (1) Primary neurulation involves the neural ectoderm. (2) Secondary neurulation occurs by way of the caudal eminence and the neural cord. Additional contributions to the nervous system are made by the neural crest, which arises at the neurosomatic junction (i.e., at the junction of neural ectoderm and somatic ectoderm), and by neural discs (so-called placodes), which were regarded by Streeter as "islands" of neural ectoderm situated in the "ocean" of somatic ectoderm. After table 19-1 from R. O'Rahilly and F. Müller, "Human Embryology and Teratology," 3rd ed. Copyright ©, 2000, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

ectoderm, fusion of surface ectoderm, and finally interposition of mesenchyme. Failure of fusion of the neural folds leads to anencephaly and/or spina bifida, whereas a defect in the formation of mesenchyme results in reopening of an already formed neural tube and/or favors the development of an encephalocele.

The neural ectoderm is at first (stage 8) a pseudostratified epithelium. Mitotic figures are present and are superficial (Fig. 2.1).

The neuropores are the openings that are left before final fusion of the neural folds (Figs. 2.3B, C, and 2.4A, B). The rostral neuropore appears and closes first (during stage 11), followed by the caudal neuropore (during stage 12). It must be emphasized that a specific pattern of multiple sites of fusion such as has been described in the mouse is not found in the human (O'Rahilly and Müller, 2002). However, additional small loci, variable in position, may be encountered at stage 10 (Müller and O'Rahilly, 1985, figure 2; Nakatsu *et al.*, 2000, figure 2).

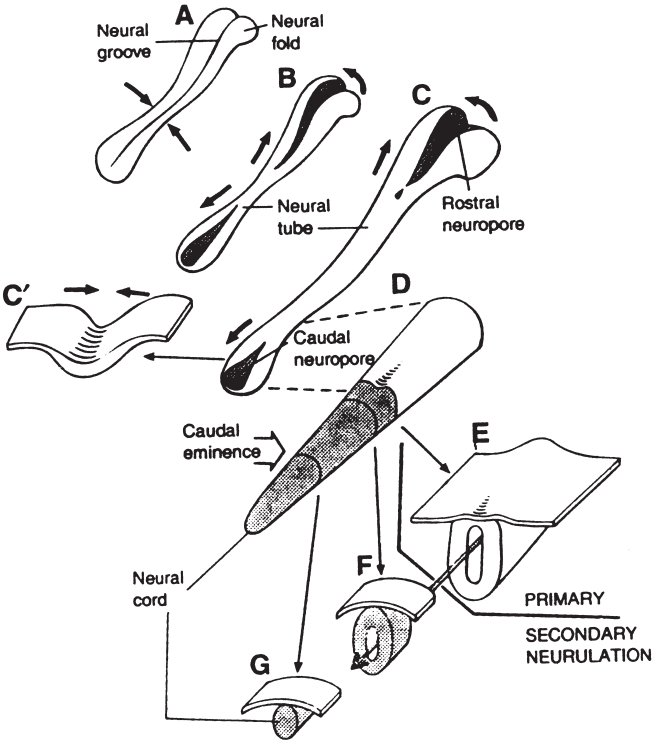

FIGURE 2.3 Primary and secondary neurulation. **(A)** The neural folds and neural groove. **(B)** The folds begin to fuse (stage 10). **(C)** Continuation of the fusion rostrally and caudally leaves two neuropores, which soon close (stages 11 and 12). **(C′)** The arrows indicate the fusion of the left and right neural folds. **(D)** A slight pit indicates the site of the former caudal neuropore, beyond which the neural tube is formed by secondary neurulation. In **E** to **G** the surface ectoderm has been added. The long arrow is placed in the lumen of the neural tube, which develops by both primary and secondary neurulation (**E** and **F**). The cavity formed by secondary neurulation **(F)** appears in the solid neural cord **(G).** From R. O'Rahilly and F. Müller, "Human Embryology and Teratology," 3rd Ed. Copyright ©, 2000b, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

Secondary Neurulation

This is the continuing formation of spinal cord without direct involvement of the surface ectoderm, i.e., without the intermediate phase of a neural plate (Fig. 2.3D–G). It begins once the caudal neuropore has closed (during stage 12). The caudal eminence, which is already recognizable very early (stages 9 and 10) and slowly replaces the primitive streak, is an ectoderm-covered mass of pluripotent mesenchymal tissue. It provides structures comparable to those formed more rostrally from the three germ layers. Its derivatives include the caudal portions of the digestive tube, caudal blood vessels, notochord, somites, and spinal cord. The caudal eminence (stage 12) gives rise to a solid cellular mass known as the neural cord, which forms the nervous system of the caudal part of the body. The central canal of the more rostrally situated spinal cord extends into the neural cord. The caudal eminence gives rise to at least somitic pair 32 and those following. The mesenchyme for pairs 30–34 is the material for sacral vertebrae 1–5.

The impact of a disturbance of secondary neurulation is difficult to evaluate, and even in animals there is no experimental evidence "that an open spina bifida can result solely from defective secondary neurulation" (Copp and Brooks, 1989).

Neural Crest

Neural crest cells, mostly pluripotent, are given off dorsolaterally from the neural folds at the neurosomatic junction (Fig. 2.4A). They can be distinguished very early in the mesencephalic region (stage 9, Müller and O'Rahilly, 1983), which is earlier than previously indicated. The formation of neural crest cells in the head takes place mainly during primary neurulation, that of the spinal cord chiefly during secondary neurulation. The neural crest cells lose cadherins when they become migratory, but they reexpress them during formation of the peripheral ganglia. The migration of neural crest cells depends on the extracellular matrix through which they travel. Fibronectin and laminin in the matrix facilitate migration, whereas chondroitin sulfate proteoglycans inhibit it. The induction of neural crest is probably caused by local interactions between neural and nonneural ectoderm (induced by a particular range of BMP-4 activity); signals from the mesoderm are also important, and fibroblast growth

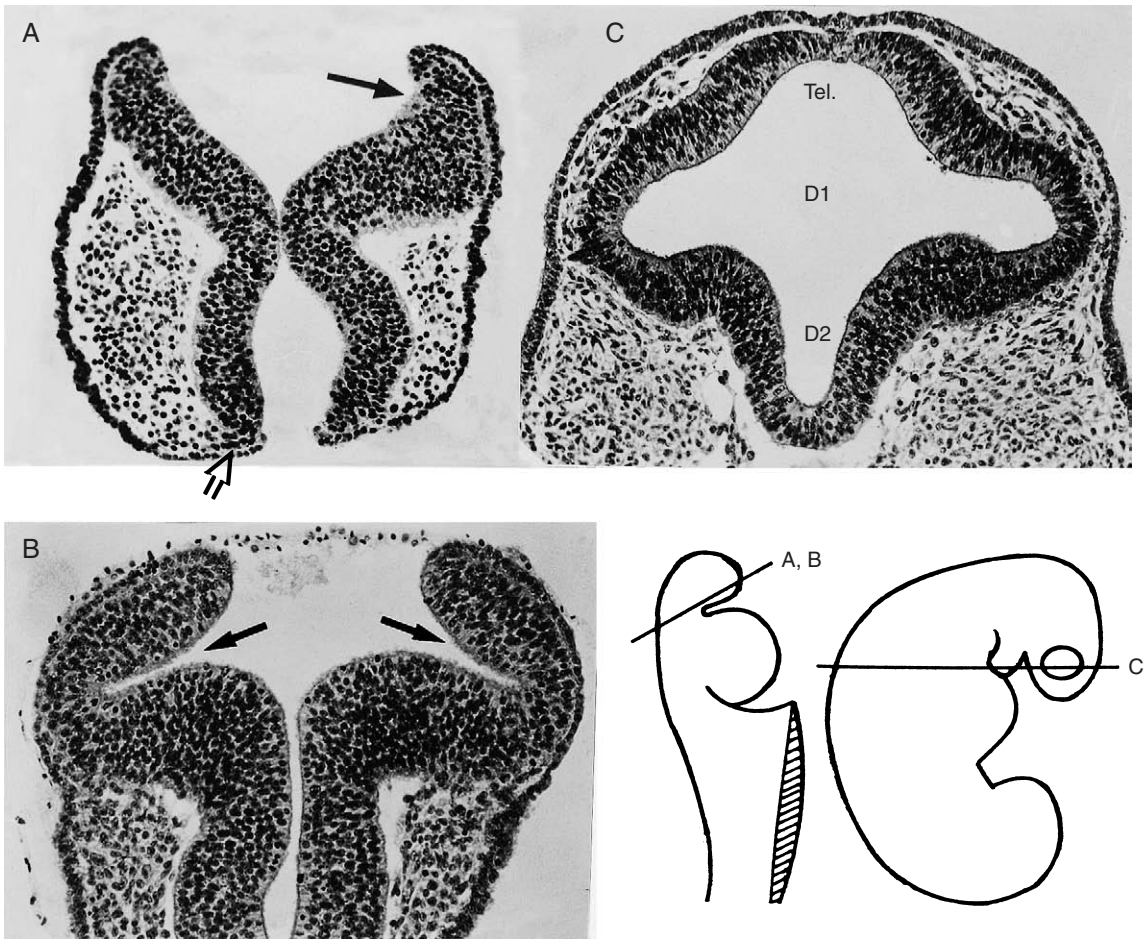

FIGURE 2.4 Sections showing rostral neuropore, optic sulci, and the location of mitotic figures in the early development of the prosencephalon. Rostral is uppermost. **(A)** A widely open rostral neuropore (stage 11). The optic sulcus of the right side is marked by a *black arrow.* Although the telencephalon has already begun its appearance (stage 10), it is not visible in this section. The narrow part of the neural groove leads to the mesencephalon, which gives off neural crest cells *(white arrow)* that are important for the future development of the head. **(B)** In a more advanced embryo (stage 11), the optic sulci *(large arrows)* have become deeper and the optic vesicles are well defined. The rostral neuropore is still open. **(C)** Here (stage 12) the rostral neuropore is closed by fusion of surface ectoderm and neural ectoderm, which over a certain distance are sealed together. The telencephalon medium (Tel.) and its ventricle are visible rostral to the optic vesicles of D1. The unpaired caudal segment represents D2. Levels of sections A and B are indicated on left side of inset, C on right. B is from R. O'Rahilly and F. Müller, "The Embryonic Human Brain," 2nd Ed. Copyright ©, 1999, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

factors seem necessary (at least in birds). Neural crest in the hindbrain is restricted to Rh. 2, 3, and 5–8. It is maintained that crest cells are killed by the secretion of BMP-4 in the even-numbered rhombomere 4. Neural crest cells develop into a variety of cells and tissues. Their specification into neurons is believed to depend on a concerted action of neurotrophins and other growth factors.

NEUROCYTOGENESIS

The cells of the nervous system arise from the neural folds and tube at two main sites: (1) the ventricular layer and (2) the neural crest. It should be noted that the term *spongioblast* has long since been abandoned and that the term *neuroblast* (for immature neurons) is incorrect.

Because the neural plate is exposed to the amniotic fluid (Figs. 2.1A, 2.4A, B), the mitotic figures of this germinal layer are in a superficial location. They become separated from the amniotic cavity when the neuropores close and cell division is characterized by interkinetic nuclear migration. As the neural tube develops, the mitotic figures are adjacent to the future ventricular cavity (Fig. 2.4C). This layer of cells is termed the ventricular layer or zone. Marginal and intermediate layers soon develop. The marginal layer, at first almost acellular, later contains the processes of postmitotic cells. In the neopallium, Cajal–Retzius cells and afferent fibers constitute the primordial plexiform layer. The intermediate layer is characterized by larger, more rounded cells with more widely spaced nuclei belonging mostly to postmitotic cells. The subventricular layer, which appears in the neopallium only after the establishment of the cortical plate (stage 21), is formed by cells at the interface between the ventricular and intermediate layers. These cells continue to divide without interkinetic nuclear migration and may be a source for therapeutic cellular replacement. Further details of the neopallial layers are given later.

Morphogenesis of the brain is dependent not only on cell production but also on apoptosis (Linden, 1997), which is believed to affect half of the neurons formed. Its function seems to be the removal of an excess of neurons and the establishment of appropriate synaptic connections. The process occurs in the brain in such regions as the cortical subplate, the granular cells of the cerebellum, and the pyramidal cells of the hippocampus. It takes place in the olfactory epithelium throughout life. The apoptotic zones of the embryonic human nervous system have been studied and tabulated by Iliés (1969). Reduction of cell death can cause severe malformations, e.g., failure of closure of the neural tube (Kuan *et al.*, 2000).

Neural Stem Cells

Neuronal stem cells persist in the adult mammalian central nervous system (e.g., in the ependyma; Rao, 1999) and participate in plasticity and regeneration, but they have the immunocytochemical markers of glia (Fields and Stevens-Graham, 2002). The only site in the adult peripheral nervous system where production of neural stem cells is documented is the olfactory neuroepithelium (Alvarez-Buyilla *et al.*, 2001, cited in Geuna *et al.*, 2001). A pool of progenitor cells within the human dentate gyrus continues to produce new granule cells throughout life.

Cloned human neural stem cells implanted into the lateral ventricles of monkeys of 12–13 weeks became distributed into two subpopulations (Ourednik *et al.*, 2001): one contributed to corticogenesis by migration along radial glia to the cortical plate and differentiated into neurons and glia; the other remained undifferentiated and contributed to the subventricular zone.

Special Neurons and Their Connections

Genes specific for the central nervous system "are expressed only in the nervous system and repressed in other tissues" (Lunyak *et al.*, 2002).

Catecholaminergic cell groups have been detected very early (stages 13 and 14) in the human rhombencephalon and mesencephalon, and similar groups are soon found in the hypothalamus (stages 15 and 16). A band of densely packed cells corresponding to the primordia of the dopaminergic substantia nigra and ventral tegmental area has been recorded (at approximately stage 20; Verney *et al.*, 1991).

Moreover, it is now believed that catecholaminergic neurons in the human embryo arise along the entire cerebral axis rather than from a few localized sources.

Cajal–Retzius cells are among the first-formed neurons and their early presence is proven by *reeler* immunoreactivity (Zecevic *et al.*, 1999). The population of Cajal–Retzius cells in the future molecular layer matures late in trimester 2 (Verney and Derer, 1995) and is most striking near the middle of prenatal life (Tsuru *et al.*, 1996). These cells are thought to be fully mature when they express neurofilament proteins strongly and when the pyramidal neurons are already generated. *Reelin* produced by the Cajal–Retzius cells is responsible for the normal migration of the neurons from the ventricular layer to the periphery of the wall of the brain.

A distinction has been made between Cajal and Retzius cells (Meyer *et al.*, 1999). Cajal cells lie closer to the pia, are smaller, and are frequently triangular or piriform. They appear when the Retzius cells have already largely disappeared.

Bergmann cells are modified radial glial cells of the cerebellum that develop early in the fetal period (Choi and Lapham, 1980).They are essential for the migration of the Purkinje cells, which will be present at the end of trimester 1 (Rakic and Sidman, 1970).

Purkinje (piriform) cells are established early (stage 21). They form "multiple populations of chemically distinct cells that migrate in a coordinated fashion" to form sagittal bands of cells (Hawkes and Mascher, 1994). Their characteristic shape is acquired by the middle of prenatal life, although migration, as well as changes in shape and size, continues postnatally (for about 18 months?).

DEVELOPMENT OF THE NEURAL PLATE AND GROOVE

The primordium of the central nervous system appears (at stage 8; Fig. 2.1A) before the heart or other organs become evident, at a time when very few morphological features are present. At that time, the embryo is a slightly vaulted disc that possesses a longitudinal axis. The axis is indicated by (1) the primitive streak and groove, which begin at the primitive node and proceed caudally; and (2) the notochordal process (Fig. 2.1, inset) and the neural groove. Retinoic acid is implicated in the pattering of the rostrocaudal axis of the brain and the induction of *HOX* gene expression in the mouse and rat (Morriss-Kay, 1993; Ruberte *et al.*, 1991).

The neural groove is seen only in the largest embryos of the group (stage 8b; Fig. 2.1A). The neural ectoderm of the groove and of the bilateral vaulted areas isthe first visible sign of the future nervous system. The neurenteric canal (Fig. 2.2, inset) may be important in the formation of a split notochord (diastematomyelia), and its persistence may lead to a dorsal enteric cyst.

When one to three pairs of somites have appeared (stage 9), the neural groove is considerably deeper and the three major divisions of the brain (prosencephalon, mesencephalon, and rhombencephalon) can be identified in the unfused neural folds. They are distinguishable by their position in relation to the mesencephalic flexure and not as so-called vesicles, as so commonly stated. The rhombencephalon is the longest portion of the brain at this time.

Neuromeres

Neuromeres are morphologically identifiable transverse subdivisions perpendicular to the longitudinal axis of the embryonic brain and extending onto both sides of the brain. They appear early (stage 9) and subdivisions are soon visible (stage 11). In the hindbrain they are termed rhombomeres (Rhs.).

Four primary rhombomeres (A, B, C, D) and the otic disc can be discerned in the open neural folds (stage 9) before the neural tube has begun to form. Rh. A lies between the mesencephalic flexure and the otic disc, Rh. B is adjacent to the otic disc, Rh. C is at the base of the mesencephalic flexure, and Rh. D is adjacent to the occipital somites. Eight secondary rhombomeres (Table 2.2) develop from them. Rh. A divides into Rh. 1, 2, 3; Rh. B becomes Rh. 4; Rh. C. divides into Rh. 5, 6, 7; and Rh. D becomes Rh. 8. The development of the neuromeres in the human embryo has been described in detail elsewhere (Müller and O'Rahilly, 1997) and the arrangement at 5 weeks (stage 14) is summarized in Table 2.2. Other schemes, including six prosomeres described in the mouse, are not supported for the human (Müller and O'Rahilly, 1997). Later (stage 15) a longitudinal organization begins to be superimposed on the neuromeres (Fig. 2.5).

TABLE 2.2 The 16 Secondary Neuromeres of the Human Embryo and Their Stage of Appearance

No.	Neuromere	Abbreviation	Stage
1	Telencephalon medium	T	10
2	Diencephalon 1	D1	10
3–5	Diencephalon 2	D2	10
	3 Parencephalon rostralis	Par.r.	14
	4 Parencephalon caudalis	Par.c.	14
	5 Synencephalon	Syn.	13
6	Mesencephalon 1	M1	12
7	Mesencephalon 2	M2	12
8	Isthmus rhombencephali	Isth.	13
9–16	Rhombomeres 1–8	Rh.	11

Domains of gene expression coincide more or less with the neuromeres in some instances, but in others they may cross interneuromeric boundaries.

Early Gene Expression

Because chromosomal anomalies are present in patients with holoprosencephaly at the level of p21, p24-7, and 18p, those chromosomes are clearly important in the normal development of the brain. Furthermore, within the 7q36 band are more genes that are necessary (Gillessen-Kaesbach, 1996; Gurrieri and Muenke, 1996).

Preliminary studies have been undertaken on the role of *Pax* genes in the early development of the human embryo (Gérard *et al.*, 1995). *Pax 3* is expressed in the neural groove and closed neural tube, and later in the mesencephalon, rhombencephalon, and spinal cord. *Pax 5* expression is restricted to the mes-rhombencephalic boundary and the spinal cord. *Pax 6* is expressed in the optic neuromere (D1) of the neural tube and later in the rhombencephalon, spinal cord, and somites, but not at the level of the mesencephalon. Mesencephalon and cerebellum both require the *Wnt-1* gene for development; it is expressed in a restricted area of the neural plate. Furthermore, *En* and *Wnt* genes are involved in the patterning of the mesencephalon and metencephalon in human and mouse embryos (Song *et al.*, 1996). Regionalization in the neural tube is regulated by genes that display temporally and spatially restricted expressions.

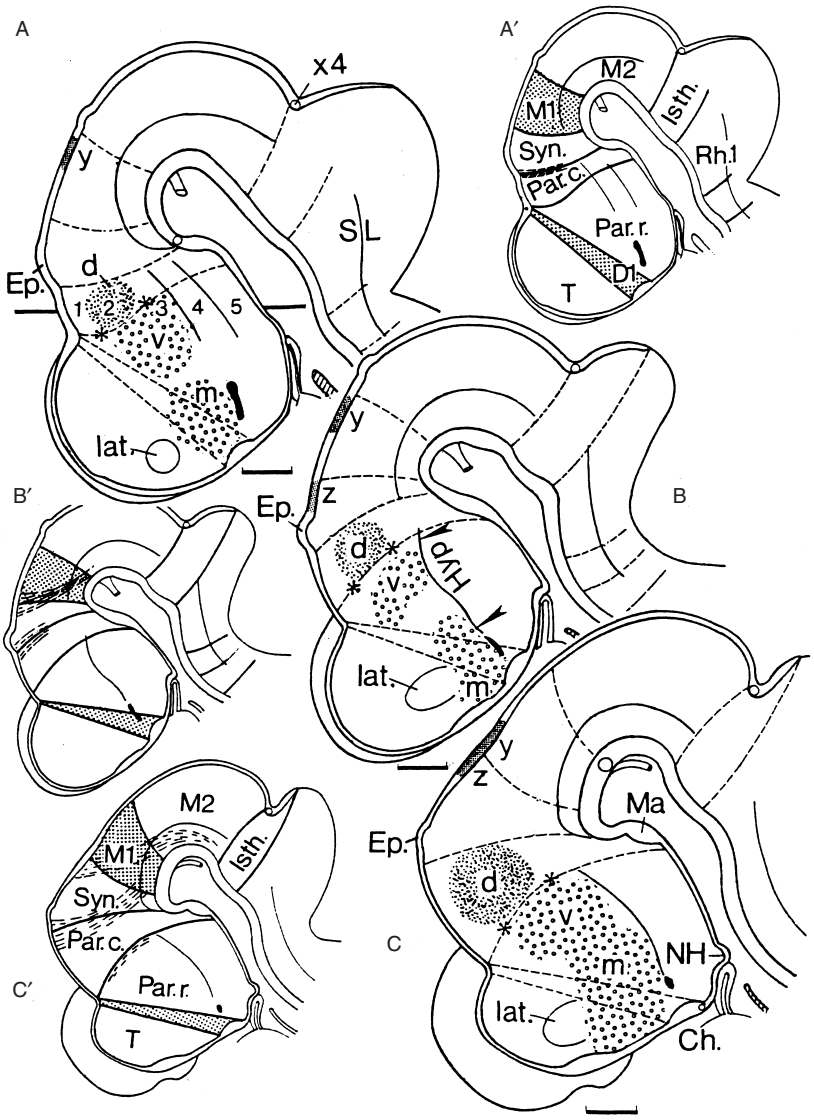

FIGURE 2.5 Median reconstructions at **A** stage 15, **B** stage 16, and **C** stage 17. The opening to the optic ventricle, now small, is shaded black. The horizontal line in **A** indicates a section that would include all five longitudinal zones of D2. The asterisks in **A, B,** and **C** mark the sulcus medius. **A′, B′,** and **C′** are key drawings to show the limits of the neuromeres, and D1 and M1 are stippled. In **A′** the habenulointerpeduncular tract is shown by interrupted lines. In **B′** the tract of the posterior commissure has been added higher up (more caudally). In **C′** the three tracts shown are, from above down (caudorostrally), the tract of the posterior commissure, the habenulointerpeduncular, and the tract of the zona limitans intrathalamica. Ch., optic chiasma; D, dorsal thalamus; Ep., epiphysis cerebri; m, medial ventricular eminence; Ma, mamillary region; NH, neurohypophysial recess; SL, sulcus limitans; v, ventral thalamus; X4, trochlear decussation; y, commissure of superior colliculi; z, posterior commissure; Bar in A = 0.2 mm; in B = 0.22 mm; in C = 0.4 mm. From F. Müller and R. O'Rahilly, Acta Anatomica, 1997. Copyright ©, 1997, S. Karger AG. Reprinted by permission of S. Karger AG.

A high degree of conservation of the pharyngeal *Hox* code has been found in a study of various groups of *Hox* genes that have been shown to be expressed in the human rhombomeres and pharyngeal arches (Vieille-Grosjean *et al.*, 1997).

THE BRAIN FROM 4 TO 6 POSTFERTILIZATIONAL WEEKS

The external development of the brain from 4½ to 7 weeks (stages 12–18) is represented in Fig. 2.6. The optic and otic primordia are shown.

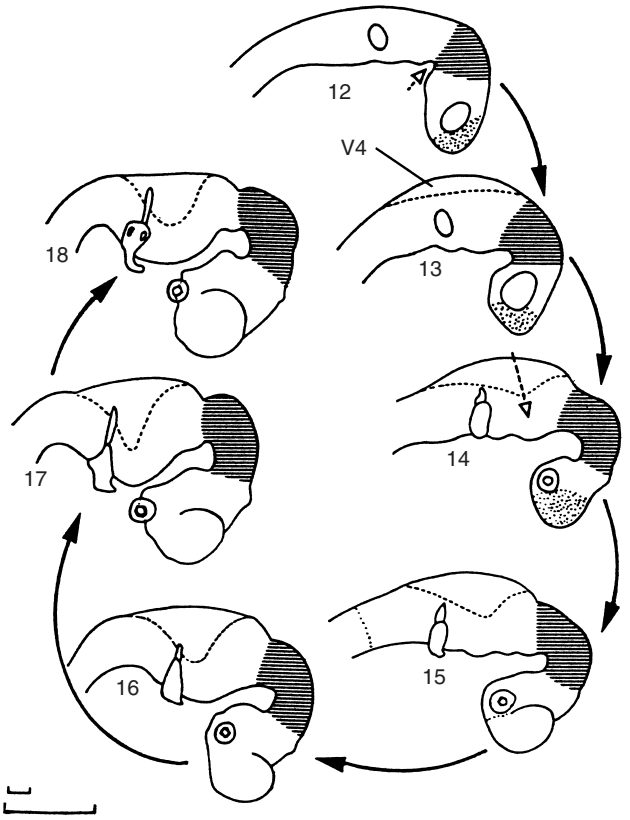

FIGURE 2.6 External form of the brain from about 4–6 weeks (stages 12–18), based on graphic reconstructions by the authors. The mesencephalon is hatched. The stippling at stages 12–14 shows the extent of the telencephalon. The arrows at stages 12 and 14 indicate the mesencephalic and pontine flexures, respectively. The magnification has been decreased progressively from stage 12 (large bar, 1 mm) to stage 18 (small bar, 1 mm). V.4, fourth ventricle.

The two components of the forebrain, the diencephalon and the telencephalon, can be detected extremely early (stage 10), as first shown by the present authors (Müller and O'Rahilly, 1985, 1987), i.e., at or before 4 weeks. The end component is the telencephalon medium or impar (stage 11), a week before the future cerebral hemispheres begin to evaginate. The widely open forebrain (Figs. 2.4A, B) presents two diencephalic neuromeres: D1, the optic part, characterized by the optic sulci; and D2, the thalamic part. Neuromere D1 is related to the chiasmatic plate and is characterized by evagination of the optic vesicles. Neuromere D2 is in line with the hypophysial primordium, which can be recognized because the neurohypophysial region of D2 is adjacent to the adenohypophysial epithelium, which, in turn, is immediately rostral to the oropharyngeal membrane.

The neural folds grow mediad (stage 11) and fuse to form the rostral wall of the telencephalon medium, which then (stage 12) expands as a neuromere (Fig. 2.4C, stippled in Fig. 2.6). A new subdivision, the synencephalon, is recognizable (stage 13) as a dorsolateral outpocketing in the caudal portion of D2, and later it gives rise to the pretectum and prerubrum. The pontine flexure becomes identifiable (stage 14) and the cerebral hemispheres evaginate from the telencephalon medium (stage 15). As the pontine flexure deepens, the brain changes from its tubular appearance to a more compact form (stages 16–18).

In contrast, the endlessly repeated scheme of three "vesicles" being transformed into five gives a totally inadequate, indeed erroneous, idea of the development of the human brain (O'Rahilly and Müller, 1999b).

SOME INDIVIDUAL REGIONS OF THE BRAIN

Tables 2.3–2.14 summarize the timing and sequence of events as determined by the authors.

Telencephalon: Formation of the Neocortex (Table 2.3)

Ventricular Zone

The layer adjacent to the ventricular cavity is where the primary proliferative phase takes place (Fig. 2.7A). Most of the mitotic divisions that generate neurons and radial glia are localized here and are characterized by interkinetic nuclear migration. Subsequently, the ventricular zone develops into the ependymal zone.

Neurons and glia are derived from the same progenitors (Fields and Stevens-Graham, 2002). More

TABLE 2.3 Development of the Neocortex

Features	Stage
Neocortical areas distinguishable from other cortical areas	16
Primordial plexiform layer with one row of horizontal cells	17
First synapses in primordial plexiform layer	17
Ventricular layer diminishing to 75–80%	18–20
Primordial plexiform layer with several rows of cells; choroid plexus; Cajal-Retzius and subplate cells	19
Neopallial fibers; thalamocortical earlier than corticothalamic[a]	20, 21
Cortical plate; formation of subplate and layer 1	21
Claustrum	22
Internal capsule	22, 23
External capsule	23

[a]This is not so in rodents, in which corticothalamic fibers appear earlier than thalamocortical fibers.

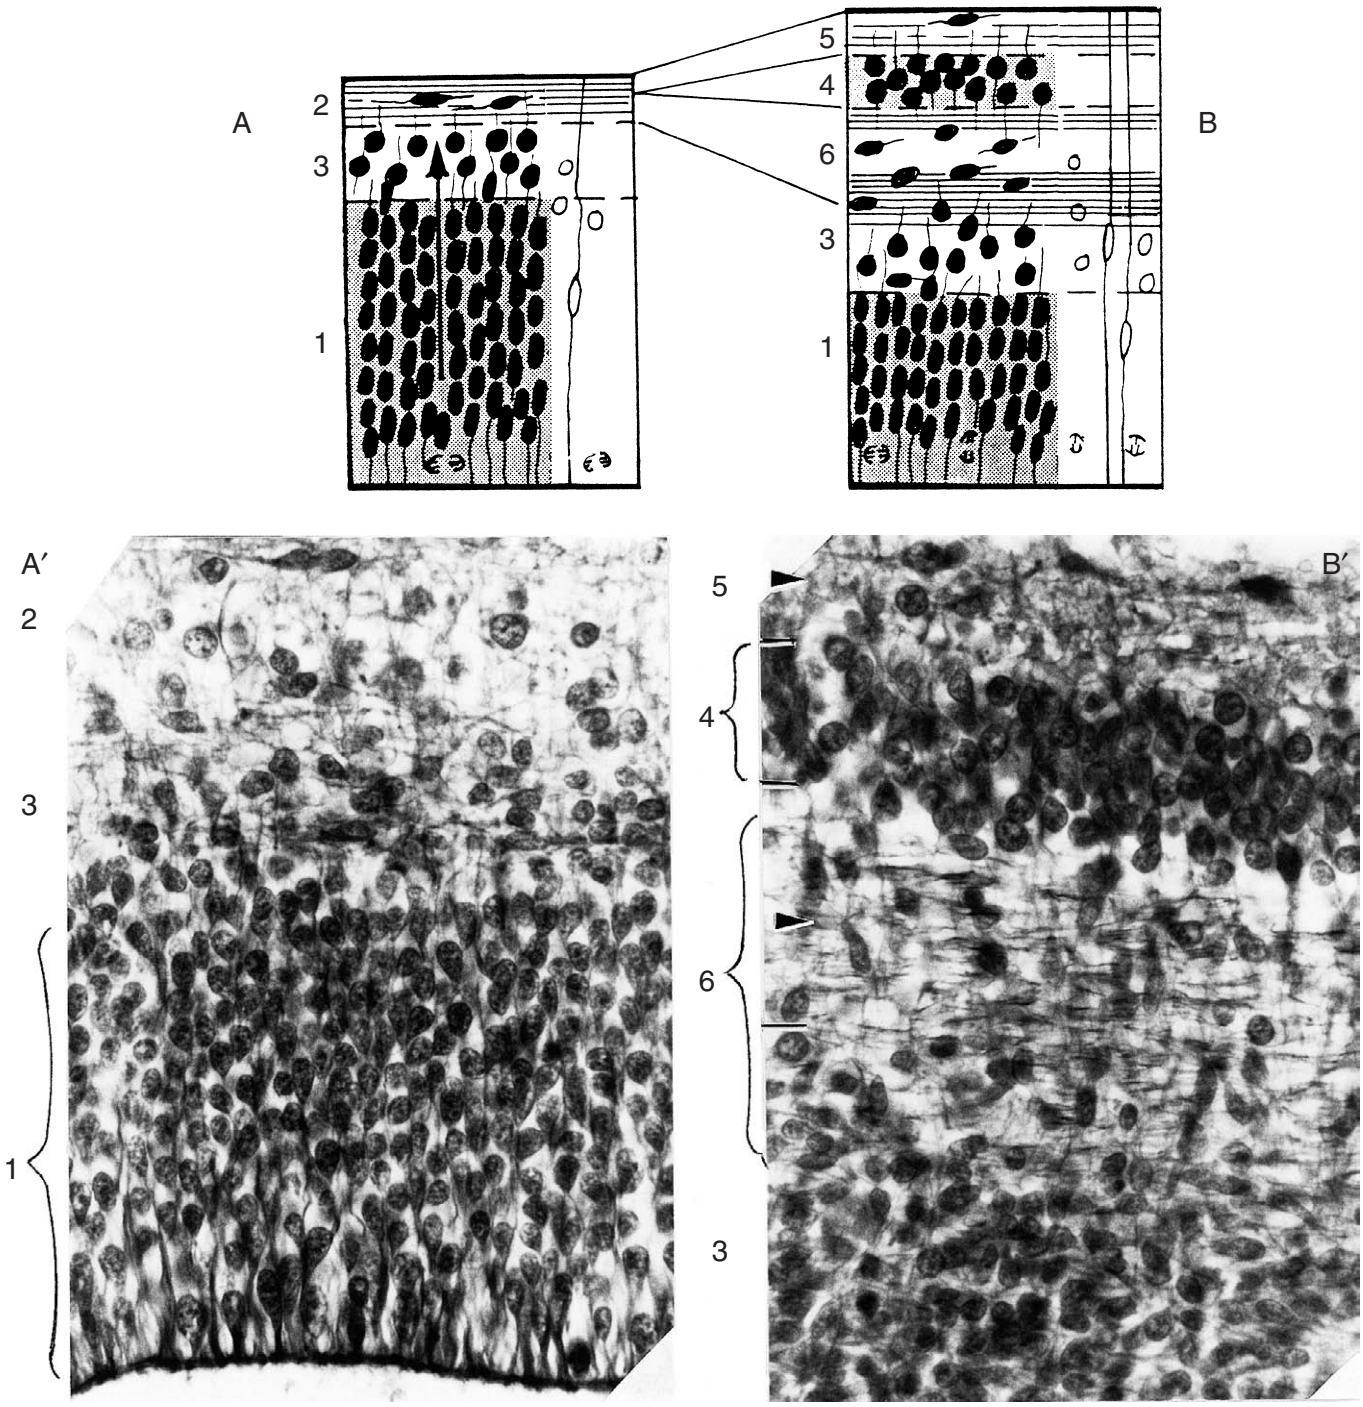

FIGURE 2.7 Formation of the neopallium by production of neurons, glial cells, and fibers. The layers are numbered here according to their order of appearance. **(A)** The intermediate layer (3) is between the ventricular (1) and primordial plexiform (2) layers (stage 18). The cells in layer 2 are Cajal–Retzius, the spherical cells in layer 3 are the precursors of subplate neurons. **(B)** The cortical plate (4) represents future layers 2–6 of the cerebral cortex (stage 21). Future layer 1 (marked 5 here) is superficial; the subplate (6) is deeper. Reelin-positive cells are found in 5. The fibers at the interface between 6 and 3 are dopaminergic. Some radial glial cells are shown at the right-hand side, where the neurons have been omitted for clarity. **(A′)** Section of a frontal region without a cortical plate (at stage 23) corresponding to A, showing radial fibers in the ventricular, and tangential fibers in the intermediate layer. **(B′)** Section (at stage 23) corresponding to B. Tangential fibers have appeared in the subplate. From R. O'Rahilly and F. Müller, "The Embryonic Human Brain," 2nd Ed. Copyright ©, 1999, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

neurons than glial cells are produced early in development, whereas later (probably at the time of formation of the cortical plate) the percentage of glial cells versus neurons increases. Two proliferative phases are described and both extend well into the fetal period. The account below is based largely on studies in the mouse.

During proliferative phase 1, neurons and radial glial cells develop. Stem cells divide asymmetrically; one daughter cell usually remains in the proliferative unit, whereas the other leaves the ventricular layer (Rakic, 1991, 1996). The first neurons in the neopallial wall migrate into the marginal layer as future Cajal–Retzius cells. Together with afferent nerve fibers, they form the primordial plexiform layer (Fig. 2.6), in which the cells of the future cortical layer 1 and of the subplate mature first. Here is where the first synapses develop (Molliver *et al.*, 1973; Larroche, 1981; Choi, 1988). The postmitotic cells that will become the neurons of layers 2–6 migrate from the ventricular to the intermediate zone and later (stage 21) into the cortical plate.

During proliferative phase 2, most of the glial cells are produced in the subventricular and intermediate zones. The precursor cells arise in the ventricular layer but move into the subventricular and the intermediate zones when the cortical plate begins to form at 7 weeks (stage 21). In these two strata, interkinetic nuclear migration does not occur and almost no neurons are produced (except in the olfactory bulb). Formation of glial cells, which was minimal during phase 1, increases greatly at 8 weeks (probably at about stage 23). Radial glia can generate neurons by asymmetrical cell division (Noctor *et al.*, 2001, in Fields and Stevens-Graham, 2002). Phase 2 continues throughout the fetal period, and the production of both glial and neural cells is believed to end together. A secondary proliferative population is lacking in the subiculum, hippocampus, and dentate gyrus.

During and after migration, the young neurons that arise in the ventricular layer differentiate. The progression from a neuroepithelial cell to a specific neuron is programmed by specific genes, and different types of receptors of a neuron respond to different transmitters. Thyroid hormone receptors are particularly important for normal development of the brain.

Five categories of neuronal migration are described:

1. *Nonradial migration*. If neurons do not use radial glia as a migratory substrate, they have to glide across one glial fiber to another (O'Rourke *et al.*, 1995).
2. *Radial migration* of neurons from the ventricular to the subventricular layer and beyond is most likely mediated by radial glial cells. Radial migration is prominent in the development of the telencephalic cortex (Sidman and Rakic, 1973).
3. *Tangential migration*, which may be more prevalent than previously suspected, concerns mostly young neurons parallel to the pia (O'Rourke *et al.*, 1995,). It occurs in the cerebral cortex (Zecevic and Milosevic, 1997; Marin *et al.*, 2001; Ulfig *et al.*, 2001) and in the rhombencephalon (Fig. 2.10A3).
4. *Combined radial and tangential migration.* In the cerebral cortex γ-aminobutyric acid (GABA)–positive cells use both directions for dispersing from the ventricular zone: radial migration toward the pia, tangential migration parallel to the pia. In the cerebellum radial migration is from the ventricular zone, tangential from the rhombic lip (p. 40 and Fig. 2.10B).
5. *Chain migration provides* "a steady supply of new GABAergic neurons destined for the olfactory bulb" and originating in the subventricular layer of the cortex (Verney *et al.*, 2002). The cells migrate as a "chain of neurons ensheathed by a protective layer of glial cells" (Wolf *et al.*, in Hatten, 2002; Lois, 1996).

Intermediate Zone

This layer is characterized by larger, more rounded, and more widely spaced nuclei belonging mostly to postmitotic cells (Fig. 2.7A).

Marginal Zone

This is considered to be an axon-free and a cell-free layer, which, after its initial development, is present only in the hippocampal primordium. In all other telencephalic parts an initial marginal zone is replaced by a primordial plexiform layer as soon as corticipetal fibers arrive (Fig. 2.7A). It is now believed by some that a primordial plexiform layer is present not only in the neopallium but in all parts of the brain (Zecevic *et al.*, 1999), as was already suspected earlier for the diencephalon by the present authors (Müller and O'Rahilly, 1989a).

Development of Fibers

The development of fibers is associated with the change of the marginal into the primordial plexiform layer. The development of axons depends on adhesion, guidance, migration, and growth to reach appropriate targets. Three phases have been distinguished: (1) initial elongation, (2) collateral sprouting, and (3) pruning of extraneous connections.

The earliest afferent (probably catecholamine) fibers in the human embryo can be detected in the primordial plexiform layer of the future temporal cortex at

6 weeks (stage 17). This is the neopallial wall overlying the primordium of the amygdaloid region. Such fibers can easily be identified in silver-impregnated sections (Fig. 2.7A). Catecholamine fibers may perhaps participate in early synaptogenesis within the subplate in the human embryo (Larroche, 1981). The following is the usual pattern later in development. As the cortical plate forms the primordial plexiform layer, the latter is separated by the cortical plate into two parts: future layer 1 and the subplate (Fig. 2.7B). Accordingly, the fibers are also separated into two sets: a group remains in future layer 1 and another group now constitutes axons of the subplate. The initial subpial plexiform layer contains fibers that express neurofilament proteins, and phosphorylated fibers are found later (Zecevic *et al.*, 1999). Thalamocortical fibers were found by the authors in embryos of stages 20 and 21 (Table 2.3). Thalamocortical input seems to have little influence on the initial organization of the cortex of the mouse (Rakic, 2001). In the subplate a few dopaminergic fibers are present at 7–8 weeks (stages 21–23) (Zecevic and Verney, 1995). At the time (stage 21), "when the first cortical plate neurons are present," catecholamine fibers "penetrate the lateral cerebral wall." They become located mainly in the subplate, only sparsely in the subependymal layer (Verney *et al.*, 2002). A few dopaminergic fibers are also present in the subplate at 7–8 weeks (stages 21–23) (Zecevic and Verney, 1995; Verney *et al.*, 2002). At 8 weeks (corresponding to stage 23), two types of fibers were observed in the "cortical anlage": the serotoninergic fibers from the raphe and another kind that does not resemble the classical CA fibers (Verney *et al.*, 2002). In the human, penetratio of monoamine fibers of the cortical plate occurs at the end of trimester 1, and the highest density is found in the deep part of the human cortical plate and in the subplate (Verney *et al.*, 1993).

Primordial Plexiform Layer

This layer, also known as the preplate (Fig. 2.6A), has a significant role in the structural organization of the neocortex (Marín-Padilla, 1992). It consists of fibers and early neurons, and its composition is far more complex than hitherto believed (Zecevic *et al.*, 1999; Meyer *et al.*, 2000). Among the fibers are (1) corticipetal fibers, as mentioned above; (2) horizontal fibers from Cajal–Retzius cells; and (3) apical dendrites from radially migrating neurons during the formation of the cortical plate. The first neopallial synapses are detected in the primordial plexiform layer of embryos of 6 weeks (approximately stage 17: Choi, 1988; Zecevic and Milosevic, 1997). The neurotrypsin gene, which is expressed in the developing human brain from about $6\frac{1}{2}$ to 15 weeks, is a regulator of synaptic development. Mutation of the gene is associated with nonsyndromic mental retardation (i.e., with apparently normally developing brain and no other clinical features) (Molinari *et al.*, 2002).

Certain portions of the primordial plexiform layer are considered to be functionally active quite early (at stage 20) in the human embryo (Marín-Padilla and Marín-Padilla, 1982), and this stratum assumes an important role in the functional organization of the adult cerebral cortex. It represents the barrier at which newly arrived neurons normally stop their migration and become detached from their substrate of glial fibers. Preplate cells are responsible for the formation of a localized extracellular matrix. The *reeler* gene product is an ECM-like protein that is expressed by its cells and indicates a critical role for ECM in cortical lamination.

During migration the apical dendrites of all neurons reach layer 1 (Marín-Padilla, 1992). However, only pyramidal neurons are retained and expand their original connections with that layer; other types of neurons lose their connections. The structural and functional contacts with the elements of layer 1, their orderly placement in the cortical plate, and their preservation as early differentiated neurons until ready to begin their specific phenotypic differentiation and maturation are considered to be dependent on layer 1.

In the *reeler* anomaly in the mouse the primordial plexiform layer remains undivided and the cortical cells accumulate below it. In addition, the cortical position of neurons is inverted: the earliest formed lie most superficially, whereas the later formed stop their migration at successively deeper cortical levels.

Cortical Plate

This important stratum develops within the primordial plexiform layer (stage 21), mainly in the area of the future insula, and it expands over the whole neopallial area (stage 23; Fig. 2.6B, B′). The plate represents the future layers 2–6 of the cerebral cortex. Future layer 1 (part of the primordial plexiform layer) is superficial and subpial, whereas the subplate is deep to the cortical plate. During the development of the cortical plate (stage 21), basal forebrain fibers grow tangentially through the subplate. In the primordial plexiform layer the earliest generated neurons are the most peripheral. In the plate, however, the oldest neurons are in the depths, whereas the earliest are superficial ("inside out" placement).

Various types of abnormality of the cortical plate are known, e.g., nodular, vertical neuronal stripes with polymicrogyria, a four-layered cortex probably of

vascular origin, and lissencephaly caused by defective neuronal migration traced to the *LIS 1* gene on chromosome 17.

Subplate

This stratum appears in stage 21, much earlier than hitherto believed (Müller and O'Rahilly, 1990b and Table 2.3). Neurons in the subplate throughout the neocortex are believed to be required for "cortical target selection" and for the ingrowth of thalamic axons. At $6\frac{1}{2}$ weeks both dopaminergic and noradrenergic fibers have been recorded. At about 7 weeks, catecholamine axons enter the telencephalic wall and occupy the subplate and, more sparsely, the marginal layer (Verney *et al.*, 2002). It is possible, therefore, that the initial contact between catecholaminergic fibers and GABA-positive neurons is established at this early time (Zecevic and Milosevic, 1997; Verney *et al.*, 2002). However, several classes of afferent fibers wait for weeks before penetrating the cortical plate and the role they play in the transitory synaptic organization of the subplate is still unclear.

Subventricular Zone

This layer appears only after the establishment of the cortical plate (stage 21). It is formed by cells at the interface between the ventricular and intermediate zones. The cells divide without interkinetic nuclear migration and form a distinct population in the mouse. They may possibly have different functions in different areas. The cells may also be a source for therapeutic replacement. In the mouse the subventricular layer of the neopallium remains active into adulthood. The production of cells in the subventricular zone is considered to be the secondary proliferative phase. Most glial cells are produced here and in the intermediate layer. A few dopaminergic fibers are visible at 7–8 weeks (Zecevic *et al.*, 1999, probably stages 21–23).

Subpial Granular Layer

This layer, associated with the name Bruns, is present before the middle of prenatal life (Choi, 1988; Marín-Padilla, 1995). It is fully developed by the end of trimester 2, when regression begins, and it disappears during trimester 3 (Spreafico *et al.*, 1999). The cells are located above those of Cajal–Retzius (Verney and Derer, 1995). Mitotic figures are not found, and the layer is formed by a tangential "chain migration" from the subventricular layer of the olfactory bulb, whence cells are given off shortly after the appearance of the neocortical plate. The layer is composed of both differentiated and undifferentiated cells, and it contains glial precursors that become transformed into astrocytes and later migrate into the gray matter (Marín-Padilla, 1995). Most, if not all, cells are neurons (Meyer *et al.*, 1999). They produce *reelin* early in the fetal period (Meyer and Wahle, 1999) and represent a precursor pool of neurons that complement earlier generated cells during the critical period of cortical migration.

The following developmental events have been studied by immunohistochemistry (Meyer *et al.*, 2000): (1) appearance of *reelin*-expressing neurons along the outer aspect of the neuroepithelium and establishment of a cell-sparse marginal zone (stages 16–18); (2) formation of a monolayer of horizontal, calretinin-positive and/or GAD (glutamic acid decarboxylase)–positive neurons, concurrent with the segregation of a *reelin*-positive subpial cell compartment; (3) condensation of a "pioneer plate" populated by calretinin-positive, GAD-negative pioneer cells (stage 21); and (4) appearance of the cortical plate proper within the framework of the pioneer plate (stages 21–22).

The Corpus Striatum and Other Basal Nuclei
(Table 2.4)

Both the diencephalon and the telencephalon contribute to the complicated formation of the corpus striatum. The diencephalon, which gives rise to the medial ventricular eminence, has a relatively short proliferative phase, and this seems to extend postnatally (Brana *et al.*, 1995) in contrast to the long phase of the telencephalon, from which the lateral ventricular eminence originates. These eminences, named by the present authors, were formerly known incorrectly as "ganglionic" *(Ganglienhügel).*

The medial ventricular eminence appears early. It arises as a thickening rostral to the optic stalk (Fig. 2.8A) and represents the ventral part of the torus

TABLE 2.4 Development of the Corpus Striatum

Features	Stage
Amygdaloid body:	
Medial ventricular eminence	14

Globus pallidua internus	21

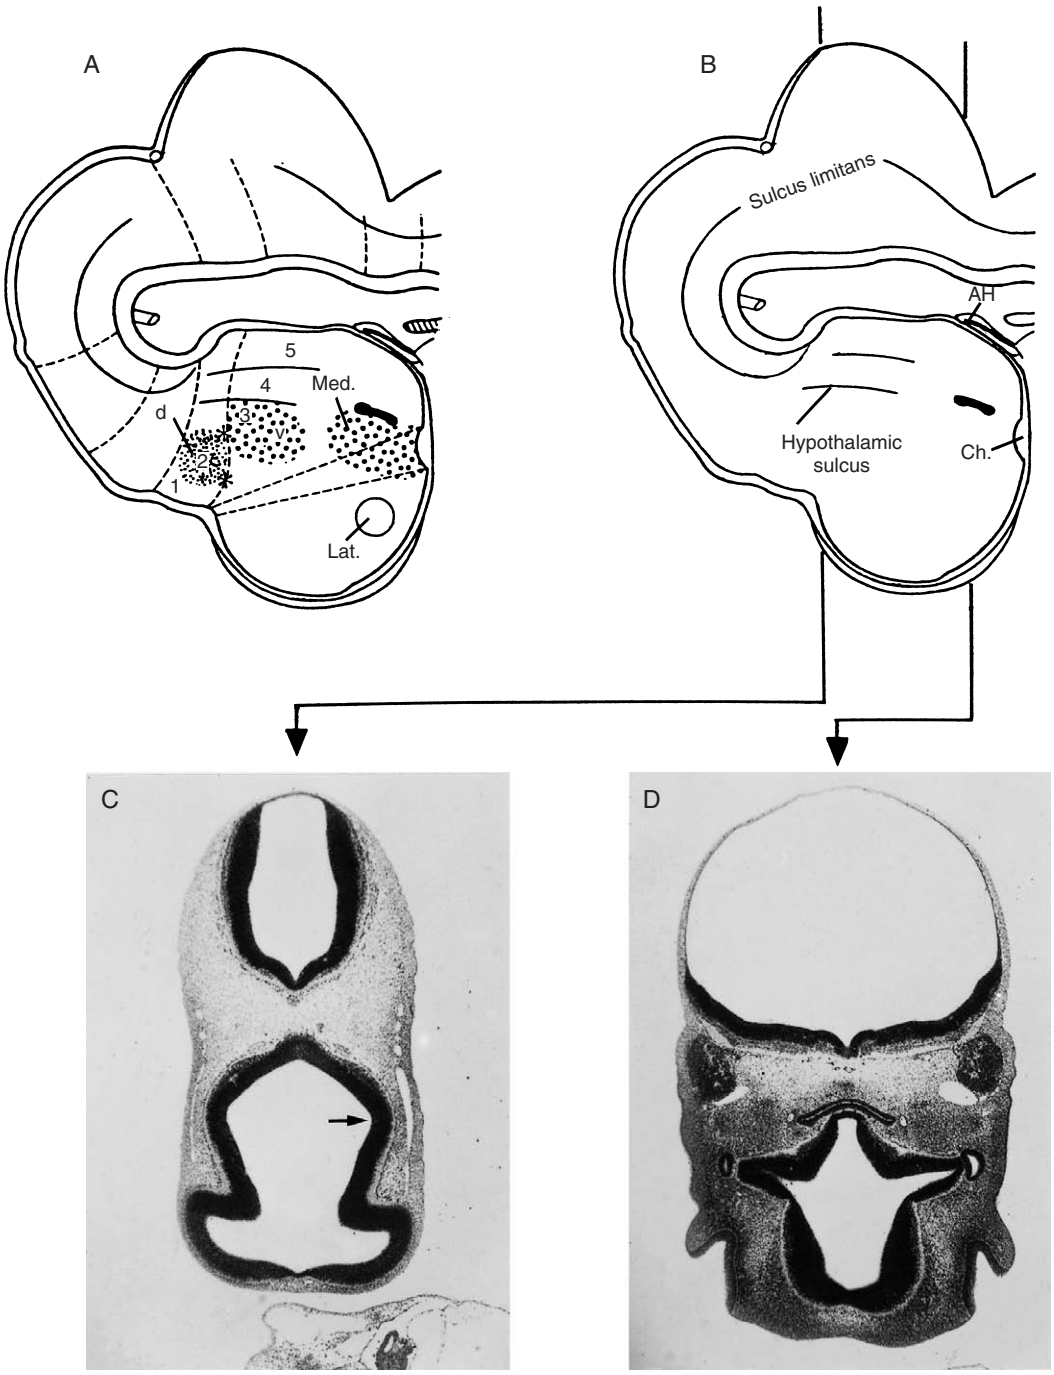

FIGURE 2.8 **A** and **B** are graphic reconstructions of the brain (at stage 15) by the authors. **(A)** A scheme of the transverse (neuromeric) and the longitudinal subdivisions of the diencephalon. In **A** the longitudinal parts are indicated by numbers: 1, epithalamus, 2, dorsal thalamus; 3, ventral thalamus; 4, subthalamus; 5, hypothalamus (with early evagination of the neurohypophysis). The asterisks are at the ends of the sulcus medius, which is the site of the future tract of the zona limitans intrathalamica; the tract is shown in Fig. 2.5C′. **(B)** The planes of section of the two photomicrographs. **(C)** Section at the level of the evaginating cerebral hemispheres *(below)*, showing the very thin lamina terminalis. The hypothalamic sulcus is indicated by an arrow. The rhombencephalon visible here is the rostral area of Rh.1. **(D)** Section at the level of the adenohypophysis. The optic stalks are still in open communication with the third ventricle. The thickening rostral to the optic stalks is the torus hemisphericus, which represents the medial ventricular eminence. The very wide caudal area of Rh.2 with the trigeminal ganglion is evident in the upper part of the photomicrograph. AH, adenohypophysial primordium; Ch, chiasmatic plate; d, dorsal thalamus; Lat, lateral ventricular eminence; Med., medial ventricular eminence; v, ventral thalamus.

hemisphericus, which separates the developing telencephalic hemispheres from the diencephalon. Later, because of growth gradients, the medial eminence becomes displaced rostrally into telencephalic territory.

The lateral ventricular eminence is purely telencephalic and neostriatal, and appears as a discrete internal swelling in the neopallial wall (circle in Fig. 2.8A). Cell production occurs in the ventricular and later also in the subventricular zone, although an intermediate layer seems to be lacking. Migration from the matrix begins at about 5 weeks (Kahle, 1969).

The eminences are characterized by their large size and by the exceptional persistence of their subventricular layer. At the end of the embryonic period, both eminences lie along the floor of the lateral ventricle, separated from each other by a faint "intereminential sulcus" (a term introduced by the present authors). Exhaustion of the matrix, which proceeds caudorostrally, does not begin until trimester 2 (Sidman and Rakic, 1982). The medial eminence is probably more closely related to the (diencephalic) globus pallidus than to the (telencephalic) lateral eminence, and seems to be related also to the nucleus accumbens, the tail of the caudate nucleus, and the caudal part of the putamen (Hewitt, 1958). The claustrum arises (at stage 21) shortly before the internal capsule enters the telencephalon and before the fibers of the external capsule are present.

The Olfactory Region (Table 2.5)

Neurons that produce luteinizing hormone–releasing hormone (LHRH; Schwanzel-Fukuda *et al.*, 1996; Verney *et al.*, 2002) develop from the medial parts of the nasal pits (stage 16; Fig. 2.9D) and probably earlier from the nasal discs (stage 13). These cells are transported (stage 19) by fibers of the vomeronasal nerve and the nervus terminalis to the olfactory bulbs and to the forebrain septum. These gonadotropin-producing cells are accompanied by TH-positive neurons (Verney *et al.*, 2002). Cells in the ventricular layer of the olfactory ventricle destined for the subpial granular layer are given off shortly after the appearance of the cortical plate. The vomeronasal organ in the human contains no recognizable neuroepithelium (Smith *et al.*, 2002) and its function is still unclear.

TABLE 2.5 Development of the Olfactory Region

Features	Stage
Nasal discs	11
Terminal–vomeronasal neural crest	13
Olfactory eminence (thickened telencephalic wall opposite nasal disc)	14
Nasal pit	15
Olfactory field of brain with intermediate layer; neurons with luteinizing hormone–releasing-hormone develop; first olfactory nerve fibers; islands in olfactory tubercle	16
Fibers from olfactory tubercle to medial forebrain bundle; fibers of terminal and vomeronasal nerves; fibers from olfactory tubercle to amygdaloid region; olfactory fibers enter olfactory bulb	17
Anterior olfactory nucleus ?; vomeronasal ganglion; fibers from olfactory bulb to olfactory tubercle	18
Ganglion of N. terminalis	19

The Forebrain Septum (Table 2.6)

The basal part of the medial telencephalic wall (septum verum) forms as the cerebral hemispheres expand beyond the lamina terminalis, and it extends between the olfactory bulb and the commissural plate (Fig. 2.9, inset). The earliest part of the septum is the olfactory tubercle (stage 16), which contains cellular clusters and receives the nervus terminalis (stage 17) (Humphrey, 1967; O'Rahilly *et al.*, 1988; Müller and O'Rahilly, 1990a). Connections to the olfactory bulb and the amygdaloid nuclei develop. The septal nuclei are cellular agglomerations at the periphery of the intermediate layer. The first septal nucleus develops caudomedial to the olfactory tubercle and is probably the diagonal nucleus. The identification of the nucleus of the diagonal band is based on the observation of fiber projections to the hippocampus (stage 20). Some cells of the nuclei basales (of Meynert) may begin to differentiate caudally toward the end of the embryonic period.

The Amygdaloid Region (Table 2.7)

The future amygdaloid body appears as four nuclei consisting of postmitotic cells located in the intermediate layer. These arise from rapid cell production

TABLE 2.6 Development of the Forebrain Septum

Features	Stage

TABLE 2.7 Development of the Amygdaloid Region and Nuclei

Features	Stage
Medial ventricular eminence for most of the future amygdaloid nuclei; superficial neurons with fibers	14
Fibers begin to form medial forebrain bundle	15
1–2 amygdaloid nuclei: cortical and anterior	17
Mediolateral and basolateral nuclei	18
Amygdalohabenular fibers[a]	19
Fibers to stria medullaris thalami; fibers between amygdaloid nuclei and hippocampus	21–23

[a] A direct connection between the amygdaloid and habenular nuclei has been shown in the rat and is also present in the human.

almost exclusively in the ventricular zone of the medial ventricular eminence (stages 17 and 18), which is diencephalic. However, the overlying cortex belongs to the future temporal pole and acquires a primordial plexiform layer early. Ascending fibers of the future medial forebrain bundle have been recognized by immunological methods at about 7 weeks (Zecevic and Verney, 1995), and they reach this region rapidly. It seems possible that those monoamine fibers influence the rapid formation of the amygdaloid nuclei. Elongated (probably Cajal–Retzius) cells are found, and connections of the amygdaloid nuclei with the stria medullaris thalami develop (stage 18).

The Hippocampal Formation (Table 2.8)

The hippocampal formation is a convenient term used for the dentate gyrus, the hippocampus, the subiculum, and the parahippocampal gyrus. It can be discerned early but it develops slowly. The first sign is a marginal layer situated dorsomedially in the telencephalic roof at about 5 weeks (stages 14 and 15). Soon this area extends as far rostrobasally as the olfactory bulb (stage 16) and shows a discrete thickening near the ventricle (Fig. 2.9A). The dentate area then becomes visible (stage 17). The hippocampus *sensu stricto* can be recognized (stages 18–23) by (1) its projection into the ventricle, (2) its broad marginal and intermediate layers, and (3) its narrow ventricular layer. A C-shaped form is present at $6\frac{1}{2}$ weeks (stage 18). The embryonic development is characterized mainly by cellular production and migration. Whether the cells in the various components of the hippocampal formation appear simultaneously or develop successively (dentate area, hippocampus, presubiculum) seems to depend on the species. The rostral, middle, and occipital regions are alike in the embryo; the successive curved, S-shaped, and infolded organizations develop during the fetal period (O'Rahilly and Müller, 1999a, Figure 25-5). An intermediate form of cortex develops in the hippocampal formation, where a condensation of postmitotic cells forms a plate during the fetal period, i.e., after that in the neocortex.

The Diencephalon (Table 2.9)

At 5 weeks a longitudinal subdivision (stage 15; Müller and O'Rahilly, 1988c, 1997) is superimposed on the transverse organization provided earlier by the neuromeres (stages 9–14) (Fig. 2.5). The sulcus limitans extends from the spinal cord into the hindbrain and midbrain, but it ends at the supramamillary recess (authors' reconstructions). (The correct spelling is *mamillary*, derived from the Latin *mamilla*.) Other interpretations have been discussed elsewhere (O'Rahilly and Müller, 1999a).

In the human embryo, the hypothalamic sulcus, together with the marginal ridge, contributes to the establishment of five longitudinal zones. These are, from the roof to the floor: epithalamus, dorsal and ventral thalamus, subthalamus, and hypothalamus (Figs. 2.5, 2.7A). The hypothalamic cell cord, in which the preopticohypothalamic tract develops, is well advanced at this time. It blends with the interstitial nucleus in the prerubral area, where the medial longitudinal fasciculus arises. The habenular nuclei are evident in the epithalamus, in which fibers of the fasciculus retroflexus develop. Two commissures become visible (stage 15): the posterior commissure at the transition to the mesencephalon, and the supramamillary commissure.

Dopaminergic cells extend from the mamillary area to the infundibulum, and catecholaminergic fibers of the fasciculus retroflexus enter the habenular region (stages 15 and 16; Verney *et al.*, 1991). It is likely that radial glial cells aid in subdividing the wall of the prosencephalon.

All embryos are exposed to maternal estrogen, and male fetuses additionally to their own testosterone; the hypothalamus is especially involved. Later, these

hormones play a "housekeeping" role in the growth and maintenance of cells of the brain in both sexes. A shortage of estrogen is believed to affect memory and thought processes.

The Mesencephalon (Table 2.10)

The midbrain (Fig. 2.6) can be recognized very early (stage 9) by the mesencephalic flexure, and soon (stage 12) it consists of two neuromeres, M1 and M2. The oculomotor nucleus appears in M2 (stage 14), although the trochlear nucleus lies in the isthmus rather than strictly in the midbrain. The tegmental region begins to develop early (stage 13), and marginal and intermediate zones become visible (stage 14). The commissure of the future superior colliculi arises at 5 weeks (during stage 15). The ventral proliferative area (stage 15) develops several rows of cells that represent the primordium of the interpeduncular nucleus. These cellular groups become traversed (stage 20) by fibers that probably belong to the rubrocerebellar tract (superior cerebellar peduncle). The interpeduncular nucleus, which is situated immediately dorsal to the interpeduncular fossa, is an important dopamine-producing area, as are also the ventral tegmental area (dorsal to it) and the substantia nigra. The connection with the habenular nuclei by the fasciculus retroflexus (habenulointerpeduncular tract; Fig. 2.5) is completed by about 7 weeks (stage 21). The dopamine-producing areas in the human have been illustrated elsewhere (O'Rahilly and Müller, 1999a, figures 20-5 to 20-9).

The ventricular zone and the ventral tegmental region, including the substantia nigra, have been shown at 5 weeks by immunological methods (Puelles and Verney, 1998). They are the first areas to display TH-immune reactivity in human embryos of about 6½ or 7 weeks (Freeman *et al.*, 1991). Nigrostriatal fibers develop at about the same time (Puelles and Verney, 1998), which agrees well with the survival of human dopamine suspension grafts (Freeman *et al.*, 1995b). Such fibers extend initially into the subventricular zone of the lateral ventricular eminence (Freeman *et al.*, 1995a). Dopamine-producing cells from the ventral part of the midbrain are best developed near the end of the embryonic period (Brundin *et al.*, 1989).

The Cerebellum (Table 2.11)

The paired cerebellar primordia can be distinguished early (stage 13) but develop rather slowly during the embryonic period. The cerebellar cells are derived mainly from the alar plates of the isthmus and from Rh. 1. A very limited contribution from Rh. 2 is also probable.

TABLE 2.11 Development of the Cerebellum and Isthmus Rhombencephali

Features	Stage
Isthmus present; nucleus of N.4	13
Cerebellar primordium is widest part of brain	14
Decussation of N.4; isthmic nucleus; extramural fibers in N.4; future superior medullary velum; intermediate zone; vestibulocerebellar fibers enter marginal layer of cerebellum; fibers between marginal and intermediate zones (trigeminocerebellar?)	15
Intra- and extraventricular thickenings; rhombic lip with mitotic activity	17
Cell production in dentate nucleus; dentatorubral fibers	18
Inferior cerebellar peduncle	21
External germinal layer	23

Two main components, which differ with regard to timing, source, and future localization, are characteristic of the cerebellum (Fig. 2.10B).

1. The ventricular and subventricular zones give origin to the piriform (Purkinje) cells and to the deep cerebellar nuclei. These early-forming precursor cells migrate peripherally. The piriform cells begin to appear at 7 weeks (stage 21; Müller and O'Rahilly, 1990b) rather than at 9 weeks (Sidman and Rakic, 1973). Fibers that are mostly trigeminal develop between the ventricular and intermediate zones (stage 15), and vestibulocerebellar fibers enter the marginal zone (stages 15–17; Müller and O'Rahilly, 1989a, b).

2. The rhombic lip, which is only the most lateral part of the alar plate and is continuous with the roof plate (Ellenberger *et al.*, 1969), corresponds to the subventricular zone. The lip begins its mitotic activity (approximately at stage 16) after that in the ventricular zone and its cells contribute mainly to the external germinal layer, although they may be involved also in the development of the dentate nucleus. The cells of the rhombic lip migrate tangentially and centrally. The external germinal (or granular) layer has been observed by the present authors to begin at 8 weeks (stage 23), which is 2–3 weeks earlier than reported by other workers (Sidman and Rakic, 1973; Zecevic and Rakic, 1976). The cells divide *in situ* and their proliferation lasts much longer than that in the ventricular zone, perhaps continuing for several months after birth (Friede, 1989). The granule cells are formed later from cells of the external germinal layer that migrate centrally.

Inferior and superior cerebellar peduncles begin their development during the embryonic period.

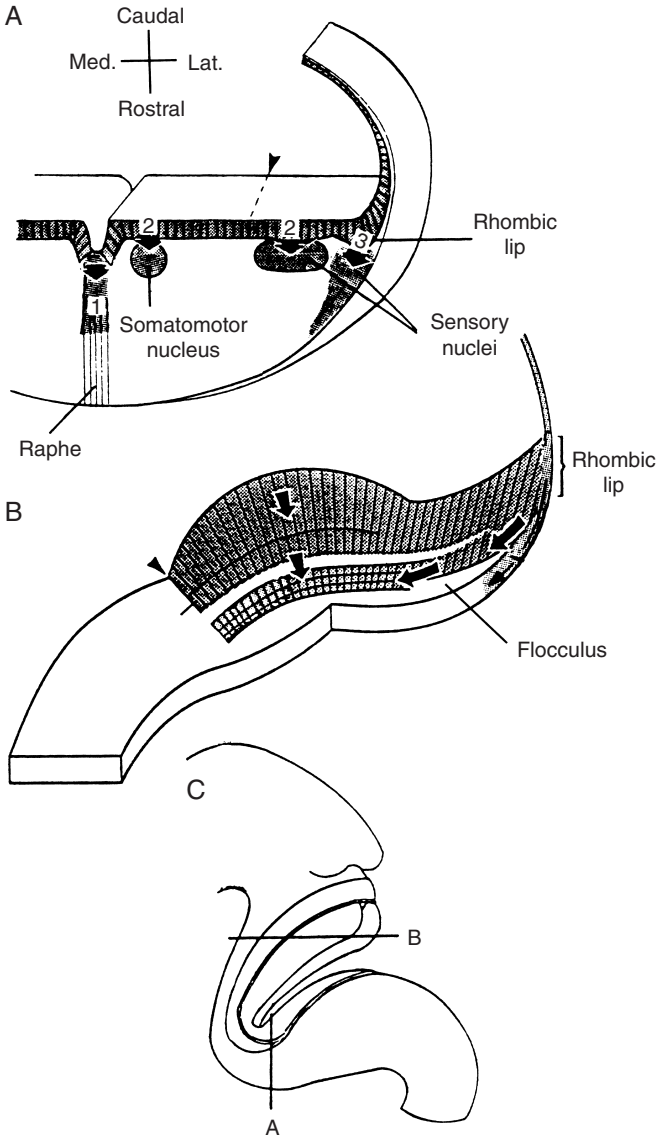

FIGURE 2.10 Cerebellum and cranial nerves. **(A)** Schematic representation of the rhombencephalon with early migrating cells (1) from the floor plate to the raphe, (2) from the ventricular layer for motor and sensory nuclei, and (3) from the rhombic lip for the cochlear nuclei **(B)** At the level of rhombomere 1 the primordium of the cerebellum shows an intraventricular thickening towards the fourth ventricle (future corpus cerebelli) and an extraventricular thickening (area of future flocculus). The vertical arrows indicate the radial route of the neurons that originate in the ventricular layer. The horizontal arrows show the tangential and superficial migration of neurons from the rhombic lip. The sulcus limitans is indicated by arrowheads in A and B. **(C)** Left lateral view of the hindbrain showing the planes of section of A and B. From R. O'Rahilly and F. Müller, "The Embryonic Human Brain," 2nd Ed. Copyright ©, 1999, Wiley-Liss. Reprinted by permission of John Wiley and Sons, Inc.

Remainder of the Rhombencephalon and Related Cranial Nerves (Tables 2.12 and 2.13)

The development of the rhombencephalon, its neuromeres, neural crest, cranial nerves, and their nuclei and ganglia (Tables 2.12 and 2.13) as well as tracts, has been studied in detail by the authors, and an account of the rhombencephalon at the end of the embryonic period is available (Müller and O'Rahilly, 1990c).

The hypoglossal nerve is the first to appear in Rh. 8. Its original four roots are segmentally arranged and innervate the four occipital somites. Although neural crest is present, no ganglia are formed, and that of Froriep (Froriep and Beck, 1895) is not present in human embryos.

The ganglia of the cranial nerves are derived from two sources: (1) their proximal parts from neural crest cells and (2) their distal portions from epipharyngeal

discs (Fig. 2.1). Accumulation of neural crest cells at their future loci can be seen early (stage 10), and a little later (stage 11) they are more compact. Participation of the epithelium of the pharyngeal arches (there are no branchial structures in mammals) can next be observed (stage 12), when the ganglia of the cranial nerves form a complete series. It has been shown in other species that the rhombencephalic floor plate is induced by the notochord and that it controls the pattern of cellular types that appear along the dorsoventral axis. By releasing chemoattractants the floor plate acts as an intrinsic organizer of axons in the developing brain and spinal cord. Throughout the rhombencephalon, cells are produced in the ventricular zone and in the rhombic lip (Fig. 2.10A). Cells that migrate from the ventricular layer settle in the intermediate zone and form the nuclei of the cranial nerves (Table 2.12), as well as groups of catecholaminergic neurons.

The subventricular zone of the rhombic lip gives rise to postmitotic cells that migrate tangentially along the external surface of the brain stem, where they form the transient corpus pontobulbare, which has been reconstructed and described elsewhere (Müller and O'Rahilly, 1990c). Two streams of cells migrate from the lip (stages 20–23). A site of origin of the rhombic lip that has been largely ignored in the literature is in the region of the vestibulocochlear nerve (Shaner, 1934); it is represented schematically here (Fig. 2.10A).

Motor Nuclei of the Cranial Nerves (Table 2.12)

The motor nuclei are organized segmentally. To reach their targets, motor axons follow highly stereotyped pathways leaving the hindbrain only via exit points in the even-numbered rhombomeres. The cells of the trigeminal motor nucleus are located in Rh. 2 , Rh. 3, and a few in Rh. 1. Their fibers exit from Rh. 2. The cells of the nucleus of the facial nerve arise in Rh. 4 and 5, their fibers leave in Rh. 4; the localization of the glossopharyngeal nuclei is in Rh. 6 and 7, and the fibers exit in Rh. 6.

In most published diagrams the visceromotor material is shown already located laterally in relation to the somatic motor nuclei during development, although that is imprecise. At first (stages 12 and 13) the cells of each group are congregated in an uninterrupted cell column: a medioventral column of visceromotor and a ventrolateral column of somatomotor cells (Table 2.13). The visceromotor cells begin to migrate toward the sulcus limitans (stage 13; figures 8 and 10 in Müller and O'Rahilly, 1988a, b). The relocation of those cells and their organization into definitive nuclei are almost finished by 6 weeks (stage 18), except for the facial nucleus, which occupies its final position early in the fetal period (Table 2.13 and O'Rahilly *et al.*, 1984; Müller and O'Rahilly, 1990c). The movement of the visceromotor cells is frequently cited as an example of neurobiotaxis (Ariëns Kappers, 1932), whereby functionally active fiber tracts would attract nerve cells and direct the migration of entire groups toward them.

Sensory Nuclei (Table 2.12)

The pontine nucleus of the trigeminal nerve is visible at about 6 weeks (stage 18), as is also the medial accessory olivary nucleus (stage 19). Early in the fetal period, the complete olivary nucleus is present and five subdivisions have been distinguished (Müller and O'Rahilly, 1990c). Cochlear and vestibular nuclei are recognizable at 8 weeks (stage 23), more by their topography and their relationship to fibers than by the characteristics of their cells.

Serotonin-Producing Nuclei

The raphe nuclei, which are related to the locus ceruleus, the substantia nigra, and the red nucleus, are essential for the development of the brain because of their neurotransmitters. The locus ceruleus is recognizable early at its rhombencephalic level (stage 14). The septum medullae (Fig. 2.9A), which is penetrated by fibers from nuclei of the cranial nerves, soon becomes evident (at stages 15 and 16), and its tall cells spread out from the rhombencephalic floor plate (stage 16). Connections of the raphe nuclei with the forebrain develop at 7–8 weeks (stages 21–23), probably via the central tegmental tract, and the nuclei come to be situated within the septum medullae (stage 23). Two distinct raphe nuclei at 8 weeks (stage 23) have been reconstructed (O'Rahilly and Müller, 1999a, figures 23–27).

The rhombencephalon is one of the most rapidly developing parts of the embryonic brain. At the end of the embryonic period (stage 23), its organization is so complex that functional activity should be assumed.

With regard to fibers and tracts in the rhombencephalon, the lateral longitudinal fasciculus begins to form early (stage 12), adjacent to the sulcus limitans, and later it extends from the hindbrain to the isthmus rhombencephali. The ventral longitudinal fasciculus begins to appear a few days later than the lateral, as does also the common afferent tract, which consists of afferent vestibulospinal fibers and fibers of the tractus solitarius (stage 17). The numerous rhombencephalic tracts present at the end of the embryonic period closely resemble those found in the newborn (Müller and O'Rahilly, 1990c).

VENTRICLES, CHOROID PLEXUSES, AND CIRCUMVENTRICULAR ORGANS

The Ventricles

The embryonic ventricular system (O'Rahilly and Müller, 1990) begins its definitive development with the closure of the caudal neuropore (during stage 12). Because the walls of the brain are of uniform thickness at this time (up to stages 13 and 14), the ventricles follow closely the shape of the brain. Future changes are caused mainly by alterations in the thickness of the walls (e.g., by the thinning of the roof of the fourth ventricle and the formation of the ventricular eminences) and by evaginations.

The first cavity of the telencephalon to appear is that of the telencephalon medium, which is visible very early (stages 12 and 13, Fig. 2.4C). At 5–6 weeks (stages 15 and 16) the lateral ventricles are distinguishable, and soon the medial and lateral ventricular eminences of the forebrain produce indentations, as does the cerebellar plate in the lateral wall of the fourth ventricle. Growth of the ventricular eminences transforms the formerly even outline of the lateral ventricle into a C-shaped cavity, and a first indication of anterior and inferior horns can be seen at 7 weeks (stage 21). The interventricular foramen can soon be recognized (at about stage 17; Fig. 2.9) as a wide opening, and by 8 weeks (stage 23) it is considerably reduced.

The fourth ventricle becomes evident at about 5 weeks (stages 13 and 14; Fig. 2.6). The isthmic part of it is compressed by the growing cerebellum. The lateral recesses of the fourth ventricle are long, lateral expansions at 8 weeks (stage 23).

Three different liquids are in contact successively with the developing brain: (1) the amniotic fluid until closure of the neuropores, (2) the ependymal fluid after closure, and (3) the cerebrospinal fluid after the formation of the choroid plexuses. The term "ependymal fluid" is used here for the fluid believed to be produced by the lining cells that will later develop into ependymal and choroid plexus cells.

The Choroid Plexuses

The ventricular cells that do not form neurons or glioblasts constitute lining cells known as ependymoblasts, which give rise to ependymal cells and choroid plexus cells. The plexus fold of the lateral ventricles at 7 weeks (stages 18 and 19) consists of three to four rows of cells. Choroid villi, which are absent at first, soon develop stumpy projections in the plexus fold (stage 20), although the villi become more slender (stage 21) when the epithelium is composed of about two rows of cells. The choroid plexuses are voluminous at the end of the embryonic period (stage 23) and their epithelial layer consists of a single row of cells.

In the bilaminar roof of the third ventricle, folds are seen at 8 weeks (stage 23), and they are the first indication of the choroid villi that develop during the fetal period.

The roof of the fourth ventricle is characterized by folded and unfolded epithelia. Choroid villi and bilateral choroid folds appear at 6–7 weeks (stages 18 and 19). The choroid primordium is slightly ahead of that in the telencephalon. Two membranous areas develop in the rhombencephalic roof. The area membranacea rostralis is rostral in relation to the plexus folds and appears first (stage 18). The area membranacea caudalis is more caudal and is present a little later (stages 19 and 20). The caudal area corresponds to the central bulge of Brocklehurst (1969) and to the saccular ventricular diverticulum of Wilson (1937). The formation of the median aperture was believed by Brocklehurst to be related to this area, although no openings in the roof of the embryonic fourth ventricle were observed by the present authors. Both areae mebranaceae have been discussed in relation to the formation of the subarachnoid space (Weed, 1916, 1917). Intraventricular fluid would leave the fourth ventricle and enlarge the mesenchymal meshes at the surface of the medulla oblongata. Illustrations and further details are given in a detailed article by O'Rahilly and Müller (1990).

The Circumventricular Organs

The circumventricular organs consist of "modified ependymal elements, which despite their modification, still retain their epithelial lining character" (Kuhlenbeck, 1970). They begin their development only late during the embryonic period, and the few present at that time lack the characteristics of the definitive arrangement, such as a highly specialized vascularization.

A median evagination of the mesencephalon is the first of these to appear (stage 15). It is found for at least another couple of weeks (stage 19), and it was observed by Hochstetter (1929). It consists of elongated cells with a basal nucleus and a long cytoplasmic apex. A dense capillary network develops at its extrapial surface.

The neurohypophysis appears as an evagination of the diencephalon (stage 16), although its area is clearly defined much earlier (stage 10) by its relationship to the adenohypophysial primordium. Folding of the wall and lengthening of the stalk are observed at 6 weeks (stages 17 and 18). Production of mesenchyme between

adeno- and neurohypophysis begins at the same time. However, even at the end of the embryonic period (stage 23), the median eminence is not yet evident. The hypothalamohypophysial system is functional by the end of trimester 1 (Mai *et al.*, 1997).

The epiphysis cerebri is visible as an evagination at 5–6 weeks (stage 16) and it forms a rostrally directed protrusion containing follicles. Some nerve fibers from the habenular area soon (stage 19) enter the primordium.

The subcommissural organ, which is ventral to the posterior commissure and adjacent to the cavity of the third ventricle, contains elongated cells with their apices toward the ventricular cavity (stages 19–21; O'Rahilly and Müller, 1990, figure 5G, H).

The paraphysis, which is at the di-telencephalic border and belongs to the telencephalon medium, possesses one or more evaginations formed by a single layer of cylindrical, ciliated cells. It is at the height of its development at the end of the embryonic period.

The area postrema, which in the newborn lies dorsal to the nucleus of the tractus solitarius, contains "a few neurons, and many nerve fibers of undetermined origin" (Netsky and Suangshoti, 1975). Its presence is indicated by penetrating nerve fibers from the tractus solitarius, as seen by the present authors. This innervation accords well with the claim, based on clinical evidence, that vagal fibers are functionally involved in the area postrema.

THE CEREBRAL ARTERIES
(Table 2.14)

The brain is supplied by two pairs of vessels, namely, the internal carotid and the vertebral arteries. At about 4 weeks (stage 10) the internal carotid possesses two divisions (stage 13). The caudal division becomes the posterior communicating artery (stage 14), which gives rise to the posterior cerebral artery. The posterior communicating is a relatively large vessel prenatally and in the newborn. At about 6 weeks the cranial division of the internal carotid gives origin to the anterior choroidal (stage 16) and the middle and anterior cerebral (stage 17). Also by this time, two longitudinal vessels (stage 13) fuse to become the basilar artery (stage 16), and anastomoses of cervical segmental vessels on each side have formed the vertebral arteries (stage 16). When the two anterior cerebral vessels become united by the anterior communicating artery at 7 weeks, the circulus arteriosus is complete (stages 20 and 21). Caroticobasilar anastomoses (stage 13) formed by the trigeminal, otic, and hypoglossal arteries normally disappear, but any one of them may persist. The stapedial artery (stage 17), which traverses the primordium of the stapes, is a temporary channel that contributes to the formation of other vessels, particularly the middle meningeal artery. Detailed information can be found in Padget (1948), from whose valuable illustrations simplified drawings have been constructed and additional stages added (O'Rahilly and Müller, 1999a).

TABLE 2.14 Development of the Main Arteries

Vessels	Stage
Internal carotid begins	12
Trigeminal, otic, hypoglossal	13
Posterior communicating	14
Basilar and vertebral	15, 16
Anterior choroid, ophthalmic	16
External carotid, hyaloid; posterior choroid; posterior cerebral	17
Labyrinthine	19
Anterior communicating	20
Circulus arteriosus	20, 21

MEASUREMENTS
(Tables 2.15 and 2.16)

Mean measurements were calculated in 60 embryos from $2\frac{1}{2}$ to $3\frac{1}{2}$ weeks (stages 6a–9; Table 2.15). It was found that (1) embryos with a neural groove (stage 8b) tend to be longer than those (stage 8a) without; (2) the neural groove (stage 8b) suddenly becomes much longer (stage 9); (3) embryos with a neural groove (stage 8b) have a long primitive streak; (4) the primitive streak increases in length (stage 8) but soon becomes reduced (stage 9); and (5) although embryonic length increases throughout, embryonic width decreases (from stage 8b to stage 9) in association with the altered shape of the embryo.

TABLE 2.15 Mean Measurements (mm) in 60 Embryos of Stages 6a–9

Stage	6a	6b	7	8a	8b	9

[a]D1 and D2 relate to stages 9–12. D2 becomes subdivided in stage 13 into three parts: parencephalon rostralis, parencephlon caudalis, and synencephalon.

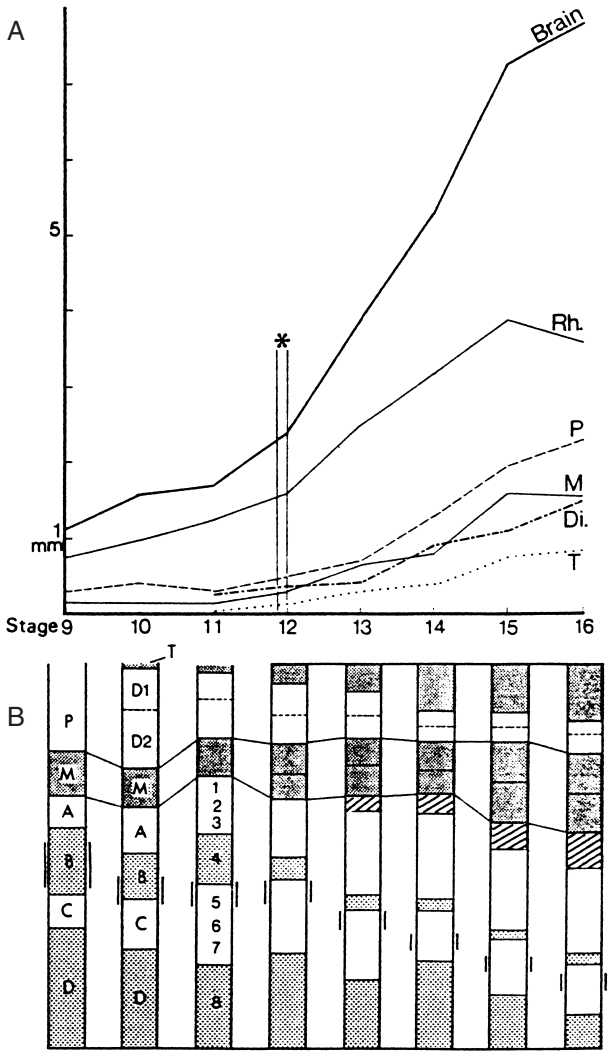

FIGURE 2.11 **(A)** Lengthening of the brain and its subdivisions in millimeters; from about 3½ to 5½ weeks (stages 9 to 16) based on the author's data. The asterisk indicates the transition from an open neural tube to a closed system. See also Table 2.16a. **(B)** Changes in length of the parts of the brain indicated as percentages of the total length. Vertical lines outside the rhombencephalic part of the columns indicate the site of the otic primordia. See also Table 2.2. A, B, C, D, early (primary) rhombomeres; Di., diencephalon; D1, diencephalon 1; D2, diencephalon 2; M, mesencephalon; P, prosencephalon; Rh., Rhombencephalon; 1–8, rhombomeres; T, telencephalon. The isthmus rhombencephali is shown by diagonal hatching.

Further measurements (Fig. 2.11 and Table 2.16a, b) show that the prosencephalon occupies nearly one-fourth of the total length of the brain, both early (stages 9 and 10) and again about 2 weeks later (stage 16). The telencephalon medium continues to increase and is accompanied by a relative reduction in the diencephalon. The rhombencephalon occupies more than half of the total length of the brain. The isthmus and Rh. 1–3 show a threefold increase in length (stage 16) compared to the earlier Rh. A (stage 9). The otic primordium, which is at first opposite Rh. B, descends progressively to Rh. 5 (stages 14–16) and hence it is not a reliable indicator of rhombomeric level. Rh. D and its successor, Rh.8, decrease from a maximum (stage 9) to a minimum (stage 16).

The absolute longitudinal growth of the brain and its parts were measured (stages 9–16) and found to be uniform, except for the midbrain, the length of which doubles (between stages 14 and 15; Fig. 2.11 and Table 2.16a). The closure of the rostral neuropore (near the end of stage 11; asterisk in Fig. 2.11A) is neither accompanied nor immediately followed by any significant change in growth.

SUMMARY

The brain begins to develop very early in the embryonic period (stage 8). At 8 postfertilizational

weeks (stage 23) it is quite complex and the rhombencephalon closely resembles that of the newborn. In the mesencephalon, dopamine-producing areas are believed to be functional. The most advanced regions of the prosencephalon are the forebrain septum, amygdaloid body, habenular nuclei, and subthalamic and hypothalamic nuclei.

Investigations of the timing and sequence of the development of the brain, like that of other organs, require the use of morphological stages. It is frequently not appreciated that a considerable body of precisely staged information concerning the human embryo is now available. Studies of the developing brain in species other than Homo sapiens continue to yield valuable information, but great caution is needed in efforts to extrapolate the results to human beings.

CEREBRAL CORTEX (Fig. 3.1)

Neocortex

The general aspects of neocortical development will be dealt with before discussing development of individual regions (visual, auditory, somatosensory and frontal regions and callosal neurons), glial and vascular differentiation, and development of gyrification, structural asymmetry, and gender differences.

General Features of Neocortical Development

From the fourth to the fifth week[1] of development, the developing isocortex is about 140 µm wide and consists of two layers: the ventricular and marginal zones (Zecevic, 1993). Electron microscopy and Golgi

[1]week: weeks after fertilization; w.g. weeks of gestational age

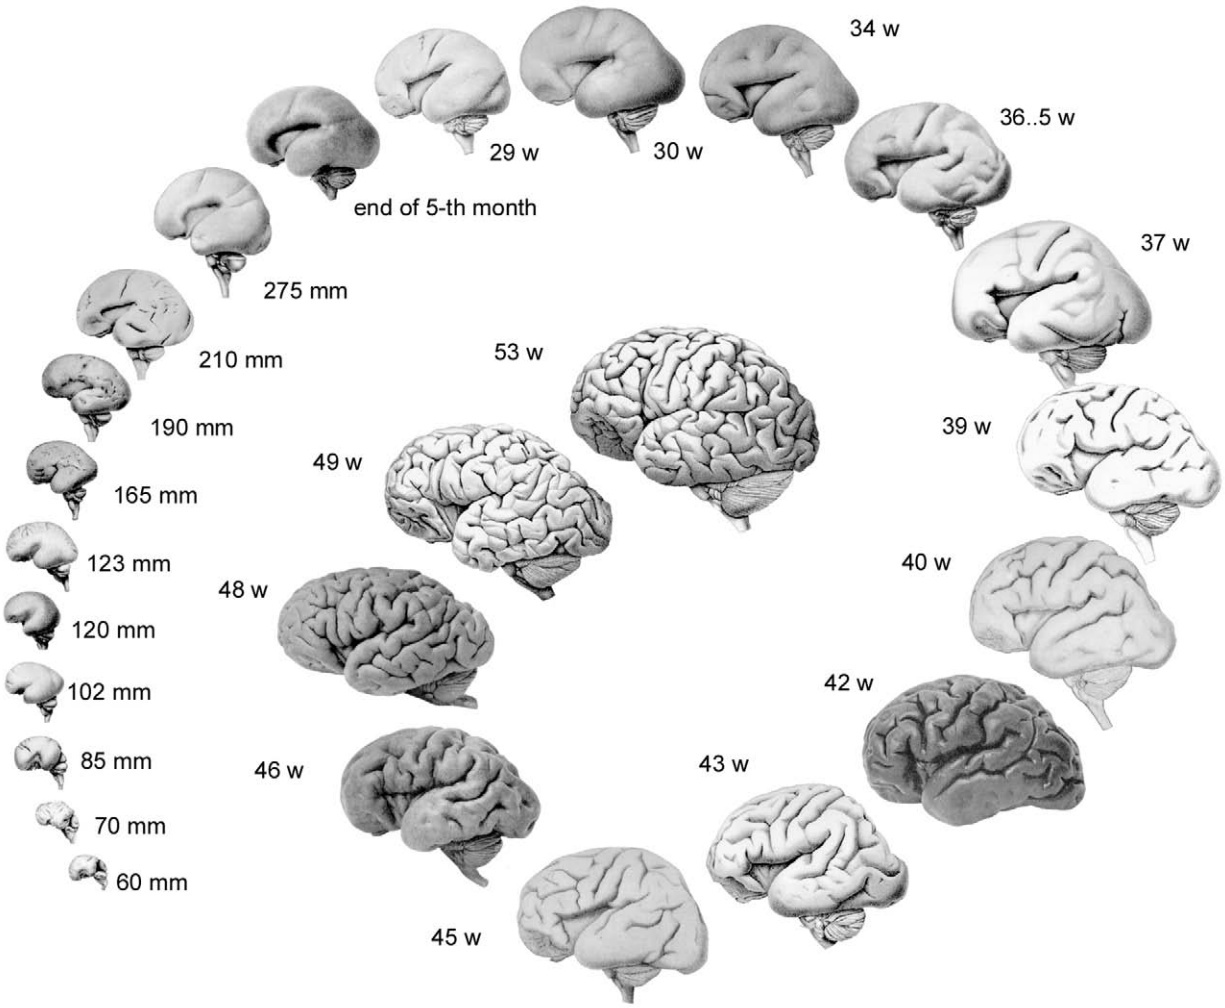

FIGURE 3.1 External morphology of brains showing the growth of the hemispheres and the development of the sulcal pattern during the period covered in this text. Modified from Retzius (1896).

impregnation studies have shown that the cortical wall is made up exclusively of bipolar ventricular cells and their pial-directed processes. Within a week (6 weeks), the intermediate zone appears between the ventricular and marginal zones and the total cortical thickness reaches 220 μm. The radial glial scaffolding that will guide subsequent migration of young neurons (Rakic, 1972; see Hatten 1999 for detailed review) begins to be established between 5 and 7 w.g. (Choi, 1988). At this time, detached cells (mainly simple or branched bipolar neurons with occasional horizontal cells) begin to appear in the ventricular zone and incipient intermediate zone. Horizontal cells at the intermediate/ventricular boundary may represent early Cajal–Retzius cells. The precocious development of these cells has been shown with a wide variety of cellular markers (Meyer and Gonzalez-Hernandez, 1993; Zecevic *et al.*, 1999). Synapses in the future layer of the cortex begin to appear at 6–7 w.g. (Zecevic, 1998).

The cortical plate begins to appear at about the seventh week of development in the ventrolateral part of the telencephalic wall. At about this time the intermediate zone can be divided into a superficial part, which will be known as the presubplate layer, and a deeper part, which will become the future white matter. Development of the cortical plate coincides with rapid increase in the density of synapses in the future layer I (Zecevic, 1998).

By about 8 w.g. a subventricular zone appears between the ventricular and intermediate layers. Both the ventricular and subventricular zones are sites of intense proliferation during the first half of the second trimester (Simonati *et al.*, 1999) producing large and small neurons and some glial cells. Proliferating cells are also found in the internal capsule and cerebral cortex white matter from 15 w.g. (Kendler and Golden, 1996). The number of proliferative cells in the internal capsule decreases by the end of the second trimester,

whereas mitosis continues in the cerebral cortex white matter well into the last trimester, probably responsible for the production of glial cells of the deep white matter.

Recent studies of defective cortical lamination in the reeler mutant mouse have led to the identification of reelin, a secreted extracellular matrix glycoprotein that is believed to have an important role in the normal development of cortical lamination. Immunoreactivity for reelin is initially found at 11 w.g. in mono- or bipolar Cajal–Retzius cells of the marginal layer (future layer I) (Meyer and Goffinet, 1998) and is subsequently found in different cell types of the superficial cortex.

The neurotrophin superfamily of proteins includes brain-derived neurotrophic factor (BDNF), nerve growth factor, neurotrophins-3, 4/5, and 6. All these neurotrophins share structural similarities, have overlapping functional effects, and recognize two classes of cell surface receptors: low and high affinity. The low-affinity receptor is known as the p75 neurotrophin receptor (Bothwell, 1991), whereas the high-affinity receptors are the trk subfamily of tyrosine protein kinases (trkA, trkB, trkC) (Bothwell, 1991). Somata immunoreactive for trk appear in the cortical subplate at 15 w.g. (Chen *et al.*, 1996), and the number of these subplate neurons peaks by 24 w.g. Cells immunoreactive for trk are never seen in the cortical plate, marginal zone, or ventricular zone, although trk-immunoreactive fibers appear in the marginal zone at 14 w.g. and this neuropil staining extends into the cortical plate by 16 w.g. (Chen *et al.*, 1996). Neurons immunoreactive for p75 are first seen in the subplate at 15 w.g., immunoreactivity increases to peak at 20 w.g., declines from 22 w.g., and completely disappears by 34 w.g.

Apoptosis in many regions of the cerebral cortex (frontal, motor, somatosensory, and visual) appears to occur mainly at the end of gestation, as indicated both by estimations of neuronal numbers (Rabinowicz *et al.*, 1996) and TUNEL labeling of fragmented DNA (Chan and Yew, 1998). The increase in apoptotic index with gestational age is inversely proportional to the decline in immunoreactivity to Bcl-2, the oncoprotein with a protective function against apoptosis (Chan and Yew, 1998).

Development of Visual Cortex

Cytoarchitectural and Ultrastructural Development In the fetal human visual cortex, a presubplate zone can be distinguished below the cortical plate as early as 13 w.g. (Kostovic and Rakic, 1990). In the visual cortex the presubplate zone is extremely narrow but sharply delineated from the underlying intermediate zone, and in Golgi preparations at this age the presubplate can be seen to contain a population of large neurons with no clear orientation. By this stage, the cortical plate neurons have begun to develop apical and basal dendrites, and the latter extend to the presubplate zone. Transformation of the deep cortical plate into subplate zone occurs later in the visual area (13 w.g.) than in the somatosensory cortex (12 w.g.), and the change begins earlier in the lateral occipital lobe than in the medial occipital lobe. At this age, Cajal–Retzius cells are the principal neuronal elements in the marginal zone (developing layer I; Zheng *et al.*, 1989). Axosomatic and axodendritic contacts are also visible in immature layer II at this age.

During the period from 16 to 18 w.g., the visual region subplate increases dramatically in thickness, in line with the ingrowth of axonal plexuses and growth cones, and enlargement of extracellular spaces. At 17 w.g., degenerating apical dendrites are occasionally seen in developing layer I (Zheng *et al.*, 1989).

Between 18 and 30 w.g., the visual cortical plate begins to show lamination. Synapses at this age are present in the subplate zone, in the deep half of the cortical plate, and in the marginal zone (Kostovic and Rakic, 1990). Postsynaptic structures in the subplate at this time include large proximal dendrites, randomly oriented small dendritic branches, and growth cone–like swellings. Toward 30 w.g., synapses spread into the superficial part of the cortical plate. From 30 w.g., the visual cortical subplate begins to dissipate and has disappeared by 1 month after birth (Kostovic and Rakic, 1990), although those authors suggest that some large multipolar neurons with ultrastructural features similar to subplate neurons survive into the adult cerebral hemisphere.

The adult level of neuronal density is reached in the striate cortex at about 16 weeks after birth (Zilles *et al.*, 1986). Dendritic development of cortical neurons plateaus at about 11 weeks after birth in the case of layer V pyramids and 15 weeks after birth for layer III pyramidal neurons (Becker *et al.*, 1984).

Development of Connections The development of intracortical connections in the visual cortex has been studied using carbocyanine dye tracing techniques (Burkhalter *et al.*, 1993). Vertical (intracolumnar) connections between layers II/III and V, linking neurons within the same cortical column and serving the same point in visual space, develop at 26–29 w.g. On the other hand, connections between columns develop later, at about 37 w.g. with layers IVB and V. The fiber density of connections increases rapidly after birth and shows a uniform plexus at about 7 weeks after birth. The adult-like patchiness of the intracortical connections develops at more than 8 weeks of gestation. Long-range horizontal connections within layers II/III

begin to develop at 16 weeks after birth, well after horizontal connections between layers IVB/V, and reach mature form before 15 months after birth. An interesting difference between the pattern of development of long-range projections formed between layers II/III on the one hand and layers IVB/V on the other is that the lower layer horizontal projections develop by collateral elimination (i.e., loss of inappropriate connections), whereas upper layer horizontal connections develop by precise targeting of appropriate destination regions.

Development of thalamocortical projections to the prestriate cortex (Brodmann's areas 18, 19, 20 and 21) have been followed during prenatal development using the transient acetylcholinesterase (AChE) activity of the pulvinar to prestriate cortex projection (Kostovic and Rakic, 1984). Thalamocortical projections from the pulvinar reach the subplate zone of prestriate cortex between 17 and 20 w.g. From 21 w.g., AChE positive fibers accumulate in the subplate and from 26 w.g. these thalamocortical fibers begin to invade the prestriate cortex. After 35 w.g., AChE activity in the pulvinar decreases and pulvinar thalamocortical fibers cannot be identified.

Development of Chemically Identified Neuronal Classes Distribution of γ-aminobutyric acid (GABA), calbindin D28k, and nitric oxide synthase (NOS) immunoreactivity and reactivity for NADPH-diaphorase has been followed in the developing human visual cortex (Yan *et al.*, 1992, 1997; Judas *et al.*, 1999). Calbindin D28k and NOS studies have both found transient patterns of immuno- and histochemical reactivity.

Calbindin-immunoreactive neurons are present in the visual cortex by 15 w.g. (Yan *et al.*, 1997), when they are found scattered in the ventricular, intermediate, and marginal zones. By 20 w.g., calbindin-immunoreactive neurons are still in the marginal and intermediate zones, although immunoreactivity has begun to appear in layers V and VI, the only two layers that have differentiated from the cortical plate by this age. Calbindin-positive bipolar and multipolar neurons can be seen in the cortical plate at 26 w.g., and by 34 w.g. a periodic pattern of neuropil immunoreactivity can be seen in layers III and IV. Transient calbindin immunoreactivity is seen in Cajal–Retzius cells in the marginal zone, migrating neurons in the intermediate and ventricular zones, and tangential fibers in the intermediate zone.

NADPH-diaphorase-reactive and NOS-immunoreactive cells appear transiently in the subplate of the human fetal cerebral cortex (15 w.g.; Judas *et al.*, 1999) and in some cortical regions, including the striate cortex, are transiently expressed in somata and proximal dendrites of pyramidal neurons themselves. The transient overexpression of NOS in both neuropil and specific neuronal populations may indicate that NO plays a significant part in development of fetal cortex.

Development of Auditory Cortex

By 11 w.g., the auditory cortex consists of marginal zone, cortical plate, intermediate, subventricular, and ventricular zones (Krmpotic-Nemanic *et al.*, 1979). At this age, immature multipolar neurons can be seen in Golgi impregnations in the marginal and superficial intermediate zones. Apical processes of cortical plate neurons branch in the marginal zone, whereas the basal processes of cortical plate neurons arborize within the superficial intermediate zone. Also at this age, AChE-reactive Cajal–Retzius cells can be identified in the marginal zone (Krmpotic-Nemanic *et al.*, 1987). During the 13th w.g., the deepest part of the cortical plate becomes less dense. In Golgi impregnations, the number of multipolar neurons increases in the superficial part of the intermediate zone and the deeper layers of the cortical plate. At the same time, the superficial part of the intermediate zone becomes well defined and the incipient subplate begins to appear as large, round nuclei. By 14 w.g., the subplate is characterized by large cell bodies with round, pale nuclei. In Golgi impregnations subplate neurons appear as polymorphous neurons with no particular orientation, in contrast to the radial orientation of cortical plate pyramidal neurons.

Developing auditory thalamocortical fibers can be readily identified by their AChE. These fibers penetrate the auditory cortex subplate at 16–18 w.g. and grow into the auditory cortical plate at 22–28 w.g. (Krmpotic-Nemanic *et al.*, 1983). The intensity of approaching auditory thalamocortical afferents is so great at 22 w.g. that the edge of the band of AChE reactivity precisely defines the boundary between auditory and adjacent nonauditory temporal cortex (Krmpotic-Nemanic *et al.*, 1980). By 24–26 w.g., AChE reactivity in ingrowing afferents appears in the middle of the cortical plate and the subplate region begins to reduce in intensity. A columnar arrangement of AChE activity in the middle third of the cortical plate appears by 28 w.g., with alternating zones 140–200 μm wide separated by narrow interspaces of lower staining intensity, appearing at this stage (Krmpotic-Nemanic *et al.*, 1980). The development of this complex pattern of AChE activity in the auditory cortex coincides with the onset of auditory cortical evoked potentials at 30 w.g. (Vaughan, 1975).

Analysis of cellular column development in the fetal human auditory cortex indicates that there is a

progressive increase in linear orientation of cells in the upper cortical layers during fetal life (Buxhoeveden *et al.*, 1996).

Development of Somatosensory Cortex

The overall sequence of development of the somatosensory cortex is similar to that seen in the visual cortex, but each step occurs at a slightly earlier stage (Kostovic and Rakic, 1990). The presubplate stage occurs just before 12 w.g. when dendritic and axonal processes as well as large cell bodies with pale nuclei begin to accumulate below the cortical plate. Electron microscopy at this stage reveals that the cortical plate is made up of geometrically regular processes and vertically oriented cells, while the presubplate consists of a loose arrangement of neuronal processes of variable orientation. Even at this early age a few asymmetric synapses on the large proximal dendrites located within the presubplate sone and the most superficial part of the intermediate zone. However, the cortical plate itself is free of synapses at this age.

The subplate proper forms at about 12–13 w.g. (Kostovic and Rakic, 1990). A broad but poorly delineated tissue band develops between the subplate proper and the cortical plate. By about 14 w.g., the cortical plate of the somatosensory cortex is about 250 μm thick and the subplate zone is clearly divided into an upper transitional ("loose") zone and a cell-poor lower subplate zone. Asymmetric synapses are present in both upper and lower parts of the subplate zone and in the marginal zone.

Between 15 and 18 w.g., the cortex increases rapidly in thickness as many afferents invade the region. The region of the subplate invaded by axons from the ventral posterior lateral thalamus is marked by transient AChE activity as seen for the pulvinar and medial geniculate projections discussed above for other cortical regions. Cortical lamination begins to appear in the somatosensory cortical plate at 20 w.g. as a pale band at the border between the superficial two-thirds and the deep one-third of the cortical plate. Synapses begin to appear in the cortical plate, with most being concentrated in the lower layers (Kostovic and Rakic, 1990). By 22 w.g. the subplate is up to 5 mm thick, making it the thickest layer of the cerebral wall, and a variety of neuronal morphologies appear in the subplate from this age.

After 35 w.g. a six-layered laminar pattern becomes visible in the developing somatosensory cortex, although the borders of individual layers are poorly defined. The subplate is progressively reduced in size toward birth and disappears at about 1 month postnatal, although some remnants of it may be seen up until 6 months after birth. The loss of subplate neurons may be due to both apoptosis and incorporation into the developing cortex.

Development of Frontal Cortex

Cytoarchitectural and Ultrastructural Development

The cortical plate is formed in the frontal region between 7 and 9 w.g. (Mrzljak *et al.*, 1990) and by 10–12 w.g., the frontal cortical anlage consists of a marginal zone, cortical plate, primordial subplate, intermediate zone, subventricular zone, and ventricular zone. At this early stage, neurons in the cortical plate have a simple bipolar morphology and the subplate contains inverted pyramidal neurons, numerous immature neurons with small cell bodies and horizontal or oblique dendrites, radial glial fibers, and immature dendrites.

Between 26 and 29 w.g., differentiation of the cortical plate begins to reveal the cortical layers, with lower cortical layers appearing from the cortical plate before upper layers. The subplate of the frontal lobe reaches its maximum width at around 28–30 w.g., and between 32 and 36 w.g. the subplate begins to show regional variation, with thinning of the subplate at the bottom of sulci. Golgi impregnations at this age (25–36 w.g.) show several types of Cajal–Retzius neurons in the marginal zone (future layer I) and these are immunoreactive for calretinin (Spreafico *et al.*, 1999). Deeper in the cortex, the late fetal period sees rapid differentiation of layer III and V pyramidal neurons and nonpyramidal neurons. The total lengths of basal dendritic trees of both lower layer III and layer V pyramidal neurons show rapid increases from 26 w.g. (Mrzljak *et al.*, 1990). By contrast, pyramidal neurons in the superficial part of layer III still display less developed basal and apical dendritic trees. The first dendritic spines are seen on the apical and basal dendrites of layer V pyramidal neurons at 26–29 w.g., and fusiform neurons begin to be discernible in the lower cortical layers at this time. At about 26–27 w.g. a very specialized type of nonpyramidal neuron, the "double bouquet" neuron, appears in the frontal cortex, but the first immature basket neurons are not seen in layer V until after 30 w.g. During the last half of gestation, the subplate neurons can be seen to form projections both into the developing cortex and down to subcortical targets, suggesting that there are two distinct populations of neurons in the subplate: projection neurons and cortical plate interneurons.

From birth onward, the frontal cortex shows large increases in size of the dendritic trees and spine growth of pyramidal neurons. There is a decrease in cell packing density as neuropil increases and the mature appearance of the six-layered cortex begins to develop. Several types of interneuron (multipolar and bitufted nonpyramidal neurons, chandelier and neurogliaform

cells) do not appear until after birth. Unlike in other (primary sensory and motor) cortical regions, the subplate layer of the prefrontal cortex contains neurons well into postnatal life (Kostovic *et al.*, 1989).

Development of Connections Thalamocortical fibers grow into the frontal lobe cortical plate between 26 and 24 w.g. (Kostovic and Goldman-Rakic, 1983), and this is correlated with both rapid growth of dendritic length of pyramidal neurons and the period of initial synaptogenesis (Molliver *et al.*, 1973). During the latter half of gestation, ingrowing thalamocortical fibers in the cortical plate are distributed in a more diffuse pattern (Kostovic and Goldman-Rakic, 1983) than in the adult primate prefrontal cortex (Giguere and Goldman-Rakic, 1989). Afferents from the basal forebrain are believed to enter the prefrontal cortex at about 30–34 w.g. (Kostovic, 1990). The growth of commissural and associative pathways is believed to occur mainly during the perinatal and infant period, when there is a further differentiation and growth spurt of pyramidal and nonpyramidal neurons in layer III (Mrzljak *et al.*, 1988, 1990).

Development of Chemically Identified Neuronal Classes and Afferents The development of dopaminergic and noradrenergic innervation of the frontal cortex at midgestation (20–24 w.g.) has been studied by Verney and coworkers (1993). Even though the cortex is still immature at this age, the widespread catecholaminergic innervation of the different areas and layers of the fetal cortex is comparable to that seen in the adult, indicating early differentiation of these afferents. Nevertheless, there is strong innervation of the subplate at this age, and somata of tyrosine hydroxylase–immunoreactive neurons are visible in the subplate, so that some reorganization of catecholaminergic innervation of the cortex is likely during late prenatal and early postnatal life.

Neurons immunoreactive for neuropeptide Y (NPY) are first seen in the frontal cortex at 14 w.g. (Delalle *et al.*, 1997; Uylings and Delalle, 1997) when they are found mainly in the lower subplate. NPY-immunoreactive neurons begin to appear in the cortical plate at 15 w.g., and the number of NPY-immunoreactive neurons in both cortical plate and subplate increases from 23 to 28 w.g. After about 28 w.g. the cortical plate and marginal zone are transformed into the six cortical layers of postnatal life. The number of NPY-immunoreactive neurons in the subplate begins to decline and the proportion of all NPY-immunoreactive cells found in the cortex increases. The laminar distribution of NPY-immunoreactive neurons becomes homogeneous over the first 2–4 years of postnatal life.

NADPH-diaphorase-reactive and NOS-immunoreactive neurons appear in the frontal lobe as early as 15 w.g. (Yan *et al.*, 1996) and are mainly found in the subplate at these early ages (Ohyu and Takashima, 1998; Downen *et al.*, 1999). An adult-like distribution of large heavily stained, nonpyramidal, sparsely spiny type I cells in the cortex appears very early (by 32 w.g.) although most heavily stained cells are located within the white matter during prenatal life. Smaller lightly stained type II cells appear later (from 32 w.g.), especially in layers II–IV of the developing cortex and increase in number up until term (Yan *et al.*, 1996).

Somatostatinergic neurons undergo a similar pattern of development to that seen for NOS-immunoreactive neurons. The earliest somatostatinergic neurons appear in the subplate of the fetal frontal cortex at about 22 w.g. (Kostovic *et al.*, 1991). Around 32 w.g., there is an increase in somatostatinergic neurons at the boundary between the subplate and cortical plate. Around the time of birth there is reorganization of somatostatinergic neurons in the cortex as peptidergic neurons increase in the upper layers and decrease in the lower layers and subplate.

Development of Callosal Neurons

Very few data are available concerning the development of callosal neurons in the human fetal cortex. The cingulate cortex is known to contain callosally projecting neurons as early as 25 w.g. (DeAzevedo *et al.*, 1997), in both the cortical plate and subplate. Callosal neurons in the cortical plate at 26–32 w.g. are mainly spiny pyramidal cells with somata distributed throughout the depths of the plate. At this stage they have well-differentiated apical and basal dendrites. Subplate callosal neurons are relatively smooth cells with many different morphologies (radially oriented, horizontally oriented, multipolar, and inverted pyramidal) and distributed throughout the subplate thickness.

Development of Cortical Glia and Vasculature

The time of development of glial cell types in the human cerebral cortex has been followed through Golgi impregnation, immuno- and lectin and enzyme histochemical markers (Stagaard and Møllgard, 1989; Fujimoto *et al.*, 1989; Wilkinson *et al.*, 1990; Marín-Padilla, 1995; Wierzba-Bobrowicz *et al.*, 1998; Pal *et al.*, 1999).

In very young embryos (about 4–6 w.g.) vimentin immunoreactivity is found throughout the cells of the neuroepithelium (Stagaard and Møllgard, 1989). By 9 w.g., radial glia are clearly distinguishable by their vimentin immunoreactivity (Wilkinson *et al.*, 1990) and they will retain that immunoreactivity until late fetal life. Cells showing immunoreactivity for S-100 and

with the morphology of astrocytes appear by 9 w.g. (Wilkinson *et al.*, 1990), but glial fibrillary acidic protein–immunoreactive astrocytes cannot be clearly distinguished until 14 w.g. according to those authors. Biochemical assays of fetal brain also indicate production of glial fibrillary acid protein (GFAP) from about 17 w.g. (Pal *et al.*, 1999). Maturation of oligodendrocytes in the fetal cerebrum begins from about the end of the first trimester, with the first appearance of carbonic anhydrase II–positive oligodendrocytes from 17 w.g. (Wilkinson *et al.*, 1990).

The differentiation of astrocytes in the cerebral cortex has been followed in detail by Marin-Padilla (1995). Marin-Padilla proposes that, at the beginning of cortical development, there are three glial precursors in the developing neocortex: (1) radial neuroctodermal cells with nuclei above the primordial plexiform layer, which lose their ependymal attachments to become early astrocytes of layer I; (2) neuroectodermal cells with nuclei below the primordial plexiform layer, which retain their pial and ependymal attachment to become type I radial glia and serve to guide neurons during later fetal development (see section on general cortical development); and (3) neuroectodermal cells, which lose their pial attachment, are transformed into type II radial glia, and eventually become fibrous astrocytes of the subplate and developing white matter. Protoplasmic astrocytes of the gray matter appear from 15 w.g., by migration from layer I and appear coincidentally with vascularization of the cortex. The transformation of layer I glial cells into astrocytes and their incorporation into the cortical plate is supported by the findings of Spreafico and coworkers (1999).

Microglial cells in the cerebral cortex can be identified as early as 5–6 w.g. (Fujimoto *et al.*, 1989), when round nucleoside diphosphatase (ameboid) cells appear in the cortical wall. By 7 w.g., ramifying cells can be seen mainly in the marginal layer (developing layer I). Density of ramified microglia increase progressively from 13 w.g. (Woerzba-Bobrowicz *et al.*, 1998), so that by 22 w.g. numerous poor and highly ramified microglial cells are present throughout all layers of the cortex. At least some of the highly ramified cells are derived from the ameboid microglia, and the invasion of the cortex by ramified microglia coincides with vascularization of the differentiating cortex (Rezaie *et al.*, 1997).

At 15 w.g., the only vessels coursing through the developing cortex are radially oriented vessels (presumably arteries) arising from leptomeningeal arteries (Norman *et al.*, 1986). These early vessels course through without branching, to supply the subcortical tissue. From about 20 w.g., horizontal vessels arise from the radial vessels, particularly in the lower levels of the differentiating cortex. As horizontal branches in the lower half of the cortex increase through 20–27 w.g., these branches also begin to appear in the upper cortex. Shorter radial vessels appear from 27 w.g., and just before and after birth a fine network of capillaries proliferates, particularly in layers IV and V (Norman *et al.*, 1986; Mito *et al.*, 1991; Miyawaki *et al.*, 1998).

Development of Gyrification, Structural Asymmetry and Gender Differences

Developmental changes in gyrification of the human brain have been studied using unbiased stereological techniques (Mayhew *et al.*, 1996). Those authors found that there are transient increases in gyrification between 85 and 129 mm crown–rump length (approximately 12–17 w.g.) and toward the end of the fetal period. This is in agreement with findings that the proportion of intrasulcal cortex rises from about 22% at 17–18 w.g. to 66% in the newborn and adult (Henery and Mayhew, 1989). These findings indicate that the transition from fetal to adult gyrification values occurs at about the time of birth.

Left/right asymmetries in the temporal speech areas of the human fetal brain have been studied by Chi *et al.* (1977). They reported that asymmetries of the transverse temporal gyri and planum temporale associated with left hemispheric speech and language dominance become recognizable by 31 w.g. and that these asymmetries appear as soon as the relevant gyri become clearly recognizable. In other regions, fetal cerebral asymmetry has been found in the prefrontal cortex and striate/extrastriate cortex (de Lacoste *et al.*, 1991). Striate/extrastriate cortex is far more asymmetric in male fetuses than females. In terms of total cerebral volume, male brains tend to have a larger right hemisphere, whereas female brains tend to have two hemispheres of the same size or a left hemisphere slightly larger than the right. These gender-based differences may arise from the early action of testosterone on fetal cerebral cortical growth.

Neurochemical analysis of cortical development also indicates the early onset of cerebral asymmetry. Bracco *et al.* (1984) have found that there is asymmetric development of choline acetyltransferase (ChAT) in the brains of fetuses aged 26 to 40 w.g. Values of ChAT are much higher in the right first temporal gyrus (Brodmann's area 22) than in the left, even though there is no asymmetry in levels of ChAT at this age in the precentral gyrus (Brodmann's area 4). The level of ChAT in the right area 22 is comparable to that in the adult brain, suggesting that there is precocious development of ChAT in the temporal lobe during fetal life, which could also account for the early asymmetry.

Hippocampal Formation and Connections with Entorhinal Cortex

The archicortical plate begins to show evidence of morphological differentiation at about 10 w.g., and its major subdivisions can be distinguished on cytoarchitectural criteria from about 11 to 15 w.g. (Kostovic *et al.*, 1989, 1993). Synapses have been identified in the hippocampal formation as early as midgestation (Kostovic *et al.*, 1989) and dendritic spine development is evident at 26 w.g. on pyramidal neurons of cornu Ammonis, relatively advanced compared to visual cortex (Purpura, 1982).

Analysis of entorhinal cortex development using Golgi and Nissl staining techniques has been undertaken by Kostovic and coworkers (1993). Those authors found that the first signs of cytoarchitectural differentiation of the entorhinal cortex are at 10–10.5 w.g., when multilayered spreading of the deeper part of the cortical plate appears, along with the appearance of a monolayer of large neurons at the superficial part of the cortical plate, adjacent to the marginal zone. Golgi impregnation at the same age shows that large neurons with widely bifurcating apical dendrites occupy the cortical plate–marginal zone interface. The authors called these early differentiating cells "promoters" because the cells develop area-specific morphology before the appearance of the full set of cytoarchitectonic features of the entorhinal cortex. By 13 w.g., the entorhinal cortex shows the first appearance of its major characteristic cytoarchitectonic feature—the lamina dissecans, separating two principal layers of the cortex. At this stage the authors were also able to distinguish five cytoarchitectonic subdivisions, indicating the early areal differentiation of the entorhinal cortex. Golgi preparations at 13 w.g. show significantly advanced neuronal differentiation compared to 10.5 w.g. with differentiation of the other cortical plate neurons already well developed.

Hevner and Kinney (1996) have used carbocyanine dye tracing techniques to identify connections of the hippocampal formation during fetal life. They found that robust connections between the entorhinal cortex, hippocampus, and subiculum are present at 19 w.g. (the earliest age they studied) and that these connections are essentially the same anatomically as those seen in adult primates. Projections to the hippocampus and subiculum originated from neurons in layers II and III of the entorhinal cortex, whereas projections to the entorhinal cortex originated from pyramidal neurons in CA1 and subiculum. On the other hand, projections from the entorhinal cortex to the dentate gyrus and connections with adjacent neocortex are only rudimentary at 22 w.g. (the last age they studied), suggesting that hippocampal pathways develop before isocortical pathways.

The development of NO-synthesizing cells in the prenatal human hippocampus has been studied by Yan and Ribak (1997) using NADPH-diaphorase histochemistry. Strongly reactive nonpyramidal neurons appear in the hippocampal subplate at 15 w.g. and increase rapidly in both this region and the overlying cortical plate between 17 and 24 w.g. The distribution pattern of NADPH-diaphorase-positive cells stabilized at about 28 w.g., when reactive cells are mainly distributed at the border between the cortex and subcortical white matter in the case of the entorhinal cortex and subiculum, and between the cortex and alveus in the case of the hippocampus. Moderately stained nonpyramidal neurons appear in the dentate gyrus at 17 w.g. and increase in this region up to 28 w.g. A third type of nonpyramidal neuron, small and lightly stained, can be first seen at 32 w.g. and increases in number by term. In addition, hippocampal pyramidal and granule neurons transiently show NADPH-diaphorase activity, mainly between 15 and 24 w.g.

Interest in the possible involvement of disordered hippocampal development in the etiology of schizophrenia has prompted several studies of receptor development and binding in the prenatal human hippocampus. Gurevich *et al.* (1997) have found that dopamine D2 receptor mRNA is expressed very early during development in both subiculum and cornu Ammonis. D2 mRNA–positive neurons appear in both the subiculum and cornu Ammonis as early as 13 w.g. Even at this early stage, some of the D2 mRNA–positive cells in CA1 have clearly pyramidal morphology, while the most densely stained have the appearance of immature, newly migrated neurons. The proportion of D2 mRNA–positive cells decreases during development (from 13 to 25 w.g.) to about 20–26%. By the 34th week only mature pyramidal neurons in the deeper layers express D2 mRNA. Since dopamine may play a direct role in normal cellular differentiation of cortical neurons, it is possible that the presence of the D2 dopamine receptor in the hippocampus may have a special morphogenetic role in the maturation of neurons in specific fields of the hippocampus.

Serotonin receptors in the developing hippocampus appear to be well developed by the end of fetal life, with strong signals for 5-HT_{1A} mRNA being found in cornu Ammonis stratum pyramidale and the granule cell layer of the dentate gyrus by 35 w.g. (del Olmo *et al.*, 1998). Muscarinic cholinergic receptor binding is also well developed by midgestation (21 w.g.; Egozi *et al.*, 1986; Gremo *et al.*, 1987), with early evidence of receptor heterogeneity and an age-related decline during prenatal life.

Several genes are known to regulate apoptosis in various tissues. One of them is *bcl-2*, which encodes for the protein Bcl-2, which is expressed in many neurons during development. Chan and Yew (1998) have examined apoptosis and Bcl-2 expression in the developing hippocampus. Apoptosis in the polymorphic and molecular layers of the human fetal hippocampus becomes more prominent as fetal age progresses, but the apoptotic index in the pyramidal layer remains low and variable throughout prenatal life. On the other hand, Bcl-2 expression is strong in the pyramidal neurons during early gestation (14–27 w.g.) and declines to negativity during late fetal life (32 w.g.).

The expression of neurotrophin receptors in the developing human hippocampus has been investigated by Chen *et al.* (1996). Trk-immunoreactive neurons are first seen in the hippocampus at 16 w.g. At this early stage and up to about 19 w.g., most hippocampal trk-immunoreactive neurons are scattered within the stratum oriens and stratum pyramidale of the cornu Ammonis and show multipolar or fusiform morphology with a short dendritic branching pattern (Chen *et al.*, 1996). After 20 w.g., there is a progressive increase in the number of trk-immunoreactive neurons in the cornu Ammonis. Those authors also reported that trk-immunoreactive neurons are present within the hilar region of the dentate gyrus between 16 and 34 w.g. In contrast, only a small population of transiently p75-immunoreactive neurons are seen within the hippocampal formation during fetal life. These are found in the hilar region of the dentate gyrus between 16 and 24 w.g. (Chen *et al.*, 1996). Chen and coworkers have pointed out that the distribution of trk-immunoreactive neurons in the developing human hippocampus parallels the expression of BDNF and NT-3 in this region. In particular, BDNF is highly expressed in pyramidal neurons in the CA3 and CA2 subfields, with lower levels in CA1 and the granule cells of the dentate gyrus. NT-3 is also expressed in neurons of the medial part of CA1 and CA2 and in the granule cell layer of the dentate gyrus. Nevertheless, the precise role of trk and p75 during development of the hippocampus, and the way in which these two neurotrophin receptors interact, remains to be elucidated.

DEEP TELENCEPHALIC NUCLEI

Forebrain Segmentation by Radial Glia

At 9 weeks, radial glial cells (RGCs) can be demonstrated throughout the ventricular zone by the intermediate filament protein vimentin (VIM, see "Development of Chemically Identified Neuronal Classes and Afferents"). In the forebrain, their evenly spaced, radially aligned processes can be traced to the cortical plate. Only in the prospective fimbrial glioepithelium (Altman and Bayer, 1990), IR is intense and reaches the pial surface. In subcortical areas VIM-positive radial glial processes are much less dense than in the pallial region and their course and destination can therefore be more easily assessed (Fig. 3.2). In some regions, VIM-immunoreactive processes are condensed and form boundaries, as in the external capsule, the internal lamellae of the thalamus, or the ventral thalamus (Fig. 3.2). Another marker for the demonstration of RGC is CD15 (see Mai, 2002). Antibodies against this epitope reveal a subpopulation of the VIM-positive RGC. The CD15 cells appear later in the prosencephalon, around 12–13 weeks, are much less abundant and less uniform. Initially they are concentrated in a small area at the lateral ventricular (ganglionic) eminence (LVE) close to the corticostriatal sulcus (Mai *et al.*, 2003). Their number and density reach a maximum around 24 weeks (Fig. 3.3a–c). Due to their nonuniform and highly restricted manner they outline distinct domains, like those that have been described in the mouse and wallaby brain (Mai *et al.*, 1998a; Cheng *et al.*, 2002) (Fig. 3.4a). Registration of the CD15+ processes in the mouse prosencephalon in all planes of orientation has resulted in a spatial map (Fig. 3.4b) that generally fits to the so-called prosomeric organization as characterized in the rodent brain by structural and biochemical features like expression of regulatory genes (see Keyser, 1972; Rubenstein *et al.*, 1994; Martínez and Puelles, 2000) (Fig. 3.4c).

From the location of the CD15 RGC and the orientation of their processes it is clear that the CD15 segments are not complete on the transverse axis: they align between pretectal, dorsal thalamic, and ventral thalamic domains in the alar plate but are absent from the equivalent regions of the basal plate (Fig. 3.4a, c). This incomplete dorsoventral extent might be important with respect to the continuation of the alar-basal boundary (sulcus limitans). Using the highest density and the orientation of CD15-immunoreactive processes as parameters, evidence suggests that the alar–basal boundary continues along the ventral thalamus to the choroidal roof of the forebrain at the level of the interventricular foramen. Here the radial glial cells come in contact with the intense labeling by CD15 of the commissural plate at the anterior wall of the forebrain (Fig. 3.4d) (see Rakic and Yakovlev, 1968). This site is related to the lateral plexus evagination at the border between the di- and telencephalon (Bailey, 1916). If the condensation of CD15+ RGC corresponds to the sulcus

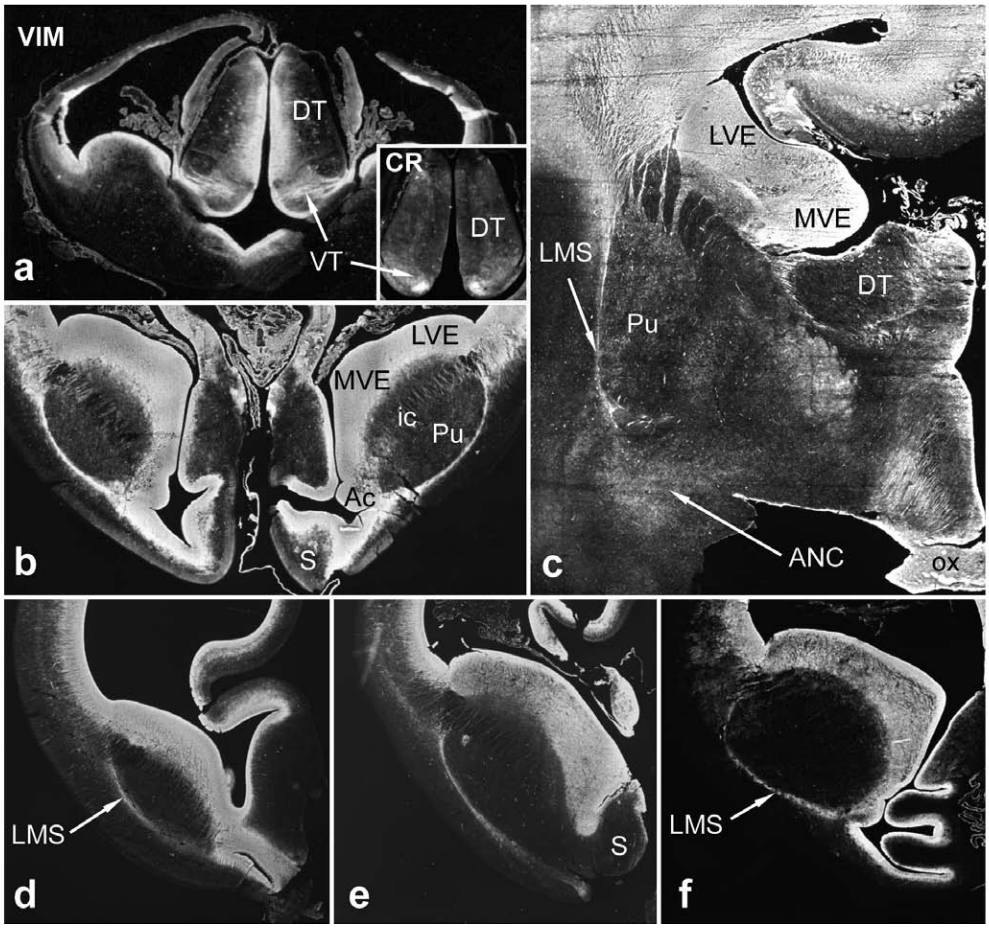

FIGURE 3.2 Coronal sections reacted for the demonstration of vimentin (VIM). **a.** Cross-section through the anterior thalamus at 10 weeks. Dense VIM immunoneactivity (IR) is seen in the dorsal thalamus (DT). The border between DT and the ventral thalamus (VT) is indicated by the shallow sulcus medialis and the unlabeled medial part of the tract of the zona limitans intrathalamica. Strands of VIM processes are typical for the VT; these converge at the stem of the tenia. *Inset:* **a.** Calretinin IR (CR) marks an area of reduced VIM IR. **b.** VIM IR at the level of the precommissural hippocampus from a 14-week fetus. The ventricular eminences (LVE and MVE) are completely filled with immunoreactive processes without distinction between both divisions. A bulge indicates the part of the VE from which the accumbens nucleus (Ac) is derived. **c.** Coronal section at 21 weeks. **A.** VIM-positive processes outline the external capsule. **d–f.** VIM IR in different section levels of the basal forebrain of a 14-week fetus. The lateral migratory stream (LMS) surrounds the lateral aspect of the putamen. ANC; amygdaloid nuclear complex; ic, internal capsule; ox, optic chiasma; Pu, putamen; S, septum.

limitans as shown in the mouse brain stem and spinal cord (Ashwell and Mai, 1997a, b), then it is unlikely that the sulcus ends at the supramamillary recess as described by O'Rahilly and Mueller (Chapter 2 of this volume), or at the chiasmatic plate as proposed by the prosomeric model (Puelles and Rubenstein, 1993); (Fig. 3.4b). The course of the sulcus limitans as suggested by our observations would correspond to the interpretation by Spatz (1921), Kahle (1956), and Richter (1965) and would fit well with the drawings from Hines (1922, e.g., her figures 18–20). However, since the sulcus limitans widens at the border between the syn- and diencephalon, a true continuation or junction of any of the diencephalic sulci is not seen (Keyser, 1972), and other parameters have to be applied before conclusive evidence is achieved. Confirmation awaits the definition of the contents of the CD15 divisions by the delimitation of regulatory gene expression patterns within these boundaries.

The same morphological features as described in the developing mouse brain also become visible in the developing human forebrain (Fig. 3.4d). CD15-positive RGC and their processes in the human forebrain outline areas that appear homologous to those in the

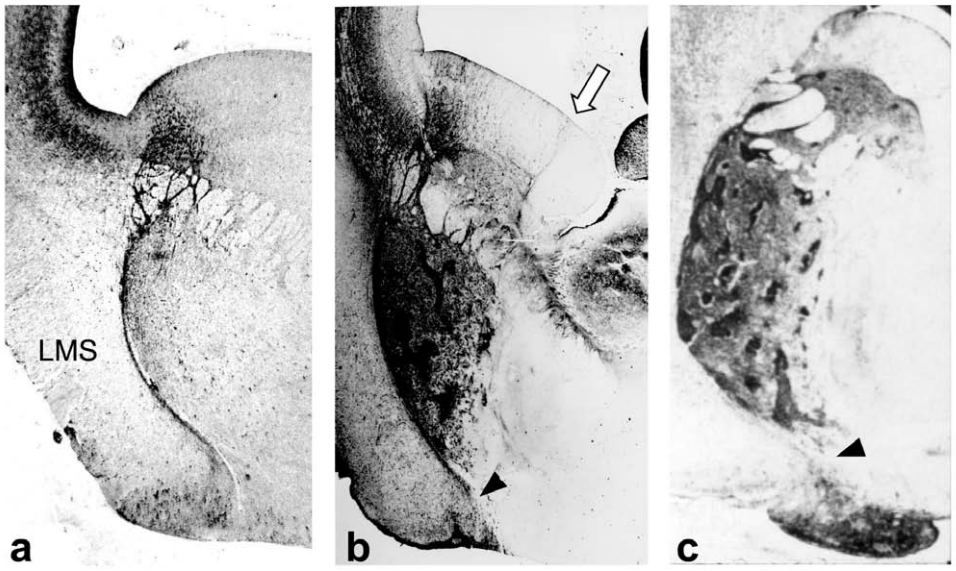

FIGURE 3.3 Frontal sections cut at the level of the ventricular eminence and striatum. **a.** At 13 weeks CD15 immunoreactivity *(black)* is very pronounced along the lateral portion of the striatum, outlining the lateral migratory stream (LMS) in the external capsule. A set of immunoreactive processes separates from the perimeter of the putamen to continue toward the pial surface *(arrowhead)*. **b.** At 17 weeks CD15 IR becomes more intense and involves the dorsal striatum, where the differentiation between patch and matrix compartments is advanced. Processes in the LMS separate at the border between the dorsal and ventral striatum (at the level of the intersection with the anterior commissure) and proceed between the olfactory tubercle and accumbens nucleus medially and the piriform cortex laterally. **c.** At 25 weeks CD15 IR is present in the dorsal striatum. *Arrows* point to the border between the piriform cortex and the olfactory tubercle; the *open arrow* in **b** points to the interstriatal glial sling, separating the LVZ and MVZ.

mice, providing evidence that the same boundaries exist in the human (Fig. 3.4e).

The intense labeling of the individual processes of RGC allows them to be traced from the ventricular epithelium through the brain substance. During early CNS development RG processes are radially oriented from the ventricular to the pial surfaces, and this spatial registry between both extremes appears to be maintained during the subsequent developmental steps; therefore, the orientation of RG processes at later (fetal) time still indicates the registration between corresponding ventricular and pial locations. Tracing of CD15-positive RG processes, which is easier because it labels only a subgroup of RGC, has allowed selective visualization of a wide-ranging and precisely organized system that has several interconnected components (Fig. 3.5). These can be arbitrarily separated into a lateral stream that connects the lateral ventricular zone with the basal forebrain, an intereminential sling, and a portion associated with the stem of the choroid plexus.

Lateral Stream

The lateral stream is composed of processes of the VIM and CD15-immunoreactive RGC cells that are located in the lateral ventricular eminence close to the corticostriatal sulcus. They cross through the internal capsule (or stem bundle, respectively) and pass to the external capsule. As a thin but extensive sheet, these processes outline the lateral perimeter of the putamen (Figs. 3.2a, 3.3). Several major relations can be distinguished in CD15-stained sections (Figs. 3.5 and 3.6): first, with CD15-immunoreactive patches in the dorsal striatum that stand in continuity with the CD15-positive processes along the lateral caudate nucleus and putamen (Fig. 3.3b, c); (Mai *et al.*, 1999a; see below); second, with the lateral portion of the olfactory recess of the lateral ventricle (Fig. 3.2); third, with the pial surface of the piriform cortex (Fig. 3.3) and finally, with the amygdaloid nuclear complex. The processes that pass to the piriform cortex separate from the external capsule at the level of the border between the dorsal and ventral putamen and pass between the olfactory tubercle and accumbens nucleus medially and the piriform cortex laterally, thus defining the border of the isocortical plate (Mantelkante of His) (Figs. 3.3 and 3.5). The processes that proceed to the amygdaloid nuclear complex mark the superficial nuclei (supraamygdaloid area of Brockhaus, 1940) which thus stand out against the unstained deep amygdaloid nuclei, indicating a border between both divisions (Figs. 3.5 and 3.6; compare to Fig. 3.11).

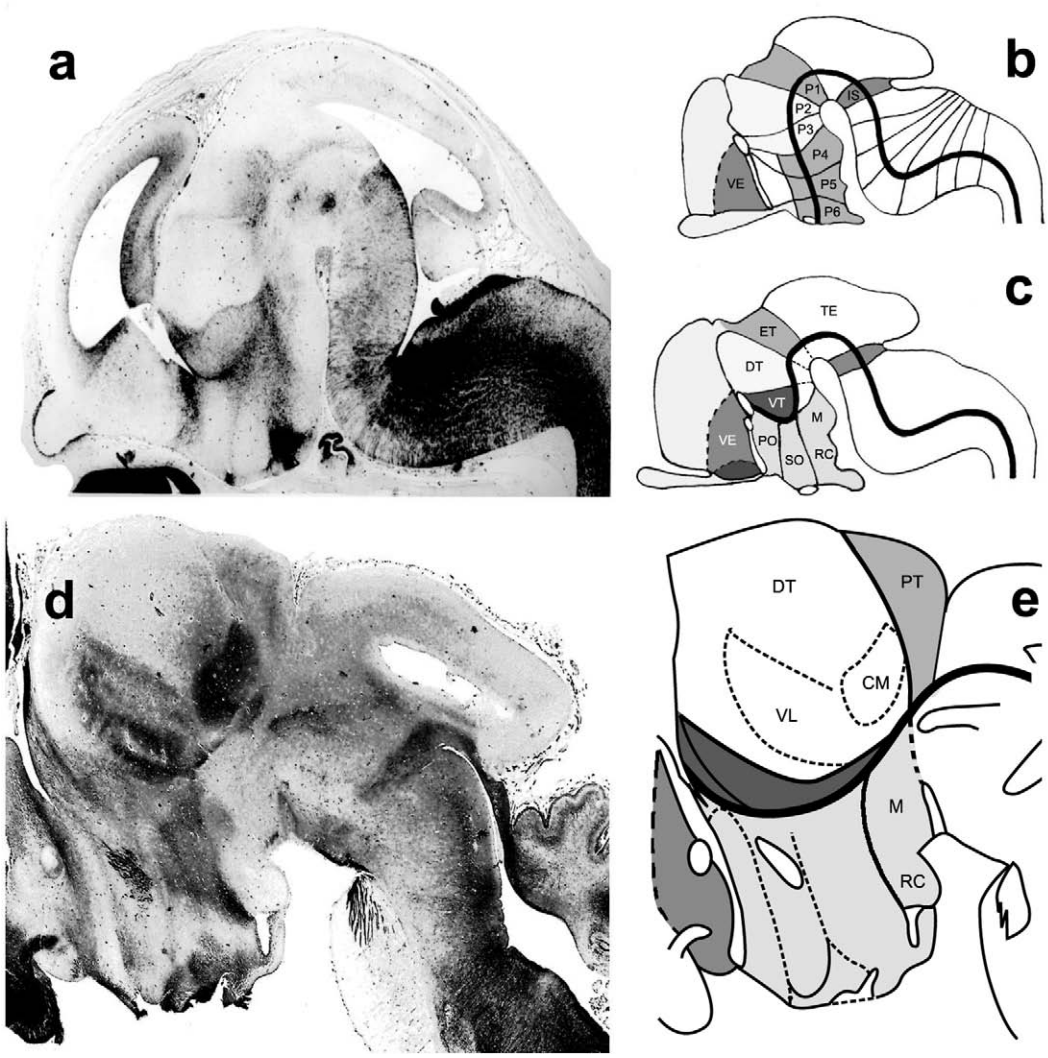

FIGURE 3.4 Comparison of the CD15 immunoreactivity (IR) between the mouse and human brain. **a.** Sagittal section close to the midline through a mouse brain at the embryonic age of 12.5 days. **b.** Modified drawing of the prosomeric boundaries as interpreted from the expression of transcription markers. According to this model, the alar–basal boundary (sulcus limitans) ends at the optic recess. **c.** Schematic drawing representing the major divisions as evidenced by CD15 and vimentin IR. The sulcus limitans in this schema continues along the ventral thalamus to the anterior choroidal roof at the level of the anterior interventricular foramen. **d.** Parasagittal section through a human fetal brain at the age of 15 weeks. **e.** Outlines of segments distinguished in the human brain by CD15 IR as interpreted from the distribution pattern of CD15 IR.

The location and arrangement of the CD15-immunoreactive processes from the proliferative neuroepithelium to the external capsule and further to the above described destinations corresponds to that of the lateral (cortical) migratory stream (LMS) as described in the brains of various nonhuman species (Brunjes *et al.*, 1998; Stoykova, *et al.*, 1996, 1997). Since radial glial processes act as a guidance structure for migrating postmitotic neurons, those disclosed in the human brain might likewise provide a substrate for the migration of a comparable population of cells. In analogy to findings in nonhuman brains, it appears that the correspondence between the starting and end points of the radial glial connection allows the correlation between matrix (proliferation) and homing (settling) areas of cells. Knowledge about that correlation may aid the neuropathological evaluation of abnormal migration patterns as a consequence of restricted vascular lesions into the VE (Solcher, 1968; Ulfig, 2002).

Besides forming a scaffold responsible for the migrational restriction of cells from the lateral ventricular eminence, the CD15 processes might also help to establish a boundary between striatum and pallium

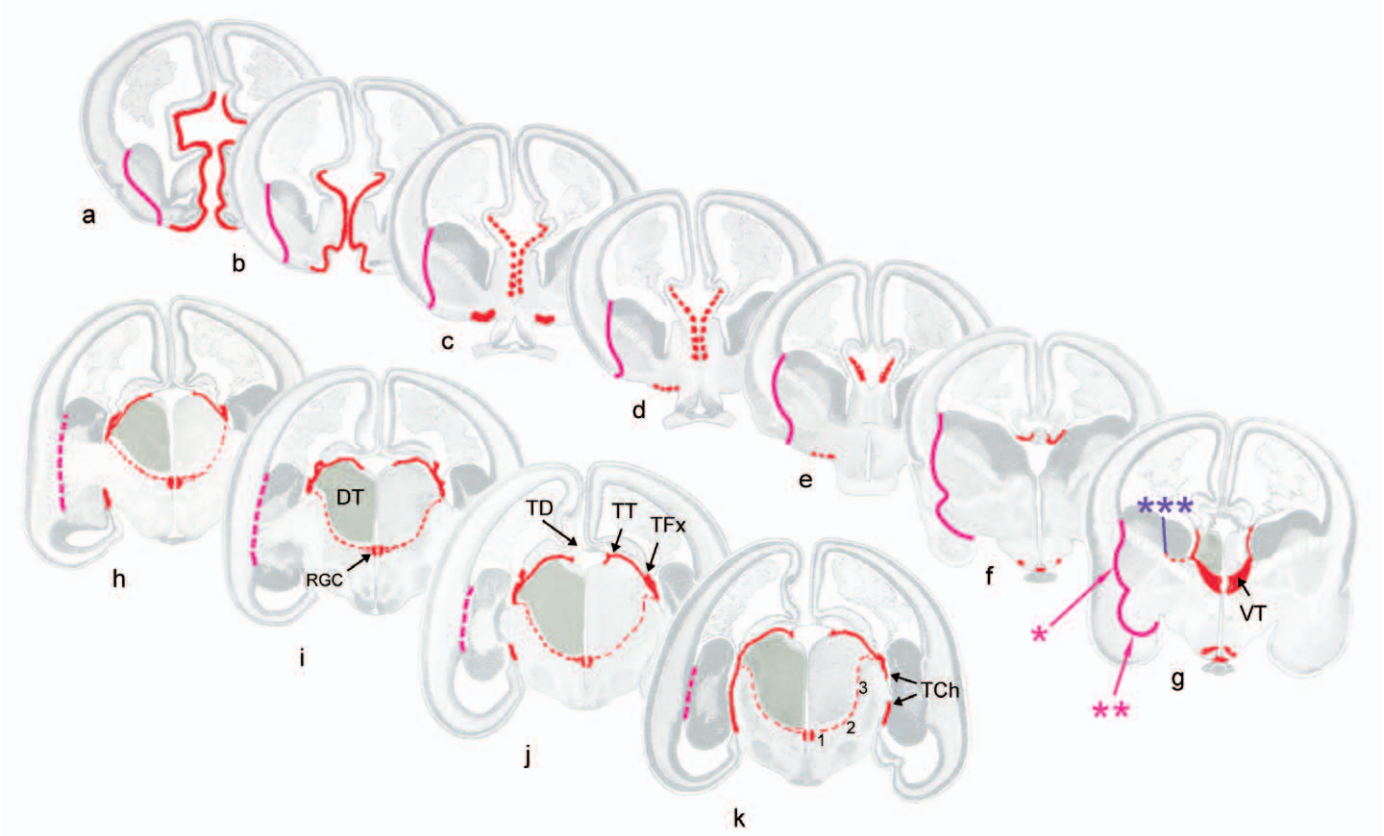

FIGURE 3.5 Series of coronal sections of a human fetus of approximately 14 weeks. The arrangement and extent of the CD15-immunoreactive processes are schematically indicated from rostral **(a)** to caudal section levels **(k).** In each section the cross-sectional area of the dorsal thalamus has been darkened on the left side. In **g,** the processes in the external capsule, corresponding to the lateral migratory stream, are indicated by an asterisk. The continuation of the CD15 processes into the amygdaloid nuclear complex are indicated by two asterisks. Three asterisks point to the intereminential CD15 glial sling. At the level of the interventricular foramen **(g).** a dense stream of radial glia processes passes from the ventricular epithelium through the ventral thalamus (VT) toward the choroid tenia (Ch). Posteriorly **(h–k)** small stripes of radial glial cells (RGCs) are still found at the ventricular border of the ventral thalamus, but only few radial glia processes can be traced along the perimeter of the dorsal thalamus *(broken lines)*. TCh, choroid tenia; TFx, fornical tenia; TT, thalamic tenia. Reproduced from Retzius, 1896.

during forebrain development (Götz *et al.*, 1996). Its location and orientation fits well to the striatopallial boundary, which becomes disclosed by virtue of the expression of transcription factors and of adhesion molecules such as R-cadherin (Matsunami and Takeichi, 1995; Stoykova *et al.*, 1996, 1997; Chapouton *et al.*, 1999; see also Puelles, 2001). In the Pax 6 mutant mouse, the boundary is no longer existent and restriction of cell migration is lost (Chapouton, 1999). Finally, this boundary might be a locus of increased vulnerability with respect to vascular accidents (Solcher, 1968).

Intereminential Area

CD15 IR demarcates the LVE from the MVE (Figs. 3.3b and 3.5g). This demarcation appears at 16 weeks but becomes pronounced in the following weeks by the steady increase in the number of RGCs and their processes in the LVE, whereas the MVE remains largely free of IR (Figs. 3.3b and 3.9a). Even more, at the interganglionic boundary an intense CD15 sling is formed. This boundary extends from the ventricular surface (sulcus interstriatus of Brockhaus, or the intereminential sulcus of O'Rahilly and Müller, Chapter 2 of this volume) perpendicularly through the VE to an area of focal increase of CD15 IR at the exact location where the ventral margin of the caudate nucleus and the internal capsule meet (Fig. 3.3b). This point, which remains visible until the consumption of the matrix cells in the GE around the time of birth, is connected with other CD15 processes (see below).

Albeit not yet described in nonhuman brains, there exists indirect evidence that this glial sling is important

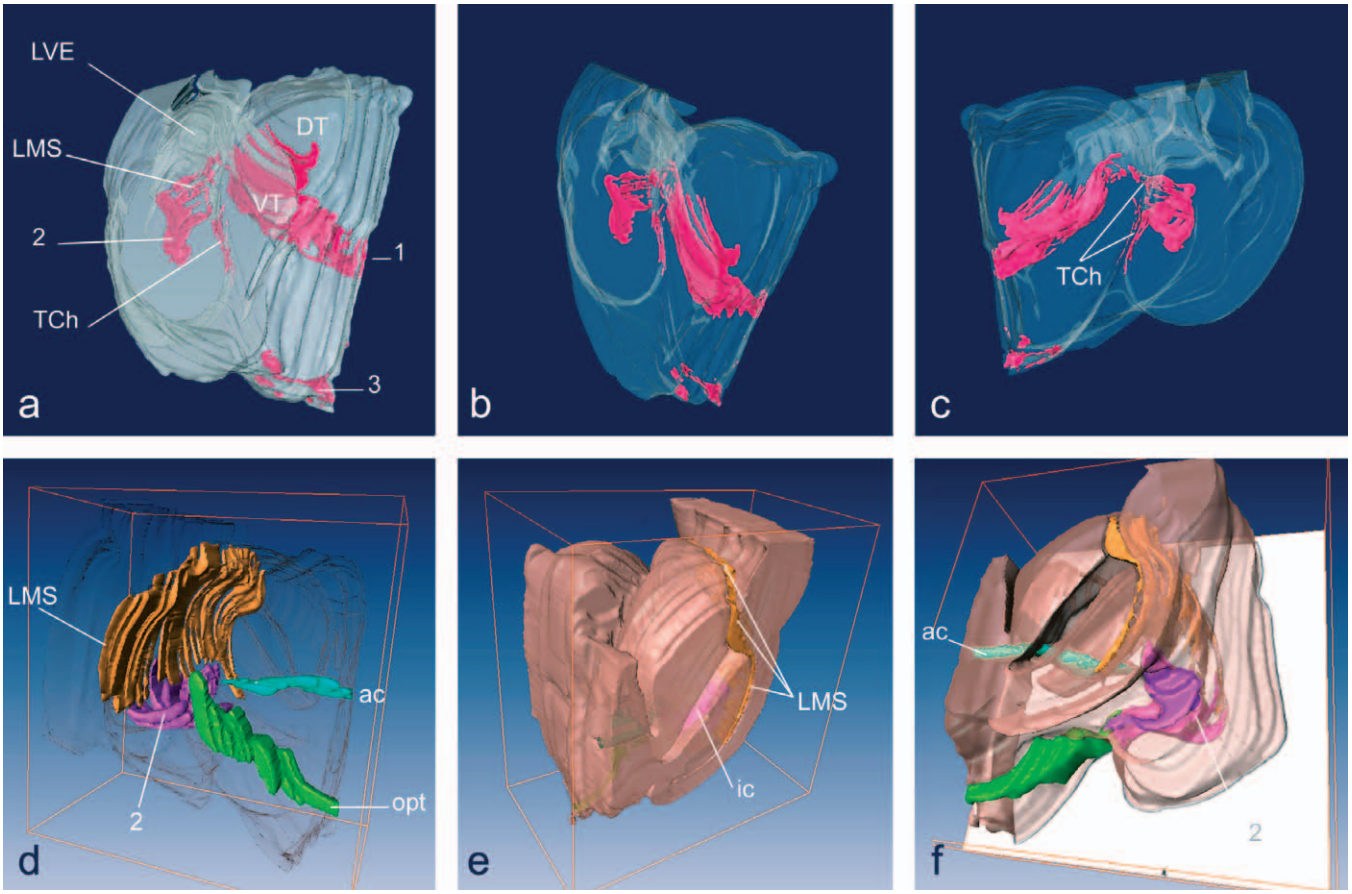

FIGURE 3.6 Computer reconstructions of the CD15-immunoreactive strands of processes in the prosencephalon of a human fetus at age 15 weeks **(a–c)** and 17 weeks **(d–f).** 1, Indicates the radial glial cells and processes in the ventral thalamus (VT) which converge at the stem of the choroid tenia (TCh). 2, Set of processes between the external capsule and the amygdaloid nuclear complex. 3: Set of radial glial cells in the hypothalamus. for axonal navigation of thalamocortical and corticothalamic axons (Metin and Godement, 1996; Molnar *et al.*, 1998, Auladell *et al.*, 2000). These axons pass through diverse territories, like the ventral thalamus, telencephalic stalk, and basal ganglia, before they finally reach the presumptive targets in the neocortex and thalamus, respectively. On this route through the diverse territories the thalamic and cortical axons are dependent on several path-finding steps. One important location that the thalamic and cortical axons must meet for correct routing in the subcortical telencephalon could well match by topography to the glial sling of the intereminential border (reaching from the ventricular surface to the internal capsule) (Metin and Godement, 1996; Tuttle *et al.*, 1999; Molnar *et al.*, 1998). CD15 might provide a guidance cue as has been suggested for optic and olfactory axons (Marcus *et al.*, 1999; Plank and Mai, 1992; see Mai, 2002).

Linkage of the Ventricular Zone of the Ventral Thalamus to the Root of the Tenia

The ventral thalamus constitutes another region where the registration between ventricular and pial surfaces is obvious (Forutan *et al.*, 2001). Here CD15 characterizes a subpopulation of radial glial cells located in the ventricular surface along the entire extent of the ventral thalamus (Figs. 3.5g and 3.6a). Processes of these cells can be followed distally where they converge at the stem or root of the choroid tenia (10–15 weeks). Because the RG processes converge at the root of the tenia, this structure becomes particularly well visible in CD15 stained sections as a thin, continuous line at the dorsolateral surface of the thalamus, thereby attaining different topographic relations with the plexus (choroid tenia, fornical tenia, thalamic tenia; Fig. 3.5h–k). At the anterior midline the tenia forms part of the choroidal roof of the forebrain and is here contiguous with the

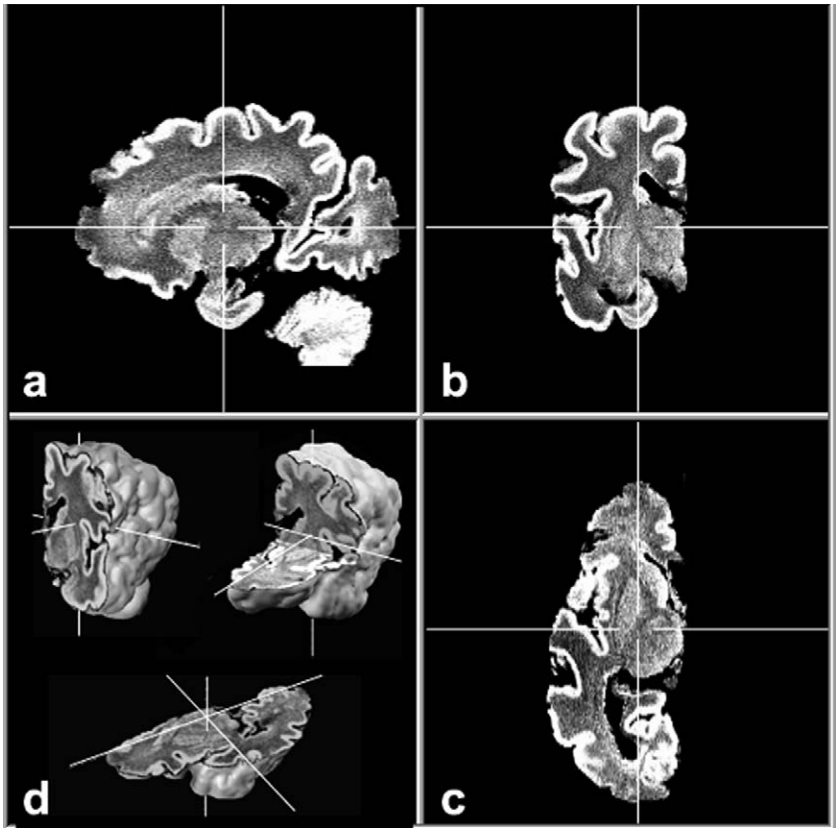

FIGURE 3.7 Magnetic resonance (MR) images of an autopsy brain of 36 weeks showing the high contrast and resolution obtained. From an MR image series the brain volume was calculated such that the brain can be virtually sliced in any orthogonal plane. The centers of the crosses in **a–c** indicate the voxel which is common for all sections. In **d,** the location of the sections in the reconstructed brain is visualized. Three-dimensional navigation is possible as is the matching between the MR images with the sections after histological or histochemical treatment.

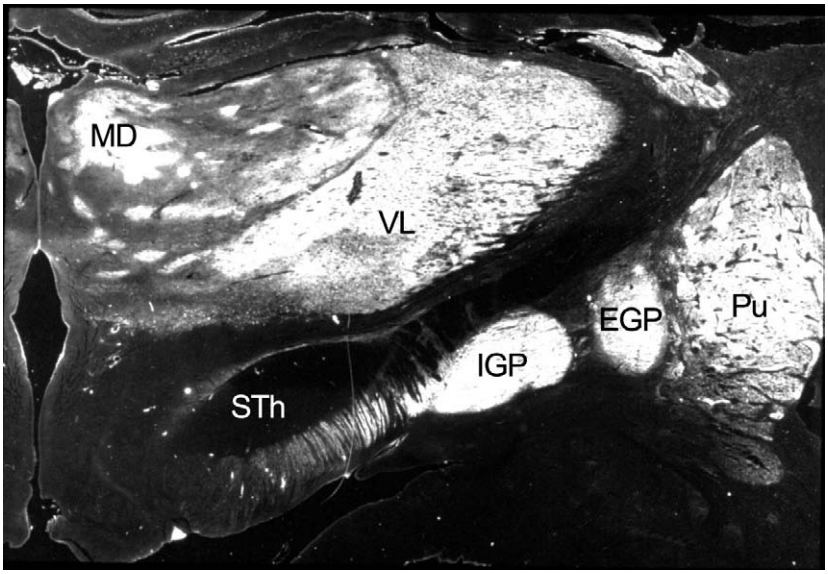

FIGURE 3.8 Lumogram (immunoreaction product appearing in white) showing CD15 IR in the thalamus and basal ganglia at age 27 weeks. EGP, IGP, external and internal globus pallidus; Pu, putamen; STh, subthalamic nucleus; VL, ventrolateral thalamus.

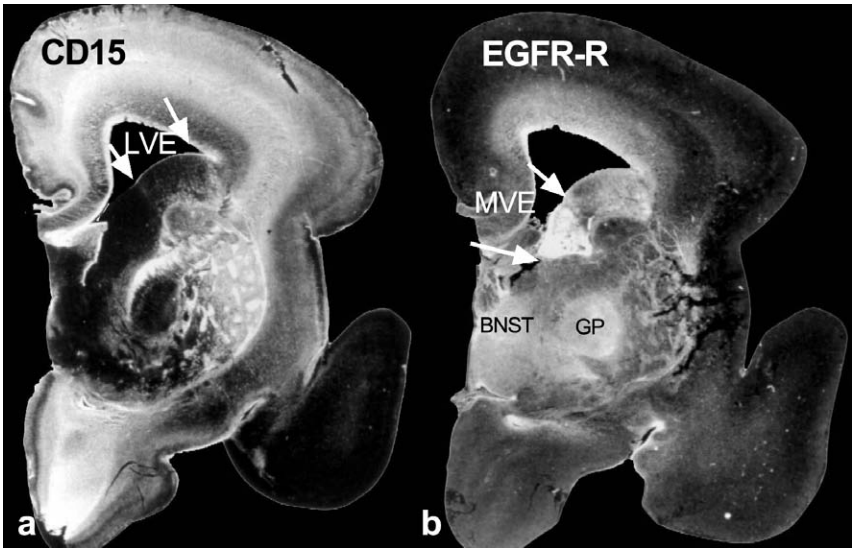

FIGURE 3.9 Distribution of CD15 and epidermal growth factor receptor (EGFR) in the forebrain of a transverse section through the 22-week fetal forebrain. In the deep-forebrain structures CD15 is concentrated in the lateral ventricular eminence (LVE) and dorsal striatum; EGFR is enriched in the medial ventricular eminence (MVE), globus pallidus (GP), and bed nucleus of the stria terminalis (BNST).

likewise highly CD15-positive commissural plate and lamina terminalis (Fig. 3.4e, compare with Fig. 3.13). The three-dimensional orientation of the CD15-positive stem of the choroid corresponds to the choroid fissure and the hem of the hemispheres; its curvature directly reflects the changes in shape which the prosencephalon has undergone. In a caudal direction the CD15 IR of the stem of the tenia is continuous along the infra-choroidal tenial leaf with the sulcus terminalis; thereby outlining the junction between the cerebral hemisphere and diencephalon. From the depths of the sulcus terminalis IR is continuous with the patch of IR at the base of the intereminential border (thereby forming a boundary between the medial ventricular eminence and the stria terminalis on one side, and the thalamus on the other) (Fig. 3.6b, c). This stretch, located between the ventricular eminence and the pulvinar; possibly corresponds to the corpus gangliothalamicum, a passageway for the stream of migrating cells in transit from the LVE to the posterior thalamus (Rakic and Sidman, 1969).

Summary

Shortly after the beginning of the fetal period a three-dimensional scaffold appears, which by its topography fits well to the organization described in the mouse brain. This, in turn, matches the topological data obtained from expression patterns of regulatory genes and guidance factors. Radial glial cells of this system apparently provide a substrate for neuronal or glial cell migration, as suggested by its high, transient expression in areas of described migration, as in LMS or the corpus gangliothalamicum. In addition, the units specified by CD15-positive RGC and processes might provide the boundaries for regional domains in which specific nuclei with characteristic neuronal types appear and differentiate, or they might impose barriers to deter the growth of axonal pathways (see Silver *et al.*, 1993). The further development of many areas in the forebrain, particularly the basal ganglia, amygdaloid complex, and thalamus, supports this view (see below).

All relations described above apparently represent not separate entities but form a three-dimensional interrelated scaffold (Fig. 3.6). At this early fetal period it appears to be rather complicated; however, since its origin is in the direct correspondence between the ventricle and pial surface (at an earlier developmental stage) its registration is an important step for the description of fundamental subdivisions of the brain architecture and for the future modeling of the formal development of the human brain.

Corpus Striatum and Other Basal Nuclei

The development of the deep telencephalic nuclei is closely related to the lateral and medial eminences which make different contributions to the individual nuclei (see O'Rahilly and Mueller, Chapter 2 of this volume). Both structures show molecular and clonal

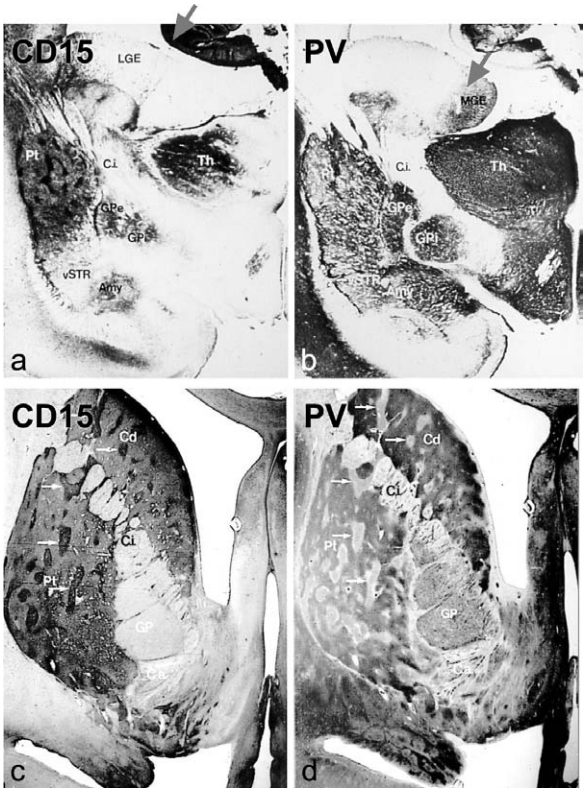

FIGURE 3.10 Distribution of CD15 **(a, c)** and parvalbumin **(b, d)** in the forebrain of transverse sections through the fetal forebrain at the age of 18 weeks **(a, b)** and of 3 weeks postnatal **(c, d).**

differences (Halliday and Cepko, 1992; Acklin and van der Kooy, 1993; Olsson *et al.*, 1995, 1997; Rubenstein *et al.*, 1997). In the fetal human brain molecularly distinct subsets of radial glial cells can be discriminated by CD15 (Mai *et al.*, 2003), epidermal growth factor receptor (EGFR) (Mai *et al.*, 1995), antibodies against S1515 and parvalbumin (Figs. 3.9 and 3.10). Some distribution patterns show differing localization with only partial overlap in their distribution. CD15 IR marks the LVE (see above); EGFR IR becomes present (predominantly) in the medial part of the VE at 15 weeks in radial glial cells, and their processes are often directed ventrally. The separation between the two neurochemically distinct compartments of the VE is maintained throughout the rostrocaudal extent of the VE.

Figure 3.9 demonstrates the principally dichotomous character of the labeling in the deep telencephalic nuclei in relation to the labeling of either the LVE or the MVE. Such results lead to suggest that distinct sets of radial glial cells contribute differently to the chemical organization of the deep forebrain structures; in other words, it is probable that structures like the basal ganglia, the amygdaloid nuclear complex, and the bed nucleus of the stria terminalis are populated by neurons that have different birthplaces and specific molecular tags as established in the mouse. In the human forebrain there is presently only minimal information concerning the location of the respective progenitor cells, the derivation of neurons which settle in different parts of a given structure, the migratory pathways, and the settling areas (see Hamasaki *et al.*, 2003) despite several detailed descriptions of the morphological development of the normal basal forebrain (Richter, 1965; Kahle, 1956; Lemire *et al.*, 1975; Kostovic, 1990; Ulfig, 2002). Such information is indispensable before an understanding of the architecture of the forebrain region, where many distinct developing cell pools that are closely associated can be derived.

Basal Ganglia: Dorsal Striatopallidal System (Dorsal Striatum and Dorsal Pallidum)

The dorsal striatum (caudate-putamen) and the globus pallidus are clearly identified at the ninth week. Around 15 weeks, the dorsal striatum attains an inhomogeneous organization due to the formation of cytoarchitectonic and histochemical compartments, termed *patch* and *matrix*, that together contribute to a mosaic organization (Kostovic, 1990). Even before, from 13 weeks, the first patches of tyrosine hydroxylase IR (Zecevic and Verney, 1995) and CD15 IR appear in the putamen (Mai *et al.*, 1999a) (Fig. 3.3). CD15 patches in the caudate nucleus appear 4 weeks later. The discrete nature and the precise margination at this time make it probable that the dopaminergic fibers and CD15 interact in an unknown way. The ventral striatum does not become immunoreactive for CD15 until the last few weeks before birth (see below) and therefore the border between the dorsal and ventral striatum is easily recognized throughout the fetal period.

Sections stained for parvalbumin and the S1515 antigen disclose IR in the MVE and during the last trimester an inverse pattern in the striatum if compared with CD15 IR (Fig. 3.10). It is therefore very probable that the patch/matrix components of the human striatum receive different contributions from molecularly distinct divisions of the VE. The CD15 IR in the matrix compartment progressively increases during further development; therefore, the contrast with patches disappears around birth.

The vast majority (90%) of the neuronal population of the striatum are projection neurons, with connections to the globus pallidus and substantia nigra. Applying a retrograde tracing technique, efferent fibers were observed at 10 w.g. (Sailaja and Gopinath, 1994). In CD15-stained sections delicate fiber bundles are noted by 17 weeks which pass to the external pallidal lamina and the globus pallidus (and later to the substantia

nigra) (Mai *et al.*, 1999a). The appearance of fibers in the pallidum at 17 weeks is coupled with transient IR in this structure which peaks at 22 weeks (Fig. 3.8) and disappears at birth. It appears that the occurrence of CD15 striatopallidal fibers and the emerging IR at their target site in the pallidum are coupled events, so that ingrown CD15-positive axons establish functional interactions and provoke CD15 expression. The differentiation of the large cholinergic interneurons occurs after the 16th week (Kostovic, 1990).

The two pallidal segments and the subthalamic nucleus have their origin in a primordium directly under the surface of the ventrolateral diencephalon. Between the third and the fifth month the three nuclei become displaced in a rostral direction. Thereby the globus pallidus attains first a characteristic location below the hemispheric stalk and then—after rotation in rostrolateral direction, correlated with the expansion of the hemispheres in caudal direction—next to the putamen (intussusception of Spatz). The subthalamic nucleus is pushed anteriorly by the unfolding fibers of the cerebral peduncle. At about 5 months the three nuclei, which are initially arranged in a longitudinal sequence, are seen in one frontal section (Kahle, 1956; Richter, 1965; Lemire *et al.*, 1975). In accordance with the early exhaustion of the matrix zone of the area from which all three nuclei originate, the differentiation occurs synchronically and early (before the third month), and myelinated fibers appear before birth.

Basal Forebrain Area

Basal forebrain area (BFA) is a broad topographic term describing a heterogeneous set of structures on the medial and ventral cerebral hemisphere. The BFA comprises various cellular structures, the ventral striatopallidal system (VSPS), the septal nuclei, the olfactory tubercle, the magnocellular basal forebrain system (DB,NBM), the bed nucleus of the stria terminalis (BST), extended amygdala, and dispersed cell populations such as the neurophysin-immunoreactive neurons (Mai *et al.*, 1993). These diverse constituents form an intricate complex to which the various traversing fibers, like the medial forebrain bundle, ventral amygdaloid fibers, inferior thalamic peduncle, and neurotransmitter bundles, contribute. Nevertheless, all of them can be identified and defined by means of their chemical properties; therefore, the term "substantia innominata" has become superfluous (Alheid and Heimer, 1988; DeOlmos and Heimer, 1999).

The Ventral Striatopallidal System (Ventral Sriatum or Accumbens Nucleus, Part of Olfactory Tubercle and Ventral Pallidum) The ventral striatum shows marked differences compared with its dorsal counterpart. Neurons in the dorsal striatum are homogeneously distributed and the organization into patch and matrix compartments is obvious. The ventral striatum contains smaller neurons, which are more densely packed and more irregularly distributed, often forming strings or islands of cells. These cells are embedded in a more strongly stained ground substance and the processes are thinner with less myelin (Brockhaus, 1942). Patch-matrix compartments are not characteristic; instead the ventral striatum is "invaded" by nonautochthonous elements and the relationship between the distribution pattern of D1 and D2 receptors and AChE activity are different in the ventral and dorsal striatum (Berendse and Richfield, 1993). Such differences are underlined by different input and output relations (see Haber and Gdowski, Chapter 21 of this volume) and the chemical characteristics of constituent neurons. The various components of the BFA are much easier to separate in adulthood because the differentiation of this region is very heterochronous and the appearance and peak production of neuroactive substances occurs at different times. In spite of this, a detailed ontogenetic analysis is still missing.

In the nonhuman brain, the ventral striatum is often divided into core and shell regions on the basis of chemoarchitecture and fiber connections (Groenewegen *et al.*, 1999, Haber and Gdowski, Chapter 21 of this volume). As distinguishing feature between both divisions, the abundance of calbindin-28 in the core region as compared with its absence in the shell region has been described. In addition, a medial segment of the core region has been discriminated on the basis of the presence of AChE activity, substance P, neurotensin, serotonin, and μ-opiatereceptor (Haber and MacFarland, 1999). It appears, however, that it might be misleading to adopt the well-established shell-core organization found in rodents for the more complex three-dimensional organization in the human.

On the other hand, it has been already stressed by Brockhaus (1942) and Namba (1957) that the organization of the striatum follows a ventral-to-dorsal gradient that leads to the distinction of a ventral perimeter (fundus subventricularis), an intermediate fundus striati, and the dorsal striatum. This organization, also adopted in a recent human brain Atlas (Mai *et al.*, 1997), is supported from developmental findings. The fundus subventricularis was subdivided by Brockhaus (1942) into a medial and lateral part. This separation is supported by the transient appearance of a distinguished (sub-)ventricular zone that overlies the medial fundus subventricularis (medial accumbens nucleus) (Fig. 3.3b). From this portion of the VE the cells of the medial part of the accumbens nucleus appear to be derived.

Important for the interpretation of the ventral striatum are islands of cells that appear as distinct units (Brockhaus, 1942; Sanides, 1957; see also Nauta and Haymaker, 1969, their figure 4-15). In single sections these islands appear randomly located. However, their reconstruction in the adult brain revealed a very characteristic spatial and topographic arrangement where all islands are shown to be connected with the subependymal region of the caudate nucleus, the remnant of the VE (Hartz-Schütt and Mai, 1992). This organization, elaborated in the adult human brain on the basis of the determination of AChE activity, exists in a strikingly similar way also in the fetal brain and thus appears as a principal feature of the human basal forebrain organization. The strands described in the external capsule correspond to the lateral ventricular stream (described above) and their continuation in the adult amygdaloid nuclear complex (ANC) corresponds to the portion of the LMS that is depicted in Fig. 3.11. Strands that pass medial to the caudate and putamen correspond to a stream of immunoreactive glial fibers that probably have their origin in the MVE. The orientation of the radial glial processes from the MVE corresponds to this stream in the adult involving the bed nucleus of the stria terminalis and olfactory tubercle. By this indirect evidence it is suggested that the latter

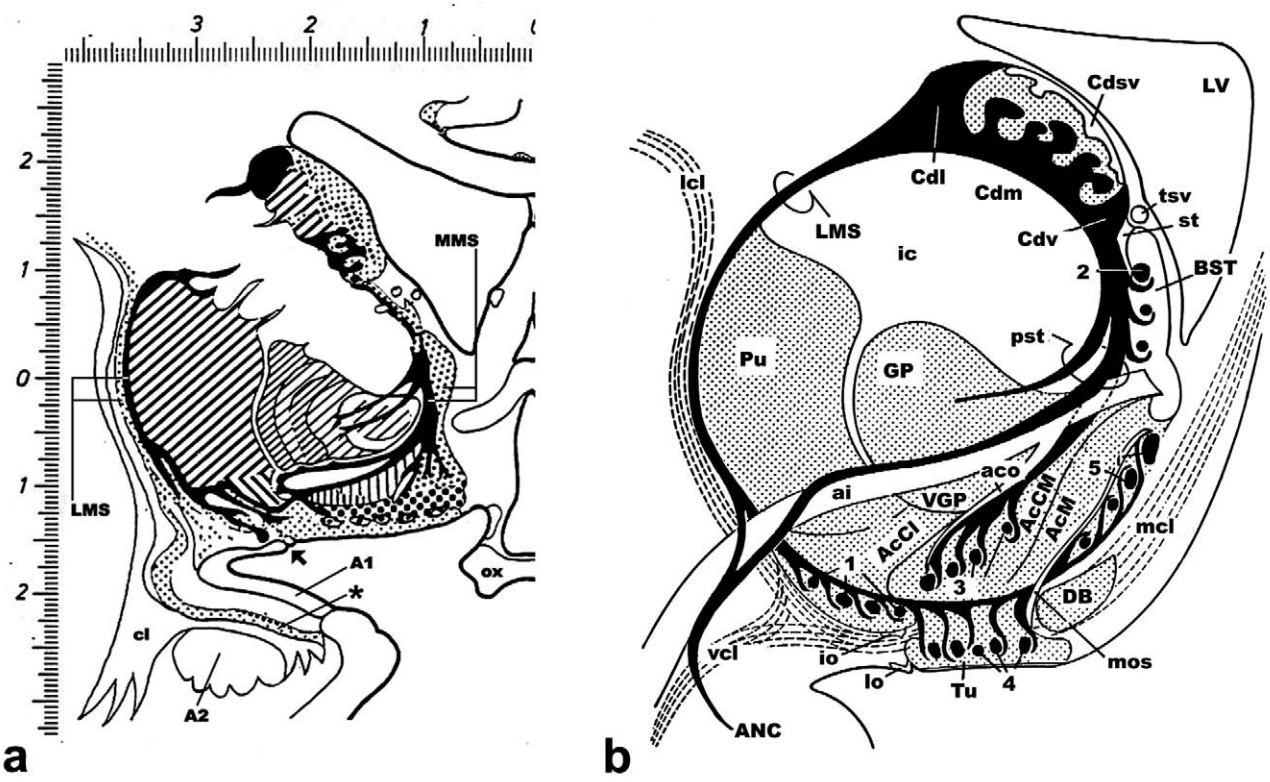

FIGURE 3.11 Distribution of acetylcholinesterase (AChE) activity in the adult human brain. **a.** Schematic representation of the distribution at the level of the anterior commissure and optic chiasma. **b.** Summary diagram of the organization of cholinergic structures in the forebrain, which is based on a serial reconstruction of sections. Strands of AChE emerge from the subependymal region of the caudate nucleus and reach five areas that are characterized by their globular character, called "terminal" islands (labeled here 1–5). The AChE strands in the external capsule correspond in their location to the lateral ventricular stream and then to the portion of the LMS that separates the superficial and deep parts of the ANC (A1 and A2, respectively; compare to Figs. 3.6 and 3.7). Strands that pass medial to the caudate and putamen and cross the internal capsule as parastriate fibers (pst) correspond to a stream of immunoreactive glial fibers that during development link the medial ventricular eminence (MVE) with the bed nucleus of the stria terminalis (BST), the great terminal island (Calleja), and the olfactory tubercle (Tu). 1–5, Different clusters of teminal islands; ai, anterior commissure; A1, superficial amygdaloid region; A2, deep amygdaloid region; AcCL, accumbens nucleus, centrolateral part; AcCM, accumbens nucleus, centromedial part; AcM, accumbens nucleus, medial part; aco, anterior commissure, olfactory limb; ANC, amygdaloid nuclear complex; BST, bed nucleus of the stria terminalis; Cdm, caudate nucleus, medial part; Cdl, caudate nucleus, lateral part; DB, diagonal nucleus; io, intermediate olfactory stria; lcl, lateral corticolenticular fibers; LMS, lateral migratory stream; lo, lateral olfactory stria; LV, lateral ventricle; mcl, medial corticolenticular fibers; MMS, medial migratory stream; mo, medial olfactory stria; pst, parastriate bridges; Pu, putamen; PuV, ventral putamen; st, stria terminalis; tsv, thalamostriate vein; Tu, olfactory tubercle, vcl, ventrolateral corticolenticular fibers; VGP, ventral pallidum.

structures are supplied with cells from the MVE that migrate through a corridor, named, the medial migratory stream.

The Olfactory Tubercle The olfactory tubercle is characterized as a territory that becomes invaded by terminal islands (Fig. 3.11b) (Hartz-Schütt and Mai, 1992) as already indicated in the foregoing text. The constituent cells of these islands most probably derive from the LVE (and MVE) and pass through the LMS and MMS, respectively. The continuity with striatal tissue is supported by the high cholinesterase (ChE) content (Kostovic, 1986) and by the direct continuation (between 3 and 4 months) of the CA–fiber system from the rostral neostriatum to the olfactory tubercle; these fibers were reported to aggregate into fluorescent islands (Nobin and Björklund, 1973).

In light of the described organization, it appears questionable to distinguish in the human brain between shell and core regions and to disregard the two most important features of the ventral striatum: the gradient character and the patterning by the terminal islands.

The Magnocellular Basal Forebrain System The magnocellular basal forebrain system consists of the medial and lateral parts of the nucleus basalis of Meynert (NBM), the nucleus of the diagonal band of Broca (NDB), and the medial septal nucleus (Mufson *et al.*, 2003; Morres and Mai, 1992). The precursor neurons of the basal nucleus of Meynert derive from the VE (Ulfig, 2002). The earliest signs of ChE activity appear as early as 9 w.g. in the area where the prospective basal nucleus develops. The first ChE-reactive bundles (among them a well-developed fiber stratum passing through the lateral pallium) form between this age and 10.5 w.g. The first ChE-reactive cells appear at 15 w.g. and the basal nucleus can be segregated into several strongly reactive subdivisions. Innervation of the developing cortex and subcortical areas by ChE-reactive fibers occurs between 16 and 28 w.g. Well before birth, an overall high degree of structural and chemical complexity is achieved (Kostovic, 1986).

While many studies have been aimed at assessing the cytology and chemistry of neurons of the cholinergic cells, the role of glial cells has received less attention. Interestingly, a high density of CD15-positive astrocytes with the complementary absence of GFAP-immunoreactive astrocytes has been stressed (Morres *et al.*, 1992). This CD15 IR becomes obvious around 35 w.g.

Amygdaloid Nuclear Complex

The terminology and topological interpretation of the amygdaloid nuclear complex (ANC) is still inconsistent. Brockhaus (1938), who provided a very extensive description of the structural organization of the human ANC, distinguished a superficial and a deep region, the latter comprising the lateral, basolateral or basal (intermediate), accessory basal (medial), and paralaminar (ventral) nuclei, respectively (see Gloor, 1997, pp. 596–600). This separation between superficial and deep regions in the human, on the basis of cell and fiber stains, appears relevant because it concurs with the division that was later stressed as important in the interpretation of the rodent ANC (Swanson and Petrovich, 1998; Swanson, 2003). The organization of radial glial fibers during the middle fetal period also speaks for this separation (see above, Fig. 3.5).

The view that the ANC is a derivative of the MVA as proposed by Mueller and O'Rahilly (1990), and; O'Rahilly and Mueller (1999, p.144; also this volume) is in accordance with the high expression of EGFR in both the MVE and the ANC. Cells of the amygdala are considered to represent the earliest postmitotic neurons in the telencephalon, and therefore the major sub-

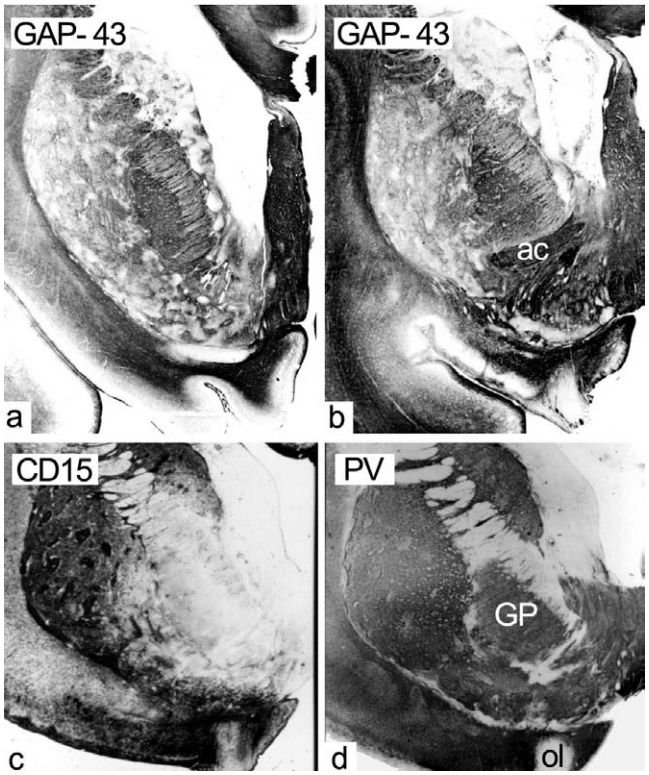

FIGURE 3.12 Distribution of GAP-43, CD15, and parvalbumin (PV) in cross-sections though the basal forebrain. **a, b.** GAP-43 shows a variegated pattern in the ventral striatum as compared to the dorsal part (18 weeks). **c.** In the CD15 (24 weeks) section the IR is continuous with the retrobulbar region. **d.** Parvalbumin shows a distinct border between the deep nuclei and paleocortex (24 weeks).

divisions and nuclei of the ANC are already discerniable (between 8 and 9 weeks) (Macchi, 1951; Lemire *et al.*, 1975; Mueller and O'Rahilly, 1990; also O'Rahilly and Mueller, Chapter 2 of this volume). By the eighth week (approximately stage 21–23), all nuclei are identifiable and differentiation takes place between the superficial and deep nuclei. After 13 weeks the ANC undergoes a rotation that is directed medially (Kostovic, 1992).

Around 14 weeks, the continuation of the CD15-positive LMS (as described above) by VIM and CD15 IR marks the territory of the superficial ANC. From 16 weeks, moderate CD15 IR is found for the first time within the deep nuclei. Initially IR is restricted to the dorsal knoblike portion of the basal nucleus (Ap.im), which protrudes into the superficial region. During cell differentiation, IR progresses in a graded fashion from dorsal to ventral. The accessory basal nucleus (Ap.i) shows the most intense labeling. Many other substances display differential distributions within the human ANC, such as GAP-43 (Ulfig *et al.*, 1999) and calcium-binding proteins (Setzer and Ulfig, 1999) (Fig. 3.12). In spite of the heterogeneous distribution, these substances have not yet provided clues for a systematic parcellation of the ANC.

DIENCEPHALON

The embryonic development of the diencephalon is described in the foregoing chapter by O'Rahilly and Mueller. By the end of the embryonic period all of the ventricular sulci in the prosencephalon are present (Figs. 3.13 and 3.14). The dorsal, medial, and ventral sulci then characterize four divisions of the diencephalon: epithalamus (ET), dorsal thalamus (DT), ventral thalamus (VT), and hypothalamus (HT). Within the hypothalamic division; Kahle (1956) and O'Rahilly and Mueller (Chapter 2 of this volume) distinguished an additional subthalamic division. ET, VT, and HT differentiate first but already between stages 20 and 21 (18–24 CRL) the DT begins burgeoning growth (Lemire *et al.*, 1975). As a consequence, the increasing size of the DT leads to a shift of the ET caudally and displacement of the VT laterally.

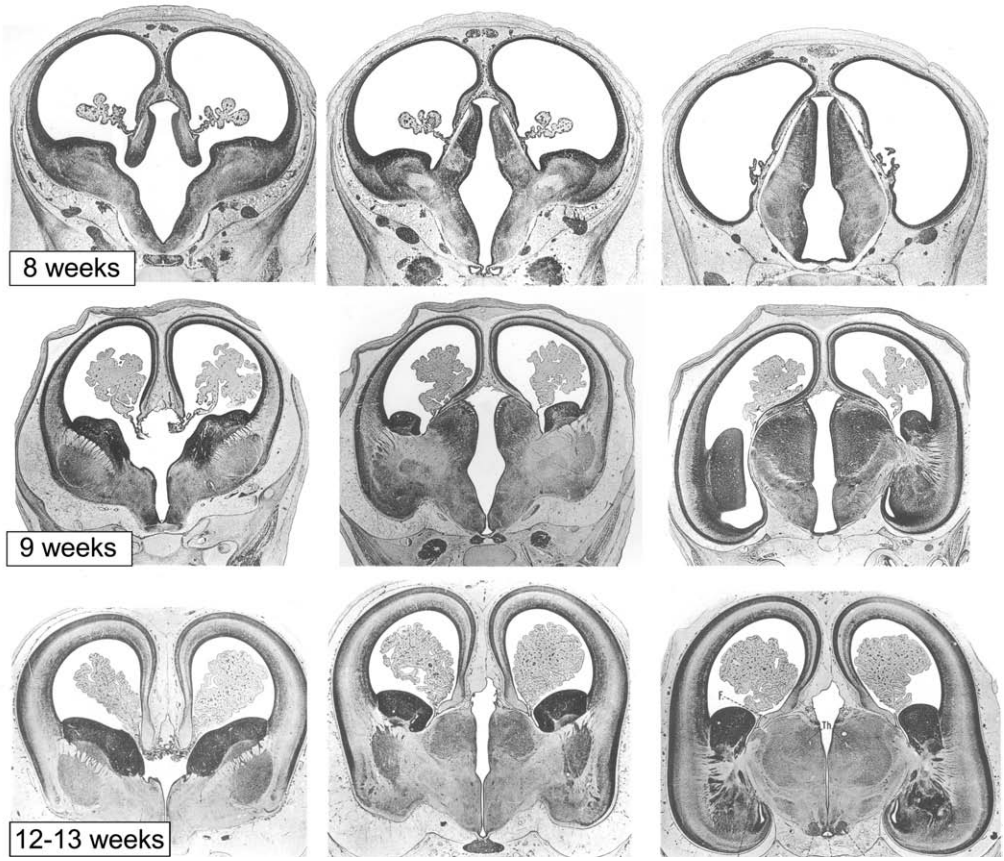

FIGURE 3.13 Transverse sections through the forebrain at 8, 9, and about 12–13 weeks. Modified from Hochstetter (1919).

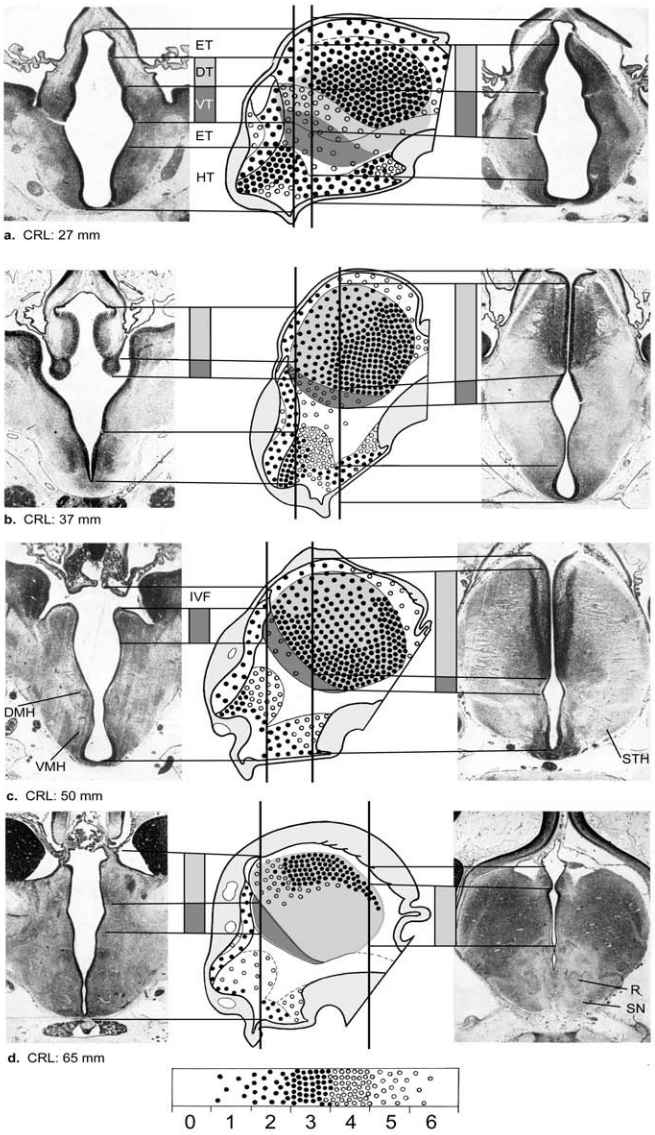

FIGURE 3.14 Characteristics of the matrix layer of the wall of the third ventricle of human embryos at the approximate ages of 8 weeks (27 CRL), 9–10 weeks (37 CRL), 11 weeks (50 CRL), and 12 weeks (65 CRL). The location of the photographs on the left and right sides is indicated in the diagrams by perpendicular lines, and correspondence with the matrix zones shown in the photographs is provided by the horizontal lines. The progression from proliferation of cells within the matrix, migration of cells out of the matrix into the mantle layer (differentiation zone), and exhaustion of the matrix layer is subdivided into different phases (0–6, *bottom line*) advancing from the situation before migration (0) to beginning (1), advanced (2), and full (3) migration and the phases of beginning (4), advanced (5), and complete (6) exhaustion of the matrix. Comparison of the various ages represented shows that the matrix zones show considerable variation, indicating that migration phases show different time profiles. Local differences in the course of the matrix phases are primarily arranged in longitudinal zones. Theses zones are separated by horizontal lines and are indicated as ET (epithalamus), DT (dorsal thalamus), VT (ventral thalamus), ST (subthalamic longitudinal zone), and HT (hypothalamus). Modified from Kahle (1956).

These divisions represent basic elements that are founded on the histogenetic proliferative properties of the germinal (matrix) zone, constitute the material for nuclear differentiation, and represent true genetic entities. Antibodies against several epitopes have disclosed a zonal pattern with borders corresponding to the described divisions. This pattern or its constituents may persist even when the development has proceeded and the structural organization becomes more complicated.

Kahle (1951, 1956) analyzed the dynamics and progression of the proliferation and migration of cells in the diencephalon. Both events are reflected in distinct morphological changes: during the phase of migration the germinal epithelium (matrix) broadens and becomes progressively less marginated against the mantle layer. At the peak of migration an obvious borderline disappears. During the phase of "beginning exhaustion" the decreasing width of the matrix is accompanied by a restored margination. Finally, in the phase of "complete exhaustion" the matrix becomes extremely narrow and transformed into the ependymal lining. He mapped the heterochronous development of the matrix in different regions of the diencephalon for the definition of morphological entities. The corresponding changes are seen in Figs. 3.13 and 3.14, which show transverse sections through the forebrain from the time of transition from embryonic to fetal life until about 13 weeks (65 CRL). Comparison of the various ages represented demonstrates considerable variation in the matrix zones, indicating different time profiles for migration phases.

Dorsal and Ventral Thalamus

Cooper (1950) and Kahle (1956) described in detail the great changes in the position and the cytological appearance of the thalamic structures. Figures 3.13 and 3.14 show the associated changes on transverse sections through the diencephalon that are representative of the time between the end of the embryonic period (stage 23 or approximately 57 days) until 13 weeks. Figure 3.14 demonstrates how the cytological changes are correlated with the appearance of the germinal layer of the third ventricle. The fast growth of the dorsal thalamus, which occurs between 7 and 11 weeks, gradually decreases the earlier predominance of the ventral thalamus and likewise displaces the ventral thalamus ventrally and laterally. At 8 weeks, the dorsal thalamus, which has already reached about the same size as the ventral thalamus, is separated from the epithalamus by the deep sulcus dorsalis. The zona limitans intrathalamica, which passes laterally from the sulcus medialis and which is regarded to correspond

to the future external medullary lamina (Miura, 1933), divides the dorsal and ventral thalamus. Within the dorsal thalamus a lateral and medial territory are recognizable at the beginning of the fetal period (Fig. 3.2a). In the medial part, differentiation is retarded; in the lateral part, the ventral lateral geniculate body can be recognized at 10 weeks (Gilbert, 1935). Between 10 and 14 weeks, segregation of neurons into different thalamic nuclei begins, whereby first the lateral geniculate nucleus, then the centrum medianum and the mediodorsal nucleus (Lemire *et al.*, 1975) are distinguished (Grünthal, 1934; Cooper, 1950; Yamadori, 1965; Yakovlev, 1969; Rakic and Sidman, 1969; Rakic, 1974; Kostovic and Goldman-Rakic, 1983; Mojsilovic and Zecevic, 1991). After 14 weeks all major thalamic nuclei can be recognized. At this time the ventricular zone is already reduced to ependyma and no mitotic figures were detected in Nissl-stained specimens (Mojsilovic and Zecevic, 1991). Differentiation still shows a gradient from lateral to medial, but a caudal-to-rostral gradient of maturation is obvious only for the ventral nuclei. The definitive cytological organization is reached between 16 and 18 weeks in most parts of the thalamus (Cooper, 1950; Kahle, 1956), except in the pulvinar which is then only poorly developed. Cells for the pulvinar appear to proliferate in the lateral ventricular eminence from which they enter the thalamus by a transient cell layer termed the corpus gangliothalamicum. This structure is located under the external surface of the developing pulvinar of fetuses from the 18th to the 34th week (Rakic and Sidman, 1969).

Neurochemical differentiation of the dorsal and ventral thalamus is observed from the earliest phase of fetal development. As noted above, intensely stained vimentin-immunoreactive processes are denser at the borders between epithalamus, dorsal, and ventral thalamus. In the same locations, parvalbumin is present by 10 weeks (Fig. 3.15). Cholinesterase activity was observed at 10.5 w.g. in the prospective mediodorsal nucleus (MD) (Kostovic and Goldman-Rakic, 1983). This activity increases strikingly after 16 w.g. until a peak activity is reached between 20 and 28 w.g., which correlates with the period when outgrowth and establishment of thalamocortical axons occurs. Afterward the cholinesterase activity is gradually reduced and becomes virtually undetectable in the MD by 6 months of age. Calretinin appears at 14 weeks in the ventral thalamus. It has been described that the derivatives of the ventral thalamus retain the calretinin IR after migration to their homing sites, thus facilitating identification of such cell clusters during later development (Forutan *et al.*, 2001). In the dorsal thalamus, calretinin-immunoreactive structures include the intralaminar nuclei (labeled from 16 weeks), the anteroventral and limitans nuclei (from 18 weeks), and the mediodorsal nucleus (from 22 weeks). Calbindin IR is very helpful for the discrimination of thalamic cell groups. It is a reliable marker from 14 weeks for the ventrolateral parts of the ventroanterior and ventrolateral nuclei, and also in the ventromedial nucleus. The SMI-32 antibody stains neurons in the ventroposterior lateral nucleus (VPL) from 21 weeks, in the magnocellular part of the ventroanterior nucleus between 23 and 39 weeks, and in the anterior part of the ventrolateral nucleus (VLA) and ventromedial nucleus (VM, lateral leaf) between 23 and 27 weeks. SMI-32 IR thus enables one to distinguish VPLs from those adjacent nuclei that are positive for calbindin. SMI-32 IR is also found in the centrum medianum and parafascicular nucleus (CM/PF) complex.

FIGURE 3.15 Distribution of parvalbumin (PV), calretinin (CR), and GAP-43 in neighboring transverse sections of the forebrain at age 10 weeks. In the diencephalon, parvalbumin and calretinin are concentrated in the ventral thalamus, thereby marking the border with the dorsal thalamus. This border is indicated medially by a shallow furrow, medial hypothalamic sulcus. A transversely oriented parvalbumin-immunoreactive band is seen demarcating the habenula from the dorsal thalamus. Parvalbumin IR is also found at the meningeal blade facing the thalamic surface. GAP-43 IR outlines thalamo- and corticofugal fibers.

In contrast to the early and intense labeling of VIM- positive radial glial cells (RGCs) in the dorsal thalamus stands the absence of CD15, which is confined to the ventral thalamus. When CD15 labeling appears in the dorsal thalamus at 14 weeks, it is not associated with RG processes but with the neuropil in differentiating prospective nuclei (Figs. 3.8 and 3.16). The occurrence of this granular CD15 labeling is very precise in time and specific for each nucleus (Forutan *et al.*, 2001). It progresses from the centrum medianum and the ventral nuclear group to the lateral and medial geniculate nuclei (16 weeks), the medial division of the ventroposterior nucleus (VPM), and the limitans nucleus (Mai and Schönlau, 1992; Mai *et al.*, 1999b). VPL and VPM are recognized by the high CD15 IR and the sharply demarcated borders between both nuclei. The pulvinar becomes progressively labeled after 20 weeks. At this time only the subventricular region

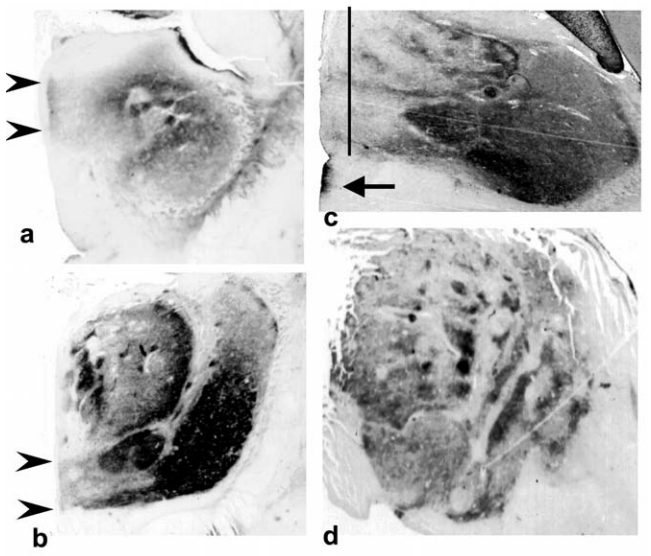

FIGURE 3.16 CD15 IR discloses a relationship between the (sub-)ependymal zone and differentiating nuclei (**a:** 17 weeks; **b:** 16 weeks). **c, d:** Variegated or tubular pattern in MD (**c:** 19 weeks; **d:** 23 weeks). The perpendicular line in **c** indicates the orientation of the section shown in **d.** *Arrow:* stretch of CD15 radial glial cells in the ventral thalamus.

remains unlabeled. A thin but well-delimited CD15-positive leaflet extends from the ventrolateral and VPL nuclei to the ventricle. It represents the ventral margin of the thalamus, which is thus well delimited against its surroundings.

The distinction between the individual nuclei of the ventral nuclear group is facilitated by comparison with sections stained for calbindin and SMI-32 (see above). Within the ventral nuclei, calbindin IR is present in the ventrolateral fields of VA (VAL), in the anterior part of the ventrolateral nucleus (VLA), and in the VM. SMI-32 is concentrated, from 17 w.g., in VLA and VPL; CD15 and SMI-32 mark the same overlapping field in the VPL (Forutan *et al.*, 2001).

CD15 expression in the mediodorsal nucleus shows a variegated pattern, which differs from the rather uniform pattern found in the other thalamic nuclei. The intensely labeled patches reveal a tubular organization that is reminiscent of the modular organisation of the patch and matrix compartments of the striatum (Fig. 3.16c, d).

CD15 appears in the dorsal thalamus (at 14 weeks) when the proliferative activity ends (Kahle, 1956) and the thalamic nuclei are already becoming discernable by cytoarchitectonic criteria (Rakic and Sidman, 1969; Rakic, 1974; Mojsilovic and Zecevic, 1991). This speaks against a direct correlation with the process of migration and the in- or outgrowth of thalamocortical and corticothalamic axons (Dekaban, 1954; Kostovic and Goldman-Rakic, 1983). Instead, it coincides with the period of outgrowth of local processes and the targeting of presynaptic terminals. This interpretation is supported by the intranuclear gradients for CD15 expression that run in parallel with morphogenetic gradients of cellular differentiation as described in the developing rat brain (Altman and Bayer, 1989).

A comparison between the chronology of CD15 expression in the lateral geniculate nucleus and parameters of maturation of the visual system has revealed congruent temporal profile patterns with respect to morphological signs of early maturation (Mai and Schönlau, 1992). The rapid transformation from a very-high-intensity labeling to an almost complete loss of IR was coincident with visual experience and the period of synaptic stabilization at the end of the critical period. This result suggests that high CD15 expression is linked to aspects related to initial synaptic events after stabilization of synaptic contacts (Mai and Schönlau, 1992).

The way that CD15 is expressed in the intralaminar nuclei supports the view that they are composed of two separate groups of nuclei: the (CM/PF) complex and the central nuclei (central medial, central lateral nuclei, and paracentral nuclei) (see Percheron, Chapter 20 of this volume). CM/PF are among the first thalamic nuclei to become CD15 positive and are filled with intense homogeneously distributed CD15 IR, which is clearly marginated. By contrast, calbindin IR is extremely low and calretinin IR entirely absent. On the other hand, the central nuclei appear later in development, contain irregular CD15 material with many patches, are poorly marginated, and show areas with intense calretinin IR. Finally, the medial subventricular division appears also distinct, and may be regarded as part of the periventricular gray matter. The inverse labeling of CM/PF by CD15 and calbindin is interesting in light of the recent description of the involvement of this structure in Parkinson's disease and in supranuclear palsy (Henderson *et al.*, 2000) since a reciprocal staining pattern for CD15 and calbindin has been also found in the adult human substantia nigra (Oeder, 1998).

CD15 staining also reveals a possible relationship between circumscribed ventricular areas and differentiating nuclei. As a transient phenomenon, fine punctiform and homogeneously distributed CD15 material has been described that stretches from the ventricular zone to some differentiating nuclei, like the ventral nuclear group, the CM/PF complex, and the anteroventral nucleus. This has been interpreted to reflect the derivation of the constituent cells of these nuclei from the corresponding parts of the ventricular neuroepithelium (Forutan *et al.*, 2001). If correct, CD15

IR would disclose the correspondence between the location of immature but committed cells in circumscribed patches of the neuroepithelium and their target structure. This interpretation not only implies that subdivisions of the thalamus arise from histogenetic primordia with discrete progenitor domains in the neuroepithelium but also that their spatial relationship is preserved until differentiation.

Hypothalamus

The ontogenesis of individual hypothalamic cell groups and nuclei in humans has been the issue of many classical reports (reviewed in Diepen, 1962) and recent accounts (O'Rahilly and Mueller, Chapter 2 of this volume; Koutcherov *et al.*, 2002). As stressed by O'Rahilly and Mueller, no staging system exists for the fetal period exists; thus, it is not surprising that the data provided for important developmental events can vary considerably. Those regarding the beginning of migration in the hypothalamus range from 6 weeks (CRL 9–11) to 10 weeks (LeGros Clark, 1938; Kahle, 1956; Diepen, 1962). This may be due to the very heterogeneous matrix morphology at the beginning of the fetal period. Some areas are passing through advanced stages of migration while others show early signs of exhaustion.

Neurogenesis and migration in the human hypothalamus occurs, as in the rodent brain, in three waves (Koutcherov *et al.*, 2002; Altman and Bayer, 1986). The first generated neurons migrate into the future lateral longitudinal zone of the hypothalamus where they give rise to the lateral hypothalamic area, posterior hypothalamus, lateral tuberal nucleus, and perifornical nucleus. These structures are generally associated with arousal and autonomic responses in feeding and reproduction, whereas their connections are dominated by the medial forebrain bundle and the fornix (Koutcherov *et al.*, 2002). The second wave of postmitotic neurons settles in the prospective intermediate longitudinal zone or hypothalamic core. These neurons form more conspicuous cell groups that include the medial preoptic nucleus, anterior hypothalamic nucleus, ventromedial nucleus, dorsomedial nucleus, and mamillary body. These cell groups are thought to mediate autonomic responses in the regulation of homeostasis. Limbic afferents from the hippocampal formation, amygdala and septum, and major intrahypothalamic connections are characteristic pathways for this region. The last neurons to be generated are those which differentiate in direct proximity to the ventricular wall, or periventricular zone. Nuclei in this zone are the suprachiasmatic nucleus, the arcuate nucleus, the paraventricular nucleus, and the supraoptic nucleus. They are considered critical for the regulation of biological rhythms, neuroendocrine output, and integrated autonomic responses and are directly connected with the retina, pituitary, and autonomic centers in the brain stem and spinal cord (Fig. 3.17). In humans, all the nuclei are apparent by 13 w.g. (see Gluckman and Bassett, 1988).

The sites of settlement and differentiation thus already reflect the advanced regionalization of the adult human hypothalamus with three longitudinal subdivisions, the *periventricular* or *midline* zone, the *intermediate* zone or *core*, and the *lateral* zone (Crosby and Woodburne, 1940). This arrangement, which is typical throughout phylogeny (see Nauta and Haymaker, 1969), is confirmed in the neurogenetic pattern of the developing hypothalamic nuclei (Altman and Bayer, 1986) and validated by chemoarchitectonic (Koutcherov *et al.*, 2003) and functional evidence (Swanson, 1991).

At the beginning of the fetal period the three longitudinal zones are already discriminable. The *intermediate* zone of the hypothalamus is generally characterized by a lower cell density than the *lateral* zone, with the exception of distinct cell clusters of potential nuclei. The *periventricular* or *midline* zone at this age is a layer of tightly packed cells in the proliferative neuroepithelium. The fetal development of the human hypothalamus has been described on the basis of chemoarchitectonic criteria in much detail by Koutcherov (Koutcherov *et al.*, 2002), and therefore most of the following data derive from their report (Fig. 3.17).

Lateral Longitudinal Hypothalamic Zone

As in the other regions of the human brain, strong transient expression of parvalbumin heralds structural differentiation of the hypothalamus and is observed by the early fetal period. GAP-43 IR, which is present at around 10 weeks, suggests that axonal end-arbors and provisional synaptic contacts are formed. The fornix appears at 12 weeks, and IR for GAP-43 and synaptophysin in its fibers is found after 15 weeks. From 17 weeks, cells of the prospective perifornical nucleus are ensheathing the fornix.

The lateral tuberal nucleus develops at 16–19 weeks as a tightly packed group of small neurons in the ventrolateral margin of the lateral hypothalamic area. The nucleus is outstanding by its marked GAP-43 negativity within the otherwise GAP-43-positive area. Another distinguishing feature is the densely packed small calbindin-immunoreactive cells and the absence of the large calretinin neurons that are characteristic of the neighboring lateral hypothalamic area. Late in the development, shortly before birth, a very dense

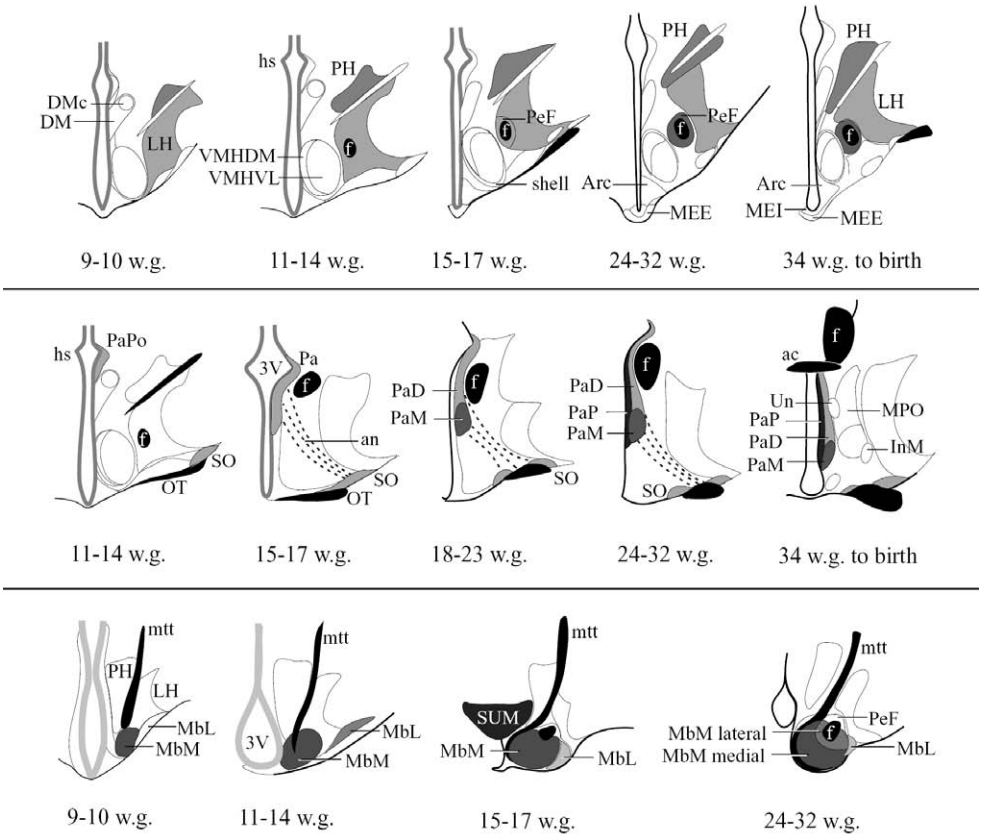

FIGURE 3.17 The organization of major cell groups in the developing human hypothalamus shown at landmark stages of fetal differentiation. The hypothalamus is depicted at three rostrocaudal levels *(upper, middle, and lower line)* for each developmental stage. Please note that these diagrams are not drawn to scale. 3V, third ventricle; AN, accessory neurons; Arc, arcuate nucleus; DM, dorsomedial nucleus of the hypothalamus; DMc, caudal portion of the DM; f, fornix; hs, hypothalamic sulcus; InM, intermediate nucleus; LH, lateral hypothalamic area; MbL, lateral mamillary body; MbM, medial mamillary body; MEE: median eminence, external part; MEI, median eminence, internal part; MPO, medial preoptic nucleus; mtt, mamillothalamic tract; ot, optic tract; Pa, paraventricular nucleus (PaD, PaM, PaP, PaPo: dorsal, medial, parvocellular, posterior parts); PeF, perifornical nucleus, PH: posterior hypothalamus; SUM, supramamillary nucleus; SO, supraoptic nucleus; Un, uncinate nucleus; VMHDM, ventromedial hypothalamic nucleus, dorsomedial part; VMHVL, ventromedial hypothalamic nucleus, ventrolateral part. From Koutcherov *et al.*, 2003.

labeling by synaptophysin clearly differentiates this nucleus from the surrounding ventral tuberomamillary nucleus (Koutcherov *et al.*, 2003).

The very heterogeneous matrix morphology is reflected in the already differentiated organization of the human lateral hypothalamic zone into various subcompartments and great chemoarchitectonic differences between its constituent structures. For example, cells in the posterior but not the lateral hypothalamic area show distinct CD15 IR from 19 weeks until birth. Furthermore, the lateral hypothalamic area contains calretinin- and calbindin-positive neurons and GAP-43 IR early in fetal gestation, unlike the adjacent tuberomamillary nucleus, which acquires calbindin-positive neurons only late in gestation. Finally, Koutcherov *et al.* (2000b) showed abundant NK-3 IR in neurons of the perifornical nucleus, thus distinguishing this structure from its NK-3-negative surrounding.

Intermediate Zone of the Hypothalamus

The next significant event in the development of the human hypothalamus is differentiation of the intermediate hypothalamic zone, which occurs between 16 and 34 weeks (Koutcherov *et al.*, 2003).

The medial preoptic nucleus, located rostrally in the hypothalamus at the level of the optic chiasm, can be identified at 10 weeks as a condensed cluster of cells with strong transient expression of parvalbumin. However, its differentiation is protracted and continues after birth (Swaab and Hofman, 1988). A clear distinction into several subnuclei and their homologues to the nuclei of rodent hypothalami cannot be made (Koutcherov *et al.*, 2003; Lu *et al.*, 2000).

The ventromedial hypothalamic nucleus and the dorsomedial hypothalamic nucleus are already recognized between 10 and 12 weeks (Gilbert, 1935). Both nuclei develop in a field of vimentin- and CD15-

immunoreactive radial glial fibers that arch from the middle of the subsulcal ventricular wall and which become more prominent after 14 weeks (Fig. 3.2a). This ontotopographic feature has led some authors to suggest that both nuclei in the human also derive from the same anlage, with comparable connectivity and similar functional associations (Koutcherov *et al.*, 2003) as in the rat (Altman and Bayer, 1986).

In the ventromedial hypothalamic nucleus a distinction between a well-differentiated and more compact dorsomedial part and a bigger, more dispersed, ventrolateral part can be made after 13 weeks on the basis of a complimentary distribution of calbindin- and calretinin-positive cells. After 17 weeks, a third principal part with GAP-43-immunoreactive positive fibers forms a shell around both the other parts (core region). This is reminiscent of the situation seen in the adult rat, where the cell-poor shell is a prominent target for the amygdalohypothalamic fibers carried via the stria terminalis (Krettek and Price, 1978; Post and Mai, 1980). The dorsomedial hypothalamic nucleus appears ventral to the hypothalamic sulcus and close to the ventricular zone after 10 weeks. At 12 weeks it has a well-defined oval structure where compact and diffuse parts can be distinguished by Nissl staining. This differentiated organization persists until 24 weeks, but afterward the compact and diffuse compartments become progressively less defined.

The mamillary body differs from the rest of the hypothalamic nuclei because of the absence of a regular mantle layer (Kahle, 1956). It can be identified for the first time between 9 and 11 weeks, and from the beginning of differentiation a larger, spherical, medial part and a smaller, droplet-shaped lateral mamillary subnucleus can be distinguished. From 14 weeks the medial part becomes wrapped dorsomedially by the mamillothalamic tract, and 2 weeks later the fornix reaches its lateral boundary. A supramamillary nucleus (SUM) was recognized by Koutcherov *et al.* as a transient structure between 15 and 17 weeks, but not later in gestation.

Periventricular or Midline Zone of the Hypothalamus

The midline hypothalamus is composed of structures differentiating in direct proximity to the ventricular lining. During early stages of fetal development (i.e., 9–10 weeks) the primordia of the midline structures are concealed because of the cell-dense periventricular neuroepithelium.

The neurons for the paraventricular (Pa) and supraoptic (SO) nuclei and the accessory cell groups derive from a common neurogenetic primordium at the hypothalamic sulcus (Mai *et al.*, 1997). This location corresponds to the homologous source of cells in rodents (Altman and Bayer, 1986; van Eerdenburg and Rakic, 1993). From here, neurons migrate laterally and ventrally to their homing sites, possibly along radial glial processes shown in Fig. 3.2a. The onset of differentiation at 11 weeks coincides with the expression of vasopressin and neurophysin (Fellmann *et al.*, 1979; Burford and Robinson, 1982; Mai *et al.*, 1997; Goodyer, 1988). Oxytocin cells are found later, between 14 and 15 weeks. By 19 weeks the posterior and dorsal parts of the Pa attain their postnatal morphology and topography. At 20 weeks the densely packed, magnocellular neurons of the medial Pa begin to form and reach their postnatal morphological appearance by 24 weeks. From 24 weeks small calbindin-positive neurons are found throughout the Pa.

By 27 weeks the adult-like subnuclear cytological and chemical organization of Pa can be demonstrated (Koutcherov *et al.*, 2000a, 2002) and the number of neurons in the adult human Pa is reached (Gouldsmit *et al.*, 1992). At this time, small calbindin-stained cells are present throughout the Pa, with the exception of the parvocellular portion. The population of cells that express vasopressin, however, still increases until birth to remain constant only thereafter (Murayama *et al.*, 1993). Interestingly, a subpopulation of the Pa and SO neurons features coexpression of neurophysin (NPH) with CD15 (Mai *et al.*, 1994). This population also labels the hypothalamohypophyseal fiber bundle arching from the medial Pa toward SO and further ventromedially to the external component of the median eminence. The number of NPH+/CD15+ neurons peaks around birth when up to about 60% of the NPH-immunoreactive neurons are also positively labeled for CD15. Afterward, the number of CD15 neurons declines and colocalization of the two peptides becomes gradually lost (Mai *et al.*, 1994).

The initial stages of the generation of the arcuate nucleus cannot be assessed by simple morphological examination because it is concealed by the funnel of tightly packed periventricular cells. From 19 weeks until the perinatal period the nucleus harbors a prominent calbindin-immunoreactive fiber bundle that extends from the ventricular to the ventral pial surface of the hypothalamus. At 22 weeks, the earliest neuropeptide-Y-immunoreactive neurons appear. Their axons are located in the internal component of the median eminence, segregated from the NPH-positive neurohemal pathway arising from the SO and Pa and running in the external segment. The arcuate nucleus is rich in many other neuroactive substances, including neurokinin B, somatostatin, neurotensin, luteinizing hormone-releasing hormone (LHRH), and catecholamines (Spencer *et al.*, 1985; Schwanzel-Fukuda *et al.*,

1989; Swaab, 1997; Chawla *et al.*, 1997). Absence of LHRH neurons in the arcuate nucleus, which is due to failure to migrate from the olfactory placode into the brain, appears to be the basis of Kallman's syndrome (Schwanzel-Fukuda *et al.*, 1989; Swaab, 1997).

The cells of the suprachiasmatic nucleus originate from the neuroepithelium of the midline recess of the floor of the optic evagination of the third ventricle. From the beginning of differentiation, at 19 weeks, a central part, specified by vasoactive intestinal polypeptide (VIP), and a dorsally located part with neurophysin/vasopressin cells, can be distinguished. These latter cells are developmentally distinct from those of the SO and Pa. At 23 weeks a GAP-43-positive fiber bundle, presumably the retinohypothalamic tract, connects the optic tract with the suprachiasmatic nucleus, forming a dense and well-marginated plexus (Koutcherov *et al.*, 2002). At 35 weeks calbindin-positive cells appear in the central part, completing the characteristic chemoarchitectonic adult feature of the nucleus (Mai *et al.*, 1991). Differentiation of the suprachiasmatic nucleus is relatively late consistent with reports that the SCh is still immature at term since it then contains only 13% of the adult number of vasopressin neurons. However, oscillations by a fetal biological clock occur, and these oscillations may be entrained by the mother already before birth, probably as early as at 30 weeks (Reppert, 1992; Mirmiran *et al.*, 1992).

Besides the lateral-to-medial gradients of hypothalamic differentiation, a caudorostral gradient also exists (Kostovic, 1990). Morphological evidence suggests that this gradient develops in correspondence with the hypothalamic segments mentioned in "Forebrain Separation by Radial Glia," Fig. 3.4d and e).

In many of the studies mentioned, the nuclear organization of the human hypothalamus has been reported to show a close correspondence with that of rodents. However, the elaboration of a growing list of similarities between the human and rodent hypothalamus does not exclude relevant differences in the nuclear organization. LeGros Clark (1936) already stressed a number of features that distinguish the human hypothalamus, like the extensive distribution of large cells, the differentiation of the tuberal nuclei, the relative size and differentiation of the posterior hypothalamic nuclei and of the medial mamillary nucleus, and the reduced size of the lateral mamillary nucleus.

Fiber Systems

At the beginning of the fetal period, many hypothalamic fiber systems have already developed (see O'Rahilly and Mueller, Chapter 2 of this volume). At 11 weeks, fornix fibers reach the mamillary nucleus. Continuous maturation of the fornix is marked by the appearance of CD15 IR which transiently becomes very strong between 25 and 34 weeks. The mamillothalamic tract has been described at 14 weeks (Yamadori, 1965). The final stage of neuronal differentiation is heralded by the onset of myelination, which occurs mostly after birth (Vogt and Vogt, 1902; Krieg, 1960; Diepen, 1962; Yakovlev and Lecours, 1967.

The human fetal hypothalamus is supplied by rich neurotransmitter and neuropeptide systems. Probably most of them are operative in the human hypothalamus prior to the onset of synaptogenesis. Monoaminergic fibers in the medial forebrain bundle appear at 7 weeks (Zecevic and Verney, 1995). Catecholamine fibers in several hypothalamic nuclei are present in 3- to 4-month-old fetuses (Nobin and Björklund, 1973). At the same time, hypothalamic nuclei become supplied by cholinergic fibers. All neuropeptide systems under study could be demonstrated in the hypothalamus and median eminence between 10 and 20 weeks (Gluckman and Bassett, 1988; Goodyer, 1988; Bugnon *et al.*, 1987). Neuroactive substances may be detected much earlier by immunoassay in whole-brain homogenates (Gluckman and Bassett, 1988).

The early appearance of neurotransmitter and neuropeptide systems indicates that they have other functions during development. They might influence ontogenetic events, such as neurogenesis and morphogenesis, postnatal neuro- and gliogenesis, and axonal growth and synaptogenesis; they might also regulate energy expenditure and fetal metabolism or have impact on sex hormones in the developing brain.

Functional Differentiation

It has long been known that the multitude of vital bodily processes mediated by the hypothalamus (including cardiovascular regulation, sleep, metabolism, stress, thermoregulation, water and electrolyte balance, appetite regulation, sexual behavior, and immune responses) necessitates an intricate interaction among the nuclei. Yet, relatively little information is available in the human about the differentiation patterns of cell groups that are required for the establishment of a functional network (see Swaab *et al.*, 1993, 1997; Saper, Chapter 17 of this volume). The knowledge of the organization and functioning of neurotransmitter and neuropeptide systems is important because of the ability of pharmacological agents to interact with these compounds and to cause defects of the brain.

MIDBRAIN

The midbrain contains several regions with major clinical significance, which have attracted developmental studies.

Substantia Nigra

The development of the human fetal substantia nigra is considered to be important because of the potential use of its immature neurons in therapy for Parkinson's disease. Between 8 and 10 w.g., the region of the developing substantia nigra is occupied by small round cells (Sailaja and Gopinath, 1994). Between 10 and 13 w.g., cells become more loosely packed, and by 14 w.g. pars compacta and reticulata can be clearly distinguished. The cellular density of the pars reticulata decreases from 14 to 20 w.g., so that the adult pattern of reticulata can be recognized by 22 w.g. and neurons of the pars compacta assume adult morphological characteristics in Golgi and Nissl-stained material by about 20–22 w.g. (Sailaja and Gopinath, 1994). The nearby crus cerebri begins to develop at 14 w.g. as descending projection fibers pass through this region.

Immunoreactivity for tyrosine hydroxylase (TH) can first be seen in a few cells in the ventral mesencephalon as early as 5.5 w.g. (Silani *et al.*, 1994). Immunoreactive cells accumulate in the developing substantia nigra over the next few weeks, so that from about 8 w.g., TH immunoreactivity is localized in the perikarya and proximal dendrites of neurons of the substantia nigra, ventral tegmental area, and ventrolateral regions of the periaqueductal region (Pearson *et al.*, 1980; Sailaja and Gopinath, 1994). Immunoreactive cells seen to be lying ventrolateral to the cerebral aqueduct at 8–14 w.g. are aligned with the cell body directed ventrally, giving the impression that the cells are migrating from periaqueductal proliferative regions. From 19 w.g., groups of dopaminergic cells can be divided into the substantia nigra pars compacta, ventral tegmental area, and retrorubral area (Aubert *et al.*, 1997). When human ventral mesencephalic cells are maintained in culture, the addition of basic fibroblast growth factor stimulates increased TH activity, maintains neuronal survival and has proliferative effects on glial cells of the region (Silani *et al.*, 1994).

Substantia nigra neurons can be retrogradely labeled from the caudate at 10 w.g. after insertion of carbocyanine dyes into the caudate, indicating that at least some of the nigrostriatal pathway is established by this early age (Sailaja and Gopinath, 1994).

From about 12 w.g., substantia nigra pars compacta neurons begin to exhibit markers of dopamine transmission (Aubert *et al.*, 1997). D2 dopamine receptor (D2R) mRNA, D2R binding sites, dopamine membrane transporter mRNA, D1 receptor (D1R) protein, and D1R binding sites are all expressed from 12 w.g. This has been taken to indicate that the striatonigral neurons, which are known to express the D1R gene, have developed pathways connecting with the substantia nigra by 12 w.g. (Aubert *et al.*, 1997).

Periaqueductal Gray Matter

The periaqueductal gray is believed to have a central role in the integration and control of responses to stressful or threatening situations. Developmental changes in binding of neurotransmitters in this region have been studied by Reddy and coworkers (1996). Although binding to all types of receptors under study (nicotinic, muscarinic, serotonergic, opioid, and kainate) could be demonstrated by mid-gestation (i.e. 22 w.g.), subsequent changes in binding were different for each type of receptor. Binding of serotonin receptors decreases markedly between fetal and neonatal ages as well as between neonatal and adult ages. Binding of nicotinic receptors also decreases between fetal and neonatal ages, but remains stable from birth to adult life. Opioid receptor binding (^{3}H-naloxone) remains relatively constant from fetal to neonatal life, but increases slightly to adult life, whereas muscarinic cholinergic receptor binding remains constant from fetal to adult life. Finally, kainate binding tends to decrease with advancing age, but the differences were found not to be statistically significant. Overall, the most significant differences between fetal and neonatal ages were found to be in the serotonergic and nicotinic cholinergic receptor binding.

Interpeduncular Nucleus

The interpeduncular nucleus is an important component of the limbic midbrain circuitry and has been implicated in a wide variety of functions, including sleep regulation (Haun *et al.*, 1992) and pain sensitivity (Meszaros *et al.*, 1985). The human interpeduncular nucleus is cytoarchitecturally simple but chemically complex, with a lateral subdivision showing high muscarinic and serotonergic binding in the dorsal subdivision of the nucleus and high opioid binding in the medial subdivision. This chemoarchitectural subdivision is apparent at all ages of development from midgestation (19–26 w.g.) through infancy (38–74 weeks postconception) to childhood (4 years). The levels of muscarinic, nicotinic, and, to some extent, serotonergic receptor binding decline through development, but opioid and kainate remain relatively constant from midgestation to maturity.

Development of Glia in the Mesencephalon

The human fetal mesencephalon has been used as a study area to examine the development of microglia and astrocytes (Wierzba-Bobrowicz *et al.*, 1997). Ameboid microglia are already present in the fetal human mesencephalon at 8 w.g., and the number of these cells peaks at about 12 w.g. Ameboid microglia

are progressively replaced by ramified microglia from 11 w.g., and astrocytes also appear at about 11 w.g. Similar changes in the numbers of ramified microglia and astrocytes may be seen in human fetal mesencephalon, suggesting that there may be interactions between these two types of glia during development.

CEREBELLUM AND PRECEREBELLAR NUCLEI

Introduction

At the end of the embryonic period (stage 23 or approximately 57 days gestation), the developing cerebellum has a layered structure, with two germinal zones and the beginnings of some of the major neuronal populations already present (Müller and O'Rahilly, 1990). Adjacent to the fourth ventricle lies the ventricular germinal layer. A broad intermediate layer intervenes between the ventricular layer and the internal fiber layer. The intermediate layer contains cells that correspond to the future Purkinje cells. Further still from the ventricular surface lies the developing deep cerebellar nuclei. Finally, the external surface of the developing cerebellum is covered by an external germinal layer.

Two genes, *En-1* and *En-2*, which appear to specify the cerebellar domain, have been identified in mice (Davis and Joyner, 1988). Animals with targeted disruption of *En-1* show cerebellar and collicular agenesis (Wurst *et al.*, 1994), whereas *En-2* knockout results in subtle defects in cerebellar foliation (Millen *et al.*, 1994). In the developing human fetus (18–21 w.g.), the RNA signal for both EN1 and EN2 is strongest in the cerebellar granular layers, white matter of the vermis and flocculus, inferior olive, arcuate nucleus, and premigrational neurons of the corpus pontobulbare (Zec *et al.*, 1997).

The gross development of the human fetal cerebellum has been followed by magnetic resonance imaging (Press *et al.*, 1989; Hansen *et al.*, 1993). Fusion of the cerebellar vermis begins in the eighth to ninth week of gestation. By the third month, the midportion of the vermis and the cerebellar hemispheres begin to proliferate more rapidly than the rest of the cerebellum and the shape begins to swell centrally. The horizontal fissure appears by the end of the fourth month, and soon thereafter the cerebellar hemisphere growth overtakes that of the vermis so that the inferior vermal groove develops. The semilunar lobule and gracile lobe of the cerebellum expand to displace the flocculonodular lobes and cerebellar tonsils inferiorly. The nodule is progressively pushed anteriorly to indent the roof of the fourth ventricle (Press *et al.*, 1989; Hansen *et al.*, 1993). Peak growth of the rhombencephalon and cerebellum occurs after birth (Koop *et al.*, 1986), at about 400–500 days after conception, and is probably mainly accounted for by the development of the cerebellar cortex (see below).

Development of Cerebellar Cortex

Purkinje Cells

Differentiation of Purkinje cells in the human cerebellum has been followed by Zecevic and Rakic (1976). Those authors divided Purkinje cell differentiation into three stages. The first stage occupies the fourth fetal month (12–16 w.g.), and during this time Purkinje cells are bipolar in shape and are distributed several cells deep. Their somatas are relatively smooth during this early stage, with only a few processes at their apical and basal cell poles. At this early stage, some immunoreactivity for plasma proteins may be detected (Jacobsen and Møllgard, 1983). The second stage runs from 16 to 28 w.g., and during this stage the Purkinje cells become organized into a single layer. The somata of Purkinje cells begin to develop additional randomly directed processes and numerous somatic spines. This period of dendritic and other process outgrowth is accompanied by transient Purkinje neuron immunoreactivity for microtubule-associated protein 5 (MAP5; Ohyu *et al.*, 1997). At the beginning of the second stage, the first synapses begin to appear on the somatic spines of the immature Purkinje cells and on their immature dendritic spines, and these increase in number during the second stage. Toward the end of the second stage (23–24 w.g.), Purkinje cells can be labeled by immunoreactivity for the GM3 ganglioside (Heffer-Lauc *et al.*, 1996) and begin to show strong immunoreactivity for EAAT4, a glutamate receptor subtype (Itoh *et al.*, 1997). The third stage of Purkinje cell development extends through the remainder of prenatal life (28–40 w.g.), the first year of postnatal life, and even continues after 1 year of age. During the third stage, the dendritic arbor takes on its characteristic flattening in the plane perpendicular to the axis of the folium. Somatic spines disappear and spines begin to develop on the secondary and tertiary branches of the expanding dendritic tree. Elongation of Purkinje cell dendrites is accompanied by the development from about 35 to 36 w.g. of the glycolytic enzyme aldolase C, which is a selective marker for Purkinje cells in the adult cerebellum (Royds *et al.*, 1987). Maturation of the Purkinje cells in humans appears to occupy a much greater period of time after birth than is the case in nonhuman primates.

Milutinovic *et al.* (1992) reported that Purkinje cells in both the cerebellar hemispheres and vermis undergo substantial reduction in numbers between 12 w.g. and 25 w.g., with approximately 90% of the loss occurring between 12 and 20 w.g. This period of neuronal loss would coincide with migration of immature granule cells past the Purkinje cell layer, the formation of Purkinje cells into a single layer, and the formation of the first synapses on somatic spines of Purkinje cells. Immunoreactivity for the apoptosis promoter protein Bak has been shown to be weak in Purkinje cells under 17 w.g. but is strongly present from 19 to 34 w.g. (Obonai *et al.*, 1998). Expression of the apoptosis inhibitor protein Bcl-x is also intense during the period from 24 to 38 w.g. (Sohma *et al.*, 1996). These results indicate that control of Purkinje cell numbers arises from complex interaction between apoptosis promoter and inhibitor factors during fetal development. After birth, Bcl-x protein is expressed in Purkinje cells at low levels until adulthood (Sohma *et al.*, 1996). Immunoreactivity for Bak remains low throughout early adult life, but increases again in elderly subjects (Obonai *et al.*, 1998).

The hypothesis that Ca signaling has an important role in developmental processes of the cerebellum has prompted several recent studies of the development of intracellular Ca-signaling molecules and calcium-binding proteins (inositol 1,4,5-triphosphate receptor type 1, IP3R1; ryanodine receptor, RyR; calbindin D-28k, CB; and parvalbumin, PV) in the prenatal human cerebellum. Immunoreactivity to IP3R1 appears in the nascent Purkinje cell layer as early as 13 w.g. (Milosevic and Zecevic, 1998; Miyata *et al.*, 1999; Zecevic *et al.*, 1999). This immunoreactivity to IP3R1 increases by the 17- to 24-w.g. period, but the labeling is curiously patchy, with regions of strong immunoreactivity interspersed with immunonegative zones. Immunoreactivity for IP3R1 increases in the dendrites and spiny branchlets as these develop, progressing rapidly during the 6 months after birth (Miyata *et al.*, 1999). Immunoreactivity for RyR is expressed for the first time at 18 w.g. in the cell bodies and proximal dendrites of Purkinje cells. The patchiness of Purkinje cell layer labeling observed with immunoreactivity to IP3R1 can also be seen with RyR immunoreactivity, although the RyR-immunoreactive patches are smaller that those seen with IP3R1 (Milosevic and Zecevic, 1998).

Immunoreactivity for CB can be seen as early as 4–5 w.g. in bipolar migrating neurons (Milosevic and Zecevic, 1998), and by 10–13 w.g. labeled Purkinje cells and axons of the inferior cerebellar peduncle can be seen. Immunoreactivity for PV can be seen for the first time at 11 w.g. labeling cells in the rostral part of the external germinal layer. By 13 w.g., a bundle of PV-immunoreactive fibers arising from the pontine nuclei can be observed in the cerebellar intermediate zone. At this time, alternating CB- and PV-immunoreactive fiber bundles can be seen on frontal sections throughout the intermediate zone of the cerebellum. By 18 w.g., uneven patches of CB immunoreactivity can be seen in the Purkinje cell layer, which correspond to those observed with IP3R1 immunoreactivity. Immunoreactivity to PV labels Purkinje cells by 18 w.g. (Yew *et al.*, 1997) and at this age also showed discontinuities in labeling (Milosevic and Zecevic, 1998) as seen with immunoreactivity for intracellular Ca^{2+} receptors. The discontinuities in immunoreactivity noted with these four markers as well as immunoreactivity to phosphorylated and nonphosphorylated neurofilament (Milosevic and Zecevic, 1998) continue to be visible until the end of prenatal life. Although the precise role of the intracellular calcium-signaling and calcium-binding system during cerebellar development remains obscure, the discontinuous pattern of immunoreactivity to these markers suggests a possible role in the developmental patterning of the cerebellum and may help define functional regions during development (Milosevic and Zecevic, 1998).

Granule Cells

As in all mammals, granule cells of the developing human cerebellum are generated in the external germinal layer and migrate to the cerebellar primordium, past the Purkinje cells, to come to rest in the (internal) granular layer. In the human, the external germinal layer can be identified by about stage 21 (51 days gestation; Müller and O'Rahilly, 1990) and can still be identified after birth. The external germinal layer can be divided into a superficial proliferative layer and a deeper premigratory layer, both of which show strong immunoreactivity for neuronal nuclear antigen during fetal life (Sarnat *et al.*, 1998) and express developmental stage-specific antigens (Moss *et al.*, 1988). The external germinal (also sometimes called granular) layer was traditionally believed to give rise to granule cells, basket cells, stellate cells, and Golgi cells (Rakic and Sidman, 1982), but recent studies suggest that only granule cells are derived from this layer (Zsang and Goldman, 1996). Migration of immature granule cells past the Purkinje cells begins at about the end of the first trimester, so that the internal granular layer begins to appear from 15 w.g. (Gudovic *et al.*, 1998) and most of the cells of the internal granular layer appear between 20 and 30 w.g. Nevertheless, it is likely that migration and differentiation of some granule cells continues (albeit at a low pace) through the first postnatal year (Gudovic *et al.*, 1998). The period of major increase in number of granule cells (20–30 w.g.)

corresponds to the arrival of mossy fibers in the internal granular layer and the appearance of the lamina dissecans (Rakic and Sidman, 1970).

The internal granular layer shows moderate immunoreactivity for MAP5 from its first appearance (15 w.g.) and throughout the rest of fetal life (Ohya *et al.*, 1997). Moderate to strong immunoreactivity for MAP5 also appears in the outer and inner halves of the molecular layer during the period from 24 w.g. to about 8 months after birth, corresponding to growth of parallel and climbing fibers into the zone beyond the Purkinje cell layer. The period of parallel fiber elongation is also characterized by positive immunoreactivity for the CD15 epitope (3-fucosyl-*N*-acetyllactosamine), which is presumably correlated with synaptogenesis (Gocht *et al.*, 1992). Interestingly, cells of the granule cell lineage, which express neuronal nuclear antigen during proliferation and premigratory stages in the external germinal layer, lose that antigen during settling in the internal granular layer. They do not express the antigen again until the period of outgrowth of parallel fibers to the developing molecular layer (from 24 w.g.; Sarnat *et al.*, 1998). Granule cells can also be identified during migration and after settling in the granule cell layer by immunoreactivity against the neuronal class III β-tubulin isotype, which also defines parallel fibers, stellate and basket neurons (Katsetos *et al.*, 1993).

Granule cells also exhibit intense immunoreactivity for the apoptosis inhibitior protein, Bcl-x, during the period from 13 to 22 w.g. (Sohma *et al.*, 1996), corresponding to the period of migration and settling of granule cells in the internal granular layer followed by the initial outgrowth of parallel fibers into the developing molecular layer.

Development of Deep Cerebellar Nuclei

At the beginning of the fetal period (8–10 w.g.), the dentate nucleus consists of only a diffusely arranged population of cells, with no differentiation of neuronal types. The dentate nucleus emerges as a distinct nuclear entity at around 16 w.g. (Mihajlovic and Zecevic, 1986), when it appears from the cerebellar white matter. It initially has the form of a thick band of cells that gradually attenuates and begins to fold from about 24 w.g., and gyri can be seen over the entire surface by about 28–29 w.g. Subdivision of the human dentate nucleus into a smaller microgyric rostral part and the larger macrogyric caudal part is achieved by 35 w.g. (Yamaguchi and Goto, 1997).

Differentiation into small and large neuron types can be first identified at 16 w.g. (Mihajlovic and Zecevic, 1986), with large neurons approximately 20 μm in their largest diameter and small neurons approximately 7–10 μm in the largest diameter. In Golgi-impregnated preparations, two principal types of large neurons can be identified in the 16- to 22-w.g. period. Fusiform neurons can be found scattered throughout the dentate nucleus at this stage and have three to four primary dendrites emerging from the apex of the cell body. Dendrites of fusiform neurons are completely devoid of spines or other appendages. Multipolar neurons at 16–22 w.g. can be further divided into three groups: border cells, central neurons and asymmetric neurons. Border neurons are concentrated at the inner and outer borders of the nuclear lamina and possess four to five primary dendrites, all of which extend into the nuclear lamina. Central neurons lie in the deeper parts of the nuclear lamina and possess three to four dendrites extending in all directions. Asymmetric multipolar neurons are evenly distributed throughout the nuclear lamina and have five to six primary dendrites, one of which is substantially longer than the rest, giving an asymmetric appearance to the dendritic field. Small neurons can be divided into two types: bipolar and small multipolar neurons.

Multipolar neurons begin to develop typical dendritic spines from about 18–20 w.g. By about 24 w.g., small neurons begin to develop spines, and by 27 w.g., small neurons begin to attain the size and shape of postnatal nerve cells. Mihajlovic and Zecevic (1986) also commented that large neurons of the dentate nucleus appeared to be more morphologically mature than Purkinje cells at the same age. The period of extension of dentate neuronal dendrites (16–26 w.g.) corresponds to mild transient expression of MAP5 (Ohyu *et al.*, 1997).

Studies of chemical differentiation of deep cerebellar nuclei neurons have shown that GABA and parvalbumin immunoreactivity appear in both neurons and fibers of the deep nuclei as early as 16 w.g. (Yu *et al.*, 1996; Gudovic *et al.*, 1987; Hayaran *et al.*, 1992).

Development of Neurotransmitter Receptor Binding in the Cerebellum

Neurotransmitter binding appears to be higher in the fetal cerebellum than in early postnatal or adult humans. Court *et al.* (1995) have found that nicotine and muscarine binding in fetuses (23–29 w.g.) exceeds binding in young adults by factors of 6 and 2, respectively, in the dentate nucleus and by a factor of 3 in the white matter. The binding of these were also higher in the external germinal layer than in the internal granule layer of the adult, indicating that immature granule cells of the external germinal layer bind nicotine and muscarine more avidly than the mature neurons. Binding of α-bungarotoxin is also raised in the dentate

gyrus compared to the adult. The M_2 subtype appears to be the predominant muscarinic receptor in the human cerebellum, but this receptor type accounts for a lower proportion of muscarinic binding in the fetus than it does in the adult. The developmental significance of these changes remains unknown.

There also appear to be significant differences in the densities of 5-HT_{1A} receptors in fetal human cerebellum compared to the adult (del Olmo *et al.*, 1994). Those authors found high densities of 5-HT_{1A} receptors over the cerebellar cortex during fetal and neonatal stages, whereas the adult cerebellum is nearly devoid of this type of binding. This transient presence of receptors may reflect a developmental role for serotonin in dendritic growth or axonal branching, but this remains to be definitively proven.

Development of Inferior Olivary Nuclei

The human inferior olivary nuclear complex is composed of three subdivisions: medial accessory olivary nucleus (MAO), dorsal accessory olivary nucleus (DAO), and principal nucleus (PIO). Analysis of human pathology suggests that the MAO and DAO project to the rostral lobules of the cerebellar hemispheres; the caudal ventral lamella of the PIO projects to the caudal cerebellar hemispheres and the dorsal lamella and rostral pole of the PIO project to the rostral lobules of the cerebellar hemispheres.

Inferior olivary nucleus neurons are generated from the germinal matrix of the corpus pontobulbare component of the rhombic lip between about 5 and 7 w.g., and neurons migrate to their final resting site in the medulla during the period from 5 and 18 w.g. At midgestation (about 20 w.g.) axons from the inferior olive extend into the cerebellar white matter (Hayaran and Bijlani, 1992). At 28 w.g., these axons make synapses with immature Purkinje cells. From 34 w.g. the climbing fibers begin to climb the Purkinje cell dendrites and this process continues into postnatal life. Pruning of the number of climbing fibers occurs postnatally (Marin-Padilla, 1985), although Gudovic and Milutinovic (1996) have claimed that the number of inferior olivary nucleus neurons declines mainly in the period from 12.5 w.g. to 25 w.g., in parallel with loss of Purkinje cells from the cerebellar cortex.

Neurochemical studies (Armstrong *et al.*, 1999) have compared neurotransmitter binding in fetal, neonatal, and adult inferior olivary nuclei. These patterns of change in receptor binding are different for each of the subdivisions of the inferior olivary complex. For the principal nucleus between midgestational fetal and neonatal (1–6 months) stages: opioid binding decreases, kainate increases, while muscarinic cholinergic, nicotinic cholinergic, and α-$_2$ adrenergic binding remain stable. For the DAO over the same period: nicotinic, muscarinic, α-$_2$, and opioid binding decreases, whereas kainate binding increases.

Development of Pontine Nuclei

Neurons of the basilar pontine nuclei are derived from the corpus pontobulbare portion of the rhombic lip and migrate around the circumference of the ventral surface of the brain stem. They contribute mossy fibers to the developing cerebellar cortex from 20 w.g. onward. The period of maturation of pontine neurons corresponds to the development of neuronal nuclear antigen, which begins to appear in pontine neurons at 14 w.g. and is strongly developed by 20 w.g. (Sarnat *et al.*, 1998).

PONS AND MEDULLA

Within the developing human rhombencephalon, selected pathways and nuclei have received attention according to their perceived clinical significance. Those systems that have been best studied are the auditory pathway, cranial nerve nuclei, and selected reticular formation nuclei, particularly those involved in respiratory and cardiovascular control.

Auditory Pathway

Auditory function develops well before birth, and assessment of auditory function is useful in assessing the developmental state of preterm infants.

The cochlear nuclei in humans consist of a larger ventral nucleus lying rostrally and a smaller dorsal nucleus lying more caudally and extending into the lateral recess of the fourth ventricle. At 12 w.g., neurons of the ventral cochlear nucleus cannot be distinguished from glia, but differentiation of neurons begins to be noticeable from 16 w.g. The number of identifiable neurons increases to about 40,000 by 21 w.g. and appears to remain stable throughout fetal and postnatal life. Cytoarchitectural features of the main ventral cochlear neuron types (large round and small spindle shaped) gradually develop after 21 w.g. (Nara *et al.*, 1993). Cytoarchitectural features of the inferior colliculus begin to appear after 12 w.g. (Nara *et al.*, 1996), and after 16 w.g. neurons of the inferior colliculus begin to differentiate into two distinct morphological classes (large and small) on the basis of appearance in Nissl-stained material.

The human olivocochlear system can be identified using immunoreactivity to choline acetyltransferase

(ChAT) and calcitonin gene–related peptide (CGRP), both of which label those central neurons of the superior olivary complex that contribute to the olivocochlear bundle. Both ChAT and CGRP immunoreactivity is visible by 21 w.g. in neurons of the dorsal and ventral periolivary region, although neurons of the medial and lateral superior olivary nuclei are still of immature appearance in Nissl stains made at this age. Neurons immunoreactive for ChAT become more dispersed as prenatal development proceeds (Moore *et al.*, 1999). Neurofilament immunohistochemistry indicates that olivocochlear fibers grow out between 22 and 29 w.g. (Moore *et al.*, 1997). This is consistent with reports of the first appearance of efferent nerves and terminals in the cochlea at 20–22 w.g. (Igarashi and Ishii, 1980) and the first appearance of mature synapses onto outer hair cells between 24 and 28 w.g. (Lecanuet and Schaal, 1996).

The development of ascending, commissural, and descending pathways associated with the auditory system have been studied with neurofilament immunohistochemistry. The first fibers of the cochlear nerve invade the ventral cochlear nucleus at about 16 w.g. (Moore *et al.*, 1997). At about the same time, several trapezoid body–lateral lemniscus axons reach the superior olivary nucleus and inferior colliculus. The ascending auditory pathway undergoes a marked expansion between 16 and 26 w.g., with collateralization of ascending axons by 26 w.g. and formation of terminal plexuses in target nuclei from 26 to 29 w.g. (Moore *et al.*, 1997). Commissural pathways (dorsal commissure of the lateral lemniscus, commissure of the inferior colliculus) develop from 22 w.g.

Myelination of auditory pathways begins at about 26 w.g. (Moore et al., 1995). At that stage linear arrays of oligodendrocytes are located alongside axons in all segments of the auditory pathway. At 29 w.g., the cochlear nerve contains lightly myelinated axons and the primary axons can be seen to bifurcate and radiate in the ventral cochlear nucleus. Further up the auditory pathways at this stage, myelination is also present in the lateral lemniscus and trapezoid body by 26 w.g., and myelination in the inferior brachium develops from about 29 w.g. Myelination continues into the first postnatal year and at 1 year of age auditory pathway myelination appears comparable to that in the mature brain.

Functional development of the auditory system parallels the morphological development outlined above. Studies of the development of the auditory blink–startle response in fetuses (Birnholtz and Benecarraf, 1983; Kuhlman *et al.*, 1988) indicate that the first short-latency responses to sound may be obtained at 25–26 w.g. This response is seen in virtually all fetuses by 28 w.g., closely paralleling the development of myelination in the auditory pathways, as outlined above.

Cranial Nerve Nuclei

Motor Nuclei

Detailed information concerning the development of motor nuclei in the human brain stem is not available, with only a few studies focusing on these structures.

Most of the major motor nuclei (motor trigeminal, abducens, ambiguus, spinal accessory) attain their final positions in the brain stem by the end of the embryonic period (8 w.g.) (Jacobs, 1970). Only the facial nucleus and accessory facial nucleus (which supplies the posterior belly of digastric and stapedius muscles) have failed to reach their final resting places by 10 w.g. The trigeminal nucleus, which consists of dorsal, intermediate, and ventral subdivisons, begins to show further differentiation into separate compartments at 10 w.g.

Cytoarchitectural development of the hypoglossal nucleus has been followed by Nara *et al.* (1989). Their data indicate that the number of neurons in the hypoglossal nucleus does not show any consistent change in the period from 16 w.g. to late adult life. This stands in contrast to their report that degenerating neurons are found between 21 and 33 w.g. (Nara *et al.*, 1989).

Human cranial nerve motor nuclei show strong activity for succinic dehydrogenase and AChE by 12 w.g. (Wolf *et al.*, 1975). Several cranial nerve motor nuclei (facial, hypoglossal, and ambiguus) show transient activity for NADPH-diaphorase between 19 and 21 w.g. (Gonzalez-Hernandez *et al.*, 1994). These nuclei are negative by 23 w.g., indicating a very short period of activity. This transient activity may indicate that NO is involved in early regulatory processes during motor nuclei development, but this requires further investigation.

Autonomic Effector Nuclei

The dorsal motor nucleus of the vagus (10) is the only autonomic effector nucleus which has been studied in detail during fetal life (Nara *et al.*, 1991). The dorsal motor nucleus of the vagus can be seen to be divided into three main subdivision (caudal, dorsal, and ventral) by 16 w.g. The dorsal subdivision is described as containing polygonal or spindle-shaped neurons, while the ventral subdivision has round or oval neurons. The caudal subdivision was described as containing more rounded neurons that the dorsal. Various anatomical parameters show gradual increase

throughout the fetal period indicating moderate development across this interval.

Detailed analysis of dendritic development of neurons in the vagal sensorimotor complex is not available. Nevertheless, a study of dendritic spine development in the dorsal medullary reticular formation indicates that dendritic spines density increases steadily from 20 w.g. to term, before declining during early postnatal life (Becker and Zhang, 1996).

One study has examined the development of substance P–immunoreactive fibers in the dorsal motor nucleus of the vagus nerve. Wang *et al.* (1993) found that substance P–immunoreactive fibers are first distributed to this nucleus at 16 w.g. By 23 w.g., these fibers were of low-to-moderate density and continued to increase in staining intensity until birth. By the last age examined the substance P–immunoreactive fibers had become coarser and with more varicosities than previously.

Sensory Nuclei

Development of the trigeminal sensory nuclei will be dealt with in Chapter 29 on the human trigeminal system.

The human nucleus of the solitary tract can be distinguished in the brain stem at about 16 w.g. and individual subnuclei can be discerned over the following weeks (Wang *et al.*, 1993). Substance P immunoreactivity can be seen for the first time at 16 w.g., at which stage it is present in fibers distributed mainly over the dorsal and dorsolateral parts of the nucleus. At this early stage the fibers are thin, smooth, with few varicosities and some terminal boutons. As for the developing nucleus of the solitary tract, the density of substance P–immunoreactive fibers increases steadily in the nucleus of the solitary tract over the fetal period until the last age examined (40 w.g.). Binding of opiates to the fetal nucleus of the solitary tract as well as the trigeminal sensory nuclei is similar to the adult by midgestation indicating possible early maturation of opioid systems (Kinney *et al.*, 1990).

Respiratory and Cardiovascular Areas

Only a few studies to date have examined the development of respiratory and cardiovascular centers in the developing human brain stem. Consequently, only an incomplete picture of maturation of these important regions is available at present.

Although the arcuate nucleus has classically been regarded as a precerebellar nucleus, its has also been implicated in central control of respiratory and vasomotor responses (Filiano *et al.*, 1990). In fact, those authors have pointed out the cytoarchitectural similarity between the human arcuate nucleus neurons and neurons in the chemosensitive S area of the ventral medullary surface in the cat. Zec *et al.* (1997) have examined the connections between the human fetal arcuate nucleus and identified cardiorespiratory regions at 19–22 w.g., using carbocyanine dye (DiI) diffusion techniques. They identified labeled fibers arising from the arcuate nucleus and reaching the medial reticular formation (nucleus paragigantocellularis), medullary raphe, as well as fibers coincident with the external arcuate fibers. None of the fibers labeled by DiI insertion into the arcuate nucleus were seen to enter the inferior cerebellar peduncle, but this may reflect a technical problem with the carbocyanine dye diffusion because of the great distance involved.

Prenatal development of substance P immunoreactivity in two regions associated with control of respiratory and cardiovascular function (parabrachial nuclei, Kolliker–Fuse nucleus, and nucleus of the solitary tract) has been studied by Wang and coworkers (1992, 1993). The nucleus of the solitary tract has been discussed above (see cranial nerve sensory nuclei) but, in brief, shows steady increase in substance P immunoreactivity throughout fetal life (Wang *et al.*, 1993). In the case of the parabrachial and Kolliker–Fuse nuclei (Wang *et al.*, 1992), low densities of substance P–immunoreactive fibers and terminals can be seen as early as 16 w.g. By 23 w.g. there is clear differentiation of staining intensity in this region, with the strongest immunoreactivity being over the lateral parabrachial nucleus. This differential staining continues until the end of fetal life, as staining intensity of the whole region continues to increase progressively throughout prenatal life (Wang *et al.*, 1992).

Somatostatinergic systems are believed to be involved in the maturation of respiratory control, and the development of somatostatin binding in 16 respiratory nuclei of the human brain stem has been analyzed by Carpentier *et al.* (1997). Somatostatin binding is particularly strong during fetal life in the nucleus of the solitary tract and dorsal cochlear nucleus, whereas moderate activity is present in other sensory cranial nerve nuclei (Carpentier *et al.*, 1996). In all respiratory regions, somatostatin binding is particularly strong in early to midgestational stages (about 20 w.g.) and declines during fetal life. In most respiratory centers, somatostatin binding declines gradually either throughout the developmental period or mainly during fetal life. On the other hand, in two nuclei (lateral parabrachial and locus coeruleus) there is an abrupt decrease in the density of somatostatin binding sites at the time of birth.

One major stimulus for studies of the maturation of cardiorespiratory regions in the fetal human brain stem

is the goal of understanding the effects of maternal smoking on the maturation of the fetal brain stem and postnatal cardiorespiratory function. Kinney *et al.* (1993) have studied nicotine binding in the developing human brain stem. They have shown that nicotine binding is heavy in midgestational fetuses in those brain stem tegmental regions serving cardiorespiratory function, arousal, attention, rapid eye movement (REM) sleep, and somatic motor control. Nicotine binding decreases sharply during the last half of prenatal life in these region, whereas binding over cerebellar relay nuclei (inferior olivary nuclei and pontine nuclei) does not change greatly. This suggests that there is an opportunity during midgestation for the development of cardiorespiratory centers to be modified by maternal smoking.

Monoaminergic Pathways

Detectable levels of noradrenaline (NA) and serotonin (5-HT) appear in the pons, medulla oblongata, and spinal cord from 5 to 6 w.g. (Sundström *et al.*, 1993). For the rest of the first trimester, levels of NA and 5-HT increase consistently, but there is a noticeable increase in interindividual variability of levels with advancing age. Immunocytochemistry of first trimester brain stem shows that immature neurons immunoreactive for TH are present by 4 weeks postconception (Sundström *et al.*, 1993), and several TH and 5-HT nerve cell groups can be found in the pons and medulla from 5 weeks. TH-immunoreactive cells matured from round uni-/bipolar cells at 5 w.g. to multipolar neurons with extensive neurite outgrowth at 8 w.g. After this stage there are only minor additional increases in somata size, but the innervation of the surrounding neuropil increases. Similarly, 5-HT-immunoreactive neurons in the human brain stem differentiate from unipolar cells at 5 weeks to large, multipolar neurons by 11 w.g., although some brain stems showed poorer differentiation of these cells by the end of the first trimester. By about the 15th week, all the major NA and 5-HT cell groups can be identified by fluorescence techniques (Olson *et al.*, 1973).

Other Reticular Formation Nuclei

The cytoarchitectural development of the gigantocellular reticular nucleus has been examined by Yamaguchi *et al.* (1994). The nucleus appears as early as 16–18 w.g., but most neurons are still immature at this age. Typical large multipolar neurons appear at 21 w.g. and myelination has been noted as early as 22–23 w.g. (Yamaguchi *et al.*, 1994). Neuronal numerical density of the giganticellular reticular nucleus declines between 16 w.g. and birth. Those authors suggested that differentiation and maturation of gigantocellular neurons progresses gradually and monotonically during fetal life.

Development of Fiber Tracts in the Pons and Medulla

Growth-associated protein 43 (GAP-43) serves as a substrate for protein kinase C and is thought to have a critical role in axonal growth (Meiri *et al.*, 1986; Skene *et al.*, 1986). GAP-43 is enriched in growth cones (DeGraan *et al.*, 1985; Meiri *et al.*, 1986) and present in high levels during the period of axonal elongation (Jacobson *et al.*, 1986; Karns *et al.*, 1987). At midgestation (19–22 w.g.), GAP-43 immunoreactivity is moderate in intensity in many brain stem nuclei, but is already absent or low in the hypoglossal nucleus, facial motor nucleus, superior olivary nucleus, and nucleus of the inferior colliculus (Kinney *et al.*, 1993). The corticospinal tract shows strong immunoreactivity in the fetal medulla and pons. This pattern was also seen at 26 w.g., whereas at 38 w.g. staining was completely absent from the facial motor nucleus. At infancy strong GAP-43 immunoreactivity remains visible in the intermediate reticular zone and begins to decline in the pyramidal tract. The pontine tegmentum remains strongly reactive, but many other brain stem tracts such as the solitary tract, medial and lateral lemnisci, amiculum and hilum of the inferior olive, transverse pontocerebellar fibers, and cerebellar peduncles are poorly immunoreactive by infancy. Since GAP-43 appears to be associated with fiber tract development and plasticity, these findings suggest that most of the major fiber tracts are well developed by the time of birth, with the exception of the pyramidal tract. This is in agreement with studies of myelination in the human fetal brain stem (Tanaka *et al.*, 1995), which found that the corticospinal tract is slow to complete myelination, whereas the medial longitudinal fasciculus, cuneate fasciculus, and solitary tract complete myelination earlier. Synapses have been observed in the human pyramidal tract as early as 23 w.g. (Bruska and Wozniak, 1994) and may represent the early formation of collateral axon synapses with brain stem regions.

SPINAL CORD

General Features of Neuronal Differentiation

In the developing brain, neuron-specific enolase (NSE), a neuronal form of the glycolytic enzyme enolase, is not expressed in germ cells or immature

neurons, and so can be taken as an indicator of the onset of neuronal differentiation. In the ventral horn of the spinal cord, NSE begins to appear at about 7–8 w.g. and is definitely present by 10 w.g. (Kato *et al.,* 1994). In the dorsal horn, NSE develops slightly later—beginning to appear at 7–8 w.g. and definitely present by 22 w.g. Marti *et al.* (1987) showed that immunoreactivity for neurofilament triplet proteins develops in the major neuronal types of the spinal cord (both ventral and dorsal gray) as early as 6 w.g.

Development of the intermediolateral cell column appears to be slightly delayed relative to both the dorsal and ventral horns. Immunoreactivity for neurofilament triplet proteins appears in cells and fibers of the lateral horn at about 35 w.g., almost 30 weeks after neurofilament immunoreactivity appears in neurons of the ventral and dorsal horns (Marti *et al.,* 1987).

Morphological differentiation of ventral horn spinal cord neurons occurs in parallel with the appearance of NSE and neurofilament protein immunoreactivity. In Golgi preparations (Choi, 1981), ventral horn cells are well differentated by 7.5 w.g. with smooth thin dendrites extending at least as far as the boundary between mantle and marginal layers, while at this stage neurons in the intermediate zone are smaller, more slender, and frequently bipolar in shape.

Glial Differentiation in the Spinal Cord

Using electron microscopy, radial glial cells can be identified in the developing human spinal cord as early as 6 w.g. (Choi, 1981), although characteristic radial glia are difficult to identify by Golgi impregnation techniques at this early stage. By 7.5 w.g., radial glia can be clearly identified in Golgi preparations and distinguished from developing nerve cells. At that stage, many radial glial cells extend their processes across the entire distance from the central canal to the pial surface. The contour of these radial glia is irregular with many laterally projecting lamellar processes. Also at this stage the radial glia in the ventral and dorsal fissures show smoother outlines than cells in other regions and have an uninterrupted extension from the central canal to the pial surface. Immunoreactivity for GFAP can be detected in radial glial cells of the human spinal cord as early as 9 w.g. (Choi, 1981).

At 16 w.g., the central canal of the spinal cord becomes much narrower than at previous ages and is lined by a single layer of cuboidal or columnar cells with short processes (Choi, 1981). At this stage, not all the processes of radially oriented cells reach the pial surface. Scattered cells with much shorter bushy projections, showing features of stellate astroglial cells, begin to appear at this stage. Oligodendroglial cells are also seen at 16 w.g. in association with myelinated axons (see "Development of Long Tracts and White Matter").

Development of Identified Cellular Populations

The most detailed study of identified neuronal populations in the human fetal spinal cord has been undertaken by Marti *et al.* (1987) who found that immunoreactivity for identified neurotransmitters appeared earlier in the ventral horn than in the dorsal horn or dorsal root ganglion cells. Immunoreactivity for CGRP and galanin appears as early as 6 w.g. in cells and fibers of the ventral horn but does not appear until 10 and 20 w.g., respectively, in fibers of the dorsal horn. Similarly, neuronal immunoreactivity for somatostatin appears in the ventral horn by 8 w.g., but somatotstatin immunoreactivity in the somata of dorsal root ganglia does not appear until 10 w.g. (Charnay *et al.,* 1987). Substance P immunoreactivity of fibers in the ventral horn appears at 6 w.g., while those fibers appear at 11 w.g. in the dorsal horn. By contrast, immunoreactivity for fibers with neuropeptide Y (appearing at 10 w.g.), enkephalin (appearing at 10 w.g.), and vasoactive intestinal polypeptide (appearing at 20 w.g.) occurs simultaneously in ventral and dorsal horns (Marti *et al.,* 1987; Shen et al., 1994).

Just as neurofilament development in the intermediolateral cell column is delayed relative to the ventral and dorsal horn, neurotransmitter development also occurs later in fetal life (Marti *et al.,* 1987). Immunoreactivity for somatostatin in cells and fibers of the lateral horn appears at about 20 w.g., 10–12 weeks after the development of somatostatin immunoreactivity in neurons of the ventral and dorsal horns. Similarly, fiber immunoreactivity for enkephalin develops at 20 w.g., substance P develops at 24 w.g., NPY develops at 24 w.g, and CGRP develops at 24 w.g., 10–18 weeks after these immunoreactive fibers can be found in the ventral horn.

Development of Long Tracts and White Matter

Immunoreactivity for the phosphorylated variant of high molecular weight neurofilament protein is present in the longitudinal processes of the marginal zone (developing white matter) and the mantle layer of the spinal cord from the embryonic to the fetal period (8–30 w.g.; Lukas *et al.,* 1993).

Immunoroeactivity for the low-affinity receptor of nerve growth factor has been studied in fetal human spinal cord (Suburo *et al.,* 1992). Positive fibers may be found in regions of the spinal cord containing primary sensory afferents (e.g., dorsal root, dorsal and dorsolateral funiculi, and restricted regions of the dorsal

horn) but are not found in the ventrolateral funiculus. Immunoreactive fibers are initially found in the periphery of the thoracic-level dorsal funiculus as early as 7 w.g. and spread into other regions in older fetuses. In the upper spinal cord, immunoreactive fibers were seen in the gracile and cuneate fasciculi, extending to the dorsal column nuclei of the medulla (11 w.g.). Labeling of the dorsal funiculus is transient and has disappeared by 20 w.g., although labeling in both thoracic and lumbar levels of the dorsolateral funiculus continues to be present until adult life. Immunoreactivity for *trk* receptors, which have essential roles in signal transduction mediated by nerve growth factor and related neurotrophins, has been shown to appear in the dorsal columns from 23 to 39 w.g. (Muragaki *et al.,* 1995).

The calmodulin-binding phosphoprotein GAP-43, which also serves as a substrate for protein kinase C, is thought to have a critical role in axonal growth (Meiri *et al.,* 1986; Skene *et al.,* 1986). GAP-43 is enriched in growth cones (DeGraan *et al.,* 1985; Meiri *et al.,* 1986) and present in high levels within developing nerves during the period of axonal elongation (Jacobson *et al.,* 1986; Karns *et al.,* 1987). An *in situ* hybridization study with antisense GAP-43 riboprobe has revealed high signal in the developing spinal cord as early as 6 w.g. (Kanazir *et al.,* 1996), with levels sustained into fetal life.

Synaptophysin is an integral membrane protein of vesicles and appears at an early stage of neuronal differentiation. Despite the relatively mature cytoarchitectural appearance of ventral horn motoneurons in the human fetal spinal cord achieved at 10 w.g. (see above), synaptophysin immunoreactivity does not develop until 12–14 w.g. (Sarnat and Born, 1999). At this stage, synaptophysin immunoreactivity is found around neuronal somata as coarsely granular reactivity and as beaded axon-like structures in the neuropil between neurons.

Detailed information about the development of individual tracts in the human fetal spinal cord is rare. One study of 5-HT- and catecholamine-containing neuron systems in the fetal brain stem (Olson *et al.,* 1973) noted in passing the presence of axons showing fluorescence consistent with serotonergic and catecholaminergic function in the spinal cord as early as 9.8 mm crown–rump length (about 12 w.g.). Sundström *et al.* (1993) have reported that fibers immunoreactive for NA and 5-HT begin to appear in the cervical cord as early as 5 w.g., in the entire spinal cord from 6 w.g., and in the gray matter of the spinal cord at 9 w.g.

The development of myelination in the developing human spinal cord has been followed using myelin stains such as Luxol fast blue (LFB) and immunoreactivity for myelin basic protein (MBP)(Gilles, 1976; Tanaka *et al.,* 1995). Myelin sheaths stain earlier and more strongly with MBP immunohistochemistry, so that the subsequent discussion will concentrate on development times as revealed by MBP immunoreactivity. The medial longitudinal fasciculus is the earliest site of myelination as assessed by both myelin staining and MBP immunohistochemistry. The medial longitudinal fasciculus first shows myelination at about 20 w.g., and myelination appears to be complete by 34 w.g. (Tanaka *et al.,* 1995). Major ascending sensory pathways, such as the cuneate and gracile fasciculi, begin to myelinate slightly later. *In situ* hybridization shows MBP mRNAs *(MBP X5b-11)* in the gracile fasciculus, and periphery of the ventral and lateral funiculi as early as 20 w.g. (Pribyl *et al.,* 1996). Based on MBP immunoreactivity, the cuneate fasciculus begins to undergo myelination at 23 w.g. and completes myelination at about 36 w.g. (Tanaka *et al.,* 1995). Descending motor tracts begin myelination somewhat later than sensory pathways (Gilles, 1976; Tanaka *et al.,* 1995). The corticospinal tracts begin myelination at about 28–30 w.g., and myelination is not complete to an extent seen elsewhere in the CNS until after birth. In contrast to this relative delay in myelination of descending motor tracts, ventral roots appear to complete myelination at about the same time (35 w.g.) as dorsal roots (36 w.g.).

In general, myelination of sensory pathways starts in the peripheral nerves, dorsal spinal nerve roots, and posterior columns of the spinal cord in the second trimester and progresses after birth in the direction of ascending transmission of sensory information, i.e., medial lemniscus, posterior internal capsule, and central corona radiata (Yakovlev and Lecours, 1967). In contrast, in motor systems, myelination first appears in peripheral nerves and ventral spinal roots. Myelination of central motor pathways begins in the corticospinal tracts in the pons and progresses both rostrally and caudally from there (Yakovlev and Lecours, 1967).

Acknowledgment

We thank Drs. Y. Koutcherov, Ch. Andressen, D. Nohr, and Dipl. Biol. Th. Voss for their efficient help and invaluable assistance for this work, and Profs. Dr. W. Wechsler and Dr. J. Bohl for providing autopsy material.

University of New South Wales
Sydney, Australia

CRANIAL NERVES

Olfactory Epithelium and Nerve

The olfactory epithelium is well delineated in human embryos by about day 37 postconception (pc) (Bossy, 1980), and axonal growth from olfactory receptor neurons through the olfactory epithelial basal lamina is evident a few days later, with olfactory glial cells accompanying the nascent olfactory rootlets (Pyatkina, 1982). By 11 weeks pc, there has been complete morphological differentiation of olfactory receptor neurons and Bowman's glands have formed in the olfactory epithelium (Pyatkina, 1982). By day 41, the olfactory nerve is seen to be divided into two plexus-like laminae (Fig. 4.1). The medial plexus receives the terminal nerve/vomeronasal organ strand of axons and these elements are directed to the caudal part of the olfactory bulb anlage (Bossy, 1980). The lateral plexus is initially smaller than the medial plexus, arises from the lateral olfactory epithelium, and is directed to the lateral portion of the olfactory bulb anlage. By day 57 pc, vomeronasal fibers are gathered into two posterior filaments, which arrive in the vomeronasal ganglion, located near the dorsomedial aspect of the olfactory bulb, and the fibers from the ganglion terminate in the developing accessory olfactory bulb (Bossy, 1980). The fibers of the terminal nerve are directed to the medial septal area. Teratological studies indicate that the initial development of the olfactory nerve fibers is independent of the presence or absence of the target structure, the olfactory bulb (Braddock *et al.*, 1995).

Later in development (11–18 weeks pc), the human vomeronasal organ has been shown to have what appear to be receptor cells (Ortmann, 1989). Ortmann reported that there appears to be a great deal of individual variation in differentiation and individual constituents of the organ. Gradual regression of the human terminal nerve system begins toward the end of the embryonic period. Nevertheless, there are still as

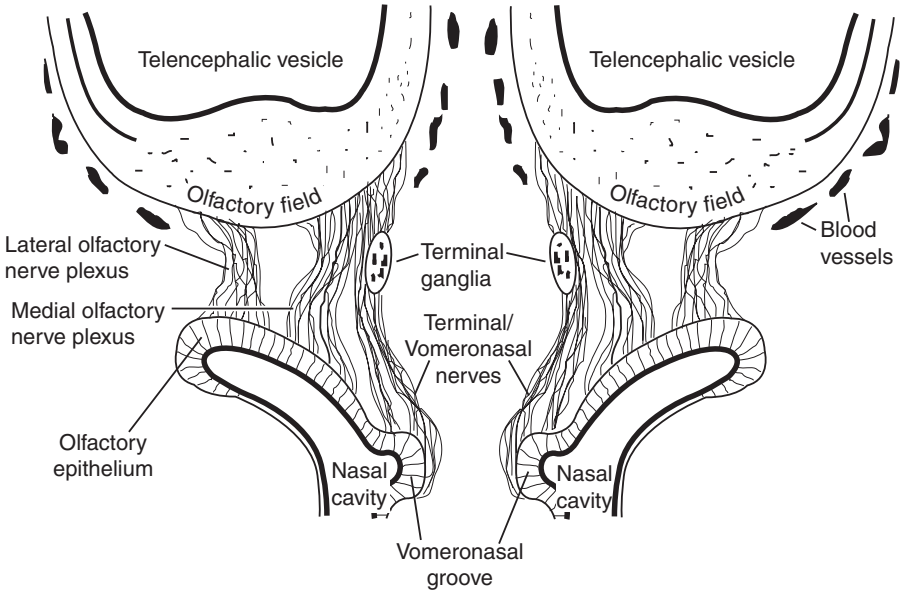

FIGURE 4.1 Diagrammatic oblique plane representation of the developing olfactory system at stage 18 (approximately 42 days postconception). Note the presence of medial and lateral olfactory plexuses and the close association of the vomeronasal organ efferents, terminal nerve, and terminal ganglion with the medial olfactory plexus.

many as 850 neurons present in the system by 4 months after birth (Oelschläger *et al.*, 1987). Termination sites of the terminal nerve system in blood vessel walls and nerve endings in the nasal epithelium indicate autonomic and sensory functions (Pearson, 1941, Oelschläger *et al.*, 1987). In rodent development, luteinizing hormone–releasing hormone (LHRH) immunoreactivity first appears in the ganglion cells of the terminal nerve system. In human embryos, LHRH can be detected in the olfactory epithelium as early as 5.5 weeks pc and migration of these cells along the developing vomeronasal/terminal nerve complex occurs shortly thereafter (Verney *et al.*, 1996). It has been proposed that the terminal nerve system and vomeronasal organ (Kjaer and Fischer Hansen, 1996) are both essential to the maturation and differentiation of the hypothalamus–pituitary–gonadal axis (Schwanzel-Fukuda *et al.*, 1985) because they provide the major source of LHRH–positive neurons for the developing hypothalamus. Failure of migration of LHRH neurons from the olfactory placode to the hypothalamus may result in Kallman syndrome, in which hypogonadotrophic hypogonadism is associated with reproductive dysfunction and, often, anosmia.

Development of the olfactory bulb occurs somewhat later than the olfactory epithelium. Lamination appears in the olfactory epithelium by about 13 weeks pc, with axodendritic synapses appearing in the presumptive glomerular layer at about 17 weeks pc (Chuah and Zheng, 1992). Although olfactory marker protein is first detected in olfactory receptor neurons at 24 weeks pc (Johnson *et al.*, 1995), it is not detectable in the bulb olfactory nerve layer and glomeruli until 32 weeks pc (Chuah and Zheng, 1987).

Mutations in the homeobox gene *Hesx1* have been shown to be associated with abnormal olfactory development in mice and humans, as well as defective development of the forebrain and Rathke pouch (Dattani *et al.*, 1998). Nevertheless, further work is necessary to identify genes specifically involved in olfactory development.

Behavioral studies of prenatal human olfactory function are few. Nevertheless, studies of the responsiveness of term infants to amniotic fluid suggest that human fetuses can detect and store chemosensory information about maternal amniotic fluid and show preferential turning towards familiar, as opposed to unfamiliar, amniotic fluid (Varendi *et al.*, 1996; Schaal *et al.*, 1998).

Retina and Optic Nerve

The retina is of course of central origin, but for the sake of a complete treatment of the cranial nerves it is useful to summarize here key stages in human retinal development. As in the developing cerebral cortex, proliferation to produce retinal neurons occurs at two different levels in the developing retina—the external

neuroblastic or ventricular layer adjacent to the optic cup lumen and the internal neuroblastic or subependymal layer (Robinson *et al.*, 1985). By the end of the embryonic period (about 8 weeks pc) the retina is composed of a pigment layer, future external limiting membrane, proliferative zone, external neuroblastic layer, transient fiber layer, internal neuroblastic layer, nerve-fiber layer, and internal limiting membrane (O'Rahilly and Gardner, 1975). By the middle of gestation all the layers of the adult retina are present. Throughout development the posterior pole or central part of the retina is always developmentally advanced compared to peripheral retina.

Some studies have examined the development of immunoreactivity for γ-aminobutyric acid (GABA) and the calcium-binding proteins (calbindin D-28k, parvalbumin) in fetal human retina. GABA expression has been seen as early as 12 weeks pc in the undifferentiated cells of the inner neuroblast layer. From 16 to about 25 weeks pc intense labeling may be found in amacrine, displaced amacrine, and some retinal ganglion cells, as well as horizontal cells in the process of migration and differentiation (Nag and Wadhwa, 1997). Parvalbumin immunoreactivity is already apparent at 13 weeks pc in the cells of the ganglion cell layer, spreading to the inner and outer borders of the inner nuclear layer by 15 weeks pc and staining horizontal cells from 20 weeks pc. By 32 weeks pc, the pattern of parvalbumin immunoreactivity has stabilized, with strong labeling of ganglion and horizontal cell somata as well as in their processes in the outer plexiform layer, nerve fiber layer, and two bands in the inner plexiform layer (Yan, 1997). Calbindin immunopositive cells are found in the ganglion cell layer and outer neuroblast layer by 13 weeks. Two weeks later, it is apparent that there are discrete populations of calbindin-positive horizontal and amacrine cells in the retina and by 24 weeks pc the laminar pattern of calbindin immunoreactivity is complete, with positive amacrine and horizontal cells and immunoreactivity in neuropil of the inner and outer plexiform layers (Yan, 1997).

Vascularization of the retina begins at about 15 weeks pc, as spindle cells appear in the vicinity of the hyaloid artery (Ashton, 1970). These spindle cells proliferate in the nerve head and subsequently invade the nerve fiber layer of the retina. These solid cords of cells become canalized to form capillaries, initially localized to the optic nerve head but progressively spreading into the retinal periphery as three fan-shaped vascular fronts (Ashton, 1970). Initially vessels are confined to the nerve fiber layer, but plexuses develop in the superficial and deep parts of the inner nuclear layer from 28 and 30 weeks pc, respectively (Gariano *et al.*, 1994). Human retinal vasculature does not undergo complete development until after birth.

Human retinal microglia have been reported to be derived from two distinct sources. Provis *et al.* (1996) have noted that microglia enter the retina from the ciliary margin prior to the onset of retinal vascularization, and from both the optic disc and ciliary margin after vascularization (14–15 weeks pc). They argue that macrophage–antigen–positive microglia become established in the retina as vessel-associated (peri- and paravascular) microglia, and that major histocompatibility complex (MHC)–positive and macrophage–antigen–negative microglia (retinal dendritic cells) become established as the parenchymal ramified microglia.

The human optic nerve has been the subject of many studies of glial and connective tissue development. Vascularization of the human fetal optic nerve mainly occurs between 12 and 14 weeks pc (Sturrock, 1975), although vessel density continues to rise until about 20 weeks pc. There is a close spatial correlation between the astrocyte population and vascularity, reflecting the close involvement of astrocytes in vascular development of neural tissue like the retina (Penfold *et al.*, 1990) and optic nerve. Microglial population size also rises in parallel with increasing vascularity, but this correlation is thought to be coincidental (Sturrock, 1984), reflecting greater ease of invasion by microglia as optic nerve vessels increase in number and size. In an immunohistochemical study of fascicle and collagen development, Jeffrey *et al.* (1995) showed that no connective tissue staining of collagen types I–VI is present at 26 weeks pc, but collagen immunoreactivity begins to appear by 34 weeks pc. Immunoreactivity for glial fibrillary acidic protein appears by 24 weeks pc, while myelin basic protein appears by 32 weeks pc (Takayama *et al.*, 1991). The meninges of the human optic nerve develop along a similar time course to the vascularization and astrocytic differentiation. A collagen-rich dural layer does not develop until about 15 weeks pc, but development is rapid thereafter, so that the optic nerve meninges are well differentiated by 18 weeks pc (Sturrock, 1987).

As in other developing mammalian motor and sensory systems, the fetal human optic nerve shows overproduction and subsequent elimination of retinal ganglion cell axons. Provis *et al.* (1985b) found that by about 10 weeks pc there are 1.9 million axons in the human optic nerve (Fig. 4.2). This peaks at 3.7 million axons at about 16 weeks pc and falls to 1.1 million axons at about 27 weeks pc. The number of substance P (SP) immunoreactive fibers in the human optic nerve and lateral geniculate nucleus also peaks at 16–17 weeks pc and declines thereafter (Wadhwa *et al.*, 1988).

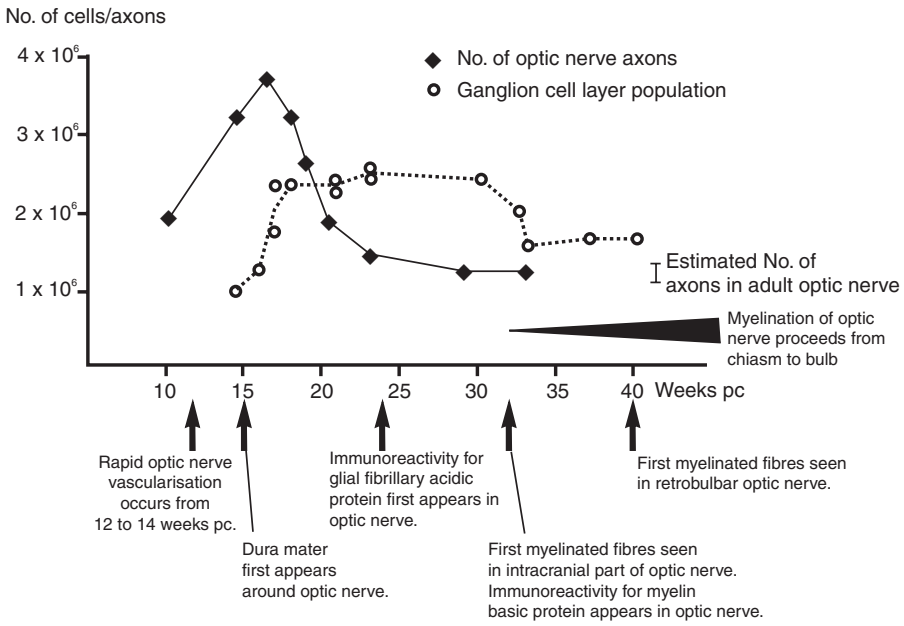

FIGURE 4.2 Major developmental events in the human optic nerve and retina. Figure representing changes in retinal ganglion cell population and optic nerve axons adapted from Provis *et al*. Human fetal optic nerve: overproduction and elimination of retinal axons during development. J. Comp. Neurol. 238, 429–451. © 1985. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. Dates of significant events in development are also indicated, as cited in the text.

The period of loss of cells from the retinal ganglion cell layer occurs after 30 weeks pc (Provis *et al.*, 1985a), indicating that many cells in the fetal ganglion cell layer do not contribute axons to the optic nerve during the period from 20 to 30 weeks pc. Myelination of the optic nerve does not begin until after 32 weeks pc, and myelination is largely complete by 7 months after birth (Magoon and Robb, 1981).

Studies with carbocyanine dye tracing techniques indicate that there is some topographic organization of axons within the fetal optic nerve according to retinal quadrant but that there is mixing of peripheral and central axons within each quadrant (Fitzgibbon, 1997). This rough patterning appears to be a passive process in that it arises as a consequence of combining the fascicles of the retinal nerve fiber layer from each retinal quadrant into a matching optic nerve quadrant. There does not appear to be any active process during development, which reorders fibers in either the optic nerve or tract. Factors controlling the direction taken by optic nerve axons at the chiasm have been the subject of considerable research in experimental animals. Analysis of optic chiasm formation in mouse and zebra fish *Pax-2* mutants (Favor *et al.*, 1996) suggests that the *Pax-2* gene regulates the expression of surface molecules involved in contact attraction of retinal ganglion cell axons entering the chiasm (Alvarez-Bolado *et al.*, 1997). The ventral forebrain midline, where the optic chiasm will develop, is formed by neuroepithelial cells expressing *Sonic hedgehog (Shh)* and it has been suggested that both *Pax-2* and *Shh* have important roles in chiasm formation.

Extraocular Muscle Innervation and Oculomotor, Trochlear, and Abducens Nerves

The cells that form the Edinger–Westphal nucleus are derived from the dorsal portion of the mesencephalic basal plate and migrate along primitive blood vessels to the tegmentum (Hogg, 1966).

An electron microscopic study of the intracranial protion of the human fetal trochlear nerve found that at 10 weeks pc this nerve has approximately 4000 unmyelinated axons arranged in 18 bundles (Mustafa and Gamble, 1978), while a specimen at 13 weeks pc had approximately 6000 axons. No other age groups have been examined to date.

Trigeminal Nerve

The trigeminal nerve contains both motor and sensory divisions. The motor division supplies the muscles of the first pharyngeal arch, namely, the muscles of mastication and the mylohyoid, anterior

belly of digastric, tensor tympani, and tensor veli palatini. Early motor cells can be seen migrating from the germinal zone of the special visceral efferent (ventromedial) column by 28 days pc (Bruska, 1991a). Medial and lateral cell groups are initially present within the developing motor nucleus, but the medial group subsequently disappears, leaving the lateral as the definitive motor nucleus (Bruska, 1991b). Windle and Fitzgerald (1994) describe trigeminal motor fibers emerging in 4-mm embryos (stage 13, 28 days pc) and the nerve is clearly present at stage 14 (Yokoh, 1968; O'Rahilly *et al.*, 1984). As for many other nuclei, cell death of trigeminal motor neurons has been reported (Hamano *et al.*, 1988). Innervation of jaw muscles occurs during the second month pc, with reflex opening of the mouth seen by 9.5 weeks (Hooker, 1942).

The sensory trigeminal neurons develop from the neural crest and epidermal placode of the mandibular arch, as in other species. The trigeminal ganglion can be recognized in the human by 26 days (stage 12, O'Rahilly *et al.*, 1984; Müller and O'Rahilly, Chapter 2). By 32 days, Bruska and Wozniak (1989) described two divisions: a smaller ophthalmic part and a larger maxillomandibular region. This has also been noted in the chick (D'Amico-Martel and Noden, 1980), although in the rat (Altman and Bayer, 1982) the separation is into a large ophthalmic maxillary region and a smaller mandibular part.

Yokoh (1968) described three short branches emerging from the trigeminal ganglion in the 4.5-mm embryo (stage 14) (Fig. 4.3). By stage 15 (about 36 days pc) the trigeminal ganglion is the largest of the cranial ganglia (Bruska, 1987) and lies directly inferior and lateral to the pons. Three divisions are recognizable, i.e., ophthalmic, maxillary, and mandibular, with nerves arising from each. By 5 weeks pc, the maxillary nerve has grown into the maxillary process and the inferior alveolar nerve is within the mandible (Pearson, 1977). Central projections to the pons develop concurrently, i.e., axons are present in the trigeminal tract from about the same time (from stage 14, Müller and O'Rahilly, Chapter 2) and the mesencephalic root of the trigeminal nerve appears from stage 16 (Müller and O'Rahilly, Chapter 2). By 8–8.5 weeks pc, central projections of all three divisions extend as far as the C_2 spinal cord level, with the maxillary and mandibular inputs terminating about one segment more caudally (i.e., C_3–C_4) than the ophthalmic (Humphrey, 1952).

As in avian and rodent ganglia, the human trigeminal ganglion shows light cells and dark cells (Bruska, 1986; D'Amico-Martel and Nodem, 1980). Satellite cells are present around the developing neurons by 6 weeks pc (Bruska, 1990), with usually two satellite cells per neuroblast by 9 weeks pc (Bruska and Wozniak ,1991). Schwann cells are present around the axons by week 9, with the first signs of myelination at 12 weeks pc (Bruska and Wozniak, 1991). SP and calcitonin gene-related peptide (CGRP) are expressed in a proportion of the ganglion cells from at least 25 weeks pc (Quartu *et al.*, 1996). Moreover, many developing ganglion cells have been shown to express the neurotrophic receptors trkA, trkB, and trk C, although unlike the rat, not all cells have been found to be immunopositive (Quartu *et al.*, 1996).

Neurons responsible for proprioception from the facial region lie in the mesencephalic trigeminal nucleus within the midbrain and pons, not the trigeminal ganglion. The mesencephalic trigeminal tract can be distinguished at stage 15 (O'Rahilly *et al.*, 1984).

The role of early innervation in tooth formation has been the subject of considerable interest (Christensen *et al.*, 1993). Epithelial thickening to form the dental lamina starts at around 6 weeks pc, prior to innervation. As epithelial buds develop, nerve fibers grow toward them, with the dental follicle receiving its first nerve fibers at the cap stage. By 15 weeks pc, a dental nerve is associated with each developing tooth. Fibers are seen in the dental papilla by 22 weeks pc, after the onset of dentinogenesis (Christensen *et al.*, 1993).

Several studies have examined the development of innervation of the face and development of perioral reflexes. Facial skin regions are the first to become sensitive and give rise to reflexes in the embryo. The earliest responses, from perioral skin, occur at around 7.5 weeks pc (Hooker, 1942) and involve contralateral flexion of the neck and upper trunk. By 8.5 weeks pc, the reflex spreads caudally to involve lateral flexion of entire trunk combined with pelvic rotation. Local reflexes first appear at 9.5 weeks pc, with mouth opening in response to stimulation of the lips. By 10–10.5 weeks pc, perioral stimulation leads to swallowing whereas eyelid stimulation causes contraction of the orbicularis oris and oculi muscles. This is about the time that the skin on the hands becomes sensitive, with palmar stimulation resulting in finger flexion. Plantar flexion first occurs at 11–11.5 weeks (Humphrey and Hooker, 1959).

Facial Nerve

The facial nerve collects axons from motor nuclei lying in rhombomeres 4/5 of the embryonic brain and exit from rhombomere 4 to innervate the second pharyngeal arch derivatives (Lumsden and Keynes, 1989; Guthrie and Lumsden, 1992). Experiments with *Hoxa1* and *Hoxb1* null mutants indicate that both genes act synergistically to pattern the hindbrain facial nerve and second pharyngeal arch (Gavalas *et al.*, 1998). In humans, the facial nerve can be identified at 4 weeks

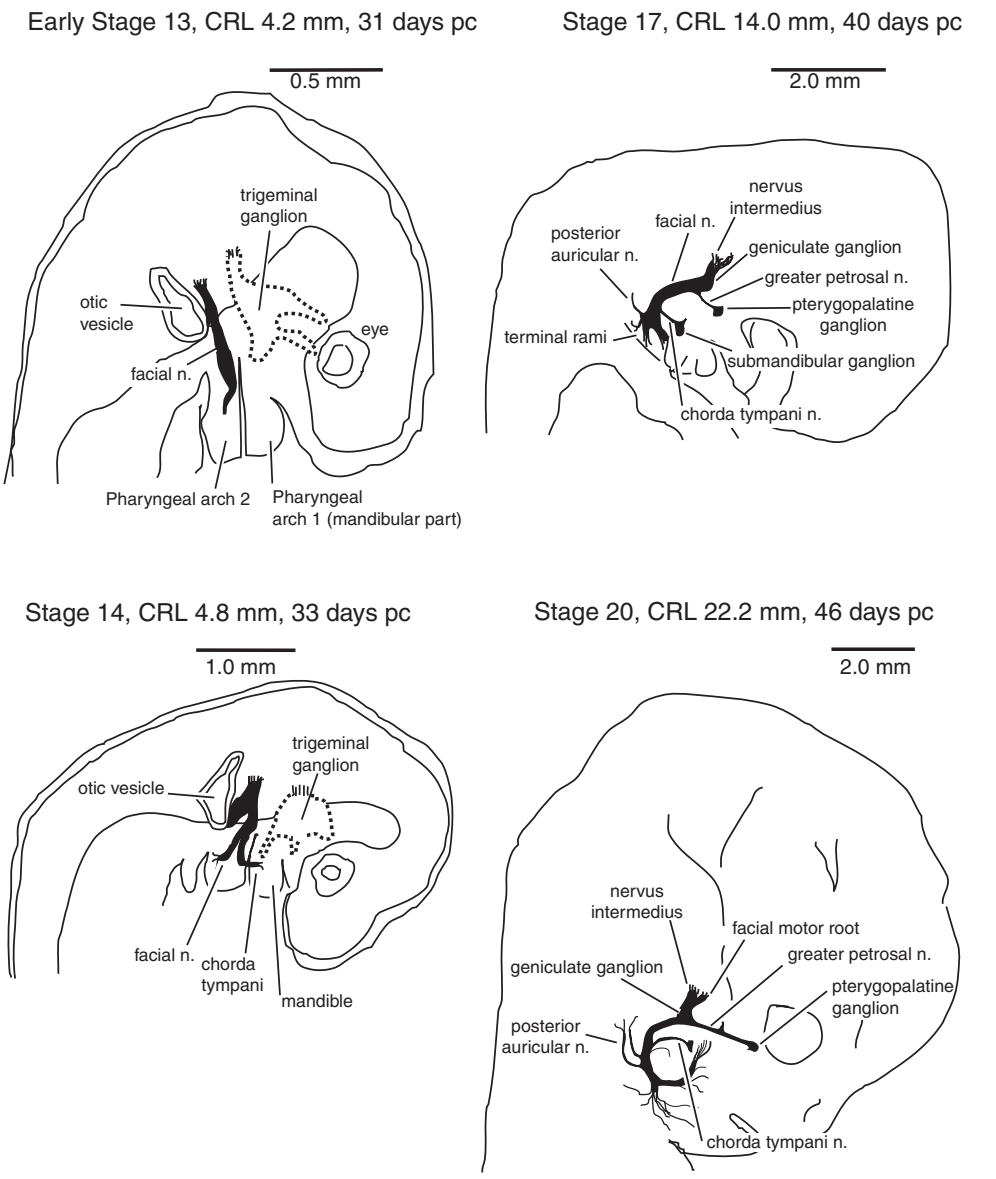

FIGURE 4.3 Development of the human facial nerve. This figure has been adapted from Gasser (1967) with permission of Annals, Inc. Note the early appearance of the chorda tympani (by 4.8 mm CRL) and the greater superficial petrosal nerve (by 14 mm CRL). Most significant rami have appeared by 46 days postconception.

pc (Gasser, 1967) as an unbranched bundle attached to the metencephalon immediately rostral to the otic vesicle (Fig. 4.3). Late in the fourth week, the facial nerve splits into two branches, with the chorda tympani coursing rostrally to enter the mandibular arch, and a caudal trunk merging into second arch mesenchyme. The geniculate ganglion and nervus intermedius appear during the fifth week pc, and the greater superficial petrosal nerve is also apparent for the first time. At about 6 weeks pc, the superficial layer of the second arch mesenchyme spreads to establish four laminae (occipital, cervical, mandibular, and temporal), which will give rise to the facial muscle groups (Sataloff, 1990). The pterygopalatine ganglion appears by about 6 weeks pc. Peripheral branches of the main trunk become apparent from 7 to 9 weeks pc, and anastomoses with branches of the trigeminal nerve develop and become extensive from 10 to 15 weeks pc. From about 9 to 14 weeks pc, the parotid gland progressively grows around the facial nerve, completely engulfing it (Espin-Ferra, 1991). The definitive communications of the facial nerve are established by 16 weeks pc.

Studies using mice with deletions of genes coding neurotrophin-4 (NT-4) and brain-derived neurotrophic factor (BDNF) have demonstrated that sensory nerve cells of the geniculate and nodose-petrosal ganglia are particularly sensitive to NT-4 deficiency, whereas facial motorneurons and superior cervical sympathetic ganglion cells are unaffected. Cells of the vestibular, geniculate, and nodose-petrosal ganglia are depleted in *bdnf*$^{-/-}$ homozygotes, whereas facial motorneurons are unaffected (Liu *et al.*, 1995).

Inner Ear and Vestibulocochlear Nerve

By day 32 of development, the otocyst lies alongside the fifth and sixth rhombomeres of the developing brain stem and the endolymphatic appendage is already set apart from the developing utricle by a fold (Bruska and Wozniak, 1994). Within a day or two, the otocyst can be seen to be divided into several pouches. A dorsal pouch represents the endolymphatic duct and site of development of the semicircular ducts, whereas a ventral pouch gives rise to the primitive cochlear duct. At about 32 days pc, the vestibulocochlear and geniculate ganglia form a common complex surrounded by a mesenchymal capsule, although three distinct ganglionic components are visible in this mass at this stage. Branches of the vestibular ganglion penetrate the otic epithelium at day 33 to form ampullary nerves, whereas the central axons of vestibular ganglion cells enter the brain stem at about the same time. The cochlear ganglion lies rostrally and medially to the vestibular ganglion and is slightly less advanced in development than the trigeminal, geniculate, and vestibular ganglia. It contributes centrally directed axons to enter the brain stem at about 37–40 days pc. The cochlea starts to curl by 6 weeks pc, reaching its full morphological development (3 mm diameter and 2.5 turns) by 10 weeks pc and its final adult size by 20 weeks pc (Lecanuet and Schaal, 1996). The organ of Corti develops in the cochlea from about 8 weeks pc, and both inner and outer hair cells can be seen by 11 weeks pc. Final cell positioning on the basilar membrane is reached by 14 weeks pc (Lecanuet and Schaal, 1996). Based on purely morphological criteria, the vestibular apparatus is considered mature by 14 weeks pc (Lecanuet and Schaal, 1996).

In the absence of tracing studies, the olivocochlear system in humans has been identified using immunoreactivity to choline acetyltransferase (ChAT) and CGRP, both of which label central neurons as well as efferents in the organ of Corti. By 21 and 22 weeks pc, ChAT immunoreactivity is visible in neurons of the dorsal and ventral periolivary region, although neurons of the medial and lateral superior olivary nuclei are still of immature appearance in Nissl stains made at this age. Neurons immunoreactive for ChAT become more dispersed as prenatal development proceeds. Neurons immunoreactive for CGRP are visible from 21 weeks pc and increase steadily from a population of about 300 at 21 weeks pc to a plateau population size of about 620 during the period from 24 weeks pc to 6 months after birth (Moore *et al.*, 1999).

Glossopharyngeal Nerve

Nerve branches from the inferior ganglion of the glossopharyngeal nerve to the aortic arches have been identified in 9- to 11-mm-long embryos (about 5 weeks pc; Golub *et al.*, 1979). The first glossopharyngeal nerve fibers growing into the third aortic arch (future carotid sinus) are also seen at this stage, and these fibers precede both vagal and sympathetic nerves in the innervation of the primitive vascular tree in this region.

The lingual branch of the glossopharyngeal nerve enters the tongue concurrently with the lingual and hypoglossal nerves and can be identified as early as 40 days (Vij and Kanagasuntheram, 1972). Glomus-like collections of cells resembling taste buds can be first observed at about 55–60 days pc and nerve fibers can first be demonstrated among these cells at this stage.

Vagus and Spinal Accessory Nerves

The developing nucleus ambiguus makes contributions to the developing glossopharyngeal and vagal nerves as early as 28–30 days pc (Brown, 1990). Functional development of visceral reflexes associated with the vagus have been correlated with maturation of nucleus ambiguus neurons. As noted above, the earliest overt evidence of swallowing in the human fetus has been reported in response to perioral stimulation at 10.5 weeks pc (Brown, 1990), whereas at 12.5 weeks pc swallowing is a consistent consequence of perioral stimulation (Humphrey, 1968). By 10.5 weeks pc, subnuclear groupings have begun to appear in the nucleus ambiguus, and these neurons are well differentiated by 12.5 weeks pc (Brown, 1990).

The ganglia of the vagus nerve are already delineated in human embryos of 4 mm length (approximately 30 days pc) and they form a common ganglionic mass up to 5 weeks pc (Streeter, 1905, 1908). By 6 weeks pc, vagal trunks have reached the walls of the stomach and a branch from the posterior trunk has reached the celiac plexus (Wozniak *et al.*, 1979). Ultrastructural studies of differentiation of fetal sensory nerve cells in the human inferior vagal ganglion have shown that there is a transition from the immature apolar and bipolar ganglion cells to unipolar type at about 8–10 weeks pc

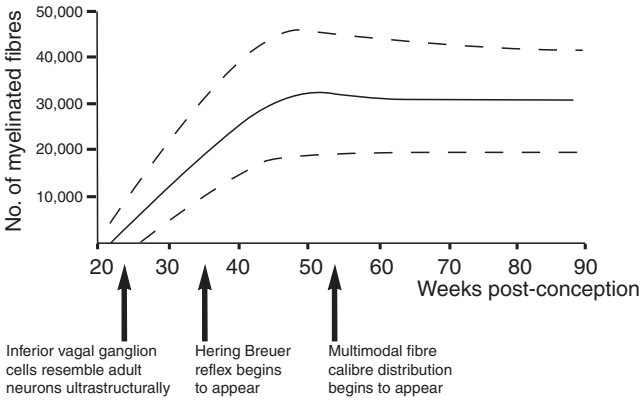

FIGURE 4.4 Significant events in the development of the human vagus nerve. Data for graph of number of myelinated vagal fibers against postconceptional age taken from Sachis *et al.* (1982). Note the large range in values for number of myelinated fibers indicating significant variation between individual fetuses and neonates.

(Bruska and Wozniak, 1980). Ultrastructurally, inferior vagal ganglion cells resemble adult cells by about 23 weeks pc.

The importance of the vagus in carrying information vital to pulmonary reflexes has prompted several studies of development of that nerve. Myelination of the human vagus nerve begins between 14 and 17 weeks pc (Wozniak and O'Rahilly, 1981). Total numbers of myelinated fibers in the vagus increase linearly from about 5000 at 26 weeks pc to as many as 40,000, the adult value, at 10 weeks after birth (Sachis *et al.*, 1982) (Fig. 4.4). Immaturity of the vagus may be responsible for the unstable breathing patterns in preterm infants. Indeed, the Hering–Breuer inspiration-inhibiting reflex, which is mediated by large myelinated vagus fibers, is reported to be weak in infants of 32 weeks pc but increases in strength until 38 weeks pc (Bodegard *et al.*, 1969). After birth, the number of myelinated axons in the vagus remains fairly constant (Sachis *et al.*, 1982), and a multimodal distribution of fiber size begins to appear at about 3 months after birth (Pereyra *et al.*, 1992). Delayed maturation of the vagus nerve has been claimed to be present in infants dying from sudden infant death syndrome, with affected infants having more small (<1.5 μm diameter) and fewer larger (>2.0 μm diameter) axons (Becker *et al.*, 1993).

Vagal innervation of human fetal viscera has received some attention, although a full dataset is not yet available. Palatine and pharyngeal muscles begin to appear at about 5–6 weeks pc and receive their innervation (from trigeminal, glossopharyngeal, and vagal nerves) from about 8 weeks pc (Doménech-Ratto, 1977). In the developing larynx (Müller *et al.*, 1981, 1985), the adult pattern of motor innervation is present from stage 23 (about 52 days pc) although sensory innervation is not complete at this stage. Leonard *et al.* (1983) have suggested that mechanical support from the left vagus and left recurrent laryngeal nerve during development ensures that the ductus arteriosus differentiates as a muscular artery, although this vessel will obliterate its lumen in early postnatal life. Inferior vagal ganglion cells can be retrogradely labeled by carbocyanine dye insertion into the pylorus from 12 weeks pc (Abel *et al.*, 1998), but see below for development of the gastric enteric plexus.

The spinal accessory nucleus is already present at about 30 days pc as a group of cells lying in the dorsolateral part of the ventral horn of the upper four to six cervical segments (Pearson, 1938; Skórzewska *et al.*, 1994a, b). At no stage during development does the spinal accessory nucleus show any continuity with the nucleus ambiguus. Several rootlets leave the nucleus, ascending on the dorsolateral surface of the spinal cord forming the spinal accessory nerve (Pearson, 1938), which ascends to join the vagus nerve at the level of the superior vagal ganglion. By 41 days pc, the external branch of accessory gives off secondary branches to supply the differentiating trapezius and sternomastoid muscles (Skórzewska *et al.*, 1994b).

Hypoglossal Nerve

The hypoglossal nucleus appears at approximately 26 days pc (O'Rahilly and Müller, 1984). Hypoglossal nerve roots emerge at about 28 days and form a hypoglossal nerve at about 32 days. The hypoglossal nerve reaches the tongue muscles by 37 days and the ansa cervicalis becomes apparent at 41 days. Further subdivisions of the hypoglossal nerve in the tongue are apparent by about 50 days, and at this time the fine terminations of the nerve approach close to the epithelium (Vij and Kanagasuntheram, 1972). No data are currently available concerning the later development of the hypoglossal nerve, although it is known that natural neuronal death in the hypoglossal nucleus occurs between about 15 and 25 weeks pc (Nara *et al.*, 1989; Milutinovic *et al.*, 1992).

SOMATIC PERIPHERAL NERVOUS SYSTEM

Dorsal Root Ganglia

Dorsal root ganglion cells develop in the human embryo at about 4 weeks pc and immediately begin to migrate ventrally, so that they come to lie within the intervertebral foramina during the seventh week and are surrounded by dural sleeves during the eighth week

of gestation (Sensenig, 1957). Ultrastructural studies of fetal human dorsal root ganglia have reported no significant morphological differences related to segmental level. In other words, the cellular types and sequence of differentiation are similar in cervical, thoracic, and lumbosacral segmental levels. In 6- to 7-week pc embryos, dorsal root ganglia are composed of loosely packed and randomly oriented cells with wide intercellular spaces and scattered processes (Olszewska *et al.*, 1979). Most cells at this stage are apolar, undifferentiated neuroblasts. Early bipolar neurons begin to appear during the seventh and eighth weeks pc. These cells are oval, with processes arising from each end. There has been an increase in cytoplasm and proliferation of organelles compared to the apolar type. Evidence of apoptosis in the form of oval cells with electron dense pyknotic nuclei is seen in dorsal root ganglia at about the eighth week. Intermediate bipolar neurons, with prominent development of rough endoplasmic reticulum, begin to appear at 9–10 weeks pc, while unipolar neurons, which have well-developed organelles and a single broad process arising form one pole, appear at about 11 weeks pc (Olszewska, 1979). The appearance of unipolar neurons correlates with the onset of reflex responsiveness from the skin of the upper limb (Hooker, 1942); signifying that both central and peripheral processes of a significant proportion of these cells have reached their appropriate target structures.

Studies of the development of proteins, growth factors, and biochemical markers within human dorsal root ganglion cells have shown that biochemical maturation coincides closely with the sequence of ultrastructural maturation summarized above. Both high molecular weight neurofilament protein and vimentin are present in dorsal root ganglion cells at 6 weeks pc (Lukás *et al.*, 1993; Almqvist *et al.*, 1994). Immunoreactivity for vimentin declines in ganglion cells but increases with age in differentiating satellite cells. Immunoreactivity for neuron-specific enolase, a neuron-specific enzyme that is useful as a marker of neuronal differentiation, develops in dorsal root ganglion cells at about the same time (7 weeks pc) as its appearance in the spinal cord (Kato and Takashima, 1994). Immunoreactivity for somatostatin begins to appear in a few dorsal root ganglion cells at 9 weeks pc (Charnay *et al.*, 1987; Marti *et al.*, 1987) and remains stable in terms of number of immunoreactive neurons throughout fetal life. Somatostatin-immunoreactive processes in the dorsal horn of the spinal cord appear at 9 weeks pc, increase in number and density during the period from 12 to 28 weeks pc, and remain stable from 36 weeks pc to 4 months after birth (Charnay *et al.*, 1987). Immunoreactivity for the low-affinity nerve growth factor receptor (NGFr) also appears at about 9 weeks pc in larger ganglion cells, and immunoreactive fibers appear in the medial dorsal horn between 12 and 20 weeks pc (Suburo *et al.*, 1992). Both of these immunoreactivities are absent in the adult. Immunoreactivity for NGFr in the lateral and superficial parts of the dorsal horn appears at 14 weeks pc and, unlike the immunoreactivity in the medial dorsal horn, remains present until adult life (Suburo *et al.*, 1992). Immunoreactivity for enkephalin and CGRP appears in dorsal root ganglia somata at 14 weeks pc, whereas galanin and SP immunoreactivity do not appear in dorsal root ganglia somata until 24 weeks pc (Marti *et al.*, 1987). There is a pronounced increase in the number and intensity of CGRP-, galanin-, somatostatin-, and SP-immunoreactive fibers in the dorsal horn around the time of birth. In rodents this has also been found to coincide with the earliest appearance of these markers in sensory fibers in the epidermis (Marti *et al.*, 1987), but this has not been investigated in human fetuses.

Development of Peripheral Somatic Nerves

The human upper limb bud appears at about 30 days pc and formation of the brachial plexus is evident from about 34–35 days (O'Rahilly and Gardner, 1975; Shinohara *et al.*, 1990; see Fig. 4.5). At between 38 and 40 days, the major branches of the brachial plexus are visible, and median, radial, and ulnar nerves enter the hand plate. By about 46–48 days all the upper limb nerves can be seen to have already adopted an orientation and arrangement similar to those seen in the adult. This is in agreement with findings that movements of the human upper limb can be observed at about 20–23 mm crown rump length (approximately 48–50 days postconception) (Windle and Fitzgerald, 1937; Fitzgerald and Windle, 1942).

Hindlimb bud development and innervation occur slightly later. Ultrastructural studies (Davison *et al.*, 1973; Fidzianska, 1976) of the sciatic nerve have shown that initially (9–11 weeks pc) the human fetal sciatic nerve is formed of fascicles of unmyelinated fibers surrounded by an epineurium of collagen and fibroblasts. At this stage some, but certainly not all, fascicles are surrounded by Schwann cell processes. Between 12 and 17 weeks pc, there is a marked increase in the number of Schwann cells, so that by the end of this period there are a few instances of one axon to one Schwann cell. The 18th week of gestation is marked by loose spiraling of the mesaxon around the axon within a Schwann cell (i.e., the beginnings of myelination), and by 23 weeks pc most Schwann cells are associated with only one axon (Davison *et al.*, 1973). The period from 17 to 20 weeks pc also sees the appearance of

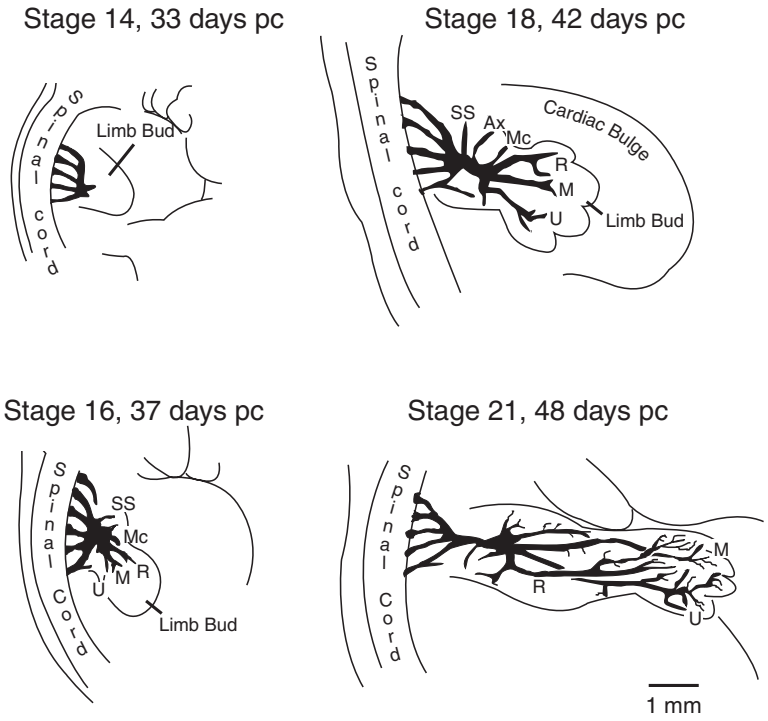

FIGURE 4.5 Development of the brachial plexus in human embryos. Note the early appearance of major nerve branches (by stage 16) and their substantial elaboration by stage 21. Ax, axillary nerve; M, median nerve; Mc, musculocutaneous nerve; R, radial nerve; SS, subscapular nerve; U, ulnar nerve. All figures have been drawn to the same scale.

lecithin, cerebrosides, sulfatides, and other lipids in the developing sciatic nerve (Davison *et al.*, 1973). As in other mammals, fetal human sciatic nerve axons show prominent beading or varicosities along their length, which may be partly artifactual, but may nevertheless reflect particular vulnerability of fetal nerve fibers (Tomé *et al.*, 1988). The fetal human sural nerve shows a similar time course of myelination to that seen in the sciatic nerve, with no myelinated fibers visible at 16 weeks pc but well-myelinated fibers plentiful by 21 weeks pc (Shield *et al.*, 1986).

The development of receptors for the somatosensory system appears to follow a rough rostrocaudal/distal-to-proximal pattern (Fig. 4.6). Free nerve endings can be found in the mouth and peribuccal region as early as 8–9 weeks pc (Lecanuet and Schaal, 1996), whereas Meissner and Pacinian corpuscles develop soon after. Tactile receptors may be seen in the face, palms, and soles of the feet by 11 weeks pc, and on the trunk and proximal zones of the arms and legs by 15 weeks. Their initial density, especially of the less differentiated free nerve ending type, is greater than in the adult, suggesting some early exuberance.

Electron microscopic studies of the human fetal phrenic nerve have shown that axons in this nerve begin to undergo myelination at about 15 weeks pc (Wozniak *et al.*, 1982) compared with 12 weeks pc for trigeminal nerve (Bruska and Wozniak, 1991). Compact myelin is apparent by 17 weeks pc, and although the phrenic nerve has a mature form by 23 weeks pc, many fibers are still in the process of myelinating at this age. Communications between the celiac plexus and the right phrenic nerve have also been seen in fetal material (Pearson and Sauter, 1971), and this may have considerable clinical significance for referred pain from foregut-derived structures.

Functional studies of peripheral nerves in very preterm infants indicate that motor nerve conduction velocity in both tibial and ulnar nerves increases steadily from about 10 m/s at 26 weeks pc to about 25 m/s at term (Smit *et al.*, 1999).

AUTONOMIC AND ENTERIC NERVOUS SYSTEM

Sympathetic Trunk and Sympathetic Outflow to Head and Limbs

The first visible anlage of the sympathetic trunk in the human fetus appears near the aorta in the thoracic and lower cervical region (late 4 weeks pc; Lutz, 1968).

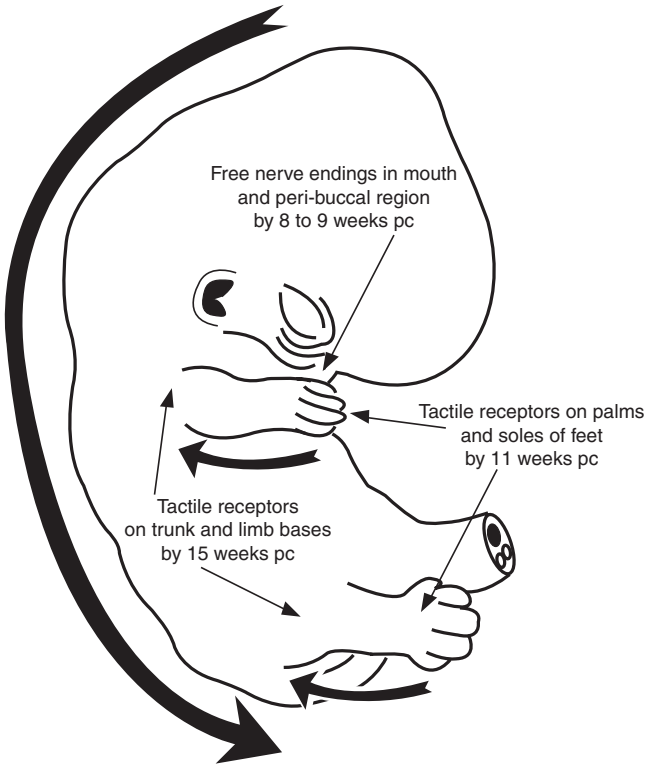

FIGURE 4.6 Schematic representation of development of tactile receptors in the human embryo and early fetus. Thick arrows indicate temporospatial gradients of receptor development. See text for citations.

Later in development (middle of fifth week pc), the sympathetic trunk extends to the base of the skull and segmentation appears in parallel with the longitudinal growth of the vertebral column.

Development of human sympathetic ganglion cells has been followed in a light and electron microscopic study of the human fetal superior cervical ganglion (Hervonen and Kanerva, 1972). Superior cervical ganglion neuroblasts already contain catecholamine at 12 weeks pc. Primitive sympathetic cells are characterized by their dark chromatin, in contrast to the larger and paler nuclei of more mature neuroblasts. At the electron microscope level, primitive sympathetic cells show a strong rim of condensed chromatin inside the nuclear membrane, do not have nucleoli, and possess scant cytoplasm.

Innervation of structures by branches of the cervical sympathetic trunk has been followed by some authors. Sympathetic nerve innervation of the area around the carotid sinus develops later than the glossopharyngeal and vagal innervation of this region. Thin fiber bundles from the anterior surface of the superior cervical ganglion reach the root of the internal carotid artery by 6 weeks pc (Golub *et al.*, 1979). Similarly, sympathetic innervation of the internal carotid plexus does not develop until late in the sixth week pc to early seventh week pc, although branches from cranial nerves are already present by early sixth week pc (Golub *et al.*, 1979).

At more caudal levels, sympathetic outflow from lumbosacral sympathetic trunk to the sciatic nerve first appears between 18 and 21 weeks pc (Koistinaho, 1991). These nerves are distributed from the outset to both epiperineurial blood vessels and to the endoneurium itself, not related to blood vessels.

Adrenal Medulla and Paraganglia

Formaldehyde-induced fluorescence of adrenal medullary cells can be demonstrated as early as 9 weeks pc (Hervonen, 1971). The number of medullary cells increases rapidly between 9 and 13 weeks pc, and fine nerve fibers are found adjacent to catecholamine-storing cells by 12 weeks pc. Ultrastructurally, the fetal adrenal medullary cells contain only the noradrenaline type of catecholamine granules until 16 weeks pc, but after that age adrenaline-type granules are also found. Synaptic contacts between preganglionic axons and catecholamine-storing cells are morphologically mature by 14 weeks pc.

Formaldehyde-induced fluorescence can be detected in paraganglia by about 8–9 weeks pc (Hervonen, 1971), but invasion of the paraganglia by nerve fibers from the sympathetic trunk does not occur until after 12 weeks pc.

Cardiac Innervation and Conducting System

Innervation of the coronary arteries begins before 8 weeks pc, by which stage both the aorta and pulmonary artery are surrounded by five or six small nerve fascicles (Smith, 1970). At about 8–9 weeks pc, an adventitial plexus of small nerve bundles is associated with both coronary arteries and their main branches. Myelination of the cardiac plexus and invasion of the adventitia by a fine plexus of nerves occurs by 120 mm crown–rump length.

Intrinsic cardiac autonomic ganglion cells are believed to migrate along the vagus nerve into the developing heart and appear as early as 6–7 weeks pc in the atrial wall (Smith, 1971a). Intrinsic ganglion cells showing mature morphological features are seen by about 16 weeks pc, although many presumably immature (binucleate) cells persist at this age. The number of binucleate cells declines between midgestation and term. By the time of birth, ganglia form an apron across the atrioventricular groove of the heart, extending onto the superior ventricular surface and up the pulmonary trunk and aorta (Smith, 1971b).

The conducting system of the fetal heart is present by 8 weeks pc (Gardner and O'Rahilly, 1976). Synaptogenesis of cardiac ganglion cells initially occurs at about the fifth week of gestation, although well-developed synapses with many synaptic vesicles cannot be seen until the eighth week of gestation (Shvalev and Sosunov, 1989; Shvalev *et al.*, 1992).

The development of peptidergic innervation of the human fetal heart has been investigated by Gordon *et al.* (1993). Those authors found that peptide-immunoreactive nerves cannot be identified in the heart until 10 weeks pc. The first identified and most prevalent nerves in the fetal heart were neuropeptide Y (NPY)–immunoreactive fibers. These fibers showed a descending atrial-to-ventricular density gradient. Somatostatin and vasoactive intestinal peptide (VIP) first appear at 10–12 weeks pc and are mainly distributed in the atria. Somatostatin immunoreactivity is found in cell bodies in the cardiac ganglia, whereas VIP- and NPY-immunoreactive fibers appear to be of extrinsic origin. Innervation by CGRP- and SP-immunoreactive fibers does not occur until late in gestation (18–24 weeks pc), suggesting that sensory innervation does not occur until at least 6 weeks after autonomic supply develops. Studies of the development of CGRP- and SP-immunoreactive fibers in autonomic regions of the spinal cord show that both of these immunoreactive sensory fibers appear at about 24 weeks pc (Marti *et al.*, 1987).

Early functional studies of the human fetal heart have used electrical stimulation to stimulate release of autonomic transmitters such as acetylcholine and noradrenaline (Walker, 1975). Electrical stimulation was found to have no effect on the human fetal heart prior to 13 weeks pc, suggesting that autonomic nerves are too immature to release neurotransmitter at this stage. After 13 weeks, responses to electrical stimulation are blocked by tetrodotoxin, indicating that the responses are indeed due to neurotransmitter release. Other studies have shown that fetal myocardium possesses intrinsic pacemaker activity not seen in adult myocardium (Coltart *et al.*, 1971). Human fetal myocardium also appears to be less sensitive to cholinergic and adrenergic agents than adult myocardium.

Later studies of isolated fetal hearts (reviewed in Papp, 1988) showed that muscarinic cholinergic responses to acetylcholine can be detected from 4 weeks pc, i.e., soon after the initiation of the first heartbeats. Similarly, β-adrenergic responsiveness to noradrenaline, adrenaline, and other adrenergic stimulants appears slightly later (at 5–8 weeks pc; Gennser and Nilsson, 1970). It appears that the parasympathetic–cholinergic control of the developing heart becomes functional (15–17 weeks pc) before the sympathetic–adrenergic neural control (23–28 weeks pc). At first, adrenergic regulation of the heart is achieved by action of paraaortic chromaffin tissues (at 9–11 weeks pc; Phillippe, 1983), prior to sympathetic neural control. Furthermore, the cooperative action of the adrenal medulla does not become effective until later in fetal life.

Studies of intact "whole body" cardiovascular function among human fetuses have been undertaken using ultrasound techniques (DiPietro *et al.*, 1996). Fetal heart rates slow with increasing gestation, going from an average of 146.8 beats/min at 20 weeks pc to 140.0 beats/min at term. With increased gestational age there is also increased heart rate variability, coalescence of heart rate and movement patterns into distinct behavioral states, and increased responsiveness of heart rate to sensory stimulation. Power spectral analysis of human fetal heart rate (see Segar, 1997 for detailed review) indicates an increase in parasympathetic contribution to the control of resting fetal heart rate with maturation.

Enteric Nervous System

There have only been a few studies of development of the human enteric nervous system. In a study of the development of innervation of the human stomach, Abel *et al.* (1998) found that expression of neurotransmitters in the pylorus progressed from the adventitia toward the mucosa. Nerve fibers immunoreactive for PGP 9.5, a neuronal protein and marker of fine axons, and SP were found in the adventitia from 8 weeks pc, whereas VIP and neuronal nitric oxide synthase (nNOS) were not expressed until 11 and 13 weeks pc, respectively. In the mucosa and submucosa, SP, VIP, and nNOS appear somewhat later, with SP first detected in the submucosa at 11 weeks pc and mucosa at 23 weeks pc, VIP first detected in the submucosa at 12 weeks pc, and nNOS first detected in the mucosa at 15 weeks pc (Abel *et al.*, 1998). Those authors also reported a craniocaudal pattern of expression in the muscular layer, with the highest concentrations of peptides and nerve protein markers found toward the duodenum. An adult-like profile of innervation and expression of these markers was not attained until 23 weeks pc.

Pelvic Viscera Innervation

The pelvic plexus is first seen at about the middle of the seventh gestational week (Slabikowski *et al.*, 1996) as a group of nerve fibers and cells surrounding the rectum and genitourinary sinus. Pelvic splanchnic nerves arising from the second to fourth sacral segments appear coincidentally with the pelvic plexus.

The pelvic plexus forms a large plate lying on the lateral side of the rectum and genitourinary sinus and behind the bladder. Secondary plexuses (uterovaginal in females and inferior vesical in males) develop over the next 2 weeks. Sacral splanchnic nerves arising from the sympathetic trunk contribute to the pelvic plexus as early as 41 days pc.

Studies of the innervation of abdominal and pelvic organs in human fetuses have shown that the peripheral autonomic plexuses are diffusely ganglionated and that distinct nerves directed to certain organs cannot be identified (Baljet and Drukker, 1981). The peripheral distribution of the autonomic nervous system appears to be organized according to regions rather than specific organs. This means that within a given region individual organs will share their supply from a diverse autonomic plexus.

Cholinergic receptors in the detrusor muscle of the human urinary bladder appear quite early in fetal life (about 13 weeks pc), and slightly later in the sphincter vesicae (17–18 weeks pc) (Mitolo-Chieppa *et al.*, 1983). Spontaneous motility of the urinary bladder is quite high between 14 and 18 weeks pc and is progressively reduced to negligible levels by the end of the second trimester. Nerves immunoreactive for NPY form a dense plexus throughout the detrusor muscle coat by 17 weeks pc (Jen *et al.*, 1995a). Tyrosine hydroxylase and dopamine β-hydroxylase–immunoreactive fibers, indicative of sympathetic innervation, are first seen in the intramural portions of the ureters at 30 weeks pc and the detrusor muscle at 35 weeks pc (Jen *et al.*, 1995a). Sensory fibers, as revealed by staining for PGP 9.5, are first seen beneath the urinary bladder epithelium at 23 weeks pc. Responsiveness of the detrusor muscle to noradrenaline does not appear until the end of the second trimester, at which time noradrenaline begins to have contractile effects on the sphincter vesicae. Presumptive noradrenergic nerves appear relatively late in prenatal life and mainly supply the intramural ureters and superficial trigone (35 weeks pc; Jen *et al.*, 1995a).

In the developing male reproductive organs (Jen *et al.*, 1995b; Dixon and Jen, 1995), NOS-immunoreactive nerve fibers could be found in the prostate as early as 13 weeks pc, but NOS-immunoreactive fibers cannot be detected in the muscle coat of the ductus deferens and seminal vesicle until 23 weeks pc. Even at 30 weeks pc, they still form only a small proportion of intramuscular fibers in the seminal vesicle and ductus deferens. On the other hand, NOS-immunoreactive fibers contribute to the submucosal plexus of the bladder from 23 weeks pc. Those authors concluded that although NO may have an increasingly important role in the autonomic control of the lower urinary tract during fetal development, its involvement in the functional control of the fetal ductus deferens and seminal vesicle is probably minor. Studies of immunoreactivity to tyrosine hydroxylase, NPY, and enkephalin have shown that most intramuscular fibers in the fetal seminal vesicle and ductus deferens are noradrenergic in type (Jen *et al.*, 1995b). A subepithelial plexus developing in the ductus and seminal vesicle around 20 weeks pc contains abundant NPY, but not VIP, unlike the adult arrangement.

This chapter describes first the innervation of human muscle and then some features of muscle organization. Muscle is the largest sense organ in the body. It contains receptors responsive to mechanical deformation, to changes in temperature, to metabolites produced by muscle activity, and to injurious stimuli that evoke pain. In addition, the nerve to a muscle may carry the afferent innervation of the joints that the muscle crosses, of the underling bone and periosteum, and of any interosseous membrane. Of all the myelinated axons in a muscle nerve, less than 20% are motor axons from α motoneurons that innervate extrafusal muscle fibers and so produce muscle contraction (Barker, 1974; see also Shoenen and Faull, Chapter 7). Cutaneous receptors are not considered part of the motor system and therefore will not be discussed at length in this chapter, even though the feedback from cutaneous receptors may be as important as that from muscle receptors in the control of movement, particularly for the upper limb. A comprehensive description of cutaneous receptors and the central somatosensory system is given by Kaas (Chapter 28).

COMPOSITION OF MUSCLE NERVES

Lloyd and Chang (1948) classified the afferent fibers coming from feline muscles into four groups based on fiber size (Table 5.1): group I, large myelinated afferents, 12–20 μm in diameter (conduction velocity range 72–120 m/s); group II, medium-sized, 6–12 μm (36–72 m/s); group III, small 1–6 μm (6–36 m/s); and group IV, unmyelinated, approximately 1 μm (0.5–2 m/s). On the assumption of a linear relationship between size and conduction velocity for myelinated axons (constant: 6; Hursh, 1939), the conduction velocities given in parentheses above are widely used to identify the group to which a particular myelinated afferent belongs. However, many workers have questioned the generality of a single scaling factor, and Boyd and Kalu (1979) recommended 5.7 for group I afferents and 4.6 for groups II and III in the cat.

The situation is further complicated by the adoption of a different size-based nomenclature for cutaneous afferents, namely, Aβ and Aδ for myelinated afferents (from mainly tactile mechanoreceptors, and from cold receptors and nociceptors, respectively) and C for unmyelinated afferents (mainly from warmth receptors and nociceptors). In the cat, the largest cutaneous afferents have conduction velocities that overlap the group II muscle afferent range. Because the threshold for activation of an afferent by an external electrical

TABLE 5.1 Afferent Nerve Fiber: Function Correlations in the Cat

Afferent	Size (μm)	Conduction velocity (m/s)	Receptor
Ia Ib	12–20	72–120	Primary spindle endings; Golgi tendon organs
II	6–12	36–72	Secondary spindle endings; Pacinian/Paciniform corpuscles; free nerve endings
III	1–6	6–36	Pacinian/Paciniform corpuscles; free nerve endings
IV	1[a]	0.5–2	Free nerve endings

[a]Unmyelinated nerve fiber.

Note that conduction velocities for comparable afferent classes are slower in human than cat axons.

TABLE 5.2 Efferent Nerve Fiber: Function Correlations in the Cat

Efferent	Size (μm)	Conduction velocity (m/s)	Function
α	10–20	55–110	Skeletomotor
β	10–20	55–110	Skeletofusimotor
γ	2–8	<50	Fusimotor
Sympathetic	1[a]	0.5–2	Vasculature

[a]Unmyelinated nerve fiber.

Note that conduction velocities for α axons are slower in humans than in the cat.

stimulus depends on axonal diameter, it is possible in the cat to activate group I afferents selectively with weak stimuli delivered to a muscle nerve or to a mixed nerve that innervates skin and muscle.

There are limited data for human muscle afferents. However, certain cutaneous nerves can be biopsied in humans producing only minor and usually transient deficits; therefore, more data are available for human cutaneous afferents. In the radial nerve, histograms of the sizes of myelinated cutaneous afferents have clear peaks at 4–5 and 10.5–12 μm, with the largest fibers 14.0–16.0 μm in diameter (O'Sullivan and Swallow, 1968; Tackmann *et al.*, 1976). The ratio of conduction velocity to axonal diameter is 4.67 for the fastest axons (Tackmann *et al.*, 1976). A comparable bimodal distribution is seen in histograms of myelinated fiber size for cutaneous afferents in the sural nerve: peaks at 3.5–4.5 and 9.0–11.5 μm, with the largest fibers 12.5–15.0 μm in diameter (Swallow, 1966), and with a velocity: diameter ratio of 4.55 (Tackmann *et al.*, 1976).

In biopsied human spindle preparations, Swash and Fox (1972) reported group I and II muscle afferents to be of comparable diameter to those measured at equivalent sites in the cat, but Cooper and Daniel (1963) considered them to be slightly smaller. However, measurements made on major stem axons before they taper are necessary to determine axonal size. This issue is of some importance because human group I afferents have slower conduction velocities than those of the cat, and equality of size would imply a different velocity: diameter ratio. For example, in the human upper limb, the fastest muscle afferents, presumably group I, have the same conduction velocity as the fastest cutaneous afferents, i.e., up to about 70 m/s (Gandevia *et al.*, 1984). In the human lower limb, the group I muscle afferents differ little in conduction velocity from the fastest cutaneous afferents (Burke *et al.*, 1981; Gandevia *et al.*, 1983; Macefield *et al.*, 1989; Shefner and Logigian, 1994). There are no data on the range of conduction velocities for the three groups of myelinated fibers or on the degree of overlap between groups, but it has been estimated that the fastest group II muscle afferents have conduction velocities of 45–50 m/s (Simonetta-Moreau *et al.*, 1999).

Unmyelinated group IV muscle affarents probably have the same velocities as unmyelinated sympathetic efferents, namely, 0.5–2 m/s. Given the longer conduction pathways and the slower afferent conduction velocities of myelinated fibers in humans, the role of afferent feedback in modulating movement may differ in cats and humans.

The efferent fibers in muscle nerve are conventionally divided into three groups based on size and function (Table 5.2): large myelinated α efferents from the α motoneurons in the anterior horn of the spinal cord, innervating the contractile bulk of the muscle (hence "skeletomotor," motor to skeletal muscle); small myelinated γ efferents from γ motoneurons, innervating the modified muscle fibers inside the muscle spindle (hence "fusimotor," motor to the fusiform receptor); and unmyelinated sympathetic efferents innervating intramuscular blood vessels. For α efferents, axonal size and conduction velocity are correlated with motoneuron properties (size, input resistance, and recruitment threshold) and with motor unit/muscle fiber properties (twitch time and strength, fatigability and histochemical profile), as detailed in "Features of Muscle" and "Muscle Units and Motor Units." In limb nerves of the cat, α efferents have diameters of approximately 10–20 μm and conduction velocities of 55–110 m/s. Few human α efferents conduct faster than 50–60 m/s, the values for the upper limb, generally being about 10 m/s faster than those for the lower limb, much as for afferent axons. Based on indirect estimates,

the majority of human α efferents conduct at a rate of over 80–85% of the maximal conduction speed. The slowest fibers may have velocities down to 60–65% of the maximum (Thomas *et al.*, 1959). Small myelinated γ efferents have diameters of approximately 2–8 μm and conduction velocities of less than 50 m/s in the cat. In humans, γ efferents are likely to conduct at less than 25–30 m/s. There is a further group of efferents, called β efferents, that innervate both the main contractile muscle (as do α efferents) and the muscle spindle (as do γ efferents). The size and conduction velocities of these β axons fall within the α range and their function is termed "skeletofusimotor." In biopsied human spindles, both large and small myelinated efferent fibers, presumably β and α axons, respectively, have been demonstrated entering the spindle (Swash and Fox, 1972).

MUSCLE RECEPTORS

The literature on mammalian muscle receptors is derived mainly from the cat, though there are some data for the muscle spindle and the Golgi tendon organ from nonhuman primates and humans. The most common receptor in muscle is the free nerve ending (Abrahams, 1986; Stacey, 1969). The most studied are the muscle spindle and tendon organs, although their afferents comprise only about 20% of the afferents coming from muscle. A number of other receptors occur in association with ligaments, joint capsules, and extramuscular tissue. With the exception of pacinian and paciniform corpuscles, discussed in "Pacinian and Paciniform Corpuscles," these extramuscular receptors will not be considered in this chapter because their physiological roles are, at present, uncertain. The interested reader should consult Barker (1974). Figures 5.1 illustrates the muscle receptors considered in this chapter and their innervation in cat muscle.

Muscle Spindle

More work has been done on muscle spindles than on any other muscle receptor. There are enough data for human and monkey spindles, not only to confirm the essential features found in the cat (see Barker, 1974; Barker and Banks, 1986; Boyd and Gladden, 1985; Cheney and Preston, 1976; Matthews, 1972) but also to establish differences. The reported differences include:

- The ratio of spindle length to muscle length is higher in cat than human spindles.
- There are more connective tissue connections between extrafusal muscle and human spindles.
- There are more intrafusal fibers in human spindles.
- The primary ending terminals on human chain fibers are scanty.
- There is nonselective γ innervation of intrafusal fibers in humans and monkeys.
- The unmyelinated terminal segment of human and monkey γ efferents is longer than in the cat.
- Afferent and efferent axons may be of similar sizes, but conduction velocities are slower for human axons.

However, the structure and function of the spindle have been a subject of debate since spindles were first recognized over 100 years ago, and such is the changing state of knowledge (see Barker and Banks, 1986; Boyd and Gladden, 1985) that older texts may contain inaccuracies.

As in the cat (Fig. 5.1), the human muscle spindle is a fusiform structure of some 7–10 mm in length, significantly shorter than the ordinary muscle fibers (so-called 'extrafusal' muscle fibers because they are outside the fusiform receptor), with which they lie in parallel. Human spindles are slightly larger than cat spindles (Cooper and Daniel, 1963) but, given the much greater size of human muscles, the relative size of human spindles is quite small, and direct or indirect attachment to extrafusal muscle rather than tendon must be more common. Human muscle spindles contain 2–14 "intrafusal" muscle fibers (Cooper and Daniel, 1963; Kennedy, 1970; Kucera and Dorovini-Zis, 1979; Swash and Fox, 1972), which is, on average, slightly more than in the cat. In the longest, the nuclei are clustered together at the equatorial region of the fibers (hence, nuclear bag fibers); in the shortest, the nuclei form a single chain along the middle portion of the fibers (hence, nuclear chain fibers). A lamellated fibrous capsule encloses the middle third of the spindle and has its greatest diameter (some 200–300 μm) at the equatorial region, where the capsule dilates to enclose a fusiform fluid-filled space (Fig. 5.1). The nuclear bag fibers and the long-chain fibers (if present) project from the capsular investment at the spindle poles before inserting onto extrafusal connective tissue, the endomysium of extrafusal fibers, or tendon. There are more connective tissue interconnections between human spindles and adjacent extrafusal muscle fibers than in cats, and occasionally the human spindle capsule encloses neighboring extrafusal fibers (Cooper and Daniel, 1963; Kennedy, 1970; Kucera and Dorovini-Zis, 1979; Sahgal and Subramani, 1986), a finding that would allow extrafusal contraction to affect muscle spindle activity more frequently than in the cat, a view

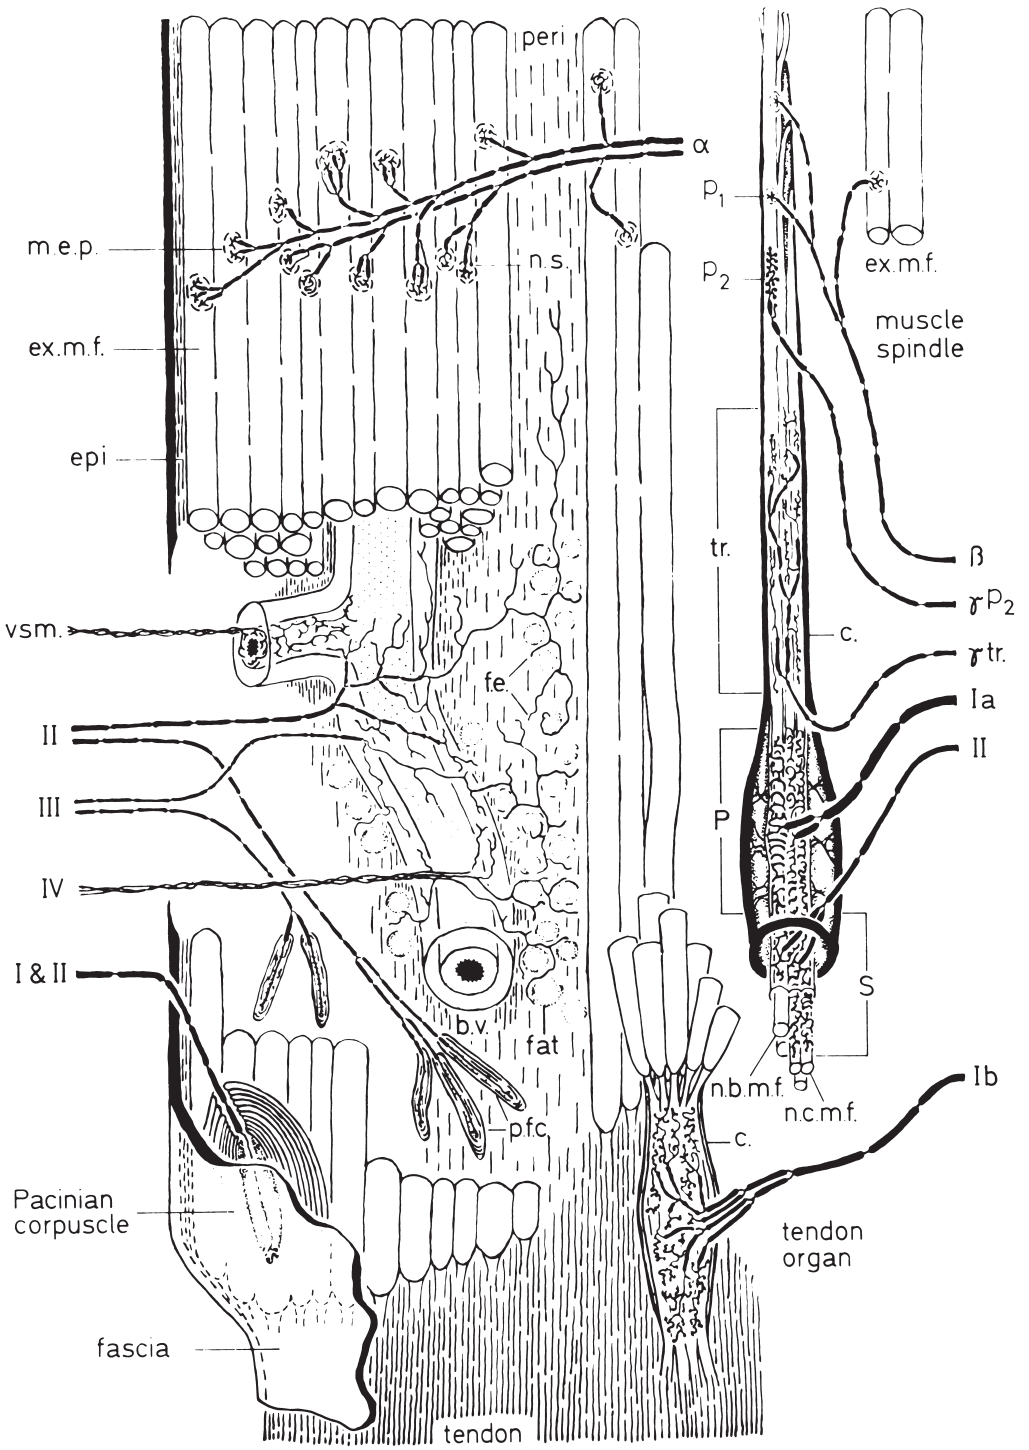

FIGURE 5.1 Innervation of mammalian skeletal muscle based on a study of cat hindlimb muscles. Those nerve fibers shown on the right of the diagram are exclusively concerned with muscle innervation; those on the left also take part in the innervation of other tissues. Roman numerals refer to the groups of myelinated (I, II, III) and nonmyelinated (IV) sensory fibers; Greek letters refer to motor fibers. The spindle pole is cut short to about half its length, and the extracapsular portion is omitted. for which there is physiological evidence (Burke *et al.*, 1987). In human muscles, it is common to find several spindles arranged in tandem, with nuclear bag fibers extending through both spindles, and there may be other complex forms such as two spindles sharing a common capsule (Cooper and Daniel, 1963; Kennedy, 1970; Swash and Fox, 1972).

Distribution

Virtually all human skeletal muscles contain spindles, except for facial muscles and the digastric, a jaw-opening muscle (Kubota and Masegi, 1977). Spindles are spread unevenly throughout both mono- and multiarticular muscles, following the distribution of the major intramuscular nerve branches (Barker and Chin, 1960; Swett and Eldred, 1960). In some cat muscles, more spindles are found along the line of pull of the tendon, in association with a greater concentration of slow-twitch motor units (Botterman *et al.*, 1978; see also Yellin, 1969). Small muscles tend to have shorter spindles; for example, 70% of spindles in the intrinsic muscles of the human hand (lumbricals) measure 1–3 mm (Voss, 1937). Because of their different anatomical locations, spindles in any one muscle are not subjected to an identical disturbance during active or passive movement, and each sends a slightly different message to the nervous system (Meyer-Lohman *et al.*, 1974; see also Binder and Stuart, 1980; Scott and Loeb, 1994). However, the summed activity of all spindles in a muscle reflects overall muscle length quite accurately, at least under passive conditions (Vallbo, 1974).

Spindle counts have been done for many human muscles (e.g., Voss, 1971). In absolute terms, counts range from less than 50 for some intrinsic muscles of the hand (Table 5.3) to 1350 for the quadriceps femoris. When muscle size is taken into account, spindle density is highest in the intrinsic muscles of the hand and muscles of the neck, and lowest in muscles of the thigh and shoulder. However, the functionally important expression of spindle numbers may be neither absolute count nor density. Larger muscles tend to have larger motor units. In view of suggestions that muscle spindles can act as monitors of the minute length changes produced by the activity of nearby motor units (for cats, Binder and Stuart, 1980; Windhorst, 1979; for humans, McKeon and Burke, 1983), a more appropriate scaling factor might be the number of motor units in the particular muscle. Table 5.3 shows that the number of muscle spindles per motor unit is not greater in the intrinsic muscles of the hand than in other limb muscles. This conclusion is consistent with the finding that kinesthetic acuity for passive movement detection (expressed in "muscle" terms) may be no greater for the distal joints of the hand than for the elbow joint (Hall and McCloskey, 1983; Refshauge *et al.*, 1995).

Intrafusal Muscle Fibers

Originally, only two types of intrafusal fiber (nuclear bag and nuclear chain) were recognized in cat and human spindles (cat, Barker, 1974; Matthews, 1972; human, Cooper and Daniel, 1963; Kennedy, 1970; Swash and Fox, 1972), but there is now anatomical and physiological evidence that there are two types of nuclear bag fiber in the cat (Baker and Banks, 1986; Boyd, 1986; Boyd and Gladden, 1985), and this has been confirmed anatomically for human spindles (Kucera and Dorovini-Zis, 1979). The bag_2 fiber tends to be thicker and longer, and to contain more nuclei than bag_1 fiber (Kucera and Dorovini-Zis, 1979). Other

TABLE 5.3 Counts for Human Muscles of Motor Units, Muscle Spindles, and Muscle Fibers[a]

Muscle	Motor units	Spindles	Spindles/motor unit	Muscle fiber/motor unit[b]
Biceps brachii	774	320	0.41	750 (209)
Brachioradialis	330	65	0.20	390
First dorsal interosseous	119	34	0.29	340
First lumbrical	98	53	0.54	110
Opponens pollicis	133	44	0.33	595
Masseter	1020	160	0.16	980
Temporalis	1150	217	0.19	1300
Medial gastrocnemius	580	80	0.14	1720
Tibialis anterior	445	284	0.64	610 (329)

[a]Data from Buchthal and Schmalbruch (1980) and Gath and Stålberg (1981).
[b]The values in parentheses for biceps brachii and tibialis anterior denote the estimated number of fibers per motor unit using direct electrophysiological (rather than anatomical) techniques.

ultrastructural features may help distinguish bag_1 and bag_2 fibers in cat (Gladden, 1976), monkey (Kucera, 1985a), and human spindles (Kucera and Dorovini-Zis, 1979), including the abundance of elastic fibers associated with bag_2 fibers and the scarcity with bag_1 fibers (Gladden, 1976). The three types of intrafusal fiber are also histochemically different and can be differentiated by the intensity of their staining for myosin ATPase, under acidic and alkaline conditions (Barker, 1974; Harriman *et al.*, 1974; Kucera and Dorovini-Zis, 1979; Ovalle and Smith, 1972).

Of the 2–14 intrafusal fibers in human muscle spindles, there are 1–4 nuclear bag fibers (always one or more bag fibers, usually one bag_1 fiber) of diameter 20–30 μm, and 3–10 nuclear chain fibers of diameter 9–12 μm. At the equator the diameter of intrafusal fibers decreases. The diameter of chain fibers becomes little more than that of a single nucleus and the myofibril content of the fibers is greatly reduced. the 50–100 nuclei in bag fibers extend over a length of 50–100 μm and, in human spindles, may be 5–6 abreast (Cooper and Daniel, 1963; Kennedy, 1970). The chain fibers contain a single strand of some 20–50 nuclei. For further morphological and for ultrastructural details the reader is referred to Kucera and Dorovini-Zis (1979) and Barker and Banks (1986). Physiological studies have shown that the dynamic response of deefferented spindle afferents comes from sensory endings on the bag_2 fiber and that static responses come from sensory endings on chain fibers (Boyd and Gladden, 1985; Proske *et al.*, 1991; Scott, 1991; see also Proske, 1997). However, the increase in the dynamic response to stretch produced by fusimotor action is mediated by activation of bag_1 fibers. The background firing rate of primary endings is controlled predominantly via the bag_2 fiber (Proske *et al.*, 1991).

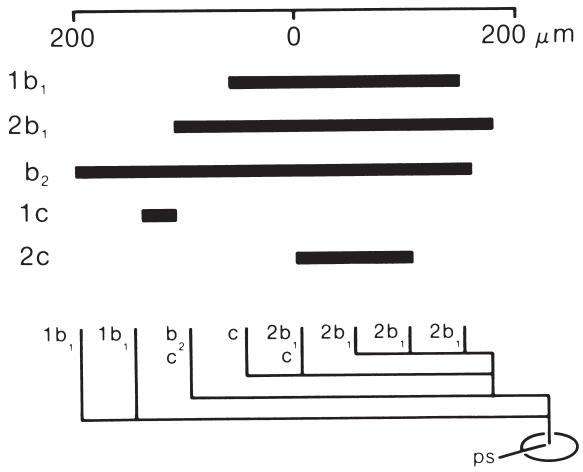

FIGURE 5.2 The extent of primary sensory contact areas *(solid horizontal bars)* for a human spindle containing two bag_1 (b_1), one bag_2 (b_2), and four chain (c) fibers. Distribution of the myelinated branches of a single Ia afferent fiber (ps) to the three types of intrafusal fiber is indicated. Reconstructed from serial, 1-μm-thick transverse sections stained with toluidine blue. Scale in micrometers, with the center of the equator at zero. Note that two of the four chain fibers received no primary ending terminals and that the contact area on bag fibers was much greater than for chain fibers. Reproduced with permission from Kucera (1986).

Sensory Innervation

Each muscle spindle receives one large myelinated (group Ia) afferent and 1–5 smaller myelinated (group II) afferents, forming a single nerve bundle that penetrates the capsule near the midequatorial region. The nerve bundle also contains some γ efferent axons which innervate the intrafusal muscle fibers. The group Ia afferent branches 2–4 times and becomes unmyelinated only 25–30 μm before its sensory terminals wrap around and indent the intrafusal fibers to form the primary ending (Kennedy *et al.*, 1975; Swash and Fox, 1972). In human but not in cat spindles, the primary ending formed by the Ia afferent is well developed only on nuclear bag fibers (Kucera, 1986; Swash and Fox, 1972). Figures 5.2 illustrates the extent of innervation by a group Ia afferent of a human muscle spindle containing seven intrafusal fibers (two bag_1, one bag_2, and four chain). The γ efferent innervation of this spindle is illustrated in Figure 5.3. Only two of the four chain fibers received Ia terminals, and the contact area between terminals and the chain fibers was much smaller than for the three bag fibers. In cat spindles, the primary ending formed by the Ia afferent classically resembles a tightly coiled spring with a number of spirals, but in human spindles there is only a single or double spiral (Swash and Fox, 1972), a number of loops instead of spirals (Kennedy, 1970), or an irregular coil with branches and varicose swellings (Cooper and Daniel, 1963; Kennedy *et al.*, 1975). The fine structure and microfilament content of the human primary ending have been described in detail by Kennedy and colleagues (1974, 1975). Local mechanical and electrical pacemaker interactions influence the output from primary spindle endings (e.g., Banks *et al.*, 1997).

Group II afferents innervate secondary endings located in the juxtaequatorial regions of predominantly the nuclear chain fibers, which are usually more extensively developed on one side of the equator. Spindles receive 1–5 group II afferents, although some human spindles appear to be devoid of secondary endings and group II innervation (Cooper and Daniel, 1963; Kucera, 1986; Swash and Fox, 1972). If there are two secondary endings on a chain fiber, they are usually

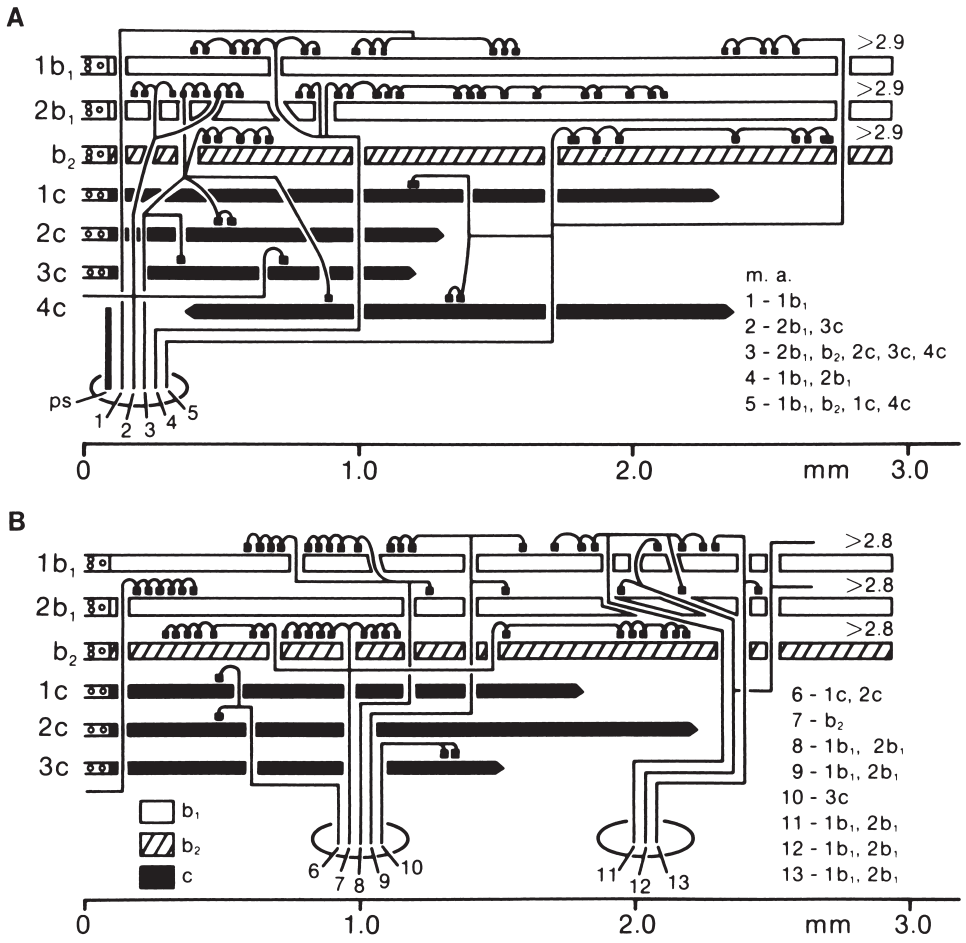

FIGURE 5.3 Representation of the nerve supply to the **(A)** proximal and **(B)** distal poles of the same human spindle as in Fig. 5.2. Equators of bag_1 (b_1), bag_2 (b_2), and chain (1*c*-4*c*) intrafusal fibers are shown on the left. Numbers at the ends of intrafusal fibers denote length of pole in millimeters. Thirteen motor axons (m. a.), all γ efferents, approached the spindle in three nerve bundles and branched to terminate in motor endings *(solid bars)* on the intrafusal fibers. The branching pattern of the single Ia afferent (ps) supplying the spindle is shown in Fig. 5.2. Reproduced with permission from Kucera (1986).

innervated by different group II afferents. Much as in the cat (Barker, 1974), secondary endings may be spiral, somewhat similar to the primary ending (Swash and fox, 1972), or have a classical "flower spray" appearance with interlacing varicose terminals (Kennedy, 1970; Swash and Fox, 1972).

Efferent Innervation

Much as in other mammals, human spindle endings are innervated by small thinly myelinated γ efferents, which enter the spindle in three discrete nerve bundles at the equatorial and midpolar positions (Kucera, 1986; Swash and Fox, 1972). There may be 8–15 γ efferents innervating any one spindle in the cat (Barker, 1974), monkey (Kucera, 1985a), or human subject (Kucera, 1986). The efferents typically lose their myelin sheath just prior to the motor ending in cat spindles, but at considerably greater distances, often several hundred micrometers, in human and monkey spindles (Kucera, 1985a, 1986). In addition, a thickly myelinated, presumably β-efferent axon may accompany the more profuse γ efferents (Swash and Fox, 1972). That γ efferents innervate only muscle spindles and are therefore exclusively fusimotor is well established. The full extent of β innervation of primate spindles has not yet been established. However, in the cat, physiological studies have demonstrated β innervation of 20–30% spindles (Emonet-Dénand *et al.*, 1980), with greater β innervation in small muscles where more than 50% of

spindles receive it (Jami *et al.*, 1982; McWilliam, 1975; Scott *et al.*, 1995).

There are no exclusively fusimotor efferents of α size (Ellaway *et al.*, 1972), suggesting that a large myelinated efferent entering a spindle is likely to be the fusimotor branch of a β (skeletofusimotor) efferent. In the monkey, Kucera (1985a) found that 4 whole spindles and 16 half-spindles (i.e., 24 spindle poles) from the lumbrical muscles were innervated by 37 γ axons and 18 β axons. It seems that whether a spindle receives β innervation depends on its location in the muscle: "the major determinant … may be proximity of the spindle to the innervation zone of extrafusal muscle fibers" (Kucera, 1985b), an association that is more likely to occur in small muscles.

In the cat, the fusimotor innervation of intrafusal muscle is reasonably selective. The γ efferents that innervate the bag_1 fiber rarely innervate bag_2 and chain fibers, and hence have a predominantly dynamic effect on the sensitivity of the primary ending (Boyd and Gladden, 1985). The γ efferents innervating bag_2 and chain fibers have a predominantly static γ action. Boyd (1986) suggested that there are two types of static axons, those innervating chain fibers and those innervating bag_2 fibers, each with a distinctly different effect on afferent discharge, and potentially different central control. The selectivity and subdivision of γ innervation of bag_2 and chain fibers in cat spindles is, however, debated by other authorities (Banks *et al.*, 1985) and may be largely random (Celichowski *et al.*, 1994). The β axons innervate either the bag_1 fiber, thereby having a dynamic action, or the long-chain fiber (should there be one in the spindle), thereby having a static action. The β axons that innervate the bag_1 fiber have conduction velocities in the slow α range, and innervate extrafusal muscle of the SO type (i.e., slow contracting, rich in oxidative enzymes; see Table 5.5 and "Classification and Properties of Motor Units"). The β axons innervating the long-chain fiber have faster conduction velocities and innervate extrafusal muscle of the FOG type (i.e., fast contracting, rich in oxidative and glycolytic enzymes) or, more rarely, the FG type (i.e., fast contracting, rich in glycolytic enzymes).

In monkey and possibly human spindles, the selectivity of γ-efferent innervation is less than in the cat (Kucera, 1985a, 1986), and individual axons may innervate bag_1, bag_2, and chain fibers or any combination thereof. For the human spindle illustrated in Figure 5.3, Kucera (1986) identified 13 γ efferents, of which 7 innervated only the 2 bag_1 fibers. Of 3 axons to the bag_2 fiber, 2 also innervated bag_1 and chain fibers. Of the 5 axons to chain fibers, 2 innervated only the chain fibers, the remaining 3 also each innervated a bag_1 fiber. The β innervation of monkey spindles has been demonstrated anatomically (Kucera, 1985b; Murthy *et al.*, 1982). There is suggestive anatomical (Kennedy, 1970; Kucera and Dorovini-Zis, 1979; Swash and Fox, 1972) and physiological (Aniss *et al.*, 1988; Rothwell *et al.*, 1990; Kakuda *et al.*, 1998) evidence for β innervation of human spindles. The anatomical evidence rests on the presence of a large myelinated axon entering the spindle in the polar bundle of nerve fibers and on the common finding of P_1 plate endings on intrafusal fibers. These latter are morphologically identical to endplates on extrafusal fibers and have been considered evidence of β innervation (Barker, 1974; however, see next paragraph). In the monkey the distribution of β axons is selective, with separate β axons innervating the bag_1, bag_2 and chain fibers (Kucera, 1985b). Selective β innervation also occurs in the cat, but it has no β innervation of bag_2 fibers. Hence, in primate spindles, selective innervation of intrafusal fibers may be a feature of the β innervation, but it is not a feature of the γ innervation.

The motor endplates on intrafusal muscle of cat, monkey and human spindles are morphologically of three different types, described as P_1 plates, P_2 plates, and trail endings (Barker, 1974; see also Kennedy, 1970; Kucera and Dorovini-zis, 1979; Swash and Fox, 1972). It has generally been considered that the morphology of the ending was evidence of innervation by a particular efferent (Barker, 1974). The P_1 plate, morphologically identical to endplates on extrafusal muscle fibers, was considered evidence of β innervation; the P_2 plate was considered the termination of dynamic γ axons on bag_1 fibers; and the trail ending the termination of static γ axons on bag_2 and chain fibers. Subsequent studies have both supported (Banks *et al.*, 1985) and challenged (Kucera and Walro, 1986) these concepts. However, both studies agree that factors other than the type of innervating efferent axon are important determinants of endplate morphology. These include the type of intrafusal fiber and the distance of the endplate from the spindle's equator (γ endplates are usually intracapsular, β endplates usually extracapsular). Predictions of motor axon type from endplate morphology are potentially erroneous (Kucera and Walro, 1986).

Golgi Tendon Organ

Golgi termed the receptor that now bears his name a musculotendinous end-organ (Golgi, 1880), a name that serves to emphasize that this receptor is not in the tendon proper. The majority of tendon organs line the aponeuroses of origin and insertion, where muscle fibers insert directly into the receptor capsule. They are also found at musculotendinous junctions and in

pennate muscles will therefore lie within the confines of the muscle itself. Less than 10% of tendon organs are found wholly within the tendon (Barker, 1974; Proske, 1981). Some tendon organs are found in association with joint capsules near tendon insertions (e.g. Backenkohler *et al.*, 1997). Tendon organ properties have been reviewed by Proske (1981) and Jami (1992).

The term "tendon spindle" has also been used for Golgi tendon organs, a name which emphasizes that this encapsulated receptor is not spherical but fusiform, much as is the muscle spindle (see Fig. 5.1). The tendon organ is much smaller than the muscle spindle: the mean length of 10 human tendon organs was 1.6 mm, mean width at the widest point 0.12 mm (Bridgman, 1970). The number of tendon organs in a muscle varies, as does the number of spindles, but there is no strict correlation and some muscles are devoid of either (Barker, 1974). In the monkey, the intrinsic muscles of the hand are rich in spindles but contain few tendon organs (Devanandan *et al.*, 1983). Spindles, judging by the numbers of their afferents in muscle nerves, are generally more plentiful than tendon organs, in a ratio of 1–2:1 (Barker, 1974).

The tendon organ has a thin capsule enveloping collagenous fascicles, which are continuous with the tendon. Extrafusal muscle fibers insert into the fascicles, so that contraction exerts a force directly onto the fascicle and its contents, the afferent terminals. In the cat, the mean number of muscle fibers inserting into a tendon organ is 10.5 (Barker, 1974). Bridgman (1970) reported that there were 10–20 muscle fibers inserted into each of 10 human tendon organs, sometimes terminating on the outer surface of the receptor capsule. As discussed in "Muscle Units and Motor Units," the fibers of different motor units intermingle and it is unusual to find more than two adjacent muscle fibers from the same motor unit. It is therefore likely that each tendon organ samples the activity of 10–20 motor units, one muscle fiber from each motor unit. In physiological studies this has proved to be the case (see Proske, 1981; Jami, 1992). The inserting muscle fibers come from motor units of different physiological type, so that if the receptor mechanism does not saturate, the afferent discharge of the tendon organ is proportional to contraction strength. Certainly, the ensemble discharge of tendon organs should follow muscle force.

Tendon organs are innervated by large myelinated afferent axons of group I size (Ib afferents) with one afferent per receptor in over 85% of cases. The Ib afferent divides into a few branches before penetrating the capsule of the receptor. Inside the capsule these branches subdivide, forming arborizations in the connective tissue fascicles of the end organ, terminating in a flower-spray appearance (Barker, 1974).

Tendon organs may be found in association with other muscle receptors, particularly the muscle spindle, the Paciniform corpuscle and free nerve endings, but the true functional significance of these associations has not been established. The association of spindle and tendon organ, to form a "dyad," may occur when the intrafusal muscle fibers of the relevant spindle insert into the musculotendinous junction alongside a tendon organ. Presumably this occurs more often in small but richly endowed muscles; perhaps that is why dyads are quite common in, for example, cat extensor digitorum brevis (Marchand *et al.*, 1971) and neck muscles (Richmond and Abrahams, 1975). Up to 10% of tendon organs have associated Paciniform corpuscles, orientated longitudinally outside or, more often, inside the capsule (Barker, 1974). There seem to be no specific features about free nerve endings innervating structures in and around the tendon organ. This may be a quite common association, at least in humans (Stilwell, 1957; Weddell and Harpman, 1940), though Stacey (1969) considers the relationship more casual than specific.

Because of the direct insertion of muscle fibers into the intracapsular fascicles containing the afferent terminals, tendon organs are exquisitely sensitive to muscle contraction, a single twitch of a single muscle fiber being sufficient to generate an afferent discharge. The tendon organ is "in series" anatomically and functionally with those motor units that have a muscle fiber inserting into it. It is anatomically "in parallel" with the remaining motor units, and it is possible for selective activation of them to unload a tendon organ and decrease its afferent discharge (Proske, 1981). However, during normal motor behavior this may not occur because each tendon organ sees a reasonable sample of different motor unit types, and because the sensitivity to contraction-induced forces is higher than to passive force applied less directly to the afferent terminals. In a similar way, passive stretch of non-contracting muscles produces forces that are poorly transmitted to afferent terminals, and the sensitivity of tendon organs to stretch is very much less than that to muscle contraction.

Pacinian and Paciniform Corpuscles

Pacinian corpuscles are rare in muscle, being associated with noncontractile tissue such as fascia, interosseous membranes, aponeuroses and tendons (Barker, 1974). Paciniform corpuscles are similar but much smaller structures, having an oval rather than round shape and a capsule with only 4–8 lamellae rather than 20–60 as in the pacinian corpuscle. There are only a few Paciniform corpuscles in muscle, occur-

ring mainly at musculotendinous junctions where they are commonly associated with Golgi tendon organs, even lying inside the capsule of that receptor (Barker, 1974; Stacey, 1969). Perhaps 1–5 Paciniform corpuscles may be associated with any one tendon organ. Elsewhere, Paciniform corpuscles are found in tendons, aponeuroses, and joint capsules. The afferent axons innervating Pacinian and Paciniform corpuscles traverse the appropriate muscle nerve and are generally of groups II and III size, i.e., 3–12 μm (corresponding to a conduction velocity range of approximately 18–72 m/s in the cat).

Free Nerve Endings

All tissue within muscle, apart from the capillary network, is richly innervated by free nerve endings derived from myelinated and unmyelinated parent axons (Abrahams, 1986; Stacey, 1969). These unmyelinated unencapsulated nerve terminals may be activated by muscle stretch, muscle contraction, nociceptive stimuli (such as trauma or the injection of algogenic agents), and changes in temperature, presumably because they are sensitive to mechanical deformation, changes in their chemical environment, and other stimuli (e.g., Abrahams, 1986; Kniffki *et al.*, 1978; Mense and Stahnke, 1983). These endings are believed to be responsible or muscle pain (Kniffki *et al.*, 1978; Mense and Stahnke, 1983), a view for which there is indirect (Kellegren, 1939) and direct evidence (Marchettini *et al.*, 1996). They also contribute to the cardiovascular and respiratory reflexes induced by exercise (Kniffki *et al.*, 1978; McCloskey and Mitchell, 1972). While free nerve endings are polymodal (i.e., they respond to a number of different stimuli), they do not form a homogeneous population. Individual afferents have marked differences in sensitivity to, for example, muscular exercise and nociceptive stimuli.

All group IV muscle afferents (i.e., unmyelinated afferents) terminate as free nerve endings, but so too do many small myelinated (group III) and some medium-sized myelinated (group II) afferents (Stacey, 1969). It is unusual for larger afferents (group I) to end as free nerve endings.

FEATURES OF MUSCLES

The development of active muscle force is the prime role of skeletal muscle. The development of force may result in muscle shortening (a "concentric" contraction) if contractile force is sufficient to overcome the load on the muscle or muscle lengthening (an "eccentric" contraction) if it is not. All muscles act against internal loads, imposed by the skeleton, as well as external loads such as objects lifted by the limbs. The contraction of one limb muscle alters the mechanical conditions required for action not only of its antagonist, but also for muscles acting on proximal and distal segments. Control of movement by the central neurons system (CNS) must take into account the mechanical interactions generated between various limb segments during movement and the gravitational force acting on the segments (Gandevia and Mahutte, 1982; Partridge and Benton, 1981). Conventional descriptions of the anatomy and physiology of muscle play down the global features of muscle control in favor of the more approachable fields, such as the description of the contractile mechanism of single muscle fibers and the various types of muscle fibers. A discussion of the molecular and mechanical events underlying muscle contraction is outside the scope of this chapter (for reviews, see Peachey, 1983; Weiss, 1996).

Peripheral Organization of Muscle

The number of muscles that act at a joint exceeds the number of degrees of freedom for motion at that joint. Theoretically, three muscles could achieve independent flexion and extension at the elbow, with or without supination or pronation of the forearm. The reason for the abundance of muscles in unclear. It does not allow a greater variety of movements, but it may reduce energy expenditure (Alexander, 1981). Human muscles have many forms; the representation of a muscle as fusiform in shape is rarely correct. A commonly used terminology refers to unipennate (or simply pennate), bipennate, and multipennate muscles. The degree of "pennation" depends on the number of visible sets of parallel muscle fascicles that insert at a particular angle into a common tendon. Other adjectives to describe muscle form include quadrilateral, triangular, circumpennate, spiral, radial, straplike, and straplike with tendinous intersections (e.g., Williams and Warwick, 1980). No uniform nomenclature is likely to describe fully the range of muscle morphology, particularly as the mechanical arrangement of muscle fascicles is even more complex at a microscopic level. Furthermore, the neural control of muscles of the same form is not necessarily the same. An example is the different central organization of splenius capitis and semitendinosis in the cat. These muscles in both humans and cats have tendinous inscriptions, so that the muscles contain end-to-end compartments rather than fascicles that run the full length of the muscle (Barrett, 1962; Bodine *et al.*, 1982; Richmond *et al.*, 1985; Trotter, 1990).

The contraction of muscle fibers ultimately acts to bring the ends of the muscle together. This is not achieved simply through independent, parallel contractile elements that span the connective tissue ends of the muscle. Each muscle fiber is enveloped outside its basement membrane by the endomysium, consisting of a network of collagen fibrils that take a mostly longitudinal path. Outside this envelope are thicker collagen strands commonly running in the direction of the tendon rather than the muscle fibers (i.e., perimysium). The endomysium contributes to the mechanical strength (or breaking strain) of the muscle and to the increase in tension when the muscle is stretched well beyond its resting length. These extracellular connective tissue elements distribute the contractile force across the muscle and tendon, and may help maintain the sarcomeres in register. Both the contractile material and the tendon have an important role in the storage of elastic energy. Individual muscle fibers taper close to their ends and separate into projections, which usually attach to the connective tissue of the tendon. It is becoming increasingly recognized that, in some fascicles in nonhuman muscles, individual fibers may not run the whole length of the muscle so that at one end they are bound to adjacent muscle fibers. At least in most mammals larger than the mouse, muscles longer than about 20 mm contain a significant component of serially arranged fibers (see Barrett, 1962; Paul, 2000; Richmond *et al.*, 1985; Trotter, 1990). This recognition will lead to questions as to how such muscle fibers develop in series and how they are controlled by the central nervous system. Already there is interest in the mechanical properties and reflex control of muscles with tendinous inscriptions (i.e., the extreme instance of fibers in series) and specific compartments (for review, see Stuart *et al.*, 1987). Most human muscles appear to be single fibered with a single zone of neuromuscular junctions, but a few (e.g., gracilis and sartorius) have multiple endplate zones and may have a significant number of in-series fibers (e.g., Paul, 2000).

Before the histochemical properties of individual muscle fibers are considered, two examples will be given to illustrate the relevance of intramuscular architecture for muscle performance. Additional details about the length and angulation of muscle fibers are reviewed by Gans and de Vree (1987).

1. Although the relationship between the length of an isolated muscle or its fibers and the contractile force is well known (e.g., Gordon *et al.*, 1966), the importance of the relationship cannot be assessed functionally unless the contractile force can be translated (according to joint and tendon mechanics) into force acting on the limb segments, and unless the muscle length can be translated into the angular position of the segment. The optimal position for force development by the dorsiflexors of the human ankle (10^8 plantar flexion) does not correspond with any of the "rest" positions adopted by the joint during sitting, standing and lying (Marsh *et al.*, 1981). Furthermore, muscle contraction significantly lengthens the intra- and extramuscular tendon and this is associated with increases in the muscle pennation angle (Herbert and Gandevia, 1995; Kawakami et al., 2000; Narici *et al.*, 1996). In addition, fascial layers surrounding single or groups of human muscles, especially in the lower limb, may directly influence the force exerted (Garfin *et al.*, 1981).

TABLE 5.4 Architectural Variables of the Average Medial and Lateral Head of the Human Gastrocnemius[a]

Variable	Medial gastrocnemius	Lateral gastrocnemius
Sarcomeres	17,614	21,371
Optimal length (mm)		
Fibers	52	63
Muscle	244	213
Index of architecture[b]	0.2	0.3
Fiber angle with respect to tendon plate (degrees)	18	9
Tendon plate length (mm)	192	154
Volume (cm^3)	160	90
Physiological cross-section (cm^2)	31.3	14.2

[a]Data from Huijing (1985).
[b]The index of architecture is defined as the ratio of the optimal fiber and muscle length.

2. The importance of the force–length relationship can be shown by considering the medial and lateral gastrocnemii, a synergistic "pair" of knee flexor and ankle extensor muscles. These muscles have significant differences in overall length, muscle fiber length, tendon length and cross-sectional area, as well as in the architecture of the fiber array (Table 5.4). Such factors will influence the angular range over which each muscle is effective. For example, the greater degree of pennation of the medial gastrocnemius reduces its working range (e.g., Woittiez *et al.*, 1983). The need for practical data about strength and the excursions of individual muscles and tendons has already prompted detailed descriptions of muscles in both human upper and lower limbs (Brand *et al.*, 1981; Silver *et al.*, 1985) and increased use of *in vivo* imaging methods such as ultrasonography. Presumably, incorporation of additional architectural features in these descriptions will enhance their usefulness in the surgical treatment

of paralyzed muscles. To understand a muscle's function requires knowledge of its unique physical and architectural features.

Muscle Fiber Types

Human muscle fibers, like those of other mammals, are not uniform in their properties. There are differences in the ultrastructure, in the biochemical and physiological properties of single muscle fibers, and in the fibers of individual motor units. In the 1870s, Ranvier correlated white and red muscles in the rabbit with rapid and slow contractions, respectively (see Dubowitz, 1985). Investigations followed of the correlation between anatomical, biochemical, and physiological properties of different muscle and, subsequently, of their constituent fibers. The following discussion concentrates on some of the histochemical classifications of human muscle fibers and the *in vivo* properties of the different fiber types.

Histochemical and Other Classifications

Many classifications have been used for the types of muscle fiber revealed by a particular (usually histochemical) technique, and some are detailed in Table 5.5. Human muscle fibers can be separated into two histochemical groups, one with high oxidative and low glycolytic activity (type I), and the other low oxidative and high glycolytic activity (type II) (Dubowitz and Pearse, 1960). This subdivision of fibers usually corresponds to groups of fibers with low and high myofibrillar adenosine triphosphatase (or mATPase) activity, respectively (Engel, 1962). The latter classification was subsequently expanded to four types because the type II fibers can be divided into three according to different susceptibility of the mATPase reaction to preincubation at various pH levels (Brooke and Kaiser, 1970). The specific levels vary but are usually about pH 9.4, 4.6, and 4.3. Most normal human limb muscles are composed almost entirely of type I, IIA, and IIB fibers with occasional type IIC, "intermediate" fiber. An early histochemical study of human muscles that employed a stain for the oxidative enzyme succinic dehydrogenase suggested a tripartite classification with low enzyme activity in large fibers, high activity in small fibers, and a group of intermediate fibers (Wachstein and Meisel, 1955). However, a study using morphological analysis of histochemically identified fibers has revived the debate about the subtypes of the type II fibers identified with the usual mATPase techniques. Type IIAB fibers were detected that had an intermediate staining reaction after preincubation at pH 4.6. The lipid and mitochondrial volumes for these fibers were below those for type IIA but above those for IIB fibers (Staron *et al.*, 1983; see also Injer, 1979). In addition, human type I fibers can also be divided into IA and IB based on a range of histochemical reactions (Askansas and Engel, 1975). Another classification concentrated on the metabolic capacity of muscle fibers. It divided fibers into three major types (Barnard *et al.*, 1971), which were subsequently named slow oxidative (SO) fibers, fast oxidative glycolytic (FOG) fibers, and fast glycolytic (FG) fibers (Peter *et al.*, 1972). Fibers that reacted strongly with ATPase (at pH 9.4, i.e., type II fibers) were associated with fast contraction times, whereas those with weak reactions were associated with slow contraction times. There is a strong correlation between the speed of muscle contraction and overall myosin ATPase activity (Barany, 1967), a correlation that holds

TABLE 5.5 Correlation of Fiber Types Based on Histochemical and Physiological Properties[a]

Property	Fiber type			
	I	IIA	IIB/IIX[b]	IIC
Histochemical fiber type				
Putative physiological type				
Peter et al. (1972)	SO (slow oxidative)	FOG (fast oxidative gycolytic)	FG (fast glycolytic)	
Burke et al. (1973)	S (slow)		FR (fast fatigue resistant)	FF (fast fatigable)
Properties of motor units				
Tension produced	Low	Intermediate	High	Intermediate
Contraction speed	Slow	Fast	Fast	Slow
"Fatigue" resistance	High	Intermediate/high	Low	High
Recruitment order	First	Second	Third	Unknown

[a]This table provides a simplified correlation between muscle fiber types and their physiological properties. Additional subtypes within the type II group have not been included. Data for IIC fibers are taken from Maxwell *et al.* (1983). It is likely that for many human muscles there is greater uniformity in the contractile and fatigue properties than predicted from data obtained in the cat.

[b]Type IIB fibers assessed with myosin ATPase histochemistry contain type IIX myosin (Ennion *et al.*, 1995).

among the fast myosin isoforms (Larsson and Moss, 1993).

Classifications are useful only if they allow further deductions about muscle pathology or performance. Recognition of the classifical type I/type II subdivision has been of practical and conceptual importance, as has the SO, FOG, FG division. For example, the presence of atrophic type I and type II fibers in a muscle biopsy suggests denervation, grouping of fibers of one type suggests reinnervation, and a predominance of type I fibers may indicate a selective atrophy of type II fibers. Furthermore, the division into type I, IIA, and IIB fibers separates the muscle into fibers with different function roles such that fiber-type composition can predict some physiological properties and vice versa (see below).

Classification of muscle fiber types has been dramatically helped by the introduction of molecular techniques, particularly those directed at the highly conserved and diverse myosin genes (e.g., Sellers, 2000). This has shown that the human IIB myosin is very similar to the IIX myosin in the rat, and thus IIB fibers should be more accurately classified as IIX fibers (Ennison *et al.,* 1995; see also Larsson *et al.,* 1991). It may represent the "default" muscle myosin gene (Goldspink *et al.,* 1991). Thus, the term IIX is rapidly replacing the term IIB. Furthermore, individual fibers may contain a mix of the various myosin isoforms such that the fiber's physiological performance will be determined by the predominant type. Myosin is the major structural protein of the thick filament and is more heterogeneous than revealed simply by the standard ATPase reaction. At least five different myosin isoforms are recognizable in human skeletal muscle by their eletrophoretic patterns (Fitzsimons and Hoh, 1981). Human type I and type II fibers also contain distinct classes of myosin light chains. The potential diversity within this major structural protein is great (for review, see Fitzsimons and Sewry, 1985; Schmalbruch, 1985; Weiss and Leinward, 1996). Recognition of the various myosin forms has become more important in assessment of pathological changes in muscle, as occurs for example in the muscular dystrophies, and for understanding the development and adaptability of human muscle.

Ultrastructural differences exist between the three common fiber types in humans. Although these differences are less than for other species, they have allowed reliable classification of fibers from human biopsy material prepared for electron microscopy (Sjöström *et al.,* 1982). The differences include variation in the apparent complexity of the M band and in the diameter of the Z discs. The latter was wider in type I (125 nm) than in either type IIA (101 nm) or IIB fibers (86 nm). The distribution of these diameters was such that accurate fiber typing was possible for 80–95% of fibers with this measurement alone and so detailed ultrastructral measurements (e.g., of mitochondria and their distribution) can be made for human muscle fibers of known type. In addition, type I fibers usually have greater numbers of mitochondria, but smaller areas of T tubules and sarcoplasmic reticulum (Dubowitz, 1985).

Another factor that varies according to fiber type is the distribution of muscle capillaries. Only about 1% of total muscle volume is occupied by capillaries, and a close correlation exists between the muscle capillarity and the maximal oxygen uptake by the muscle (for review, see Saltin and Gollnick, 1983). In human vastus lateralis there are an average of three capillaries in contact with each IIB fiber and four capillaries in contact with both type I and IIA fibers. Even when these estimates take account of differences in the size of muscle fibers (by expression of capillary counts relative to fiber area), the corrected capillary density is greater for type I fibers (Andersen and Henriksson, 1977). Many of the correlations between capillarity, fiber type and fiber diameter noted in animal studies have now been found for human muscle biopsies. An important relationship for oxygen delivery is that the number of capillaries per fiber increases as fiber diameter increases. This relationship was found in a large group of control subjects for samples taken from vastus lateralis, biceps femoris or deltoid (Carry *et al.,* 1986). Changes in muscle fiber diameter due to neuropathic or myopathic disease are usually associated with a parallel change in capillary numbers (Carry *et al.,* 1986).

Myoglobin concentration, which is related to the capcity for intracellular oxygen transport (and responsible for muscle's red color), does not vary as much between human type I and type II fibers as in other species (Németh and Lowry, 1984). The reason for this relative homogeneity is not resolved, but it is consistent with the finding that the activity of some oxidative enzymes may vary little between the two main fiber types and that the difference in the endurance properties of the main fiber types in various limb muscles is smaller in humans than in many laboratory animals and other species.

Fiber-Type Variations Between and Within Muscles

The proportions of type I, IIA and IIB fibers within an individual subject vary between muscles (e.g., Johnson *et al.,* 1973), within regions of a single muscle (Elder *et al.,* 1982), and even within a single muscle fascicle (Sjöström *et al.,* 1986). Given that muscle performance at a whole-muscle or single-fiber level is

influenced by fiber type (see below), it is perhaps surprising that there is still some controversy about the determinants of the main fiber type division (type I/II) and that factors affecting the distribution of fiber types within muscles have received so little attention.

Both genetic and environmental factors influence muscle fiber types; the former were generally believed to control the "boundaries" for the proportion of type I and type II fibers and the latter the proportion of subtypes within the type II group (e.g., Booth and Thomason, 1991). Studies of monozygotic and dizygotic twins have emphasized the role of heredity in fiber type determination (Komi *et al.,* 1977). Fiber type distributions in vastus lateralis are closer in pairs of monozygotic than dizygotic twins. In contrast, it is becoming increasingly clear that even the type I/type II distribution is mutable with prolonged changes in muscle use (Larsson and Ansved, 1985; cf. Harridge *et al.,* 1998).

In an autopsy study of 36 human muscles, the percentage of type I fibers varied within and between subjects (Johnson *et al.,* 1973). The highest percentages of type I fibers were in soleus (100% in one subject) and the lowest in orbicularies oculi. Studies of fewer muscles, often using newer methods, have confirmed these observations. Human matiscatory muscles do not fit easily into this scheme. In addition to the classical types of fiber based on ATPase staining, jaw-closing muscles contain fibers with intermediate staining properties in the ATPase reaction at pH 9.4 (Ringqvist, 1974), the pH used to distinguish type I form type II fibers. These data argue for the expression of a greater number of biochemically distinct fiber types than predicted by early classifications. There are a number of isoenzymes for fetal and adult human myosin, but a functional role for each distinct form is not yet known for adult muscle (Fitzsimons and Sewry, 1985). Individual muscle fibers may contain "hybrids" of the different isoforms (Gauthier *et al.,* 1979). Physiologically the myosin isoforms are the primary determinant of the fiber's speed of shortening (Lowey *et al.,* 1993).

Differences in the percentages of type I and type II fibers in different regions of one muscle have been reported for animal and human muscles. While these differences are usually thought to be comparatively small (only about 10%), the systematic variation across some muscles is more marked. For example, a peak in the distribution of type II fibers occurs over the anterior portion of human tibialis anterior with at least one other peak deep within the muscle (Henriksson-Larsen, 1985), and in the masseter the frequency of type IIB fibers is significantly higher in the superficial posterior part of the muscle (Ericksson, 1982). Variations in fiber type distributions according to muscle architecture have been documented in animal studies, and hypotheses have been developed to explain them (Ringqvist, 1974; for review, see Binder and Stuart, 1980; Botterman *et al.,* 1978). One hypothesis depended on the frequent association of high counts of muscle spindle endings and tendon organs in zones (usually in deep parts of the muscle) with a preponderance of type I fibers (Botterman *et al.,* 1978). The major implication of this hypothesis, namely, a close functional linkage between specialized muscle *receptors* and muscle *fibers* within an intramuscular region, has not been supported by physiological studies on human tibialis anterior (McKeon *et al.,* 1984), but it has received support from studies in some muscles in the cat (Stuart *et al.,* 1987). The variable distribution of muscle fiber types across a muscle and the possible association with the distribution of muscle receptors need further study.

There is some difficulty in estimating the different fiber types from conventional muscle biopsies. When between 13 and 17 sites within muscles were sampled (soleus, vastus lateralis, biceps brachii, and triceps brachii), the variability in fiber type distribution exceeded that of a muscle with a random distribution of fibers (Elder *et al.,* 1982). With the exception of triceps, significant within-site variability occurred. This may arise because there is significant difference in fiber type distributions at the edges of muscle fascicles with boundaries containing a higher percentage of type II fibers (Sjöström *et al.,* 1986). This factor must make an important contribution to the variation in fiber type distribution between nearby sections from the one site in the muscle. Whenever there are some muscle fibers in series, fiber type distribution may vary slightly for different cross-sections of the same muscle region. The role of local mechanical factors and possible neural influences on the fiber type distribution at the borders of whole muscle and individual fascicles is unknown.

The proportion of type II fibers in vastus lateralis of healthy sedentary individuals declines progressively with age between the fourth and ninth decade (Larsson, 1983). This change may simply represent a selective reduction in the number of motoneurons supplying type II muscle fibers.

MUSCLE UNITS AND MOTOR UNITS

The muscle fibers which have a common efferent innervation by a single anterior horn cell constitute the smallest "muscle units that can be controlled by the CNS." The term motor unit applies to both this muscle

unit and the motoneuron that supplies it. Each muscle fiber from a motor unit has the same physiological and biochemical properties. This is important for two reasons. First, it emphasizes the likely role of the motoneuron in determination of muscle unit properties (although it does not reveal how this determination is achieved). This view has been further supported by meticulous studies in which the enzyme activities for individual fibers from identified muscle units have been quantified. Uniformity among fibers from the same unit is striking compared with the variation between fibers of the same histochemical type. This enzymatic uniformity is evident despite variation in size of fibers from one motor unit (e.g. Németh *et al.*, 1986; *cf.* Larsson, 1992). Uniformity of muscle unit properties is likely to apply to human muscle (see below). Also, it defuses some of the criticism of those histochemical studies that fail to reveal separate nonoverlapping distributions of human muscle fibers (e.g., Reichmann and Pette, 1982) and that have emphasized the heterogeneity of metabolic profiles within a muscle.

The force produced by a motor unit is proportional to the number of fibers within it. The number of fibers per motor unit probably varies within a muscle and certainly varies between muscles. Anatomical techniques to determine this "innervation ratio" in humans have usually involved counts of the large-diameter axons in the motor nerve (more than 7–8 μm in diameter), estimation (from animal studies) of the percentage of the fibers that are efferent, and then measurement of the number of muscle fibers within a cross-section of muscle. The potential for errors in each of these measurements is not small. Estimates based on such indirect anatomical methods are shown in Table 5.3. An electrophysiological method using single-fiber electromyography estimates the innervation ratio for biceps brachii at about 210 fibers per motor unit, smaller than the figure obtained with anatomical methods (Table 5.3). There are insufficient data for human muscles to support uncritically the view derived from animal studies that the innervation ratio is highest for large muscles that produce large forces and lowest for small muscles (including extraocular muscles) that produce small forces.

The arrangement of muscle fibers innervated by a single α motoneuron has been investigated using an electrode inserted into the muscle so as to sample the electromyographic activity simultaneously at different depths within the muscle. The near-synchronous discharge of muscle fibers from a motor unit can be recorded from approximately circular cross-sectional regions of limb muscles with a diameter of 5–10 mm (Buchthal and Schmalbruch, 1980). Single-fiber electrodes that record from a semicircular area of 270 μm in diameter have revealed that such an area contains about 10 muscle fibers, usually derived from 6 or more motor units. These electrophysiological data show that fibers belonging to one muscle unit do not form discrete clusters but are spread across a specific subvolume of the muscle (Stålberg *et al.*, 1976) and that in normal human limb muscles the distribution of fibers across that volume is approximately uniform (Gath and Shenhav, 1985).

A combination of electrophysiological and histochemical methods has permitted visualization of the region of muscle that contains fibers innervated by a single motoneuron. Repetitive stimulation of a single motor axon *in vivo* produces selective depletion of glycogen stores within the innervated muscle fibers, as revealed by staining for glycogen. Application of this technique in the rat and cat has demonstrated that adjacent fibers rarely belong to the same motor unit (Burke and Tsairis, 1973; Edström and Kugelberg, 1968) and that there is extensive overlap of motor unit territories. There is support for a similar arrangement in humans from the biopsy findings. For example, in a patient with myokymia, a disorder associated with repeated contractions of several motor units, the contractions depleted glycogen in two regions of the biopsy, one containing IIA fibers and the other containing IIB fibers. Depleted fibers did not occur next to one another (Williamson and Brooke, 1972). This "mosaic" arrangement of fibers belonging to one unit ensures wide distribution of the contractile force into the tendon and minimization of local shearing force, and may tend to smooth the final force output. There is increased speculation about the physiological role of lateral connections between muscle fibers (e.g., Huijing, 1999; Young *et al.*, 2000).

Finally, some muscles can be subdivided into volumes according to the anatomical zones innervated by the primary branches of the nerve as it enters the muscle. Thus, although motor unit territories do not represent a discrete cross-sectional area of the muscle, there is a tendency (at least in some animal muscles) for compartments of muscle to contain unique sets of motor units (English and Weeks, 1984). If this form of "compartmentalization" is widespread among human muscles, then it represents a neural substrate for independent control by the CNS of specific regions of a muscle. Indeed, a "muscle" such as extensor digitorum communis contains anatomical compartments that insert into four separate tendons. It contains discrete zones of muscle that produce extension of each finger and that can be separately activated by the CNS. Such considerations blur the anatomical definition of what is the smallest volume that constitutes a "muscle," but emphasize the importance of the function of different

muscle "compartments," whether they are defined morphologically or according to primary motor nerve branches.

Classification and Properties of Motor Units

Classical studies by Burke and colleagues (1973) involved physiological characterization of a single motor unit in the cat and its stimulation to induce glycogen depletion with subsequent histochemical identification. The physiological assessment revealed three types of motor unit in cat gastrocnemius muscle that were termed type S (slow twitch), type FR (fast twitch, resistant to fatigue), and type FF (fast twitch, fatigable). This division, based on physiological criteria (primarily contraction speed and resistance to fatigue produced by repetitive stimulation), correlated well with the histochemical division into type SO, FOG, and FG fibers, respectively (Table 5.5). Subsequent physiological studies have revealed that in some cat muscles there are fast-twitch motor units of intermediate resistance to fatigue (F int, units) (for review, see Burke, 1981).

In an attempt to apply to humans the techniques used to classify animal motor units and their fibers, Garnett *et al.* (1978) stimulated single motor axons near the motor point of medial gastrocnemius and then biopsied the muscle. Twitch contraction times under isometric conditions ranged from 40 to 110 ms (mean 76 ms), with the suggestion of a bimodal distribution. Units with fast contraction times of less than 85 ms were designated type F and more than 99 ms type S. The division of human muscle contractile responses into slow and fast types had previously been suggested from studies of isolated bundles of fibers (e.g., Eberstein and Goodgold, 1968), and had been confirmed for single motor units in extensor digitorum brevis (e.g., Sica and McComas, 1971), but not for other muscles, including the intrinsic muscles of the hand (e.g., Burke *et al.*, 1974; Milner-Brown *et al.*, 1973; Thomas *et al.*, 1986, 1991). Separation of the responses according to contraction time also revealed characteristic differences in contractile force. In the study of Garnett *et al.*, presumed type S units produced relatively low tensions (mean 12 g) whereas presumed type F units produced a range of tensions from 5 to 204 g (mean 23 g). Type F units were conveniently separated into two groups (FR and FF) according to their resistance to fatigue. Figure 5.4 illustrates the interrelationships between three indices of mechanical performance as a three-dimensional plot (contraction time, twitch tension, and fatigue resistance). Thus three separate subpopulations of motor units emerge from the study of Garnett *et al.* These three types seem analogous to those described

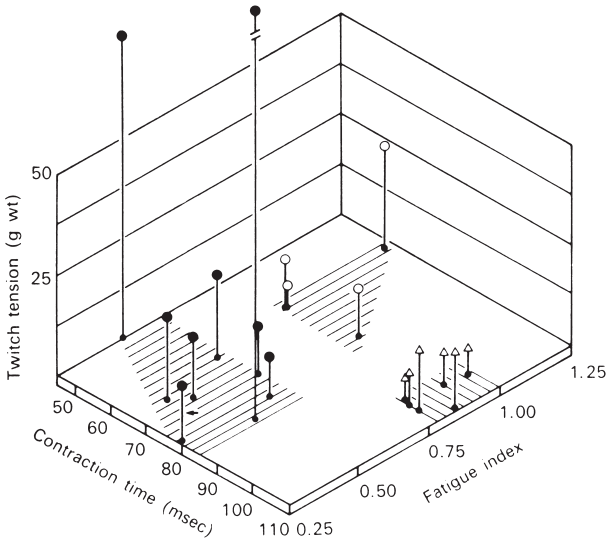

FIGURE 5.4 Three-dimensional graph to show a possible subdivision of motor units supplying human medial gastrocnemius. Data for 18 motor units isolated functionally by bipolar stimulation at the motor point. The "fatigue index" is expressed so that a value of one represents no decline in force after 3000 stimuli. The population divides into type S units (triangles: slow contraction time, high resistance to fatigue), type FR units (open circles: fast contraction time, high resistance to fatigue), and type FF units (filled circles: fast contraction time, low resistance to fatigue). The FF unit shown by an arrow had a fatigue index of zero. Reproduced with permission from Garnett *et al.* (1978). This subdivision shown here emphasizes the differences between motor units. Analysis of a larger sample of units would reveal more overlap among the groups of motor units (e.g. Thomas *et al.*, 1991).

in experimental animals. In five of six single motor units confirmation of the correlation between physiological and histochemical properties was obtained: three of four type S units contained type I fibers in the muscle biopsy, and one type FF unit contained type IIB fibers. This is the only study to attempt to correlate mechanical and histochemical properties of single human motor *units*. In contrast to these data for human gastrocnemius, data for human thenar muscles obtained with microneurographic techniques reveal a greater uniformity in contraction times, twitch forces, and fatigue properties (e.g., Thomas *et al.*, 1991). Unless large numbers of units are sampled, the full overlap of physiological properties among the various histochemical types may not be reliably determined.

Activation of Motor Units

The behavior of muscle units during voluntary contractions reveals a number of orderly features that have been documented for a variety of human skeletal muscles. First, muscle units with slow contractile speed and low-twitch tensions are activated initially,

followed by units of greater contractile speed and force. Second, the first activated units are resistant to the development of fatigue, whereas those activated during stronger contractions fatigue rapidly. Such a stereotyped recruitment of motor units (type S, then FR, then FF) or muscle fibers (type I, then IIA, then IIB) has both energetic and design advantages. For example, low forces can be achieved with finely graded force "steps," without development of fatigue while using oxidative metabolism. High forces can be achieved by full recruitment of all motor units within the muscle, although the maximal force produced can be sustained only briefly. This simplistic description of orderly motor unit activation may not occur under all circumstances. Thus, muscles that cross more than one joint or have complex actions may have slight variation in the recruitment pattern that is dependent on which muscle action is required (Thomas *et al.*, 1986; Van Zuylen *et al.*, 1988), and some peripheral feedback may favor activation of the fast-twitch (type II) muscle fibers (Garnett and Stephens, 1980). Histochemical techniques have been used to assess the recruitment of the different fiber types during prolonged bicycle exercise. Initially, glycogen depletion occurred only for type I and IIA fibers, but as exercise progressed the glycogen depletion was evident for type IIAB then type IIB fibers (Vøllestad *et al.*, 1984). This result confirms the probable physiological importance of the three subgroups of type II fibers. The pattern of motor unit recruitment in patients with upper motoneuron lesions may change during fatigue (Grimby *et al.*, 1974; for review, see Gandevia, 2001).

There is a relationship between anatomical and physiological properties of the motoneurons and the muscle units that they innervate. Small motoneurons with a low peripheral conduction velocity tend to innervate type S muscle units and large motoneurons with a high conduction relocity tend to innervate fast-twitch (type FR, FF) muscle units. Small motoneurons are usually recruited first in voluntary contractions. The "size principle" of motoneuron recruitment refers to the recruitment of motoneurons of increasing size (Henneman, 1957). The small motoneurons preferentially discharge at low rates. Thus, there is a "speed match" between the contractile properties of a muscle unit and the size and conduction velocity of its motoneuron. Furthermore, there is a "recruitment match" such that the susceptibility of a motoneuron to discharge decreases with the twitch tension of its muscle units (Burke, 1981; Henneman and Mendell, 1981; Kernell, 1986). The speed match is influenced by the total number of discharges of the relevant motoneurons such that mixed muscles that receive chronic stimulation change their properties toward those of a muscle with predominantly type S units. These changes result in a "slowing" of the myosin ATPase system, an increase in oxidative and a decrease in glycolytic enzymes. There is also a reduction in size of individual muscle fibers. Some of these changes have been documented for human muscles (e.g., Andersen *et al.*, 1999; Edwards *et al.*, 1982; Zhou *et al.*, 1985).

Finally, as suggested above, human muscle has significant plasticity, i.e., a capacity for adaptation to changes in pattern and condition of use (for review, see Edström and Grimby, 1986). In adult human muscles the compensatory changes following different exercise programs involve not only the sarcoplasmic reticulum, the contractile proteins and metabolic pathways, but also the size of individual muscle fibers and their associated capillarity. In addition to muscle fiber atrophy, which accompanies disuse, and hypertrophy, which may accompany strength training, the number of muscle fibers might change. There are limited, but controversial, data to suggest that following some training programs adult human muscle may show an increase in fiber numbers (i.e., hyperplasia), and there may be conversion between type I and type II fibers (e.g., Gonyea *et al.*, 1986; Jansson *et al.*, 1978; Larsson and Ansved, 1985; Larsson and Tesch, 1986; cf. Saltin and Gollnick, 1983), particularly from type I to IIA and type IIX to IIA.

Peripheral Autonomic Pathways

IAN GIBBINS
Department of Anatomy and Histology
Flinders University
Adelaide, Australia

GENERAL ORGANIZATION OF AUTONOMIC PATHWAYS

Together with the somatic motor pathways and neuroendocrine pathways, the autonomic pathways comprise the three motor outputs from the central nervous system (CNS). Functionally, the autonomic pathways provide motor control to a wide variety of visceral, vascular, and cutaneous effector tissues. These target tissues primarily consist of cardiac muscle, smooth muscle, or secretory epithelia, although autonomic nerve fibers also can be found in association with many other tissue types. Anatomically, autonomic pathways are characterized by the presence of final motor neurons lying completely outside the central nervous system. Usually, the final motor neurons and their associated supporting cells are aggregated into collections known as ganglia. This has led to the final motor neurons often being called "postganglionic neurons," although, strictly speaking, the term "postganglionic" refers only to the axons of these neurons.

Within the enteric plexuses of the gastrointestinal tract, the autonomic pathways contain well-defined sensory neurons and interneurons. However, there are probably no other autonomic sensory neurons outside the enteric plexuses. As discussed further below, the relations between spinal or cranial sensory pathways and autonomic motor pathways are complex and do not allow any simple and consistent classification that matches the various components of the autonomic motor pathways. Indeed, the final motor output of autonomic pathways is a coordinated series of specific patterns of activity generated in response to the full

range of sensory stimuli and central motor commands. This chapter will deal only with the peripheral components of the autonomic motor pathways. For discussion of various aspects of the organization of central pathways involved in autonomic motor function, see Chapters 8–10, 12, 13, 15, 17, 22, and 36. Unless stated otherwise, all of the information presented here pertains to humans.

Organization of Autonomic Ganglia

The final motor neurons in most autonomic pathways are aggregated into collections of cells called ganglia (from a Greek word meaning "knot"; singular: "ganglion"). The ganglia also contain satellite or glial cells (Schwann cells) that ensheath the neurons and their processes, and a varying amount of other tissues, such as blood vessels, connective tissue, cells of the immune system, and clusters of extraadrenal chromaffin cells. Depending on the pathway, a ganglion may contain from less than 10 to more than a million final motor neurons. Although there may be some variation from individual to individual, ganglia tend to have characteristic shapes and locations.

The final motor neurons in most autonomic pathways receive synaptic inputs from preganglionic neurons that have cell bodies located within the CNS. In most pathways, the preganglionic neurons provide the sole source of synaptic input to the final motor neurons. Two exceptions that will be discussed below include the prevertebral ganglia projecting to the gut, which receive additional inputs from neurons located in the enteric plexuses, and the final motor neurons within the enteric plexuses themselves, most of which do not receive any direct synaptic input from central neurons.

The axons of preganglionic neurons branch extensively within the ganglia and diverge to provide inputs for up to several hundred target neurons. In turn, each final motor neuron may receive convergent synaptic inputs from many preganglionic neurons. The divergence of preganglionic axons allows for a significant spatial amplification of the central command generated by a relatively small number of preganglionic neurons. By analogy with a somatic motor neuron and the muscle cells it innervates (a "motor unit"), a preganglionic neuron and the final autonomic motor neurons it innervates has been called a "neural unit" (Purves and Wigston, 1983). Almost certainly, the size of the neural units varies between different autonomic pathways. The convergence of several preganglionic inputs onto a single autonomic final motor neuron may allow the same neuron to be activated by different central pathways depending on the specific physiological or pathophysiological requirements at the time.

Microscopic Structure of Autonomic Final Motor Neurons

Studies in a variety of experimental animals have shown that final motor neurons in different pathways can show a wide range of morphological appearances (Gibbins, 1995). Generally, the neurons have a well-defined cell body (soma) and a variable number of dendrites, which may extend for several cell diameters, typically in the same plane as the major axis of the cell body. The dendrites usually show a relatively small degree of branching as they twist through the neuropil around other nearby neurons. Their terminal branches may be fine and varicose, although the functional significance of this morphology is unknown. Within the ganglia, the neuronal cell bodies tend to be closely packed. Most of the surface of the cell bodies and dendrites is covered with the processes of Schwann cells (satellite cells). Data from amphibians, mice, and guinea pigs indicate that synapses occur on only about 1–2% of the surface of the final motor neurons (Gibbins *et al.*, 1998).

Overall, the number of convergent preganglionic inputs to a final motor neuron seems to be positively correlated with the number of primary dendrites. Moreover, the total number of synapses formed on the cell body and dendrites of a final motor neuron also is proportional to its size (Gibbins, 1995; Gibbins *et al.*, 1998). Thus, in general, neurons with a relatively simple morphology receive a smaller number of convergent inputs and synapses than do neurons with more extensive dendritic fields. Although there have been no direct studies in humans, the relatively complex dendritic morphology of the final motor neurons in many human autonomic pathways suggests that a high degree of convergence of preganglionic inputs is likely to be common.

Autonomic Neuroeffector Junction

One characteristic feature of autonomic motor pathways is that the final motor neurons do not form neuroeffector junctions that are as well defined morphologically as the motor endplates found in the somatic motor pathways. The traditional view of the organization of the autonomic neuroeffector apparatus is that specialized neuroeffector junctions do not exist. According to this view, the terminal axons of the final motor neurons become varicose and ramify around or between the cells of the effector tissues, be they smooth muscle cells or secretory epithelia, without forming any special morphological relationship with them. When the neurons are stimulated, the transmitter diffuses relatively freely over a variable

distance (typically 50–1000 nm) from the release sites to activate receptors on the target cells.

During the last 10 years, extensive ultrastructural and functional studies in many different tissues from laboratory animals have revealed that this conventional view of the autonomic neuroeffector apparatus is likely to be wrong or, at best, too simplistic. Instead, it appears that specialized neuroeffector junctions are present in many tissues innervated by autonomic motor neurons (Bennett, 1996; Hirst *et al.*, 1996). Serial section electron microscopic analyses have shown clearly that many varicosities of the terminal axons of autonomic motor neurons form close associations with target effector cells. At these sites (autonomic neuroeffector junctions), varicosities, largely free of Schwann cell cover, come within 50–80 nm of the surface of the target cell. Within these closely contacting varicosities, small synaptic vesicles are clustered toward the prejunctional membrane adjacent to the effector cell. In some cases, these vesicles cluster toward a small prejunctional density similar to those seen in presynaptic membranes at motor endplates. Although there has been no morphological evidence to date for a corresponding postjunctional specialization, functional studies have demonstrated that the receptors mediating responses from neurally released transmitter are often different from those activated by exogenously applied agonists. The simplest interpretation of these data is that there are specialized postjunctional receptors that are activated by neurally released transmitter from close neuroeffector junctions, and that these receptors are different from extrajunctional receptors located more widely over the surface of the effector cells (Hirst *et al.*, 1996).

Recent experimental studies in laboratory mammals have shown that autonomic neuroeffector transmission to smooth muscle may occur via intermediary cell types, such as interstitial cells in the gastrointestinal tract (Burns *et al.*, 1996; Ward *et al.*, 1998, 2000) or endothelial cells in blood vessels (e.g., Häbler *et al.*, 1997). The organization and roles of these cells in autonomic pathways will be discussed in the appropriate sections below.

Autonomic Neurotransmitters

Historically, major advances in the understanding of chemical neurotransmission have come from studies of peripheral autonomic pathways, including the first demonstrations of chemical transmission itself. Compared with somatic motor neurons, the final motor neurons in autonomic pathways are now known to use a diverse array of chemical neurotransmitters. Unlike somatic motor neurons, which only have excitatory effects on their target muscle cells, autonomic transmitters may stimulate or inhibit the activity of the effector cells.

One of the most surprising discoveries of the last 25 years is that any single autonomic final motor neuron may contain five or more potential transmitters. Furthermore, the precise combination of transmitters expressed by the neurons generally varies from pathway to pathway. Typically, a particular functional class of autonomic final motor neurons utilizes a range of transmitters with different time courses of action on their effector cells (Morris and Gibbins, 1992). Rapid responses may be mediated by low molecular weight transmitters such as nitric oxide (NO) or adenosine 5′-triphosphate (ATP). Responses with somewhat longer time courses may be mediated by noradrenaline (NA) or acetylcholine (ACh), whereas the slowest responses are mediated by peptides such as neuropeptide Y (NPY) or vasoactive intestinal polypeptide (VIP). Many of these transmitters also may have prejunctional effects, which generally tend to inhibit further transmitter release. Indeed, some neuropeptides, such as opioid peptides or somatostatin, appear to have predominantly presynaptic inhibitory actions.

Not only is there considerable diversity of the combinations of transmitters used by autonomic final motor neurons, but there is a comparable diversity in the postjunctional receptors on the effector cells. Thus, transmitters such as NA, ACh, or VIP, may have excitatory or inhibitory actions depending on both the exact subclass of postjunctional receptor and the type of effector cell. For example, the action of NA on β-adrenoceptors may inhibit smooth muscle activity or stimulate cardiac muscle contractility. Similarly, VIP relaxes most smooth muscle cells but stimulates the secretory activity of many epithelia.

Regardless of the pathway within which they lie, preganglionic neurons utilize ACh as the primary transmitter mediating fast ganglionic transmission. However, many preganglionic neurons also contain neuropeptides, which tend to have one of two actions: some, such as VIP, substance P or calcitonin gene–related peptide (CGRP), enhance the excitability of the target neurons, whereas others, such as enkephalin, inhibit the release of ACh. More recently, NO has been identified as a potential transmitter in preganglionic neurons, but its contributions to ganglionic transmission are complex and not yet well characterized.

Functional Divisions of Autonomic Pathways

Peripheral autonomic pathways can be classified by a variety of criteria, such as their function (e.g., vasoconstrictor or vasodilator), their transmitter content

(e.g., NA or ACh), the location of their ganglia (e.g., cranial or pelvic, paravertebral or prevertebral), or the central origin of their preganglionic neurons (e.g., thoracic or sacral levels of the spinal cord). Many of these features tend to correlate to varying degrees, which has led to the most widely used scheme for classifying autonomic pathways into three main divisions, as originally proposed by Langley. In this scheme, the autonomic pathways are classified primarily by the sources of their preganglionic inputs. Accordingly:

Sympathetic pathways contain preganglionic inputs from neurons located in thoracic and upper lumbar spinal cord. The final motor neurons are found in ganglia associated anatomically with the spinal nerves (paravertebral or sympathetic chain ganglia), the ventral branches of the abdominal aorta (prevertebral ganglia), branches of the carotid artery (cervical ganglia), or the pelvic viscera (pelvic ganglia). Most sympathetic final motor neurons utilize NA as one of their transmitters, together with other transmitters such as ATP and peptides such as NPY and galanin. However, some sympathetic final motor neurons use ACh as their main nonpeptide transmitter and, in addition, may contain peptides such as VIP and CGRP.

Parasympathetic pathways, according to traditional classifications, contain preganglionic inputs from either of two disparate sets of central neurons. *Cranial* parasympathetic neurons receive preganglionic inputs from neurons located in the midbrain or brain stem (see Chapters 10 and 16). Their ganglia are associated with branches of the cranial nerves. Parasympathetic neurons located in ganglia associated with the *pelvic* viscera receive preganglionic inputs from neurons projecting from sacral segments of the spinal cord. The final motor neurons in parasympathetic pathways usually use ACh, NO, or both as their nonpeptide transmitters. A wide range of peptides occur in various populations of parasympathetic neurons, including VIP, CGRP, somatostatin, and opioid peptides. Under normal circumstances, no parasympathetic neurons use NA as a transmitter.

The third division of autonomic neurons is made up of the *enteric* plexuses. These neurons are aggregated into series of small ganglia located in the walls of the gastrointestinal tract. The enteric plexuses are unique among autonomic pathways for two main reasons: first, most of the enteric neurons lack direct inputs from central preganglionic neurons; second, in addition to motor neurons, the enteric plexuses contain interneurons and sensory neurons. As a consequence, much of the activity of the enteric plexuses can occur in the absence of direct central control. Nevertheless, central control of at least some enteric neurons can be achieved by the activity of vagal preganglionic inputs to the foregut, sacral preganglionic inputs to the hindgut, and prevertebral sympathetic neurons projecting to much of the gastrointestinal tract. Enteric neurons use a wide range of transmitters, including NO, ACh, ATP, and many neuropeptides. The precise combinations of transmitters vary with the projection and function of the neurons. Other potential transmitters, including serotonin (5-HT) and amino acids, such as γ-aminobutyric acid (GABA) and glutamate, also may be used by some enteric neurons. However, few if any enteric neurons synthesize catecholamine transmitters such as NA.

While the scheme summarized above is reasonably useful, it has two limitations. First, although the cranial and sacral parasympathetic pathways have some features in common, functionally they are not closely related. For example, there is no reason to link the cranial pathways involved in salivary secretion with the sacral pathways involved in micturition. Furthermore, regulation of the activity of many pelvic organs requires coordinated control via both sympathetic and sacral parasympathetic pathways, often in association with the relevant somatic motor pathways (e.g., during sexual behavior). Indeed, many of the ganglia in pelvic pathways contain mixtures of neurons, some of which receive preganglionic inputs from lumbar spinal levels (by definition, sympathetic) and others of which receive preganglionic input from sacral spinal levels (by definition, parasympathetic). Some individual neurons receive convergent inputs from both lumbar and sacral preganglionic neurons, and they may be considered to lie in both sympathetic *and* parasympathetic pathways. Consequently, I will deal with the cranial parasympathetic pathways separately from the sacral parasympathetic pathways. The latter will discussed together with the relevant sympathetic pathways as *pelvic* pathways.

The second problem with the traditional classification of the autonomic pathways is that it leads to their being considered as generic "systems" operating as blocks, usually in opposition to each other, as in the case of the sympathetic and parasympathetic divisions. However, a huge body of data from studies in animals and humans has demonstrated clearly that this idea is a gross and misleading oversimplification. It is abundantly clear from the following descriptions that neither the sympathetic "system" not the parasympathetic "system" is ever activated in its entirety. Rather, each major division of the autonomic motor outflow consists of a series of discrete functional pathways that may be activated independently or in various combinations as required by ongoing physiological or pathophysiological demands on the organism. More-

over, while many effector tissues are innervated by sympathetic and parasympathetic pathways with opposing actions, there are many situations where neurons in sympathetic and parasympathetic pathways may be coactivated. Finally, some target tissues may be innervated by multiple sympathetic or parasympathetic pathways, which may have opposing or complementary actions.

Are There "Autonomic Sensory" Neurons?

Autonomic pathways generally are defined as motor pathways. However, terms like "sympathetic afferents" are sometimes used to refer to sensory neurons with cell bodies in the dorsal root ganglia that innervate visceral targets such as the heart or gastrointestinal tract. The main argument for using this terminology is that these sensory fibers stimulate autonomic reflexes when activated. However, almost any sensory input can generate a response that contains autonomic components. For example, visual stimuli activate pupillomotor and accommodation responses, whereas olfactory and gustatory stimuli can generate salivatory and vasodilator responses. Conversely, visceral nociceptive afferents can produce responses involving somatic motor pathways, such as the contractions of abdominal muscles accompanying severe pain from the gastrointestinal tract or peritoneum. Even from these simple and obvious examples, it is clear that few if any cranial or spinal afferent pathways are associated exclusively with autonomic responses.

Although there are probably no autonomic spinal afferent neurons, within the enteric plexuses there are well-defined populations of neurons that have a primary sensory function (Furness *et al.*, 1998; Kunze and Furness, 1999). The projections of these neurons are restricted to the gut where they participate in local reflexes. They respond to distention of the gut wall or changes in its chemical environment and are essential for the generation of appropriate patterns of activity of enteric neurons regulating gastrointestinal motility, secretion, and blood flow. The intrinsic sensory neurons project either directly or via interneurons to another population of enteric neurons, which in turn project out from the gut (*intestinofugal* neurons) to prevertebral sympathetic ganglia where they can influence the excitability of neurons regulating gut activity (discussed further below).

Despite occasional reports to the contrary, there is little good evidence for genuine sensory neurons within autonomic ganglia lying in sympathetic, parasympathetic, or pelvic pathways. However, many autonomic ganglia contain axon collaterals of unmyelinated sensory neurons (Gibbins, 1995; Mawe, 1995) that may modify the excitability of the autonomic neurons under some circumstances.

Autonomic Pathways as Functional Entities

The following descriptions will focus on the microscopic, chemical, and functional neuroanatomy of the peripheral autonomic pathways of humans. Much of the microscopic anatomy is derived from old studies that have not been repeated or validated with modern techniques. Furthermore, much of the more recent chemical neuroanatomy has not taken into account the possibility that many of the markers that have been examined either may not be specific for the neuronal populations under investigation or may coexist with other markers and potential transmitters. All these problems are confounded by the difficulties in obtaining suitable human material for detailed study. Nevertheless, there are very many studies on the function of autonomic motor pathways in humans that, taken together, shed valuable light on the underlying organization of the pathways. The overwhelming message from these studies is that the autonomic motor pathways in humans, as in animals, are organized into a series of functional entities allowing the precise and graded regulation of the activity of specific effector tissues. It is in this context that the following descriptions of the peripheral autonomic pathways are presented.

CRANIAL AUTONOMIC PATHWAYS

The cranial autonomic pathways project to a wide variety of targets in the head, neck, thorax, and abdomen (Table 6.1). The pathways are associated functionally with four of the cranial nerves: the oculomotor (third cranial nerve; 3n), facial (seventh cranial nerve, 7n), glossopharyngeal (ninth cranial nerve, 9n) and the vagus (tenth cranial nerve, 10n). The last three of these pathways are associated with derivatives of the branchial arches and share many anatomical, neurochemical, and functional features. Most of the final motor neurons in each of these cranial autonomic pathways are in four pairs of major ganglia located bilaterally in the head: the ciliary (3n), pterygopalatine (7n), submandibular (7n), and otic (9n). The ciliary, pterygopalatine, and otic ganglia lie in close anatomical association with each of the main branches of the trigeminal nerve (fifth cranial nerve; the ophthalmic, maxillary, and mandibular branches, respectively; Fig. 6.1), although apparently none of them receives preganglionic inputs from this nerve (see Larsell and Fenton, 1928). Scattered throughout the cranial nerves,

TABLE 6.1 Sources of Parasympathetic Innervation to Cranial Targets

Target	Primary source	Secondary source	Potential transmitters	Function
Iris	Cil		ACh	Contract constrictor[a] Relax dilator[a] (constriction of pupil)
		PtPGn	ACh/NO/VIP	Dilation of pupil?
Ciliary muscles	Cil		ACh	Contract (accommodation)
Choriod vessels	Local neurons	PtPGn	ACh/NO/VIP	Vasodilation
Lacrimal gland	PtPGn	Cil, Otic	ACh/NO/VIP/PACAP	Secretion; vasodilation
Nasal mucosa	PtPGn		ACh/NO/VIP/PACAP	Secretion; vasodilation
Palatine mucosa	PtPGn		ACh/VIP	Secretion; vasodilation
Cerebral arteries	PtPGn	Otic	ACh/NO/VIP	Vasodilation
Superior tarsal muscle	PtPGn		ACh/VIP?	?
Tarsal (Meibomian) glands	PtPGn		ACh/VIP?	?
Hair follicles & glands	PtPGn		ACh/VIP	?
Submandibular gland	SMnGn	Local neurons	ACh/VIP ACh/NO/VIP	Secretion; vasdilation
Sublingual gland	SMnGn	Local neurons	ACh/VIP ACh/NO/VIP	Secretion; vasodilation
Parotid gland	Otic		ACh/VIP ACh/NO/VIP	Secretion; vasodilation
Facial blood vessels	Otic	PtPGn	ACh/NO/VIP	Vasodilation

[a]Pathways that are tonically active.

ACh, acetylcholine; Cil, ciliary ganglion; Otic, otic ganglion; NO, nitric oxide; PACAP, pituitary adenylate cylcase–activating peptide; PtPGn, pterygopalatine ganglion; SMnGn, submandibular ganglion; VIP, vasoactive intestinal polypeptide.

especially the intracranial ramifications of the facial and glossopharyngeal nerves, there are small aggregations of autonomic nerve cell bodies forming microganglia (Fig. 6.1). The final motor neurons of the vagal autonomic pathways (10n) probably lie entirely extracranially, mostly in microganglia associated with the target organs. As far as is known, all the preganglionic neurons in the cranial pathways are cholinergic, although at least some of these neurons also contain nitric oxide synthase (NOS; Gai and Blessing, 1996), the enzyme responsible for synthesis of NO.

Ciliary Ganglion and Oculomotor Pathways

The autonomic pathways of the oculomotor nerve (3n) are involved in the regulation of many important facets of ocular function, including the control of pupil diameter, focus (lens accommodation), and local blood flow. The final motor neurons are primarily located in the *ciliary ganglion*. Most of the preganglionic neurons project from the Edinger–Westphal nucleus via the oculomotor nerve, reaching the ciliary ganglion along the branch to the inferior oblique muscle (Grimes and von Sallman, 1960; Lang, 1981; Mitchell, 1953a; Warwick, 1954). Some preganglionic fibers probably also reach the ciliary ganglion via the long ciliary branch of the trigeminal nerve (Kuchiiwa *et al.* 1993; Zhang *et al.*, 1994).

The ciliary ganglion is a small ganglion, less than 2 mm long, which lies in fat-filled connective tissue in the posterior orbit, just anterior to the superior orbital fissure (Kuntz, 1945; Mitchell, 1953a). On average, the human ciliary ganglion contains about 3000 neurons (range 1000–6800 neurons; Pearson and Pytel, 1978b; Perez and Keyser, 1987), mostly 20–35 μm in diameter (Slavich, 1932). Most of the neurons are multipolar, bearing short branching dendrites (Kuntz, 1945; Slavich, 1932; Warwick, 1954). They are surrounded by dense pericellular networks of preganglionic terminals (Slavich, 1932). Ultrastructural studies in macaques show that many of the synapses from these terminals are made onto short spinelike processes from the cell body or dendrites of the target neurons (May and Warren, 1993; Zhang *et al.*, 1994). The final motor neurons project to the iris and ciliary muscles through postorbital fat via 12–20 short ciliary nerves that are grouped superior and inferior to the optic nerve (Grimes and von Sallman, 1960; Mitchell, 1953a). The ciliary nerves penetrate the sclera and run anteriorly in the perichoroid space to reach their targets.

A small accessory ciliary ganglion occurs in the long ciliary nerves arising from the ophthalmic nerve

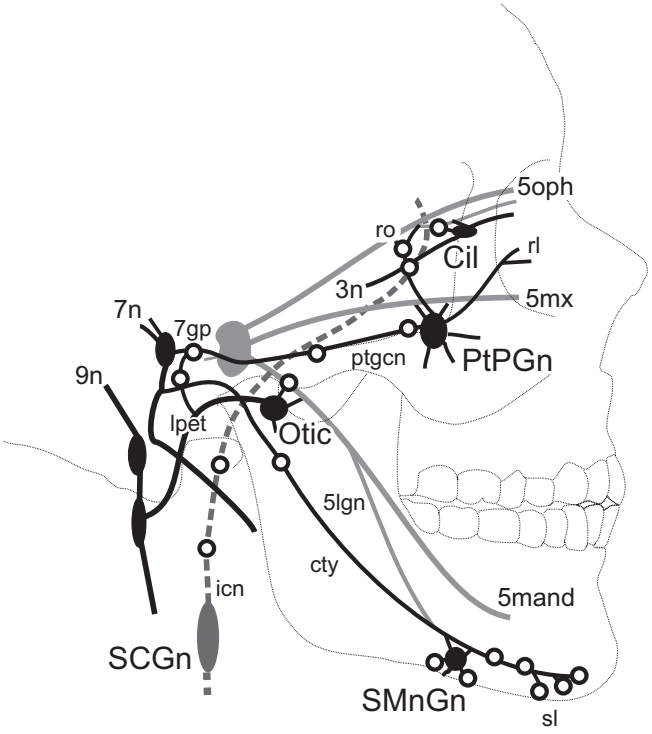

FIGURE 6.1 Distribution of major autonomic ganglia and microganglia *(open circles)* in the cranial nerves. Major branches of the trigeminal nerve are shown in gray (5oph, ophthalmic division; 5mx, maxillary division; 5mand, mandibular division). Other cranial nerves include the oculomotor nerve (3n); facial nerve (7n) and glossopharyngeal nerve (9n). The main path of the internal carotid nerve (icn) carrying sympathetic fibers along the internal carotid artery from the superior cervical ganglion (SCGn) is shown by the dashed gray line. Cil, ciliary ganglion; cty, chorda tympani; 7gp, greater superficial petrosal nerve; lpet, lesser petrosal nerve; 5lgn, lingual nerve; ptgcn, nerve of the pterygoid canal (Vidian nerve); Otic, otic ganglion; PtPGn, pterygopalatine ganglion; rl, lacrimal rami from pterygopalatine ganglion; ro, orbital rami from pterygopalatine ganglion; sl, nerves to sublingual gland; SMnGn, submandibular ganglion.

(Grimes and von Sallman, 1960; Kuchiiwa *et al.*, 1993). In addition, scattered nerve cell bodies also occur along the ciliary nerves, along the nasociliary nerve, and within the choroid (Bryson *et al.*, 1966; Flügel *et al.*, 1994; Givner, 1939; Grimes and von Sallman, 1960; Miller *et al.*, 1983; Sunderland and Hughes, 1946).

The ciliary ganglion neurons are functionally cholinergic. Although some of them contain immunoreactivity to tyrosine hydroxylase, they lack dopamine β-hydroxylase, so that none of them is likely to be noradrenergic (Kirch *et al.*, 1995). They primarily mediate pupilloconstriction and contraction of the ciliary muscles (Lograno and Reibaldi, 1986). These responses must be mediated by separate pathways and populations of final motor neurons, since pupilloconstriction and accommodation can occur independently of each other. Pupilloconstriction is likely to be achieved by the simultaneous contraction of the iris sphincter muscle and relaxation of the iris dilator muscle, both actions being mediated by muscarinic receptors (Ehinger *et al.*, 1968; Heller *et al.*, 1990; Narita and Watanabe, 1982; Suzuki *et al.*, 1983). Recent studies in monkeys indicate that some neurons in the ciliary ganglion also innervate the lacrimal gland (Van der Werf *et al.*, 1996), although their function is unknown.

The neurons located in the choroid contain NOS and VIP (Flügel *et al.*, 1994; Miller *et al.*, 1983) and almost certainly innervate the choroidal blood vessels (Flügel *et al.*, 1994; Miller *et al.*, 1983; Stone *et al.*, 1986; Uusitalo *et al.*, 1984), where they presumably cause vasodilation. These neurons also may innervate the ciliary muscles (Miller *et al.*, 1983; Stone *et al.*, 1986; Uusitalo *et al.*, 1984). However, all these targets also may be innervated neurons containing NOS and VIP that project from the pterygopalatine ganglion (Nilsson, 2000; Ruskell, 1985; see below).

Autonomic Pathways of the Facial and Glossopharyngeal Nerves

The autonomic pathways associated with the facial (7n) and glossopharyngeal (9n) nerves have several features in common: their main functions are secretomotor and vasodilator, their preganglionic neurons are closely associated in the superior and inferior salivatory nuclei, and there are direct anatomical connections between the intracranial pathways. These pathways include the pterygopalatine, submandibular, and otic ganglia, as well as numerous microganglia. Embryologically, the facial nerve is associated with the second branchial arch and its derivatives, whereas the glossopharyngeal nerve is associated with the third branchial arch and its derivatives. The preganglionic neurons in these pathways are organized according to the branchiomeric origins of the corresponding nerves. However, there is no simple relationship between the projections of the autonomic final motor neurons in these pathways and the branchial arch origins of their targets.

Pathways Through the Pterygopalatine Ganglion

The pterygopalatine ganglion (also known as the sphenopalatine ganglion or, more rarely these days, the nasal ganglion or Meckel's ganglion; Gloster, 1961; Larsell and Fenton, 1928) lies deep within the pterygoid fossa, rostral to the anterior opening of the pterygoid canal and inferior to the maxillary nerve (second division of the trigeminal nerve; Kuntz, 1945; Mitchell, 1953a). It can be considered the main parasympathetic ganglion of the upper jaw and related structures. The ganglion is about 3 mm long and contains about 56,500 closely packed nerve cell bodies

(Pearson and Pytel, 1978b). They tend to be ovoid, 20×30 μm in diameter, with thick branching dendrites that often bear knob-shaped endings (Pearson and Pytel, 1978b; Slavich, 1932; Wilson, 1984). In some cells, the dendrites are long, multibranched, and contribute to dense dendritic glomeruli (Slavich, 1932). Secretomotor neurons are larger on average than the vasomotor neurons (e.g., Kuchiiwa *et al.*, 2000; see Gibbins, 1995).

Preganglionic axons reach the pterygopalatine ganglion from the facial nerve via the greater superficial petrosal nerve and the nerve of the pterygoid canal (Vidian nerve). In addition, small groups of nerve cell bodies are found in the distal portion of the nerve of the pterygoid canal, proximal to its junction with the pterygopalatine ganglion (Nomura and Matsuura, 1972).

Final motor neurons in the pterygopalatine ganglion project to blood vessels and glands of the nasal cavity and palate via the nasal, palatine, and pharyngeal nerves (Table 6.1; Azuma *et al.*, 1982; Kuntz, 1945). Lacrimal rami carry postganglionic fibers, probably from separate populations of neurons, to the blood vessels and secretory acini of the lacrimal gland (Fig. 6.1; Ruskell, 1971; Van der Werf *et al.*, 1996). Ocular rami carry postganglionic vasodilator fibers projecting to blood vessels of the eye (Fig. 6.1; Ruskell, 1970a, b, 1985). In addition to these discrete pathways, many postganglionic axons leave the pterygopalatine ganglion and follow the periarterial plexuses to the vascular beds of the nose (Mitchell, 1954) and eye (Ruskell, 1970b). The pterygopalatine ganglion has been shown to innervate the cerebral circulation in laboratory mammals (Hara *et al.*, 1985; Keller *et al.*, 1985; Walters *et al.*, 1986). This arrangement is also likely to occur in humans, with the probable pathways following the ethmoidal arteries and nerves (Hara and Weir, 1988; Mitchell, 1954). There may be a parasympathetic innervation of hair follicles in the face and at least some of these fibers originate from the pterygopalatine ganglia (Gibbins, 1990; cf. Montagna *et al.*, 1964).

Most of the neurons in human pterygopalatine ganglia are functionally cholinergic. They stain strongly for acetylcholinesterase (AChE; Nomura and Matsuura, 1972) and contain VIP, its gene-related peptide, peptide histidine methionine (PHM), and other peptides from the same family including pituitary adenylate cyclase–activating peptide (PACAP; Lundberg *et al.*, 1984; Sibony *et al.*, 1988; Lacroix *et al.*, 1990; Uddman *et al.*, 1999) and helospectin (Hauser-Kronberger *et al.*, 1992b). Most of them (86%) also contain NOS (Gorelova *et al.*, 1996; Hanzawa *et al.*, 1997; Minami *et al.*, 1994; Tasman *et al.*, 1998; Toda *et al.*, 2000; Uddman *et al.*, 1999).

Final motor neurons in the pterygopalatine ganglion give rise to dense networks of non-noradrenergic axons found around the blood vessels (including veins to a lesser extent) and glands in the nasal mucosa (including the olfactory mucosa), oral mucosa, and lacrimal glands, where they mediate secretion and vasodilation (Chorobski and Penfield, 1932; Cauna and Cauna, 1975; Cauna *et al.*, 1972; Golding-Wood, 1961, 1973; Hanazawa *et al.*, 1997; Hauser-Kronberger *et al.*, 1992b; Higbee, 1949; Hilliges *et al.*, 1994; Konno and Togana, 1979; Kulkarni *et al.*, 1994; Lundberg *et al.*, 1984; Nomura and Matsuura, 1972; Riederer *et al.*, 1996, 1999; Rossoni *et al.*, 1979; Sibony *et al.*, 1988; Slade *et al.*, 1986; Tasman *et al.*, 1998; Uddman and Sundler, 1979; Uddman *et al.*, 1980b). Most of these neurons contain ACh, NO, VIP, and probably helospectin. However, animal studies indicate that separate populations of final motor neurons, distinguished by both morphology and transmitter content, innervate the blood vessels and secretory tissues within the cranial glands (Morris *et al.*, 1997; Yasui *et al.*, 1997; Kuchiiwa *et al.*, 2000). Some neurons in the pterygopalatine ganglion project to the smooth muscle part of the superior tarsal muscle (levator palpebrae superioris), tarsal (meibomian) glands, and other small glands in the upper eyelid (Van der Werf *et al.*, 1993; Seifert and Spitznas, 1999). However, in each case their function is unknown.

Specific populations of vasodilator neurons in the pterygopalatine ganglion, probably containing VIP, PACAP, and NOS, innervate the cerebral arteries (Edvinsson *et al.*, 1987; Suzuki *et al.*, 1984; Minimi *et al.*, 1994; Kimura *et al.*, 1997; Ignacio *et al.*, 1997; Toda *et al.*, 2000a, b). The cerebral vasodilator pathways may be tonically active to some degree (Toda *et al.*, 2000a). Neurons containing NOS and VIP also project from the pterygopalatine ganglion to the blood vessels of the eye (Miller *et al.*, 1983; Nilsson, 2000; Stone *et al.*, 1986; Uusitalo *et al.*, 1984), where they cause vasodilation and may mediate increases in intraocular pressure (Nilsson, 2000; Ruskell, 1970b, 1985).

Although secretory responses of the nasal mucosa or lacrimal glands to pterygopalatine nerve stimulation are atropine sensitive and, therefore, are mediated primarily by ACh, vasodilator responses in the cranial circulation, including the cerebral vessels, are largely unaffected by atropine treatment (e.g., Gloster, 1961; Ruskell, 1985; Toda, 1981). These responses are probably mediated by various combinations of NO, VIP, and PHM, coreleased with ACh (Barroso *et al.*, 1996; Ignacio *et al.*, 1997; Izumi, 1999; Kimura *et al.*, 1997; Lundberg, 1981; Minami *et al.*, 1994; Okita and Ichimura, 1998; Tasman *et al.*, 1998; Toda and Okamura, 1996; Toda *et al.*, 2000a, b) .

Pathways Through the Submandibular Ganglion

The submandibular ganglion is fusiform, 2–3 mm long, and is closely associated with the lingual nerve

as it crosses the superior part of the hyoglossus muscle. Preganglionic axons leave the facial nerve in the chorda tympani nerve and join the lingual nerve to reach the submandibular ganglion (Diamant and Wiberg, 1965; Mitchell, 1953a). There is also a possible preganglionic input from the glossopharyngeal nerve (Laage-Hellman and Stromblad, 1960; Reichert and Poth, 1933). Axons of the final motor neurons leave the ganglion to supply the submandibular salivary gland and, after reentering the lingual nerve, the major sublingual gland (Kuntz, 1945; Mitchell, 1953a). Additional final motor neurons in this pathway are embedded in the substance of the submandibular gland, especially around the point of entry of blood vessels and nerves (Kuntz and Richins, 1946; Magielski and Blatt, 1958; Uddman *et al.*, 1980a). A similar group of ganglion cells may occur in the sublingual gland (Chorobski and Penfield, 1932). Some axons in the sublingual and submaxillary glands may arise from final motor neurons located in the chorda tympani itself (Ekstrom *et al.*, 1984; Gibbins *et al.*, 1984).

The neurons provide a dense secretomotor and vasodilator innervation to the submandibular and sublingual glands (Diamant and Wiberg, 1965; Reichert and Poth, 1933). The axons are strongly AChE positive (Garret, 1967; Rossoni *et al.*, 1979), and at least some of them contain VIP and PHM (Hauser-Kronberger *et al.*, 1992a; Kusakabe *et al.*, 1997; Lundberg *et al.*, 1984; Uddman *et al.*, 1980a). Nevertheless, the density of innervation in humans seems to be less than that in the glands of small laboratory mammals (Garret, 1967; Lundberg *et al.*, 1984; Uddman *et al.*, 1980a). On average, the density of VIP fibers around mucous acini is greater than around serous acini (Kusakabe *et al.*, 1997).

It is likely that secretion is largely mediated by ACh but that vasodilation is largely mediated by NO, VIP, and PHM (Ekström,1999; Lundberg, 1981). However, NO, VIP, and PHM all may modify the composition of the saliva, including the content of proteins (e.g., amylase) and bicarbonate ions (Brown *et al.*, 1995; Ekström,1999; Garrett and Kidd, 1993; Larsson *et al.*, 1986) .

Pathways Through the Otic Ganglion

The otic ganglion is very small and may exist only as a group of small ganglia, medial to the mandibular nerve, just distal to its exit from the skull (Kuntz, 1945; Mitchell, 1953a). The preganglionic pathway is usually said to arise from the glossopharyngeal nerve (9n) via the tympanic plexus and the lesser petrosal nerve. However, lesioning studies strongly suggest that an additional preganglionic pathway to the otic ganglion runs via the chorda tympani nerve and that there is at least some preganglionic input from the facial nerve (Diamant and Wiberg, 1965; Kuchiiwa *et al.*, 1998; Kuntz, 1945; Mitchell, 1953a; Reichert and Poth, 1933). Postganglionic axons leave the ganglion mainly via the auriculotemporal nerve to reach the parotid gland (Kuntz and Richins, 1946). Some otic ganglion neurons may project directly to the vasculature of the jaws and the cerebral circulation (Kaji *et al.*, 1988; Segade *et al.*, 1987; Walters *et al.*, 1986), whereas others may provide weak innervation to sweat glands around the lips (List and Peet, 1938; Wilson, 1935). Studies in cats indicate that there also is a small projection from the otic ganglion to the lacrimal gland (Cheng *et al.*, 2000); this projection may correspond to one of the facial nerve pathways through the ganglion.

The neurons of the otic ganglion are morphologically similar to those of the pterygopalatine ganglion (Slavich, 1932). Most of the neurons contain VIP, PACAP, and NOS (Uddman *et al.*, 1999). They provide a moderately dense AChE-positive innervation of the parotid gland (Garret, 1967; Rossoni *et al.*, 1979). Earlier reports suggested that there apparently are relatively few VIP-containing axons in this gland (Uddman *et al.*, 1980a). However, more recent studies have revealed that there is a relatively dense innervation of the acini and blood vessels by fibers containing VIP (Hauser-Kronberger *et al.*, 1992a; Matsuda *et al.*, 1997). Otic ganglion neurons mediate a cholinergic secretion of the parotid gland and contribute to vasodilation responses in the gland and in the vasculature of the jaw (Izumi, 1999; Kaji *et al.*, 1988; Segade *et al.*, 1987). These vasodilations are likely to be mediated primarily by NO and VIP or related peptides (Nozaki *et al.*, 1993; Soinila *et al.*, 1996). Animal studies have shown consistently that some otic ganglion neurons project to the cerebral vasculature, where they probably cause vasodilation (eg. Kadota *et al.*, 1996; Suzuki *et al.*, 1988; Uemura *et al.*, 1988).

Microganglia

In addition to the microganglia already described in the distal nerve of the pterygoid canal and in association with the salivary glands, microganglia are found in several other branches of the facial and glossopharyngeal nerves (Fig. 6.1).

The largest collection of these ganglia is located in the cavernous plexus, lying intracranially but extradurally. The largest ganglion is about 1 mm in diameter and contains at least 500 neurons. It is consistently located between the internal carotid plexus, which follows the internal carotid artery, and the abducens nerve (6n; Gellert, 1934; Lang, 1981; Ruskell and Simons, 1987). In the same region are several smaller ganglia (Mitchell, 1953c), while another collection of microganglia lies between the abducens nerve and the ophthalmic nerve (Gellert, 1934). More rostrally, these

ganglia and their interconnections form the retroorbital plexus (Ruskell, 1970a; Ruskell and Simons, 1987), which communicates directly with the pterygopalatine ganglion via the orbital rami (Ruskell, 1970a).

The facial nerve communicates with the cavernous plexus via the greater superficial petrosal nerve (Chorobski and Penfield, 1932). The glossopharyngeal nerve communicates with the cavernous plexus via the lesser petrosal nerve and small filaments from the tympanic plexus located in the middle ear (Chu, 1968; Mitchell, 1954; Rosen, 1950). Groups of ganglion cells may occur along all these pathways (Chorobski and Penfield, 1932; Gibbins *et al.*, 1984; Hara and Kobayashi, 1987; Van Buskirk, 1945). In laboratory mammals, most of the neurons in the cavernous plexus contain VIP and are thought to contribute to the vasodilator innervation of the cerebral circulation (Gibbins *et al.*, 1984; Hara and Kobayashi, 1987; Walters *et al.*, 1986).

Another major aggregation of ganglion cells lies along the lingual nerve. Within the anterior two-thirds of the tongue are up to 1500 microganglia (Chu, 1968; Fitzgerald and Alexander, 1969; Gomez, 1961). They may receive preganglionic input from both the glossopharyngeal nerve (Fitzgerald and Alexander, 1969; Gomez, 1961) and the facial nerve, via the chorda tympani (Hellekant, 1972). These neurons are strongly AChE positive (Fitzgerald and Alexander, 1969) and probably contain VIP (Lundberg *et al.*, 1984) and NO. It is likely that they mediate vasodilation and mucous secretion from the lingual glands (Hellekant, 1972).

Vagal Pathways

The vagus nerve (10n) carries preganglionic fibers involved in the autonomic regulation of several organs, including the heart, the airways, pancreas, and at least the proximal part of the gastrointestinal tract (Table 6.2). Some of these neurons contain substance P (Halliday *et al.*, 1988). The vagus controls several different effectors in each organ. Furthermore, any particular target tissue may be controlled by two independent vagal pathways with opposite actions.

Most of the final motor neurons in the vagal pathways to these organs are located in ganglionated plexuses relatively close to their target tissues, although some nerve cell bodies are scattered along the vagal nerves (Botar *et al.*, 1950; Dolgo-Saburoff, 1936; Hoffman and Kuntz, 1957). The range of responses mediated by these neurons is diverse and it is not possible to generalize their function. Anatomical connections exist between the vagus and other cranial nerves, especially the glossopharyngeal nerve (Mitchell, 1953a, c, 1954), but there is little functional evidence for direct vagal control of any cranial structures.

Airways

Vagal preganglionic fibers travel to the airways in the pulmonary branches of the vagus, which arise from the vagi posterior to the root of the lung. Together with the vagal and spinal sensory fibers and sympathetic fibers, they form the pulmonary plexus. Microganglia are associated with the plexus and the peripheral ends of the vagal nerve branches in the larynx, epiglottis, trachea, and bronchi. The great majority of these ganglia are associated with the posterior wall of the trachea and bronchi, especially in the region of the bronchial bifurcation (Kuntz, 1945; Taylor and Smith, 1971). The ganglia are located both superficial and deep to the cartilages of the trachea and bronchi. Some ganglion cells are found in the submucosa, especially in the vicinity of the secretory glands (Fisher, 1964; Gaylor, 1934; Larsell and Dow, 1933; Partanen *et al.*, 1982; Spencer and Leof, 1964; Taylor and Smith, 1971). The ganglia of the extrachondrial plexus generally are larger, containing 10–20 neurons, whereas the ganglia of the subchondrial plexus contain only 4–8 cells (Fisher, 1964; Richardson and Ferguson, 1980). The extrachondrial ganglia tend to be arranged as a longitudinal chain, which originally develops as two distinct chains of ganglia on either side of the trachea (Fisher, 1964; Sparrow *et al.*, 1999; Taylor and Smith, 1971). There are extensive connections between the different layers of the tracheobronchial plexus, and small groups of ganglion cells occur at nodal points in the plexus. Ganglion cells also are located near branches of nearby blood vessels (Fisher, 1964; Gaylor, 1934; Larsell and Dow, 1933; Partanen *et al.*, 1982; Spencer and Leof, 1964; Taylor and Smith, 1971).

The nerve cell bodies within the microganglia of the tracheobronchial plexus are usually multipolar with long dendrites (Fisher, 1964; Gaylor, 1934; Larsell and Dow, 1933; Spencer and Leof, 1964). The ganglionic neuropil is complex (Larsell and Dow, 1933), and synapses between axon profiles and nerve cell bodies or their processes are common (Richardson and Ferguson, 1980). However, it is not known how many of these synapses represent vagal preganglionic inputs and how many may be derived from intrinsic neurons or collaterals of unmyelinated sensory neurons. Varicose VIP fibers which could be of either origin have been described in these ganglia (Laitinen *et al.*, 1985; Lundberg *et al.*, 1984). A high proportion of the ganglion cells are labeled for AChE (Partanen *et al.*, 1982; Taylor and Smith, 1971) and choline acetyltransferase (ChAT; Fischer *et al.*, 1996), the enzyme responsible for ACh synthesis, whereas only some of them contain detectable VIP (Dey *et al.*, 1981; Fisher *et al.*, 1996; Laitinen *et al.*, 1985; Lundberg *et al.*, 1984). Many of the neurons also contain NOS, with the

TABLE 6.2 Targets of Parasympathetic Neurons in Vagal Pathways

Target	Potential transmitters	Function
Airways		
Smooth muscle	NO/VIP	Airway dilation
	ACh	Airway constriction
Glands	ACh/NO/VIP	Secretion
Blood vessels	ACh/NO/VIP	Vasodilation
Heart		
Myocardium	ACh/±Som	Negative inotropism[a]
Sinoatrial node		Negative chronotropism[a]
Atrioventricular node		Negative dromotropism, antiarrhythmic
Valves	ACh/?	?
Endocardium	ACh/Som?/VIP?	?
Coronary vessels	ACh/NO?	Vasodilation?
Thyroid		
Follicular cells	ACh/VIP	Thyroid hormone secretion
Blood vessels	NO/VIP/?	Vasodilation
Parathyroid		
Chief cells	ACh/VIP/PACAP	Inhibition of PTH secretion?
Thymus	ACh/VIP	Mobilize lymphocytes?
Pancreas		
Acini	ACh/NO/VIP/Gal/GRP?	Enzyme secretion[a]; bicarbonate secretion[a]
Islets	ACh/NO/VIP/Gal/GRP?	Pancreatic polypeptide secretion; somatostatin secretion; insulin secretion; glucagon secretion
Blood vessels	ACh/NO/VIP	Vasodilation
Esophagus		
Smooth muscle	ACh/?	Contraction
	NO/VIP/NPY/Gal?	Relaxation
Stomach		
Smooth muscle	ACh/SP	Contraction[a]
	ATP/NO/VIP	Relaxation
Gastric mucosa	ACh/?	Acid secretion[a]; gastrin secretion; somatostatin secretion; bicarbonate secretion[a]; pepsinogen secretion;
Blood vessels	NO/VIP?	Vasodilation
Gall bladder		
Smooth muscle	ACh/?	Contraction[a]
	NO/(VIP)	Relaxation
Sphincter of Oddi	NO/VIP	Relaxation[a]
Mucosa	ACh?/NO/VIP	Secretion
Liver	ACh/?	Potentiate insulin response

[a]Pathways that probably are tonically active.

ACh, acetylcholine; ATP, adenosine 5′-triphosphate; Gal, galanin; GRP, gastrin-releasing peptide; NO, nitric oxide; NPY, neuropeptide Y; PACAP, pituitary adenylate cyclase–activating peptide; Som, somatostatin; VIP, vasoactive intestinal polypeptide.

proportion of NOS-positive neurons increasing in ganglia associated with the small bronchi (Fischer and Hoffmann, 1996). There are probably no catecholamine-containing ganglion cells in this area (Partanen *et al.*, 1982).

Axons of the vagal final motor neurons distribute through the tracheobronchial plexus to innervate mainly the submucosal glands and the smooth muscle. Within the muscle, fine varicose fibers run parallel to the smooth muscle cells (Gaylor, 1934; Partanen *et al.*, 1982). Compared with smaller laboratory mammals, the innervation of the tracheal and bronchial smooth muscle in humans is somewhat scanty (Dey *et al.*, 1981; Richardson and Ferguson, 1980). The density of innervation seems to decrease with the decreasing caliber of the airways (Belvisi *et al.*, 1995; Fischer and Hoffmann, 1996; Gaylor, 1934; Laitinen *et al.*, 1985; Richardson, 1983).

The smooth muscle of the trachea and bronchi is innervated by at least two populations of neurons: one population contains NOS and VIP; the other contains ChAT (Dey *et al.*, 1981; Fischer and Hoffmann, 1996; Fischer *et al.*, 1996; Laitinen *et al.*, 1985; Lundberg *et al.*, 1984; Uddman and Sundler, 1979). Some neurons also

contain heme oxygenase-2 (HOX-2), an enzyme responsible for the production of carbon monoxide (CO) for use as a neurotransmitter (Canning *et al.,* 1998). Neurons containing VIP also may contain other neuropeptides such as PACAP and galanin (Luts *et al.,* 1993). Most of the fibers innervating the airway smooth muscle are likely to originate from local ganglia. However, studies in animals have shown clearly that a population of neurons containing NOS and VIP project to the airways from microganglia associated with the esophageal plexus of the vagus (Fischer *et al.,* 1998).

Within the bronchial glands, axons are in close association with both the secretory cells and the myoepithelial cells (Meyrick and Reid, 1970). Many of the axons surrounding the submucosal glands contain both NOS and VIP; they probably also contain ChAT and presumably arise from cell bodies in nearby ganglia (Dey *et al.,* 1981; Fischer and Hoffmann, 1996; Fischer *et al.,* 1996; Laitinen *et al.,* 1985; Lundberg *et al.,* 1984; Uddman and Sundler, 1979). Fibers containing NOS, VIP, and probably ChAT, also likely to be of local origin, innervate pulmonary blood vessels (Dey *et al.,* 1981; Fischer and Hoffmann, 1996; Fischer *et al.,* 1996; Laitinen *et al.,* 1985; Lundberg *et al.,* 1984). Unmyelinated axon profiles have been described in the alveoli (Fox *et al.,* 1980; Hertweck and Hung, 1980), but it is not known if these endings are autonomic or sensory. However, they do not seem to contain NOS or VIP, so that an autonomic origin seems unlikely.

The vagal final motor neurons controlling airway diameter are of two functional types, mediating contraction and relaxation of tracheobronchial smooth muscle, respectively. The neurogenic constriction of the airways is mediated by cholinergic neurons acting on muscarinic receptors (Davis *et al.,* 1982; Richardson and Beland, 1976; Sheppard *et al.,* 1982; Taylor *et al.,* 1984). These neurons are probably tonically active under vagal drive, thereby contributing to resting tracheobronchial tone (De Troyer *et al.,* 1979; Nadel and Widdicombe, 1963; Severinghans and Stupfel, 1955; Sheppard *et al.,* 1982; van der Velden and Hulsmann, 1999; Vincent *et al.,* 1970). The reflex activity of the constrictor neurons can be decreased by deep inspiration (Vincent *et al.,* 1970) and can be increased by irritation of the airways (e.g., Kaufman and Wright, 1969; Nadel, 1980; Nadel and Widdicombe, 1963; Sheppard *et al.,* 1982; van der Velden and Hulsmann, 1999).

Electrical stimulation of nerves within isolated human airways smooth muscle has clearly demonstrated the presence of vagal neurons that relax both tracheal and bronchial smooth muscle. These neurons are the major source of inhibitory innervation of human airway muscle (Barnes, 1984; Richardson, 1983). The neurogenic relaxation is mediated by a transmitter that is neither ACh nor a catecholamine (Davis *et al.,* 1982; Richardson and Beland, 1976; Taylor *et al.,* 1984). Although both VIP and PHM relax preconstricted airway smooth muscle (Barnes and Dixon, 1984; Palmer *et al.,* 1986), almost the entire inhibitory response to vagal stimulation is abolished following the inhibition of NO synthesis, providing strong evidence that NO is the primary transmitter responsible for neurogenic dilation of the airways (Bai and Bramley, 1993; Belvisi *et al.,* 1992, 1995).

The neurons projecting to the submucosal glands of the airways are likely to be secretomotor. Most secretion is blocked by atropine, indicating predominantly cholinergic control. However, glandular secretion, especially from serous cells, may be enhanced by VIP (see Marin, 1986; Webber and Widdicombe, 1987), as in cat salivary glands (see Lundberg *et al.,* 1987). VIP is a potent vasodilator of human pulmonary arteries (Greenberg *et al.,* 1987) and, together with NO, may be a mediator of neurogenic vasodilation from vagal postganglionic neurons (Lundberg *et al.,* 1987; Martling *et al.,* 1985). There also is a neurogenic vasodilation of the pulmonary arteries mediated in part by NO (Scott *et al.,* 1996), but it is not known if the neurons generating this response lie within vagal pathways.

Heart

Vagal preganglionic fibers travel to the heart via (1) the superior cervical rami, originating just distal to the origin of the superior laryngeal nerve; (2) the inferior cervical ramus, arising from the recurrent laryngeal nerve; and (3) the thoracic rami from the thoracic vagal nerves (Kuntz, 1945). These nerves anastomose with the cardiac sympathetic nerves in the region of the ascending aorta and the aortic arch to form the cardiac plexus (Mitchell, 1953b). The dorsal parts of this plexus communicate with the tracheobronchial plexus in the region of the tracheal bifurcation. Small groups of ganglion cells may occur at any point along the nerves feeding into the plexus, but they become more common closer to the heart (Dogiel, 1877). The largest ganglion in the region is the "ganglion of Wrisberg," which lies inferior to the aortic arch between the tracheal bifurcation and the division of the pulmonary arterial trunk (Mitchell, 1953b) at the entry of the left superior sympathetic cardiac nerve to the cardiac plexus (Kuntz, 1945).

Ganglion cells are abundant in the extensions of the cardiac plexus associated with the heart itself (Fig. 6.2). These intrinsic cardiac ganglia mostly are found subepicardially. They are rare within the muscular tissue outside the interatrial septum and do not normally occur in the endocardium (Conti, 1948; Dogiel, 1877;

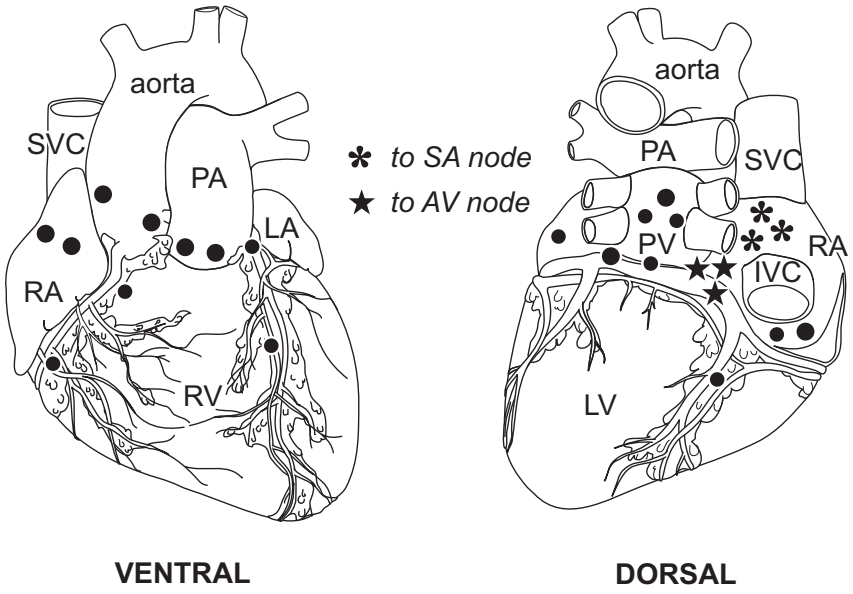

FIGURE 6.2 Distribution of microganglia of the surface of the heart. Microganglia containing final motor neurons to the sinoatrial (SA) node and atrioventricular (AV) node are indicated by different symbols. All of these ganglia are in vagal pathways. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; PA, pulmonary artery; PV, pulmonary veins; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

Francillon, 1928; Lissauer, 1909). The ganglia range in size from 5 to more than 400 neurons (Conti, 1948; King and Coakley, 1958; Pauza *et al.*, 2000; Van der Zypen *et al.*, 1974). The number of ganglia associated with the heart ranges from around 700 to 1500, containing a total of about 43,000 neurons (Pauza *et al.*, 2000). They are grouped together in five main locations together with other smaller groups of neurons (Fig. 6.2; Armour *et al.*, 1997; Conti, 1948; Dogiel, 1877; King and Coakley, 1958; Kuntz, 1945; Mitchell, 1953c; Pauza *et al.*, 2000; Perman, 1924; Smith, 1970, 1971; Van der Zypen *et al.*, 1974):

1. In the adventitia around the origins of the aorta and pulmonary trunk,
2. On the superior surface of the left atrium, extending to the area around the entry of the pulmonary veins,
3. On the superior and dorsal surface of the right atrium, extending to the dorsal interatrial groove and the entry of the superior and inferior caval veins. These neurons are particularly prominent in the area of the sinoatrial node,
4. In a circlet in the atrioventricular groove, with a large group of about 1700 neurons near the atrioventricular node,
5. Within the interatrial septum, especially in the superior ventral portion.

More than 50% of cardiac ganglia are located in the first two areas (Armour *et al.*, 1997; Pauza *et al.*, 2000). Additional isolated ganglion cells may follow the adventitial plexus of the coronary arteries to the ventricles, but they are rare (Conti, 1948; Davies *et al.*, 1952).

The neuronal cell bodies generally are multipolar, varying from 10 to 85 μm in diameter, (King and Coakley, 1958; Kuntz, 1945; Lasowsky, 1930; Pauza *et al.*, 2000; Smith, 1971), and occasionally are binucleate (Conti, 1948; Dogiel, 1877; Lissauer, 1909). The neurons may bear more than 15 dendrites, which may branch several times. Both the size of the neurons and their dendritic complexity increase with age from birth (Conti, 1948; Lasowsky, 1930). In some ganglia, dendrites from different cells may intermingle to form dendritic glomeruli (Kuntz, 1945). The neurons gathered near the atrioventricular node tend to be smaller and have fewer dendrites than those in other locations (Smith, 1971). The dendrites provide a major target for synapses from vagal preganglionic inputs (Ellison and Hibbs, 1976; Kuntz, 1945; Van der Zypen *et al.*, 1974). Studies on laboratory animals have provided evidence that some of the neurons in the cardiac ganglia probably function as interneurons (Horackova *et al.*, 1999; Randall *et al.*, 1998; Steele *et al.*, 1994, 1996) and perhaps as sensory neurons (Klemm *et al.*, 1997); it would be surprising if a similar diversity of neurons did not occur in the human cardiac plexuses.

The great majority of atrial ganglion cells are AChE positive (Van der Zypen *et al.*, 1974). Some of these

neurons also contain somatostatin, probably in its longer form, somatostatin-28 (Day *et al.*, 1985; Franco-Cereceda *et al.*, 1986; Gordon *et al.*, 1993). A separate population of cardiac neurons contains VIP (Lundberg *et al.*, 1984; Gordon *et al.*, 1993; Rechardt *et al.*, 1986). None of the intrinsic cardiac neurons normally contains histochemically detectable catecholamines (Kyösola *et al.*, 1976), although immunoreactivity to a variety of enzymes involved in monoamine synthesis has been reported in many cardiac neurons (Singh *et al.*, 1999). NOS has been detected in neurons both with and without AChE reactivity (Yoshida and Toda, 1996).

Although there is a rich innervation of the myocardial tissue, including the atrioventricular valves (Ferreira and Rossi, 1974; Marron *et al.*, 1995), in most parts of the heart only a relatively small proportion of these axons are non-noradrenergic and therefore likely to be of intrinsic origin (Chiba and Yamauchi, 1970; Kyösola *et al.*, 1976; Marron *et al.*, 1995; Rechardt *et al.*, 1986). The non-noradrenergic axons usually run in multiaxonal bundles with the noradrenergic axons. Nevertheless, there is a relatively dense innervation of the sinoatrial and atrioventricular nodes by final motor neurons in vagal pathways (Kent *et al.*, 1974; Crick *et al.*, 1994). The vagal innervation of the ventricles is less dense than that of the atria and is concentrated in the conducting tissue (Kent *et al.*, 1974; Crick *et al.*, 1994). At least some of the non-noradrenergic axons in the myocardium contain somatostatin-28 (Day *et al.*, 1985; Franco-Cereceda *et al.*, 1986; Wharton *et al.*, 1988). These fibers are most dense in the atrioventricular node and right atrium. VIP-containing axons occur in the atrial myocardium (Lundberg *et al.*, 1984; Rechardt *et al.*, 1986; Wharton *et al.*, 1988) and around coronary blood vessels (Lundberg *et al.*, 1984). Axons containing enkephalin have also been described in human myocardium (Rechardt *et al.*, 1986), but their origin is uncertain.

The major action of vagal stimulation is to reduce the rate of heart beat, mainly by the action of ACh on the sinus node (Higgins *et al.*, 1973; Levy, 1984; Levy *et al.*, 1981; Prystowsky *et al.*, 1981). Force of atrial contraction is also reduced by vagal stimulation, but effects on the ventricle are more subtle (Higgins *et al.*, 1973; Levy *et al.*, 1981). Atrioventricular conduction is reduced (Fee *et al.*, 1987; Higgins *et al.*, 1973; Kent *et al.*, 1974; Levy *et al.*, 1981; Prystowsky *et al.*, 1981) and the ventricular refractory period is increased (Prystowsky *et al.*, 1981).

From experiments in a range of species, including humans and nonhuman primates, it is likely that the various effects of vagal stimulation are mediated by different groups of ganglion cells (Fee *et al.*, 1987; Randall *et al.*,1998). Neurons located in the fat pad on the dorsal surface of the right atrium preferentially innervate the sinoatrial node and selectively decrease the rate of atrial beating without any significant effects on atrioventricular conduction (Billman *et al.*, 1989; Bluemel *et al.*, 1990; Carlson *et al.*, 1992; Nakano *et al.*, 1998; Quan *et al.*, 1999; Randall *et al.*, 1991). In contrast, neurons located in ganglia within epicardial fat pads between the inferior vena cava and the left atrium selectively innervate the atrioventricular node. These neurons decrease atrioventricular conduction with relatively few inotropic effects on the ventricles (Billman *et al.*, 1989; Gatti *et al.*, 1995; Wallick and Martin, 1990). Additional populations of neurons near the superior vena cava and aortic outlet regulate atrial force of beat (Tsuboi *et al.*, 2000) and another population at the cranial end of the medial borders of the ventricles seems to regulate ventricular force (Dickerson *et al.*, 1998; Gatti *et al.*, 1997). Furthermore, experimental evidence from animals strongly indicates that ACh released from vagal nerve endings interacts with a specific population of muscarinic receptors that are located within the neuroeffector junction and that these receptors exert their actions on cardiac contractility in a unique way (Campbell *et al.*, 1989).

The responses to vagal stimulation, especially in the ventricle, are particularly prominent in the presence of concurrent sympathetic stimulation of the heart. Under these conditions, there is likely to be vagally mediated presynaptic inhibition of sympathetic activity (Levy, 1984; Levy *et al.*, 1981; Priola *et al.*, 1998; Randall *et al.*, 1998). An important consequence of these diverse actions of the vagus on the heart is that ventricular fibrillation threshold is increased and the ventricle is protected against potentially catastrophic dysrhythmias (Eckberg, 1980; Kent *et al.*, 1974; Levy, 1984). It seems probable that a separate population of intrinsic vagal neurons is responsible for most of the inhibition of sympathetic activity (Furukawa *et al.*, 1996; Hoyano *et al.*, 1997).

Some of the effects of vagal stimulation in the human heart may be mediated by somatostatin in addition to ACh. Somatostatin decreases the duration of the cardiac action potential and decreases the force of atrial contraction. More importantly, somatostatin can suppress abnormal automaticity of cardiac muscle (e.g., in paroxysmal supraventricular tachycardia) and can restore sinus rhythm (Franco-Cereceda *et al.*, 1986, 1987; Greco *et al.*, 1984; Hou *et al.*, 1987).

Under normal resting conditions, the heart is influenced by a low tonic level of vagal activity, mediated by ACh acting on muscarinic receptors (Carlsten *et al.*, 1957). The level of tone tends to be higher in fit, well-trained athletes (Carlton *et al.*, 1965).

Vagal activity is rapidly reduced at the onset of exercise (Hollander and Bouman, 1975; Maciel *et al.*, 1987; Martin *et al.*, 1974; Pickering *et al.*, 1972) to a degree that is dependent on the magnitude of the exercise (Eckberg *et al.*, 1972; Robinson *et al.*, 1953). At the completion of exercise, vagal activity helps speed the return of heart rate to normal levels (Savin *et al.*, 1982).

In conditions when basal heart rate is very slow, such as during sleep, in highly trained athletes, and in patients with sinus bradycardia, vagal stimulation actually may result in a positive chronotopic response by shortening the time between atrial depolarizations (Yang *et al.*, 1985). While ACh contributes to this response, VIP, which has excitatory actions on the heart (De Neef *et al.*, 1984; Taton *et al.*, 1982), also may be involved. The normal effects of vagal stimulation on the coronary circulation of humans are still unclear (Young and Vatner, 1986; Feigl, 1998). ACh constricts isolated human coronary arteries in which the intima has been shown to be undamaged (Ginsburg *et al.*, 1984; Kalsner, 1985; Yasue *et al.*, 1986). Conversely, intracoronary infusion of muscarinic agonists causes epicardial coronary artery vasodilation in humans without any signs of atherosclerosis, although atherosclerotic vessels constrict both *in vivo* and *in vitro* (Feigl, 1998; Kalsner, 1985; Ludmer *et al.*, 1986; Yasue *et al.*, 1986). However, the application of exogenous ACh is not likely to mimic the responses of the vessels to stimulation of neurons that probably release some combination of ACh, NO, and VIP. On the basis of their transmitter complement, the most likely response to activation of the vagal pathways to the coronary circulation would be vasodilation.

Thyroid and Parathyroid Glands

Small groups of neurons, almost certainly lying within vagal pathways, are found associated with the thyroid gland. They project to the follicular cells and their blood vessels. Some neurons also may project to these targets from small ganglia near the larynx (Grunditz *et al.*, 1996; Ramaswamy *et al.*, 1994). These neurons are probably cholinergic and contain VIP and PHM (Ahren *et al.*, 1980; Grunditz *et al.*, 1986; Van Sande *et al.*, 1980). Both acetylcholine and a range of peptides, including VIP, PHM, and PACAP, stimulate thyroid hormone release from the follicular cells and probably also contribute to a neurogenic vasodilator response (Brandi *et al.*, 1987; Chen *et al.*, 1993; Grunditz *et al.*, 1986; Ishii *et al.*, 1968; Ito *et al.*, 1987; Siperstein *et al.*, 1988; Toccafondi *et al.*, 1984). However, some experiments in rats suggest that the involvement of VIP in responses of the thyroid to vagal stimulation *in vivo* may not be so clear-cut (Michalkiewicz *et al.*, 1994).

There is probably only sparse innervation of the parathyroid glands by vagal autonomic fibers (Luts *et al.*, 1995). The neurons are likely to be cholinergic and contain VIP and PACAP. It is difficult to predict the actions of these neurons on parathyroid hormone secretion because ACh inhibits secretion (Stern *et al.*, 1994; WIlliams *et al.*, 1985) and VIP stimulates it (Joborn *et al.*, 1991).

Thymus

Animal studies have demonstrated autonomic microganglia in the thymus that almost certainly lie in vagal parasympathetic pathways reaching the gland via branches of the recurrent laryngeal nerve (Al-Shawaf *et al.*, 1991; Bulloch and Pomerantz, 1984; Dovas *et al.*, 1998). These neurons are presumably cholinergic and contain VIP (Al-Shawaf *et al.*, 1991). They may influence the differentiation, migration, and release of lymphocytes or alter local blood flow (Antonica *et al.*, 1994; Bulloch and Pomerantz, 1984). The main effects on lymphocytes are likely to be mediated mostly via VIP, since receptors for VIP are widespread on both thymocytes and lymphocytes (Delgado *et al.*, 1999; Head *et al.*, 1998; Reubi *et al.*, 1998). The regulation of thymic activity by neurally released VIP is complicated by the presence of VIP in at least some lymphocytes (Delgado *et al.*, 1999; Leceta *et al.*, 1996).

Pancreas

Final motor neurons within vagal parasympathetic pathways are located in small microganglia scattered throughout the pancreas in interlobular septa, often in close association with the islets of Langerhans (Kroutikova, 1971; Simard, 1937; Singh and Webster, 1978; Van Campenhout, 1927). Studies in animals have shown that some of the pancreatic ganglia may receive synaptic inputs from neurons located in the gut as well as from vagal preganglionic neurons, suggesting that there may be peripheral modulation of vagal pathways to the pancreas (see Mawe, 1995).

At least some of pancreatic ganglion neurons are functionally cholinergic, and they probably provide the predominant autonomic secretomotor innervation of the exocrine and endocrine cells of the human pancreas (Forssmann and Greenberg, 1978; Singh and Webster, 1978). Most of the neurons contain VIP. Many also contain NOS and probably both galanin and gastrin-releasing peptide (GRP). They project to blood vessels, secretory acini and ducts, and the islets (Ahren *et al.*, 1991; Bishop *et al.*, 1980; De Giorgio *et al.*, 1994; Ekblad *et al.*, 1994; Marongiu *et al.*, 1993; Shimosegawa *et al.*, 1992, 1993; Sundler *et al.*, 1978; Verchere *et al.*, 1996). Presumably, as in the heart, there are micro-

anatomical, neurochemical, and functional differences between neurons projecting to specific intrapancreatic targets, but there are no studies to illuminate this point. Vagal preganglionic fibers reach the pancreas via the celiac and superior mesenteric plexuses and enter it with the pancreatic arteries (Singh and Webster, 1978; Woods and Porte, 1974). Some neurons in the vagal ganglia are surrounded by baskets of VIP-containing fibers (Marongiu *et al.,* 1993). It is not known if these fibers are of preganglionic origin or if they originate elsewhere, such as the intestinofugal neurons of the gut (see below).

Bicarbonate and enzyme secretion from the exocrine pancreas occurs at a basal rate that is then increased in two phases after a meal. Part of the basal secretion of bicarbonate and digestive enzymes from the exocrine pancreas is likely to be the result of resting vagal secretomotor activity (Anagostides *et al.,* 1984; Solomon, 1987). Increased vagal activity is responsible for the first phase of meal-induced secretion of pancreatic juice, bicarbonate, and especially enzymes (Huertas *et al.,* 1992). These effects are mediated mainly by cholinergic neurons (Anagostides *et al.,* 1984; Dreiling *et al.,* 1952; Singh and Webster, 1978; Solomon, 1987). Atropine-resistant components of the responses may be mediated by VIP, galanin or perhaps NO (Ahrén *et al.,* 1986; Barrett *et al.,* 1993; Ekblad *et al.,* 1994; Holst *et al.,* 1994; Kirschgessner *et al.,* 1994).

The secretion of bicarbonate and enzymes from the exocrine pancreas is further controlled by the vagus via its actions on the endocrine pancreas. Vagal stimulation results in increased secretion of somatostatin and pancreatic polypeptide from islet cells. These responses are reduced by atropine, indicating the involvement of cholinergic final motor neurons (Bysschaer *et al.,* 1985; Feldman *et al.,* 1979; Glaser *et al.,* 1981; Schwartz *et al.,* 1978; Walsh, 1987). Pancreatic polypeptide and somatostatin each inhibit enzyme secretion from the exocrine pancreas, but only pancreatic polypeptide inhibits bicarbonate secretion (Walsh, 1987). It seems likely that these peptides inhibit secretion by an action on the intrinsic pancreatic neurons (Holst *et al.,* 1990, 1993). The late phase of pancreatic secretion is stimulated primarily by local gastrointestinal hormones, especially secretin and cholecystokinin (CCK; De Fillipi *et al.,* 1982; Solomon, 1987; Walsh, 1987, 1988), neither of which is under direct vagal influence (Walsh, 1987).

Although there is good evidence for vagal stimulation of secretion of insulin and glucagon from the pancreatic islets of some species (Ahrén *et al.,* 1986; Havel and Valverde, 1996; Woods and Porte, 1974), the situation in humans is not at all clear (Brunicardi *et al.,* 1995; Havel and Taborsky, 1994; Taborsky *et al.,* 1998). Some reports have confirmed, and others have denied, that the vagus stimulates insulin and glucagon release in humans (e.g., Havel and Ahren, 1997; Hedo *et al.,* 1978; Kinami *et al.,* 1997; Palmer *et al.,* 1979; Russell *et al.,* 1974; Taylor and Feldman, 1982). These discrepancies may arise in part from the high level of inter and intraindividual variation in responses (Russell *et al.,* 1974; Sjöstrom *et al.,* 1980). Furthermore, vagal stimulation actually may indirectly inhibit insulin and glucagon secretion by releasing pancreatic somatostatin (Ahren, 2000; Walsh, 1987). When vagal stimulation of islet hormone secretion can be demonstrated, it is due mostly to the actions of ACh on muscarinic receptors, although peptides such as VIP, PACAP, and GRP also may be involved (Ahren, 2000). Another complicating factor is the potential involvement of NO, which may be synthesized and released from some of the islet cells in addition to being a cotransmitter with ACh and peptides from the vagal neurons (Ekblad *et al.,* 1994). NO probably potentiates both glucagon secretion and insulin secretion in response to vagal stimulation (Atiya *et al.,* 1996; Bilski *et al.,* 1995; Konturek *et al.,* 1997a). Overall, there is now a general consensus from both animal and human studies that the vagus is involved in the cephalic phase of regulation of peptide release from the pancreatic islets. The most likely role of these vagal motor pathways is to synchronize the activity of the various groups of islet cells (Taborsky *et al.,* 1998; Ahren, 2000).

Gastrointestinal Tract

The alimentary tract itself contains a highly developed system of intrinsic neurons that form the enteric division of the autonomic nervous system. Vagal input to this system occurs primarily in the esophagus and stomach, but may extend to the proximal small intestine and parts of the colon (see Christensen, 1987; Holst *et al.,* 1997; Kuntz, 1945; Roman and Gonella, 1987). The gallbladder also contains an intrinsic ganglionated plexus somewhat similar in structure to the enteric plexuses, and is under a degree of vagal control.

Distal to the roots of the lungs, the vagus nerves divide into a small number of branches that follow the distal esophagus and intermingle to form an open-meshed esophageal plexus. Immediately superior to the diaphragm, the esophageal plexus reforms into anterior and posterior vagal trunks which enter the abdomen to break up into several distinct branches supplying different areas of the stomach, biliary tract, and pancreas (Kuntz, 1945; Mitchell, 1953a; Schein, 1981; Skandalakis *et al.,* 1980). In the esophagus and stomach, most of the vagal plexus lies outside the muscle layers and communicates with the intrinsic

plexuses via fine connections (Rash and Thomas, 1962). There have been no detailed microscopic studies of the relationship between vagal preganglionic fibers and the intrinsic neurons of the digestive tract of humans, but animal studies suggest that vagal preganglionic endings ramify extensively through the ganglia of the myenteric plexus (Holst *et al.*, 1997).

Esophagus

The upper part of the esophagus contains striated muscle controlled by vagal motoneurons acting through motor end plates. In contrast, the lower part of the esophagus contains smooth muscle and is under autonomic control by intrinsic enteric neurons, by sympathetic pathways, and by the vagus (Dodds *et al.*, 1981; Phaosawasdi *et al.*, 1981). Vagal pathways provide both excitatory and inhibitory control of esophageal smooth muscle function via inputs to intrinsic neurons located mainly in the myenteric plexus. Lower esophageal sphincter tone is likely to be actively maintained by cholinergic excitatory neurons under direct vagal control (Dodds *et al.*, 1981; Holloway *et al.*, 1986; Roman and Gonella, 1987). However, following vagotomy, opening of the lower esophageal sphincter during swallowing is inhibited (Roman and Gonella, 1987), implying the presence of a vagal pathway that relaxes the muscle of the sphincter region (Goyal and Rattan, 1978; Meyer *et al.*, 1981). This response may be mediated in part by VIP, which is found together with NOS, NPY, and perhaps galanin in intrinsic neurons projecting to the muscle of the lower esophageal sphincter (Aggestrup *et al.*, 1985; Singaram *et al.*, 1994; Wattchow *et al.*, 1987b), and which relaxes the preconstricted sphincter (Domschke *et al.*, 1978). However, most of the inhibitory response is normally mediated by NO, which is probably released together with VIP from the same neurons (Guelrud *et al.*, 1992; McKirdy *et al.*, 1992; Preiksaitis *et al.*, 1994; Richards *et al.*, 1995; Singaram *et al.*, 1994; Tomita *et al.*, 1997). Inhibitory neurons also project to the circular muscle of the body of the esophagus, but it is not so clear that this pathway is under direct vagal control.

Stomach

In the stomach, the vagus influences both gastric motility and secretion (see Furness and Costa, 1987). When the stomach is being filled, vagal activation causes relaxation of gastric smooth muscle primarily in the proximal stomach, so that gastric distention can occur (Furness and Costa, 1987; Jahnberg, 1977; Meyer, 1987; Roman and Gonella, 1987; Staadas, 1975). This response occurs reflexively during swallowing ("receptive relaxation") or as a direct result of increased intragastric pressure ("accommodation"). The inhibitory transmitters involved are likely to be a some combination of ATP, NO, and VIP, which probably coexist in the same neurons (Belai *et al.*, 2000; Furness and Costa, 1987; Ekblad *et al.*, 1994; Tonini *et al.*, 2000), with much of the accommodation response likely to be mediated by NO (Tonini *et al.*, 2000). The circular muscle of the pylorus is densely innervated by neurons containing NOS and VIP, which presumably represent inhibitory inputs to the muscle (Domoto *et al.*, 1992; Wattchow *et al.*, 1987a). Indeed, functional experiments in animals have revealed a vagal inhibitory input to the pylorus (Malbert *et al.*, 1995; Paterson *et al.*, 2000), but once again, the transmitter mediating most of this response in humans is NO (Tomita *et al.*, 1999). The vagus also can stimulate increases in gastric motility, particularly in the distal stomach (Furness and Costa, 1987; Meyer, 1987), since gastric emptying is slowed significantly after vagotomy (Roman and Gabella, 1987; Staadas, 1975). The excitatory effects of vagal stimulation on gastric motility are probably mediated by intrinsic cholinergic neurons (Edin, 1980; Meyer, 1987; Tomita *et al.*, 1999).

The vagus exerts multiple controls over gastric acid secretion (Fig. 6.3). The details of this control are complex and seem to vary between species and experimental approach (Debas, 1987; Schiller *et al.*, 1980; Walsh, 1987, 1988). One pathway involves intrinsic cholinergic neurons that apparently project directly to acid-secreting parietal cells and that can stimulate acid secretion via muscarinic receptors (Debas, 1987; Feldman, 1985; Feldman *et al.*, 1979; Walsh, 1987). This pathway has a low level of tonic activity and works together with locally released histamine to produce a basal level of acid secretion (Debas, 1987). Alternatively, acid secretion can be stimulated by the release of gastrin from gastric mucosal G cells. Gastrin release is stimulated by vagal activation during eating (Debas, 1987; Walsh, 1987). In addition, there may be a low level of tonic vagal stimulation of gastrin release (Walsh, 1988). The vagal stimulation of gastrin secretion is probably mediated by intrinsic neurons utilizing GRP as a transmitter (Walsh, 1988), although immunohistochemical studies suggest that there is not a simple anatomical relationship between the projections of these neurons and the gastrin-releasing cells (Sjovall *et al.*, 1990).

The amount of gastrin released by vagal stimulation is increased by atropine, suggesting the presence of an inhibitory pathway that may be activated simultaneously with the excitatory pathway and that contains cholinergic neurons acting on muscarinic receptors (Debas, 1987; Feldman *et al.*, 1979; Feldman and Walsh, 1980; Schiller *et al.*, 1980; Walsh, 1987). The

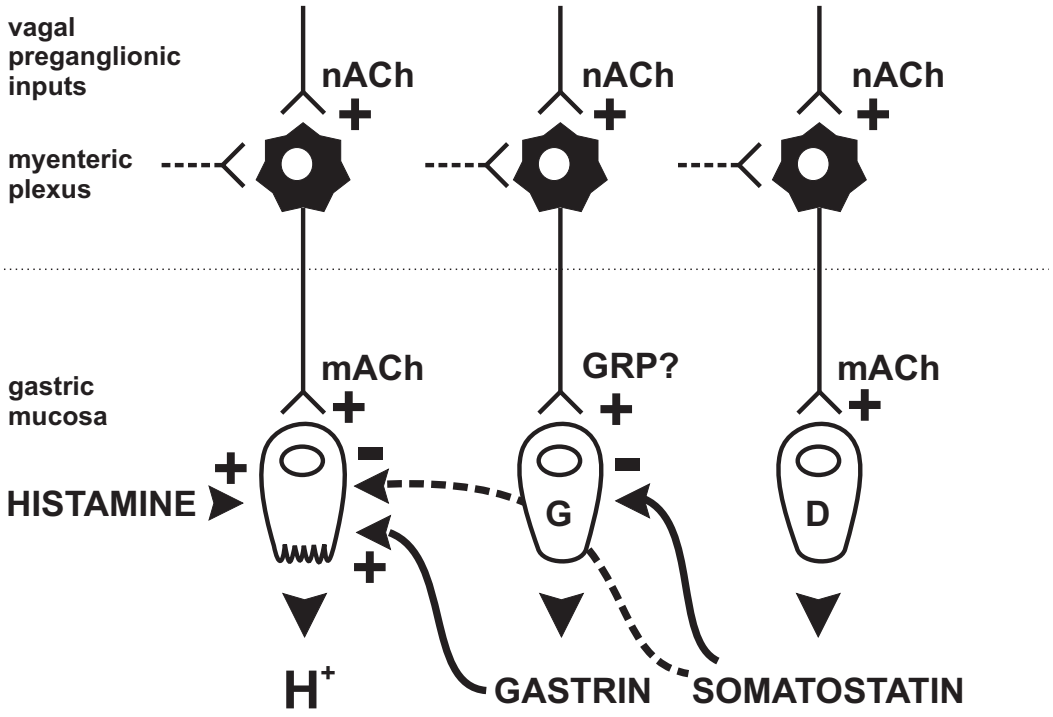

FIGURE 6.3 Simplified circuit diagram showing vagal inputs to the control of acid secretion from the stomach. Note that the acid-secreting parietal cells are in the mucosa of the proximal stomach, whereas the G cells secreting gastrin and the D cells secreting somatostatin are in the mucosa of the distal stomach. Gastrin probably reaches acid-secreting cells via the local circulation; somatostatin probably influences the gastrin cells in a paracrine manner. Many other factors also can influence acid secretion. GRP, gastrin-releasing peptide; mACh, excitatory effect of acetylcholine on muscarinic receptors; nACh, excitatory effect of acetylcholine on nicotinic receptors.

cholinergic neurons in this pathway stimulate the release of somatostatin from D cells in the gastric mucosa, which mediates the inhibition of gastrin release (see Furness and Costa, 1987; Walsh, 1988). Furthermore, somatostatin can inhibit acid secretion directly and also may be able to inhibit local histamine production (Sandvik and Waldum, 1991). Some vagal pathways may modulate somatostatin release indirectly via intrinsic VIP neurons (Holst *et al.*, 1992; Schubert, 1991). Finally, in at least some species the vagus may exert some level of inhibitory feedback control of somatostatin release (Debas and Carvajal, 1994; Holst *et al.*, 1992). However, the relative significance of this pathway in humans is not known.

Simultaneously with the secretion of acid from the stomach, vagal stimulation results in secretion of bicarbonate from nonparietal cells of the stomach, which presumably helps to buffer intragastric pH. The final motor neurons in this pathway probably are cholinergic, although other transmitters may be involved to a lesser extent (Fandriks and Jonson, 1990; Feldman, 1985; Flemstrom, 1987; Forssell and Olbe, 1987a, b; Konturek *et al.*, 1987). There is also likely to be an independent vagal pathway stimulating pepsinogen release from the gastric mucosa (Furness and Costa, 1987).

It is likely that at least some of the neurons within vagal pathways to effectors in the stomach release NO. However, the effects of NO on acid secretion are complex. Overall, experiments in animals suggest that NO will contribute to enhancing acid secretion, but the major effect of NO is to increase blood low to the gastric mucosa (Bilski *et al.*, 1994; Gustaw *et al.*, 1994; Pique *et al.*, 1992). Nevertheless, it is still unknown if this regulation is under direct vagal control.

Biliary Tree

Although much of the regulation of gallbladder activity is under the control of local hormones such as CCK, an intact vagus is required for the normal function of the gallbladder and biliary tract. Much of the innervation of the gallbladder arises from an extensive plexus of small ganglia lying between the serosal and muscularis layers. There also are small ganglia in the

connective tissue underlying the epithelium (De Giorgio *et al.*, 1994, 1995; Uemura *et al.*, 1997). Preganglionic fibers reach the plexuses of the gallbladder via the hepatic branches of the vagus (Hopton, 1973; Inberg and Vuorio, 1969; Parkin *et al.*, 1973; Schein, 1981). The organization of the ganglia within the gallbladder seems to be intermediate between that of the small vagal parasympathetic ganglia associated with organs such as the airways or heart and that of the enteric plexuses.

Immunohistochemical studies in humans and laboratory mammals have indicated that there are probably several functional classes of neurons within the ganglia of the gallbladder. Consequently, vagal activity may have excitatory or inhibitory effects on motility of smooth muscle in the biliary tree, as well as stimulating secretory activity (Mawe, 1995). Most of the neurons within the wall of the gallbladder are likely to be cholinergic (Talmage *et al.*, 1996). However, many of them contain VIP and some of them also contain NOS in addition to a range of coexisting peptides, including PACAP, somatostatin, NPY, and tachykinins (De Giorgio *et al.*, 1994, 1995; Sundler *et al.*, 1977; Uemura *et al.*, 1997).

Following vagotomy, the gallbladder may become distended and the flow of bile from the gallbladder to the duodenum via the sphincter of Oddi may decrease (Fisher *et al.*, 1985; Hopton, 1973; Inberg and Vuorio, 1969; Parkin *et al.*, 1973). Some of these effects are mimicked by atropine, suggesting that some vagal pathways may tonically activate cholinergic neurons that increase gallbladder contractile activity (Fisher *et al.*, 1985; Ryan, 1947; Schein, 1981).

The inhibition of gallbladder contractility and motility seen after vagal stimulation (Fisher *et al.*, 1985; Ryan, 1987) are probably mediated by the intrinsic neurons containing NOS and VIP (Bjorck *et al.*, 1986; De Giorgio *et al.*, 1994), although much of the inhibitory action on the smooth muscle is mediated by NO. Indeed, experimental studies indicate that a tonic relaxation of the sphincter of Oddi, presumably as a result of vagal ongoing activity, is likely to be mediated mostly by NO (Sand *et al.*, 1997; Thune *et al.*, 1995). In contrast, both NO and VIP contribute to secretory responses of the biliary tree (Feeley *et al.*, 1984; Greaves *et al.*, 1998; Konturek *et al.*, 1997b; Luiking *et al.*, 1998; McKirdy *et al.*, 1994; Nilsson *et al.*, 1994, 1996a, b; Sanger *et al.*, 1999; see Mawe, 1995).

Earlier authors have described the hepatic nerves carrying vagal fibers to the liver (e.g., Kuntz, 1945), but the direct effects of vagal stimulation on the liver of humans have been difficult to ascertain (Friedman, 1982; Lautt, 1980, 1983). Ultrastructural data suggest there is relatively little non-noradrenergic innervation of the human liver (Nobin *et al.*, 1978). However, immunohistochemical studies indicate that nerve fibers containing VIP and probably other peptides are associated with the blood vessels and interlobular connective tissue (Akiyoshi *et al.*, 1998; El-Salhy *et al.*, 1993). Moreover, recent functional studies in laboratory mammals suggest that cholinergic vagal neurons have an action that is synergistic with insulin on hepatic glucose metabolism (Moore and Cherrington, 1996; Sadri and Lautt, 2000; Xie and Lautt, 1995; Xue *et al.*, 2000). The locations of the vagal final motor neurons involved in these responses are unknown, but they are most likely to be found in the plexuses associated with the bile duct and gallbladder.

Summary

From the data presented above, some cautious generalizations can be made concerning vagal function. The vagus provides multiple excitatory and inhibitory inputs to its final effectors, including the heart. Many of the final motor neurons in these pathways are cholinergic, and in most tissues the pathways containing cholinergic motor neurons tend to be tonically active. The final motor neurons in noncholinergic vagal pathways probably utilize a range of cotransmitters, most commonly including NO and VIP (Table 6.2). These pathways may be activated reflexively under specific conditions where simple withdrawal of activity in the cholinergic pathway would be inadequate. Whereas some vagal pathways may be relatively simple, as in the inhibitory neurons to airway smooth muscle, others are complex and may involve multiple effectors with feedback via local hormones, as in the regulation of secretion of gastric acid from the stomach or peptides from the endocrine pancreas.

SYMPATHETIC PATHWAYS

The neurons of the sympathetic division of the autonomic nervous system are aggregated into two main collections of ganglia: the paravertebral ganglia, which form the sympathetic chain each side of the vertebral column, and the prevertebral ganglia, which are associated with the abdominal aorta and its major branches (Fig. 6.4). Sympathetic neurons project to most tissues of the body (Tables 6.3–6.5), commonly reaching them by following major nerves containing predominantly sensory and somatic motor nerve fibers. Within the sympathetic chain ganglia, there is little obvious topographic organization of neurons projecting to different targets, although cell bodies tend to be somewhat more clustered near the nerve trunks carrying their axons.

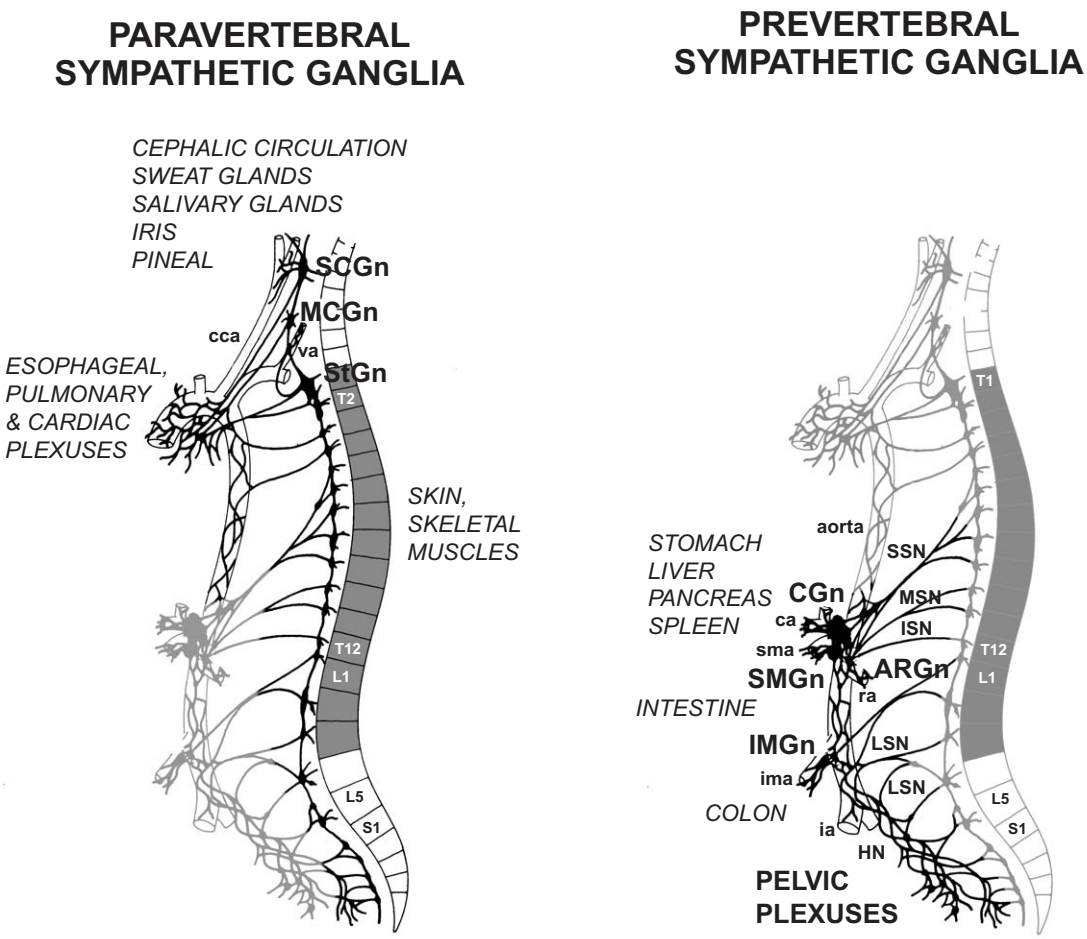

FIGURE 6.4 Anatomical arrangement of the paravertebral and prevertebral sympathetic ganglia, and their main connections. The preganglionic outflows arise from spinal segments T1 to about L3 *(shaded gray)*. ARGn, aorticorenal ganglia; ca, celiac artery; cca, common carotid artery; CGn, celiac ganglion; HN, hypogastric nerve; ia, iliac artery; ima, inferior mesenteric artery; IMGn, inferior mesenteric ganglion; ISN, inferior thoracic splanchnic nerve; LSN, lumbar splanchnic nerves; MCGn, middle cervical ganglion; MSN, middle thoracic splanchnic nerve; ra, renal artery; SCGn, superior cervical ganglion; SMGn, superior mesenteric ganglion; SSN, superior thoracic splanchnic nerve; StGn, stellate ganglion; va, vertebral artery.

TABLE 6.3 Targets of Sympathetic Neurons Projecting from Paravertebral Chain Ganglia

Target	Potential transmitters	Function
Cutaneous vasculature	ATP/NA/NPY	Vasoconstriction[a]
Cutaneous arteriovenous anastomoses	ATP/NA/NPY? ACh?/VIP	Vasoconstriction[a] Vasodilation
Skeletal muscle vasculature	ATP?/NA/NPY ACh/NO	Vasoconstriction[a] Vasodilation
Sweat glands	ACh/VIP/PHM/CGRP/Som	Sudomotor vasodilation
Piloerector muscles	NA	Piloerection ("goose bumps")
Periosteum/bone	ACh?/NO?/VIP	Osteoblast/osteoclast activity; vasodilation
Adipose tissue	NA/NPY?	Lipolysis
Various thoracic, abdominal and pelvic viscera	NA/NPY/±Gal	Various, tissue specific[b]

[a]Pathways that are tonically active.
[b]Visceral targets vary with spinal level. For details of different visceral targets, see text. Neurons projecting to visceral targets form a small proportion of paravertebral ganglion neurons.

ACh, acetylcholine; ATP, adenosine 5′-triphosphate; CGRP, calcitonin gene–related peptide; Gal, galanin; NA, noradrenaline; NO, nitric oxide; NPY, neuropeptide Y; PHM, peptide histidine methionine; Som, somatostatin; VIP, vasoactive intestinal polypeptide.

TABLE 6.4 Cranial Targets of Sympathetic Neurons Projecting from the Superior Cervical Ganglion

Target	Potential transmitters	Function
Cutaneous blood vessels	NA/NPY ACh/VIP/NO?	Vasoconstriction[a] Vasodilation
Facial vein	NA/NPY	Vasodilation
Cerebral arteries	NA/NPY	Vasoconstriction[a]
Sweat glands	ACh/VIP/PHM/CGRP/Som	Secretion; local vasodilation
Salivary glands	NA	Increase protein in saliva
Olfactory mucosa (Bowman's glands)	NA/NPY	Mucous secretion
Iris	NA/NPY	Pupillodilation
Superior tarsal muscle (levator palpebrae superiorus)	NA/NPY	Contract muscle (open eye)[a]
Cornea	NA/NPY?	?
Pineal gland	NA/NPY	Melatonin production

[a]Pathways that are tonically active.
ACh, acetylcholine; CGRP, calcitonin gene–related peptide; NA, noradrenaline; NO, nitric oxide; NPY, neuropeptide Y; PHM, peptide histidine methionine; Som, somatostatin; VIP, vasoactive intestinal polypeptide.

TABLE 6.5 Targets of Sympathetic Neurons Projecting from Prevertebral Ganglia

Target	Function
Mesenteric circulation	Vasoconstriction[a]
Myenteric plexus	Inhibit motor activity[a,b]
Submucous plexus	Inhibit secretomotor activity[a,b]
Sphincter smooth muscle	Contraction[a]
Liver	Promote gluconeogenesis, vasoconstriction[a]
Pancreas	Inhibit insulin secretion; promote glucagon secretion; promote pancreatic polypeptide secretion
Spleen	Contract splenic capsule; vasoconstriction
Kidneys	Vasoconstriction[a]; stimulate renin release; antidiuresis; antinatriuresis
Ovary	Promote ovulation
Testis	Vasoconstriction

[a]Pathways that are tonically active.
[b]These neurons receive peripheral inputs from intestinofugal neurons projecting from the myenteric plexus.

Pathways through the Paravertebral Ganglia

Arrangement of the Paravertebral Ganglia

The paravertebral ganglia are interconnected to make up the sympathetic chains extending from cervical to sacral levels (Fig. 6.4). Although they initially develop segmentally, there can be considerable fusion of adjacent ganglionic primordia, so that the total number of macroscopic ganglia is variable.

Within the cervical region, three or four major ganglia are present. The largest is the superior cervical ganglion, which is about 2.5–3.0 cm long (Fig. 6.4; Becker and Grunt, 1957; Mitchell, 1953a) and which usually contains more than 1 million neurons (Ebbesson, 1963; Pearson and Pytel, 1978a). The ganglion normally lies immediately dorsal to the origin of the internal carotid artery. It has anatomical connections with the cranial nerves (excluding the first, second, and eighth), either directly or via the internal carotid nerve and plexus, and with the first to fourth or fifth cervical spinal nerves (Hoffman, 1957; Mitchell, 1953a, c, 1954; Parkinson, 1988; Parkinson *et al.*, 1978; Pick and Sheehan, 1946). These pathways distribute the axons of the final motor neurons to most of their cephalic targets. Other targets may be reached by fibers following cephalic arteries (Mitchell, 1954). Along the proximal course of the internal carotid nerves there are small microganglia in addition to those described in the cavernous plexus (Mitchell, 1953c).

In about 60% of individuals, there is a middle cervical ganglion that is 0.7–0.8 cm long, located at about the level of the sixth cervical vertebra, just superior to the inferior thyroid artery (Fig. 6.4). It has anatomical connections with the fifth and sixth cervical spinal nerves and contributes to the esophageal, tracheal, and aortic plexuses. In some cases, the middle cervical ganglion fuses to the inferior pole of the superior cervical ganglion to create a combined "mediosuperior" cervical ganglion up to 4.5 cm long (Becker and Grunt, 1957; Hoffman, 1957; Mitchell, 1953a; Wrete, 1959).

Inferior to the middle cervical ganglion there is usually a small vertebral ganglion, lying immediately ventral to the vertebral artery. The vertebral nerves arise from this ganglion. It is sometimes fused with the middle cervical ganglion (Becker and Grunt, 1957; Mitchell, 1953a; Wrete, 1959).

The lowest ganglion of the neck is the inferior cervical ganglion, which usually fuses with the first thoracic ganglion to form the stellate ganglion (Fig. 6.4; Becker and Grunt, 1957; Harman, 1900; Hoffman, 1957; Mitchell, 1953a; Pick and Sheehan, 1946; Wrete, 1959). The combined ganglion may extend up to 2.8 cm. Sometimes it and all the thoracic ganglia down to the fourth segment are fused (Wrete, 1959).

The remaining thoracic sympathetic ganglia are usually associated with each spinal nerve, apart from the most inferior ganglia, which may fuse with adjacent lumbar ganglia (Pick and Sheehan, 1946; Wrete, 1959). The ganglia are relatively small, each containing about 90,000–100,000 nerve cell bodies.

The thoracic ganglia distribute fibers to corresponding or adjacent spinal nerves, and the more superior ganglia make direct contributions to the aortic, cardiac, pulmonary, and esophageal plexuses (Fig. 6.4). The stellate ganglion also supplies sympathetic fibers to the upper limb (Kuntz, 1945; Kuntz *et al.*, 1956; Mitchell, 1953a). The splanchnic nerves arise from the thoracic ganglia and provide sympathetic pathways to the abdominal viscera. The autonomic components of the nerves include not only axons of final motor neurons in the thoracic ganglia, but also preganglionic axons destined for the sympathetic neurons of the prevertebral ganglia. The superior thoracic (or greater) splanchnic nerve is the largest splanchnic nerve, and originates from the fifth or sixth to the ninth or tenth thoracic ganglia (Fig. 6.4; Pick and Sheehan, 1946). It has anatomical connections with the esophageal and aortic plexuses and connects distally to the celiac, superior mesenteric, and aorticorenal ganglia. Where the nerve crosses the aorta, there is usually a small ganglion (Kuntz, 1945; Mitchell, 1953a). The middle thoracic (or lesser) splanchnic nerve arises from the ninth and tenth or tenth and eleventh thoracic segments and communicates with the cardiac plexus and aorticorenal ganglia (see below). The inferior thoracic (or least) splanchnic nerve, when present, originates from the lowest thoracic ganglia and primarily feeds into the renal plexus and ganglia (Fig. 6.4).

The lumbar sympathetic ganglia are extraordinarily variable in their number and location along the lumbar sympathetic chains, and there is no constant pattern to their arrangement (Cowley and Yeager, 1949; Kuntz and Alexander, 1950; Mitchell, 1953a; Webber, 1955, 1958). On average, unfused lumbar ganglia contain from about 60,000 to 85,000 nerve cell bodies (Webber, 1958). The lumbar ganglia have variable anatomical connections with the lumbar spinal nerves and distribute fibers with the lumbar splanchnic nerves to the inferior mesenteric and hypogastric plexuses and the aortic plexus (Fig. 6.4). Many neurons in the lumbar ganglia project to targets in the lower limbs (Kuntz and Alexander, 1950; Kuntz *et al.*, 1956; Mitchell, 1953a; Pick and Sheehan, 1946; Webber, 1955, 1958). Occasionally, in the lumbar region there may be direct cross-connections between the two sympathetic chains, which is probably the only region where this occurs (Cowley and Yeager, 1949; Pick and Sheehan, 1946; Webber, 1955).

At sacral levels, the sympathetic ganglia are small and generally are regularly spaced. As many as six ganglia on each side may be present (Wrete, 1959). Both sympathetic chains meet and fuse at coccygeal levels, where there may be a single small ganglion ("ganglion impar"; Mitchell, 1953a; Pick and Sheehan, 1946). Neurons in these ganglia project via the sacral and coccygeal nerves to the pelvic plexus (Fig. 6.4) and, more distally, to large blood vessels in the pelvic region.

Associated with the sympathetic chain at all levels are large numbers of "accessory" microganglia. These ganglia are found in the ventral roots, especially at lumbar levels (Alexander *et al.*, 1949; Boyd, 1957), and in the sympathetic roots (gray communicating rami) of the spinal nerves (Boyd, 1957; Kuntz and Alexander, 1950; Kuntz *et al.*, 1956; Pick and Sheehan, 1946; Skoog, 1947; Webber, 1955). Microganglia are also found in the lumbar splanchnic nerves (Webber, 1955, 1958) and along the internal carotid nerve and vertebral nerves arising from the cervical ganglia (Becker and Grunt, 1957; Harman, 1900; Hoffman, 1957; Kuntz *et al.*, 1957; Mitchell, 1953c). The microganglia usually contain from a few hundred to a few thousand nerve cell bodies (Kuntz *et al.*, 1956, 1957; Webber, 1955, 1958), although some accessory ganglia may contain 10,000–20,000 neurons (Alexander *et al.*, 1949; Kuntz *et al.*, 1957; Webber, 1958).

Structure of Sympathetic Final Motor Neurons

The structure of the final motor neurons in human sympathetic ganglia has been observed mostly in silver-stained preparations, in which only a subset of neurons and their dendritic processes are fully stained (Fig. 6.5). The cell bodies of sympathetic neurons range from 15 to about 60 μm in diameter, with large cells (35–60 μm) being most common in the superior and middle cervical ganglia (De Castro, 1932). The cells are multipolar, bearing from 1 to 10 or 12 long dendrites. Some of these multipolar cells also have a large number of short dendrites that do not penetrate the satellite cell capsule. Other cells lack long dendrites and have only short intracapsular dendrites (De Castro, 1932; Kuntz, 1945; Ramón y Cajál, 1911). The number of dendrites and their degree of branching have been reported to increase with age (Botar, 1966; De Castro, 1932). The long dendrites may branch considerably and bear varicose terminations that form "dendritic nests" enclosing other ganglion cells. Commonly, the long branching dendrites from several nearby cells intermingle to form complex "dendritic glomeruli." The shorter dendrites usually end as fine tapering processes, but often they terminate with bulbous expansions (De Castro, 1932; Kuntz, 1945; Ramón y Cajál, 1911). Axons usually lack collaterals within the ganglia and arise from the proximal portion of a large dendrite (De Castro, 1932). In animals, there is good evidence that sympathetic neurons in different functional pathways can be distinguished by morphological features such as the size of the cell body and dendritic fields (see Gibbins, 1995). To date, there is no information available to address this issue directly in humans.

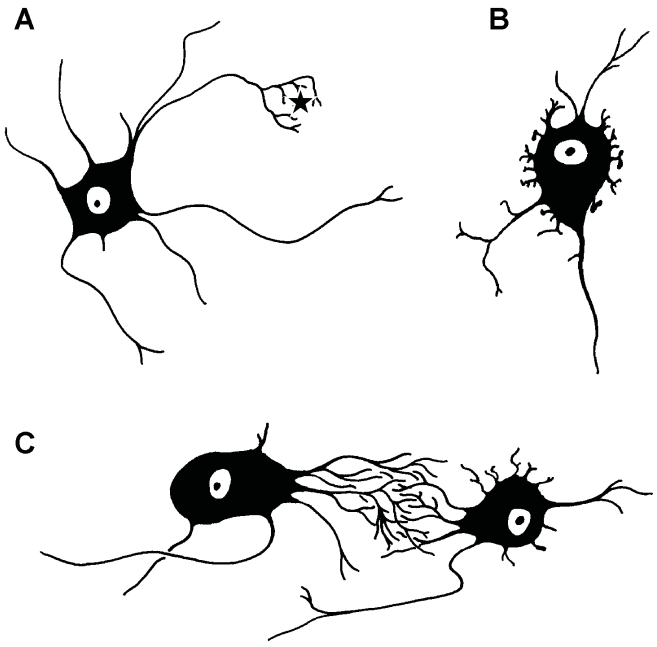

FIGURE 6.5 Shapes of sympathetic final motor neurons as seen in silver-stained preparations based on the descriptions of Ramon y Cajal (1911) and De Castro (1932). These preparations are unlikely to reveal the full extent of dendritic arborisation as would be seen by intracellular dye injections, but such data are not yet available for humans. In laboratory mammals, single neurons may bear more than 15 dendrites with a total dendritic tree length of several millimeters (Gibbins, 1995). **(A)** Neuron with long dendrites, some of which branch around another cell body *(star)*. It is not at all clear if this represents a specific functional relationship or is just a consequence of the packing of the dendrites in the neuropil surrounding the cell bodies. **(B)** This neuron shows many short intracapsular dendritic process in addition to some longer dendrites. The spaces between the short dendrites are likely to be filled by Schwann cells. **(C)** Two neurons with multibranched dendrites form a "dendritic glomerulus." Such arrangements are relatively common in sympathetic and parasympathetic ganglia. Once again, their functional significance, if any, is not known. The cell bodies are typically from 25–50 μm in diameter.

Preganglionic axons lose their myelin sheath before they reach the cell bodies of the final motor neurons within the ganglia (Pick *et al.*, 1964). They encircle the proximal axon and axon hillock region but generally end around the intracapsular dendrites, where they form synapses (De Castro, 1932; Hervonen *et al.*, 1980; Pick, 1970; Pick *et al.*, 1964; Ramón y Cajál, 1911). Preganglionic synapses also occur on the extracapsular dendrites, particularly where they form dendritic glomeruli (De Castro, 1932; Kuntz, 1945; Pick, 1970; Pick *et al.*, 1964). All preganglionic neurons in sympathetic pathways are functionally cholinergic. However, some contain neuropeptides, such as enkephalin (Helen *et al.*, 1984; Hervonen *et al.*, 1980; Przewlocki *et al.*, 1983), and many may contain NOS (Smithson and Benarroch, 1996).

Peptide Expression

As has been observed consistently in a wide range of vertebrate species (Gibbins, 1995), different functional populations of final motor neurons in sympathetic ganglia differentially express immunoreactivity to various neuropeptides (Tables 6.3 and 6.4). There also is selective expression of neuropeptides in different populations of preganglionic fibers projecting to neurons in the ganglia.

At least 80% of the neurons in the superior cervical ganglion are noradrenergic, whereas at lumbar levels, about 75% of neurons are noradrenergic. At all levels in the paravertebral chain, about 50% of the noradrenergic neurons contain NPY (Baffi *et al.*, 1992; Harkonen and Penttila, 1971; Hervonen *et al.*, 1978b; Lundberg *et al.*, 1982; Schmitt *et al.*, 1988; Tajti *et al.*, 1999). There is indirect evidence that galanin may occur in at least some populations of sympathetic

neurons. A small proportion of neurons, most of which are likely to be cholinergic, contain various combinations of VIP, somatostatin, or CGRP (Baffi *et al.*, 1992; Jarvi *et al.*, 1987; Schmitt *et al.*, 1988; Tajti *et al.*, 1999). The remaining neurons are probably non-noradrenergic and represent cholinergic sympathetic neurons (see below). They may comprise up to 20–25% of neurons in the lumbar ganglia. Most of the non-noradrenergic neurons are surrounded by the terminals of preganglionic neurons that contain enkephalin and related peptides (Helen *et al.*, 1984; Hervonen *et al.*, 1980; Przewlocki *et al.*, 1983).

Additional information on the patterns of peptide expression of the final motor neurons in the paravertebral ganglia comes from the analysis of their projections to peripheral targets.

Cutaneous Targets

The best understood paravertebral sympathetic neurons in humans are those projecting to targets in the skin. These pathways primarily are involved in thermoregulation and innervate the cutaneous vasculature, the sweat glands, and the piloerector muscles. Together these effectors make up most of the targets of the paravertebral sympathetic neurons (Table 6.3).

Humans are unique in having a dense innervation of cutaneous sweat glands throughout the skin. On average, an adult human has about 3 million sweat glands (Szabo, 1967). The size of the terminal field of individual sudomotor fibers ranges from about 25 mm^2 to more than 350 mm^2 depending on the exact location (Fig. 6.6; Riedl *et al.*, 1998; Schmelz *et al.*, 1998). In the hairy skin of the limbs, this would mean that each sudomotor neuron innervates about 100 sweat glands. However, each sweat gland is innervated by more than one sudomotor neuron (see Gibbins, 1997). The distribution of sudomotor fibers follows an irregular segmental pattern to the trunk and limbs that shows substantial variation between individuals and even between sides in the same individual (Fig. 6.6; Greenhalgh *et al.*, 1971; Randall *et al.*, 1955; Richter and Otenasek, 1946). The sudomotor fibers to the face are derived mostly from neurons in the superior cervical ganglion. Fibers reach the facial skin via the internal carotid nerve and then via branches of the trigeminal nerve (Guttman, 1940; List and Peet, 1938; Wilson, 1935). As there are 0.5–1.0 million sweat glands in the

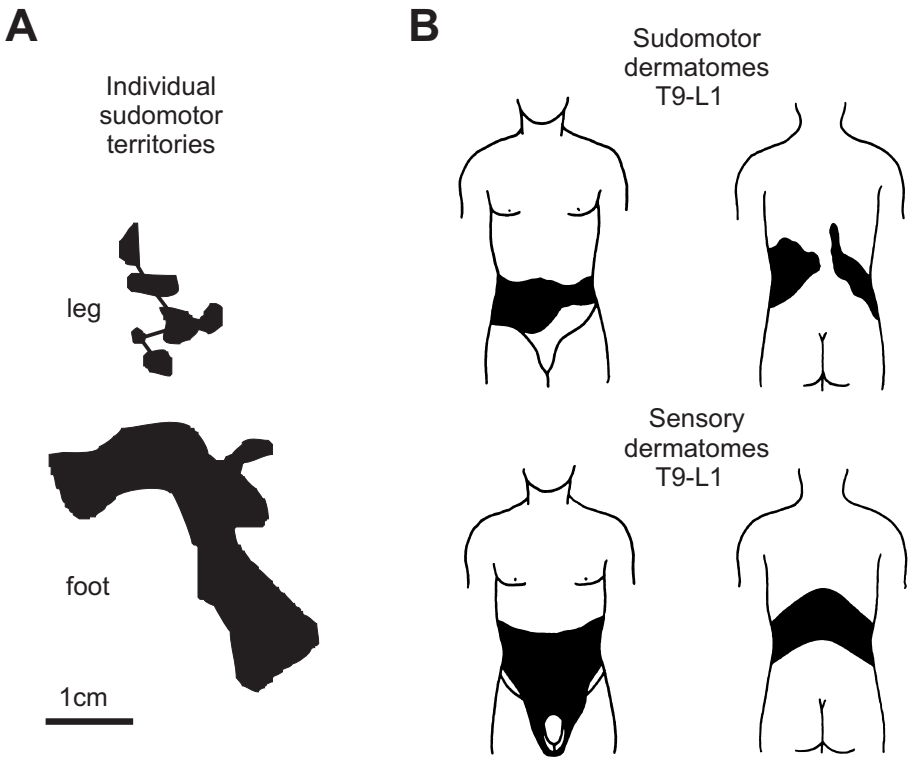

FIGURE 6.6 Organization of the peripheral projections of sudomotor neurons. **(A)** Examples of cutaneous territories of single sudomotor neurons (adapted from Schmelz *et al.*, 1998). **(B)** Distribution of sudomotor projections originating from spinal segments T9 to L1 compared with cutaneous sensory nerve originating from the same spinal levels (adapted from Richter and Otenasek, 1946). Scale bar applies to A only.

facial skin (Gibbins, 1997), sweat glands make up one of the largest targets of final motor neurons in the superior cervical ganglion.

The sudomotor neurons are functionally cholinergic (Foster and Weiner, 1970; Greenhalgh *et al.*, 1971; List and Peet, 1938; Wilson, 1935), but they also contain VIP and PHM as well as CGRP and somatostatin (Björklund *et al.*, 1986; Hartschuh *et al.*, 1984; Johansson, 1986; Schmitt *et al.*, 1988; Vaalasti *et al.*, 1985). The effect of the VIP and CGRP may be to enhance the secretomotor effects of cholinergic stimulation (Yamashita *et al.*, 1987) and to contribute to the noncholinergic vasodilator responses in hairy skin (Brengelmann *et al.*, 1981; Kaada *et al.*, 1984; Rowell, 1981). There may also be a minor noradrenergic innervation of the sweat glands (Tainio *et al.*, 1986; Uno, 1977).

Noradrenergic axons are prominent around cutaneous arteries and veins, where they generally mediate vasoconstriction (Arneklo-Nobin and Owman, 1985; Rothe, 1983; Rowell, 1977; Shepherd and Mancia, 1986). Most of the perivascular noradrenergic axons also contain NPY (Björklund *et al.*, 1986; Johansson, 1986; Lundberg *et al.*, 1983; Sugenoya *et al.*, 1998; Tainio *et al.*, 1986), which may contribute to the vasoconstrictor responses. Experiments in laboratory animals have established that blood flow through small cutaneous arteries and arteriovenous anastomoses is controlled selectively by specific populations of sympathetic vasoconstrictor neurons (Morris, 1997).

The blood vessels of the hairy skin and the skin of the face, but not of the glabrous skin of the hands and feet, are also under sympathetic vasodilator control, which is largely noncholinergic and dependent on the presence of a functional innervation of the sweat glands (Blumberg and Wallin, 1987; Fox and Edholm, 1963; Jänig *et al.*, 1983; Nordin, 1990; Rowell, 1981). Nevertheless, digital arteriovenous anastomoses are innervated by non-noradrenergic axons, at least some of which contain VIP (Hartschuh *et al.*, 1984; Hurley and Mescon, 1956); under some conditions, active sympathetic vasodilation in the skin can be seen in the absence of sweating (Bell and Robbins, 1997; Crandell *et al.*, 1995; Lundberg *et al.*, 1989). The facial vein, draining the skin of the face, is unusual in that it has a dense innervation by sympathetic noradrenergic fibers, which in this case cause vasodilation via the action of noradrenaline on β receptors (Mellander *et al.*, 1982).

Surprisingly, there is a dense noradrenergic innervation of piloerector muscles throughout the hairy skin of humans, except for most of the head (Breathnach, 1977; Orfanos and Mahrle, 1973; Uno, 1977). On average, more than 2 million hair follicles are present, each with a piloerector muscle (Szabo, 1967), forming a substantial peripheral target of the paravertebral neurons. The pilomotor neurons lack NPY, and on this basis it can be estimated that as many as 25% of neurons in the paravertebral ganglia are likely to lie in pilomotor pathways, as is the case in furry mammals such as guinea pigs and rats (see Gibbins, 1997). Pilomotor fibers generally run together with vasoconstrictor and sudomotor fibers in small fascicles to the skin. They have a similar distribution that does not closely follow the sensory dermatomes (Ray *et al.*, 1943; Wallin and Elam, 1997). Activation of the pilomotor pathway results in "goose-bumps" in a now futile attempt to trap an insulating layer of air between the hairs. These observations suggest that hairlessness has evolved only very recently in humans. All of the sympathetic neurons projecting to targets in the skin have a primary thermoregulatory function, although the sudomotor pathways to the palms of the hands, soles of the feet, and the face can be activated selectively by a variety of emotional stimuli (Gibbins, 1997). The activity of cutaneous vasoconstrictor neurons is coordinated with the activity of vasomotor neurons in other vascular beds to maintain cardiac output (Johnson, 1986), but they are relatively insensitive to changes in baroreceptor input (Wallin and Elam, 1997; Wallin and Fagius, 1988). Both lesioning and functional studies have indicated that each of these pathways can be controlled independently as components of a range of respiratory and cardiovascular reflexes in addition to their thermoregulatory roles (Bini *et al.*, 1980a, b; Jänig *et al.*, 1983; Johnson, 1986; Macefield and Wallin, 1996, 1999; Okamoto *et al.*, 1994; Randall *et al.*, 1955; Wallin and Elam, 1997; Wallin and Fagius, 1988).

Vascular Targets

The arteries in skeletal muscle vascular beds are innervated by noradrenergic vasoconstrictor neurons that contain NPY (Lundberg *et al.*, 1983). These pathways are tonically active and are under strong baroreceptor control. The skeletal muscle vasculature also is probably innervated to varying degrees by non-noradrenergic vasodilator neurons (Bell, 1996; Hjemdahl and Kahan, 1996; Jänig *et al.*, 1983; Roddie and Shepherd, 1963; Rowell, 1981), although the presence of this pathway has been disputed repeatedly (Reed *et al.*, 2000; see Joyner and Halliwell, 2000). When it can be observed, active sympathetic vasodilation of skeletal muscle vascular beds seems to be mediated by some combination of ACh and NO (Dietz *et al.*, 1997). The conditions under which sympathetic vasodilation of skeletal muscle vascular beds occurs naturally are not well known, but one possibility is during shivering, when blood flow to thermogenic

muscles needs to be increased in the absence of metabolic vasodilators.

The cell bodies of final motor neurons in both skeletal muscle vasoconstrictor and vasodilator pathways are in the paravertebral ganglia. Nevertheless, each of these pathways almost certainly is regulated independently of the other by the CNS. Furthermore, these pathways are anatomically and functionally distinct from those controlling the cutaneous vascular beds (Brengelmann, 1983; Christensen and Galbo, 1983; Gibbins, 1995; Jänig, 1988; Jänig *et al.*, 1983; Wallin and Fagius, 1988).

In addition to the cutaneous and skeletal muscle vascular beds, noradrenergic neurons, mostly containing NPY, innervate blood vessels throughout the body (Edvinsson *et al.*, 1987; Gu *et al.*, 1983a; Lundberg *et al.*, 1983; Wharton and Gulbenkian, 1987). These neurons generally are vasoconstrictors, and NPY is likely to contribute to these responses along with neuronally released noradrenaline (Franco-Cereceda and Lundberg, 1987; Kahan *et al.*, 1992; Lundberg *et al.*, 1985; Pernow and Lundberg, 1986; Racchi *et al.*, 1997; Schuerch *et al.*, 1998). Veins seem to be particularly sensitive to the constrictor actions of NPY (Linder *et al.*, 1996; Peduzzi *et al.*, 1995). The release of NPY with noradrenaline from some of these neurons has been demonstrated following their reflex activation, usually under conditions where there are high levels of sympathetic vasoconstrictor activity, such as during intense exercise, lower body negative pressure, or heart failure (e.g., Eckberg *et al.*, 1988; Hauser *et al.*, 1996; Kahan *et al.*, 1992; Morris *et al.*, 1986; Pernow *et al.*, 1986). In some vessels at least, ATP can act as a cotransmitter together with noradrenaline and NPY from sympathetic vasoconstrictor neurons (Racchi *et al.*, 1999; Rump *et al.*, 1994).

Cranial Targets

Neurons in the cervical ganglia innervate many nonvascular targets in the cranial region (Table 6.4). Within the eye, noradrenergic axons containing NPY are abundant in both the sphincter and dilator muscles of the iris (Ehinger, 1966; Nomura and Smelser, 1974; Stone, 1986). When light levels are very low the pupil is dilated by the β-adrenoceptor-mediated relaxation of the sphincter and α-adrenoceptor-mediated contraction of the dilator muscle. During normal daylight levels, these neurons are largely inactive (Sears, 1984). The smooth muscle of the levator palpebrae superioris muscle (superior tarsal muscle), which elevates the upper eyelid and keeps the eye open, is innervated by a small set of NPY-containing neurons in the superior cervical ganglion. These neurons are tonically active as long as we are awake. Sympathetic fibers also have been observed in the cornea, especially in the region of the corneoscleral limbus. Some of these fibers are associated with small blood vessels, where they presumably mediate vasoconstriction. The function of the sympathetic fibers in the cornea itself is not known (Marfurt and Ellis, 1993; Chen *et al.*, 1999).

Noradrenergic neurons in the cervical ganglia innervate the secretory cells of the parotid and submandibular salivary glands, but not the sublingual glands (Rossoni *et al.*, 1979). There is a dense sympathetic supply to the lacrimal gland (Ehinger, 1966). These neurons probably do *not* contain NPY (Lundberg *et al.*, 1983). They modulate secretion that is controlled primarily by cranial autonomic neurons. Based on animal studies, the neurons projecting to the salivary glands would be expected to have very large cell bodies (Gibbins, 1995), and they may correspond to the large cells observed in the superior cervical ganglion by De Castro (1932). Sympathetic fibers containing NPY are abundant in the nasal and olfactory mucosa. In the latter, they probably stimulate mucus secretion from the Bowman glands, which contribute to maintaining an appropriate environment for the olfactory receptors (Chen *et al.*, 1993).

The thyroid gland is innervated by noradrenergic neurons containing NPY, which originate in the middle cervical ganglion and which may stimulate hormone secretion (Grunditz *et al.*, 1984; Melander *et al.*, 1974; Romeo *et al.*, 1986). Sympathetic neurons containing NPY also project from the superior cervical ganglion to the pineal gland, where they stimulate melatonin production. They reach the pineal bilaterally via the internal carotid nerve and the "nervus conarius" that runs through the tentorium cerebelli (Korf, 1996).

Thoracic and Abdominal Targets

The sympathetic noradrenergic innervation of the heart is derived mainly from the cervical and upper thoracic ganglia (T1 to T4 or T5). These neurons exert positive inotropic and chronotropic effects on the heart. For example, they tend to be activated at the commencement of exercise, after withdrawal of vagal inhibitory tone (Eckberg *et al.*, 1972; Maciel *et al.*, 1987; Savin *et al.*, 1982). However, baroreflex-mediated tachycardia is likely to be a direct sympathetic excitation overriding the effects of vagal activity (Eckberg, 1980). The sympathetic neurons projecting to the heart contain NPY, which is released mostly under conditions of high levels of sympathetic activity to the heart, such as exercise or anoxia (Gu *et al.*, 1983a; Kaijser *et al.*, 1990, 1994; Lundberg *et al.*, 1983). A major action of this NPY is to inhibit the activity of vagal final motor neurons within the cardiac plexuses (Potter, 1985).

The cervical and upper thoracic ganglia also contain neurons that project out along the vagus to the foregut (Furness and Costa, 1987; see below). There is virtually no functional sympathetic innervation of the airway smooth muscle, despite abundant β-adrenoceptors in that tissue (Barnes, 1984; Goldie *et al.*, 1997; Partanen *et al.*, 1982; Richardson, 1983). Furthermore, there is little direct sympathetic innervation of the respiratory mucosae of the distal airways (Cauna *et al.*, 1972; Nomura and Matsuura, 1972).

A potentially enormous target of noradrenergic neurons in the paravertebral ganglia is adipose tissue. There is increasing evidence that sympathetic activity can increase lipolysis, perhaps stimulated by the central effects of leptin (Nonogaki, 2000). However, the direct innervation of adipocytes in white-fat tissue seems to be relatively sparse. The activity of any innervation of the adipose tissue is almost certainly coordinated with that of the sympathetic outflows to the endocrine pancreas and liver (Nonogaki, 2000).

In addition to sudomotor neurons and vasodilator neurons, there are probably other small populations of non-noradrenergic neurons in the paravertebral ganglia. For example, there is now good evidence that some VIP-containing paravertebral neurons innervate the periosteum (Hohmann *et al.*, 1986). These neurons may regulate the activity of osteoblasts and osteoclasts as well as influencing local blood flow to the bone (Togari *et al.*, 1997; Winding *et al.*, 1997).

Pathways through the Prevertebral Ganglia

The prevertebral ganglia lie in complex plexuses associated with the abdominal aorta and its major arterial branches (Fig. 6.4). The sympathetic final motor neurons in these ganglia regulate a wide range of effectors in the abdominal and pelvic regions (Table 6.5). The neurons contribute to the most complex peripheral autonomic circuits outside the enteric plexuses. The celiac plexus surrounds the proximal segment of the celiac artery and the root of the superior mesenteric artery. The celiac ganglion has two major poles, each about 20–25 mm by 10–15 mm, and about 3–5 mm thick, which lie either side of the celiac nerve trunk (Mitchell, 1953a). Together they contain about 1.8 million nerve cell bodies (Botar, 1966). The ganglia themselves are somewhat diffuse. Nevertheless, commonly a detached inferolateral portion on each side can be identified as the aorticorenal ganglion (interrenal ganglia). Sometimes, a distinct single superior mesenteric ganglion occurs on the aorta just superior or inferior to the origin of the superior mesenteric artery (Kuntz, 1945; Mitchell, 1953a). Preganglionic fibers reach the celiac ganglion via the superior splanchnic nerves, and the middle splanchnic nerves provide input to the aorticorenal ganglia. Most of the neurons in the ganglia are noradrenergic and innervate the gastrointestinal tract and its associated structures, including liver, gallbladder, and pancreas. The sympathetic innervation of the spleen probably originates from cell bodies in the celiac plexus (Felten *et al.*, 1987), while the innervation of the kidneys is derived largely from neurons in the aorticorenal ganglia (Ferguson and Bell, 1993; Mitchell, 1935). The aorticorenal ganglia also provide much of the innervation of the gonads (Dail, 1993; Stjernquist, 1996; Traurig and Papka, 1993).

The celiac plexus extends inferiorly toward the inferior mesenteric plexus as the intermesenteric plexus, within which small ganglia are usually found (Baljet and Drukker, 1981; Wozniak and Skowronska, 1967). The inferior mesenteric plexus surrounds the root of the inferior mesenteric artery and contains the inferior mesenteric ganglia. The main ganglion is at most 1–2 mm long and may consist only of a diffuse collection of microganglia (Kuntz, 1940; Southam, 1959; Trumble, 1933–1934). Preganglionic inputs run in the inferior splanchnic nerve and lumbar splanchnic nerves. Sympathetic final motor neurons in these ganglia project to the colon via the colonic nerves and inferiorly to the pelvic plexus via the superior hypogastric plexus (Baljet and Drukker, 1981; Mitchell, 1935; Trumble, 1933–1934).

The superior hypogastric plexus (also known as the hypogastric nerve or the presacral nerve) consists of several ganglionated nerve trunks extending from the inferior mesenteric plexus to the inferior hypogastric, or pelvic, plexus. These neurons mainly supply the pelvic viscera and will be discussed further in "Pelvic Autonomic Pathways."

The neurons of the celiac and inferior mesenteric plexuses have ranges of shapes and dendritic branching patterns similar to those of neurons in the paravertebral ganglia (Botar, 1966; Kuntz, 1938, 1940). Although the largest cell bodies in the prevertebral ganglion are not as big as those in the superior cervical ganglion, there are relatively few small cells. Most cells are between 35 and 45 μm in diameter (Botar, 1966; De Castro, 1932). In addition to their spinal preganglionic input from the splanchnic nerves, many of these neurons are unique among sympathetic pathways in that they receive excitatory inputs from peripheral enteric neurons, which are cholinergic and probably contain VIP (Furness and Costa, 1987; Gibbins, 1995; Quartu *et al.*, 1993). Thus, prevertebral sympathetic neurons can participate in peripheral reflexes that may be at least partially independent of

direct central control (Furness and Costa, 1987; Kuntz, 1938, 1940; Mawe, 1995; Szurzewski, 1981).

One population of prevertebral neurons provides vasoconstrictor innervation to the blood vessels of the mesenteries and gut. The neurons contain and release NPY in addition to noradrenaline (Ahlborg *et al.*, 1991). These pathways are under strong baroreceptor control; consequently, the level of vasoconstrictor activity in the splanchnic circulation can have a major impact on central blood pressure. Splanchnic blood flow also varies depending on the level of activity of the gut (Mathias *et al.*, 1996).

The sympathetic neurons projecting to the kidney cause vasoconstriction and have an important role in stimulating renin release. They also have complex effects on renal water and electrolyte balance, with a net result of reducing water and sodium excretion (Kopp and Di Bona, 1993). Although the renal nerves controlling different aspects of renal function may arise from distinct populations of final motor neurons, they probably all contain NPY (Ferguson and Bell, 1993). It is clear that the pathways causing renal vasoconstriction can be activated independently of vasoconstrictor pathways to other major vascular beds such as the mesentery or skeletal muscles (Jänig, 1988).

Most of the noradrenergic neurons with cell bodies in the celiac and inferior mesenteric plexuses regulate gastrointestinal motility and secretion (Fig. 6.7). One group of these neurons inhibits gastrointestinal motility mainly by inhibiting the activation of intrinsic cholinergic motor neurons with cell bodies in the myenteric plexus (Furness and Costa, 1987; Roman and Gonella, 1987). A second population of prevertebral neurons exerts a tonic inhibitory influence on the secretomotor neurons located in the submucous plexus of the intestines (Furness and Costa, 1987). In both locations, noradrenergic terminals ramify throughout the ganglia, often in close association with enteric ganglion cells (Llewellyn-Smith *et al.*, 1984). In contrast, there is a direct sympathetic innervation of the gastrointestinal sphincters that usually results in their contraction, further contributing to the sympathetic inhibition of the transit of contents along the digestive tract (Christensen, 1987; Furness and Costa, 1987; Roman and Gonella, 1987). All of these prevertebral sympathetic neurons can be activated reflexively by mechanical distention of the bowel or by chemical stimulation of the mucosa. Some of these reflexes are mediated in part by the enteric neurons projecting directly to neurons in the prevertebral

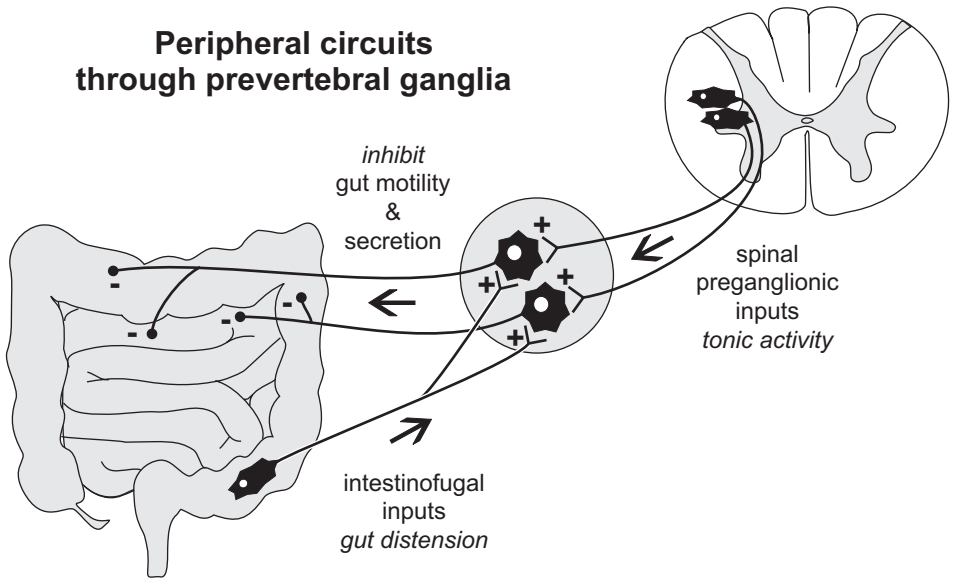

FIGURE 6.7 Diagram of the intestinofugal circuit through the prevertebral sympathetic ganglia. Sympathetic neurons in the ganglia receive inputs from both spinal preganglionic neurons and enteric intestinofugal neurons. All these inputs are excitatory and mediated by the actions of acetylcholine on nicotinic receptors. However, other substances, including nitric oxide and a range of peptides, may be released from these cholinergic terminals. The spinal inputs are tonically active, while the enteric inputs are activated in response to distention of the gut. Separate populations of sympathetic neurons project to the myenteric plexus to inhibit gut motility and to the submucous plexus to inhibit secretomotor activity. Some sympathetic neurons project back to the initial site of distension, but others project to more oral regions of the gut. Intestinofugal neurons occur throughout the small and large intestines. The arrows in the diagram refer to the direction of neural traffic.

ganglia (Fig. 6.7; Furness and Costa, 1987; Kuntz, 1938, 1940; Szurzewski, 1981). It can be argued that the primary function of the pathways through the prevertebral ganglia is to contribute to blood volume regulation by controlling fluid secretion and excretion from the gastrointestinal tract. This function is under central control via the spinal preganglionic inputs to the prevertebral ganglion cells. However, the inputs from peripheral enteric neurons that respond to gut distention allows the gut to take some level of priority in the control of the activity of the prevertebral neurons, presumably under conditions when its integrity may become compromised.

The abundant noradrenergic innervation of the parenchyma and vasculature of the liver arises from the celiac plexus (Nobin *et al.*, 1978). Sympathetic stimulation is involved in stimulating glucose output from the liver to the blood (Friedman, 1982; Lautt, 1980). Sympathetic neurons in the celiac plexus innervate the islets of the pancreas, where they have a complex variety of actions. Overall, insulin secretion is inhibited, whereas secretion of glucagon and pancreatic polypeptide is stimulated by sympathetic inputs. Most of these actions are mediated by noradrenaline, with the precise roles of peptides such as NPY and galanin being difficult to ascertain in humans (Ahren *et al.*, 1991; Ahren, 2000; Ahlborg *et al.*, 1992; Dunning and Taborski, 1988; Edwards and Bloom, 1996; Nonogaki, 2000; Verchere *et al.*, 1996; Yamaguchi, 1992). The combined effect of the activation of sympathetic pathways through the celiac plexus to the liver and pancreas is an increase in blood glucose concentration.

The functions of the sympathetic innervation of the gonads are still not well understood. There is relatively little direct innervation of the testes, with most sympathetic fibers innervating local blood vessels, where they presumably cause vasoconstriction. The smooth muscle of the epididymis is heavily innervated by sympathetic fibers, but it is likely that these fibers arise from neurons in the hypogastric plexus (Dail, 1993; Stjernquist, 1996). In contrast, the ovary is well supplied with sympathetic fibers, mostly originating from various levels of the prevertebral plexuses. The fibers are associated mainly with contractile cells around the follicles, and they probably facilitate ovulation (Stjernqusit, 1996; Traurig and Papka, 1993).

PELVIC AUTONOMIC PATHWAYS

The pelvic autonomic pathways provide sympathetic and parasympathetic innervation to a wide variety of pelvic viscera (Table 6.6). In most viscera, the primary target of the innervation is smooth muscle, although there is increasing evidence for innervation of secretory epithelia and mucosal glands. There also is some evidence that nonsympathetic innervation of the gonads may arise from parts of the pelvic plexus (Jorgensen *et al.*, 1996; Tainio, 1994). Perhaps more than any other set of autonomic pathways, the activity of the pelvic autonomic neurons must be coordinated with the activity of somatic motor pathways. This can be seen during sexual activity and the control of micturition, defecation, and continence.

The prevertebral sympathetic plexuses extend inferiorly into the pelvis as a continuous meshwork of ganglionated nerve trunks. This plexus has been divided into the superior and inferior hypogastric plexuses (e.g., Baljet and Drukker, 1981; Mitchell, 1935; Wozniak and Skowronska, 1967). The latter plexus lies on each side of the rectum and interconnects dorsal to the rectum. The plexus extends ventrally toward the bladder and internal genital organs (Baljet and Drukker, 1981; Curtis *et al.*, 1942; Mitchell, 1935, 1953a; Wozniak and Skowronska, 1967). Most earlier authors have used the term "pelvic plexus" only for the inferior hypogastric plexus (Curtis *et al.*, 1942; Davis, 1933; Mitchell, 1935; Trumble, 1933-1934; Wozniak and Skowronska, 1967). However, more recent experimental studies, mainly in nonhumans, indicate that all the neurons in the pelvic region, including the superior and inferior hypogastric plexuses, are best considered together as the "pelvic plexuses" (Costa and Furness, 1973; Keast, 1995, 1999; Owman *et al.*, 1983; Szurzewski, 1981).

The ganglia in the pelvic plexuses contain both noradrenergic and non-noradrenergic neurons (Keast, 1995; and references below). Immunohistochemical observations in humans and a range of other mammals indicate that there are many different subsets of pelvic neurons that can be distinguished by the combinations of potential transmitters they contain. The noradrenergic neurons probably mostly contain NPY, although some may contain somatostatin or galanin. It seems that most of the non-noradrenergic neurons are cholinergic and contain immunoreactivity for ChAT and the vesicular ACh transporter (VAChT), even though ACh itself may have only a minor role in neurotransmission to a specific target tissue. Many of these neurons also contain immunoreactivity to NOS, and there is now considerable evidence that NO itself is a major transmitter in most of these neurons. It seems that most of the cholinergic neurons contain NPY, and those that contain NOS also contain VIP and related peptides, such as PHM. A high proportion of the latter neurons also contain immunoreactivity for HOX-2, although the role of CO is unknown. Neurons

TABLE 6.6 Targets of Neurons Projecting from Pelvic Ganglia

Target	Potential transmitters	Function
Ureter	NO/VIP/NPY	Inhibit smooth muscle activity
	NO/VIP	Secretomotor, vasodilator
Detrusor	ATP/ACh/NPY/± NO	Contraction
	NO/VIP	Relaxation
Urethra	NA/NPY	Contraction
	ACh/NO/VIP	Relaxation
Vas deferens	ATP/NA/NPY/Gal	Contraction
	ACh/NO/VIP/NPY±Som	Relaxation? secretion?
Seminal vesicles	ATP/NA/NPY/Gal	Contraction
	ACh/NO/VIP/NPY±Som	Relaxation? secretion?
Prostate	ATP/NA/NPY/Gal	Contraction
	ACh/NO/VIP/NPY±Som	Relaxation? secretion?
Penile erectile tissue	ACh/NO/VIP/PHM	Vasodilation
	NA/±NPY	Vasoconstriction
Uterus	NA/NPY	Contraction (nonpregnant)
		Relaxation (pregnant)
	NO/VIP	Relaxation, vasodilation, secretion
Vagina	NA/NPY	Contraction
	NO/VIP	Relaxation, vasodilation, secretion
Colon/Rectum	NA/?	Inhibit activity
	ACh/?	Contraction
Internal anal sphincter	NA/?	Contraction
	NO/VIP	Relaxation

ACh, acetylcholine; ATP, adenosine 5′-triphosphate; Gal, galanin; NA, noradrenaline; NO, nitric oxide; NPY, neuropeptide Y; PHM, peptide histidine methionine; Som, somatostatin; VIP, vasoactive intestinal polypeptide.

containing NOS, VIP, NPY, and HOX-2 almost certainly relax smooth muscle but cause secretion from epithelia lining most of the pelvic viscera. A potentially confounding issue is the presence of neurons that contain immunoreactivity for tyrosine hydroxylase and NOS. Some of these neurons may use both noradrenaline and NO as transmitters, but it has not yet been established that all these neurons actually synthesize and release catecholamines.

Preganglionic inputs to the ganglion cells arise mainly from lumbar levels via the hypogastric nerves and the second to fourth sacral levels via the pelvic nerves. The lumbar inputs are directed primarily to noradrenergic neurons, and the sacral inputs generally supply non-noradrenergic neurons. However, some neurons may receive inputs from both lumbar and sacral levels (Keast, 1995, 1999; Szurzewski, 1981). Thus, some neurons may be activated by both sympathetic and parasympathetic central pathways (Keast, 1995, 1999; Mitchell, 1953a). Furthermore, sympathetic neurons with cell bodies in the sacral paravertebral ganglia contribute to the pelvic plexuses via the pelvic splanchnic nerves (Baljet and Drukker, 1981; Mitchell, 1953a; Owman *et al.*, 1983; Trumble, 1933–1934). At least some of these neurons end in the ganglia themselves where they can modify ganglionic transmission from the preganglionic inputs (De Groat and Booth, 1993; Keast, 1995). Finally, there is good experimental evidence from animals that intestinofugal neurons in the enteric plexus of the distal gastrointestinal tract project to neurons in the pelvic plexuses, raising the possibility that the activity of some final motor neurons in the pelvic plexuses can be influenced directly by peripheral enteric neurons (Luckensmeyer and Keast, 1996).

The details of the functional anatomy of the pelvic plexuses in humans are still incomplete and are best described in relation to the organs they innervate. The plexuses tend to be larger and contain more ganglia in males than in females. This simply reflects the greater variety of targets in the internal reproductive organs of males (Keast, 1995). For an excellent overview of these pathways in mammals, see Maggi (1993).

Ureter, Urinary Bladder, and Urethra

Ureter

Much of the motility of the ureter seems to be myogenic with a pacemaker located in the region of the renal pelvis (Amann, 1993). Surprisingly, there is

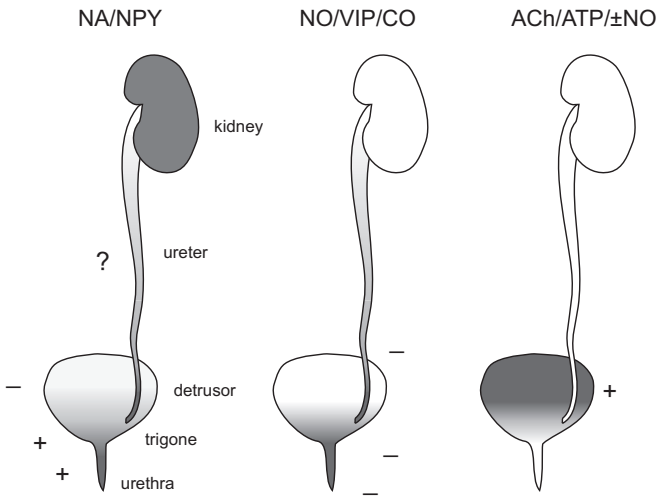

FIGURE 6.8 Diagrams summarizing the distribution of different neurochemical and functional classes of neurons projecting to the urinary tract. The density of shading represents the relative density of nerve fibers in the smooth muscle of each region of the tract. ACh/ATP?±NO, fibers releasing acetylcholine, adenosine 5′-triphosphate, and perhaps nitric oxide, which contract the detrusor. They arise from local intramural ganglia and nearby ganglia in the pelvic plexus; NA/NPY, fibers releasing noradrenaline and neuropeptide Y. They arise from the sympathetic chain, the prevertebral ganglia, and the pelvic plexus. Their function varies with location. NO/VIP/CO?, fibers releasing nitric oxide and vasoactive intestinal polypeptide. They also contain the enzyme for synthesizing carbon monoxide, whose function is unknown. These neurons inhibit smooth muscle activity and arise from intramural and nearby pelvic plexus ganglia.

little idea of how this motility is regulated by autonomic neurons (Amann, 1993; Brindley, 1988; Ferguson and Bell, 1993). The innervation of the smooth muscle of the ureters varies along their length, with the innervation density increasing distally (Fig. 6.8). Noradrenergic fibers, presumably in sympathetic pathways, contain NPY, whereas non-noradrenergic fibers, presumably in parasympathetic pathways, contain NOS, VIP, and NPY (Edyvane *et al.*, 1992, 1994; Jen *et al.*, 1996; Smet *et al.*, 1994). The neurons containing NOS, VIP, and NPY are particularly prominent at the ureterovesical junction (Goessl *et al.*, 1995; Grozdanovic and Baumgarten, 1996; Iselin *et al.*, 1997, 1998; Smet *et al.*, 1994), which they almost certainly relax, thereby facilitating urine flow into the bladder. Axons containing NOS and VIP, which probably have secretomotor and vasodilator functions, also occur beneath the mucosal epithelium of the ureter (Edyvane *et al.*, 1994; Goessl *et al.*, 1995; Smet *et al.*, 1994; Vaalasti *et al.*, 1986).

There are no intramural nerve cell bodies in the ureter (Duarte-Escalante *et al.*, 1969; Schulman, 1974), but clusters of microganglia occur around the lower segment of the ureter and in the region of the ureterovesical junction. Neurons in these ganglia contain NOS, VIP and NPY and almost certainly represent the source of the nonadrenergic axons within the lower ureter (Grozdanovic and Baumgarten, 1996; Jen *et al.*, 1996). Noradrenergic nerve terminals are prominent in the ureteric ganglia, and they form synapses onto some of these ganglion cells (Duarte-Escalante *et al.*, 1969; Schulman, 1974). The source of these fibers is unknown but they are likely to inhibit transmission from spinal preganglionic neurons through the ganglia, as occurs in the bladder ganglia (see below).

Urinary Bladder

Activation of the sacral parasympathetic pathways to the bladder is absolutely essential for micturition to occur. The smooth muscle of the body of the urinary bladder (the detrusor muscle) is densely innervated almost entirely by non-noradrenergic, presumably cholinergic, neurons (Fig. 6.8; Daniel *et al.*, 1983; Dixon *et al.*, 2000; Ek *et al.*, 1977; Kluck, 1980; Sundin *et al.*, 1977). Most of the neurons have their cell bodies in microganglia located extramurally around the base of the bladder and within the walls of the bladder itself (Dixon *et al.*, 1983; Kluck, 1980; Smet *et al.*, 1996a). These neurons contain a complex array of peptides in various combinations. Nearly all of them contain NPY, whereas less than half contain VIP. Somatostatin, galanin, CGRP, and substance P also may occur in some subsets of neurons. Furthermore, at least half of the neurons contain NOS (Dixon *et al.*, 1997, 2000; Jen *et al.*, 1996; Smet *et al.*, 1996a, b). Neurons containing VIP selectively project to the trigone region (Fig. 6.8), but apart from that, there is little information on the precise targets of the different neurochemical classes of neurons in the bladder ganglia.

The preganglionic input to neurons in bladder ganglia comes primarily from the third sacral segment, with smaller contributions from the adjacent segments. Stimulation of this pathway results in contraction of the detrusor muscle. In normal bladders, the response seems to be mediated almost entirely by ACh acting on muscarinic receptors (Hoyle and Burnstock, 1993; Husted *et al.*, 1983; Sibley, 1984; Sjögren *et al.*, 1982). However, a substantial atropine-resistant component of the response is seen in unstable or hypertrophied bladders (Husted *et al.*, 1983; Sjögren *et al.*, 1982). This part of the response may be mediated by ATP or a compound with similar pharmacological actions (Husted *et al.*, 1983; Hoyle and Burnstock, 1993). Neurons containing both NOS and VIP are likely to have an inhibitory effect on detrusor contractility (Gu *et al.*, 1983c; James *et al.*, 1993; Klarskov *et al.*, 1984; Vaalasti *et al.*, 1986). The function of NOS in cholinergic neurons providing excitatory innervation to most of the

bladder smooth muscle is not at all clear. One untested possibility is that a low level of ongoing nonsynaptic release of NO from cholinergic neurons may help to keep the detrusor relaxed when there is no overt activity of the pathway, as seen during bladder filling.

There are few noradrenergic axons in the body of the bladder, but they are more abundant in the trigone region, where most of them contain NPY (Fig. 6.8; Benson *et al.*, 1979; Daniel *et al.*, 1983; Dixon *et al.*, 1983; Ek *et al.*, 1977; Kluck, 1980; Sundin *et al.*, 1977). Here they cause sphincter-like contraction of the smooth muscle via α-adrenoceptors (Brindley, 1988; Caine *et al.*, 1975; Lincoln and Burnstock, 1993). The source of these fibers is not absolutely clear. On the basis of fluorescence histochemical localization of catecholamines, there appear to be no noradrenergic nerve cell bodies in the bladder ganglia themselves (Benson *et al.*, 1979; Dixon *et al.*, 1983; Ek *et al.*, 1977; Kluck, 1980; Sundin *et al.*, 1977). Most of the sympathetic fibers probably arise from neurons in lumbosacral chain ganglia or the pelvic plexus. However, a variable proportion of neurons within the bladder wall and vesical ganglia contain immunoreactivity to tyrosine hydroxylase. At least some of these neurons have been reported also to contain immunoreactivity to NOS and the vesicular ACh transporter, suggesting that they are functionally cholinergic (Dixon *et al.*, 1999; Jen *et al.*, 1996; Smet *et al.*, 1996a, b). These observations are difficult to interpret, but they raise the possibility that a population of neurons projecting to the bladder may have the potential to utilize a combination of catecholamines, ACh, and NO as cotransmitters (perhaps together with ATP) under certain circumstances.

Noradrenergic axons are prominent in the small ganglia lying on the outside of the bladder but are absent from the intramural microganglia (Dixon *et al.*, 1983; Kluck, 1980). These fibers probably arise from cell bodies in the lumbosacral sympathetic ganglia and reduce bladder contractile activity by inhibiting transmission through the extramural ganglia (see De Groat and Steers, 1988; De Groat and Booth, 1993a). The combined effects of noradrenergic stimulation on the trigone and the bladder ganglia are to promote continence (Lincoln and Burnstock, 1993).

The neurons in the bladder ganglia also are surrounded by fibers with various neuropeptides, including VIP, CGRP, NPY, and enkephalin (Jen *et al.*, 1996; Smet *et al.*, 1996a). These fibers could be axons of sympathetic final motor neurons, terminals of spinal preganglionic neurons, collaterals of unmyelinated sensory neurons, or projections from viscerofugal neurons located in the colon (Luckensmeyer and Keast, 1996; see below). However, in humans, the patterns of peptide expression have not been correlated with each functional population of fibers in the ganglia. Nevertheless, experiments in animals have indicated that there can be considerable modulation of synaptic transmission in the pelvic ganglia involved in regulating bladder function and that neuropeptides are likely to have an important role in this modulation (De Groat and Booth, 1993a; Keast, 1995, 1999)

Urethra

The autonomic innervation of the smooth muscle of the urethra operates in concert with that of the urinary bladder during continence and micturition. Autonomic activity also must be coordinated with somatic motor pathways projecting to the striated muscles of the lower urinary tract (see De Groat *et al.*, 1993). The smooth muscle of the urethra has a dense innervation by NPY-containing noradrenergic neurons, which, when stimulated via the hypogastric plexus, cause contraction of the muscle, particularly in males (Fig. 6.8; Andersson *et al.*, 1983; Brindley, 1988; Gosling *et al.*, 1977; Lincoln *et al.*, 1986; von Heyden *et al.*, 1998). There are also axons containing VIP and NOS in the urethral smooth muscle (Fig. 6.8; Crowe *et al.*, 1986; Ho *et al.*, 1999; Leone *et al.*, 1994; Smet *et al.*, 1996b; Tainio, 1993). In males, these neurons probably mediate noncholinergic neurogenic relaxation of the urethra distal to the openings of the vasa deferentia and the prostatic ducts during micturition and semen emission (Andersson *et al.*, 1983; Ehren *et al.*, 1994; Leone *et al.*, 1994). The coordinated activity of excitatory and inhibitory neurons to the urethra would facilitate the passage of semen along the urethra during emission while tending to prevent reflux into the bladder (Brindley, 1988).

Male Genital Tract

The autonomic innervation of the male genital tract is complex, and the way it functions is not fully understood (Brindley, 1988; Dail, 1993; De Groat and Booth, 1993b; Sjöstrand, 1981). Noradrenergic axons containing NPY and, in some cases, galanin predominate in the smooth muscle of the vas deferens, seminal vesicle, and prostate gland (Adrian *et al.*, 1981; Baumgarten *et al.*, 1971; Dail, 1993; Dixon *et al.*, 1998; Gu *et al.*, 1983b; Jen *et al.*, 1999; Vaalasti and Hervonen, 1980). When stimulated, they cause contraction of the smooth muscle, largely mediated by NA acting on α-adrenoceptors, although ATP and NPY also may be involved (Anton and McGrath, 1977; Caine *et al.*, 1975; Stjärne *et al.*, 1986). Most of the noradrenergic neurons receive preganglionic input via the hypogastric nerves and have cell bodies in ganglia located in the more superior parts of the pelvic plexuses (Bell, 1972;

Brindley, 1988; Owman *et al.*, 1983). However, some noradrenergic cell bodies have been localized in small ganglia near the prostate gland (Vaalasti and Hervonen, 1980).

The smooth muscle of the vas deferens, seminal vesicles, and prostate gland receives a sparse innervation by cholinergic neurons containing VIP and NOS. Some also contain NPY, and others may contain enkephalin or somatostatin (Alm, 1982; Del Fiacco, 1982; Dixon *et al.*, 1998, 2000; Gu *et al.*, 1983b; Jen *et al.*, 1997,1999; Vaalasti *et al.*, 1986). Axons containing NOS and VIP are more abundant in the epithelium of the vas deferens and around the secretory glands of the prostate, where they are likely to have a secretomotor function (Alm, 1982; Bloch *et al.*, 1997; Dixon *et al.*, 1998; 2000; Grozdanovic and Goessl, 1999; Gu *et al.*, 1983b; Hedlund *et al.*, 1997; Jen *et al.*, 1999; Vaalasti *et al.*, 1986). These axons are likely to originate from different populations of nerve cell bodies in local microganglia (Alm, 1982; Grozdanovic and Goessl, 1999; Gu *et al.*, 1983b).

The erectile tissues and blood vessels of the penis are innervated by noradrenergic neurons (Benson *et al.*, 1980; Gu *et al.*, 1983b) and cholinergic neurons, most of which contain NOS, VIP, and PHM (Burnett *et al.*, 1993; Ehmke *et al.*, 1995; Gu *et al.*, 1983b; Hedlund *et al.*, 2000; Polak *et al.*, 1981; Steers *et al.*, 1984; Tamura *et al.*, 1995; Willis *et al.*, 1983). The noradrenergic axons probably originate from nerve cell bodies in the superior pelvic plexus, and mostly receive preganglionic inputs via the hypogastric nerves (Bell, 1972; Brindley, 1988). The axons containing NOS and VIP in these tissues are likely to have their cell bodies in local ganglia (Gu *et al.*, 1983b; Polak *et al.*, 1981). They receive preganglionic input from the second and third sacral ventral roots via the pelvic nerves (Brindley, 1988; Weiss, 1972).

Erection requires vasodilation of the penile vessels and relaxation of the erectile tissue of the penis (the corpus cavernosum and corpus spongiosum) to allow its engorgement with blood. These responses normally are neurogenic and are mediated by the sacral parasympathetic pathways. Although VIP both relaxes smooth muscle from erectile tissues and dilates penile blood vessels (Adaikan *et al.*, 1986; Hedlund and Andersson, 1985; Kirkeby *et al.*, 1992; Steers *et al.*, 1984; Willis *et al.*, 1983), the transmitter primarily responsible for erection is not VIP but NO (Hedlund *et al.*, 2000; Leone *et al.*, 1994). These neurons probably also contain and release ACh, which by itself has little effect on erectile tissues (Benson *et al.*, 1980; Blanco *et al.*, 1988; Saenz de Tejada *et al.*, 1988). Erection is prevented by tonic activity of a noradrenergic sympathetic pathway running through the hypogastric nerves (Brindley, 1988) and part of the action of ACh seems to be to inhibit the effects of these neurons (Argiolas and Melis, 1995; Saenz de Tejada *et al.*, 1988; Sjöstrand, 1981).

There is an additional pathway running through the lumbar sympathetic ganglia that can cause erection, especially following psychogenic reflex stimulation (Brindley, 1988; Weiss, 1972; Whitelaw and Smithwick, 1951). The final transmitter in this sympathetic pathway is neither NA nor ACh (Brindley, 1988), but which of a diverse mix of potential transmitters is involved is still unknown.

Recently, HOX-2 has been found to coexist with NOS and VIP in most cholinergic neurons of the pelvic plexus, including those innervating the erectile tissues and the lower urinary tract (Grozdanovic and Goessl, 1999; Hedlund *et al.*, 2000; Ho *et al.*, 1999; Iselin *et al.*, 1997, 1998). It remains to be seen how CO may be involved in the autonomic regulation of the urogenital tract.

Female Genital Tract

The smooth muscle of the oviducts, uterus, and cervix is innervated by noradrenergic neurons containing NPY and non-noradrenergic neurons containing NOS and VIP. Much of this innervation is likely to arise from nerve cell bodies in the inferior parts of the pelvic plexuses, especially the paracervical ganglia. These ganglia lie in the broad ligament immediately dorsal to the origin of the uterine artery (Curtis *et al.*, 1942; Davis, 1933; Gemmell, 1926) and contain both noradrenergic and non-noradrenergic neurons (Alm *et al.*, 1980; Helm, 1981; Jorgensen *et al.*, 1989; Marshall, 1970; Owman *et al.*, 1967; Yoshida *et al.*, 1995). In addition, some of the noradrenergic postganglionic neurons may have cell bodies in the lumbar paravertebral ganglia or the superior hypogastric plexus (Bell, 1972; Marshall, 1970). There are no intramural ganglia in the uterus (Curtis *et al.*, 1942).

The noradrenergic innervation of the smooth muscle is generally abundant but is most dense in the isthmus of the oviduct and in the cervix (Helm, 1981; Owman *et al.*, 1967). Stimulation of these neurons causes contraction of the oviducts as well as the nonpregnant uterus, and this is mediated by α-adrenoceptors (Helm, 1981; Sporrong *et al.*, 1982). However, during pregnancy, β-adrenoceptors mediating myometrial relaxation tend to become more prominent, so that sympathetic nerve stimulation may then inhibit myometrial activity (Bell, 1972; Marshall, 1970).

Axons containing NOS and VIP are most common in the smooth muscle of the isthmus of the oviduct and in the cervix. In addition, they provide a prominent innervation to the glands in the endometrium and

cervical mucosa. They also innervate blood vessels of the cervix, vagina, and erectile tissue of the external genitalia (Alm *et al.*, 1980; Hoyle *et al.*, 1996; Lynch *et al.*, 1980; Ottesen, 1983; Ström *et al.*, 1981; Yoshida *et al.*, 1995). These neurons are likely to relax or inhibit spontaneous contractile activity of smooth muscle in the oviduct, nonpregnant myometrium, and cervix (Helm *et al.*, 1982; Ottesen *et al.*, 1982, 1983). However, they may be much less effective in inhibiting contractions of the pregnant myometrium (Ottesen *et al.*, 1982), when β-adrenoceptor-mediated relaxation is better developed. Neurons containing NOS and VIP also are likely to be responsible for dilating the vasculature of the vaginal circulation during sexual stimulation (Hoyle *et al.*, 1996; Wagner and Levin, 1980).

Colon

Preganglionic neurons in the sacral spinal cord also project through the pelvic plexus to neurons in and near the distal colon and rectum. Some preganglionic axons ascend for a large distance within the colon. The intramural neurons form part of the myenteric plexus, whereas the extramural neurons lie in small ganglia in the distal ends of the pelvic nerves running to the gut (Christensen, 1987; Keast, 1995, 1999; Mitchell, 1953a). The extramural neurons may project both to the smooth muscle of the hindgut directly and to intrinsic myenteric neurons (Roman and Gonella, 1987). Many neurons in the extramural colonic and rectal ganglia may actually project away from the gut back to the pelvic ganglia and spinal cord; such neurons probably receive inputs from distention sensitive myenteric neurons (Luckensmeyer and Keast, 1998).

Stimulation of the pelvic nerves results predominantly in contraction of the colon, mediated via cholinergic neurons, and relaxation of the internal anal sphincter via non-noradrenergic, noncholinergic neurons that probably act primarily via NO (O'Kelly *et al.*, 1993; Stebbing *et al.*, 1997). In addition, there may be a separate pelvic pathway resulting in inhibition of colonic activity and contraction of the sphincter muscle; these responses may be mediated by noradrenergic pelvic neurons (Christensen, 1987; Keast, 1995; Roman and Gonella, 1987).

Blood Vessels

As well as the vasodilator innervation of erectile tissue described above, the pelvic plexuses are likely to provide vasodilator innervation to much of the pelvic circulation (Mitchell, 1953a). Indeed, all reports on the distribution of neurons containing both VIP and NOS in the pelvic viscera cited above describe the presence of axons containing VIP and NOS around small and medium-sized arteries. These neurons almost certainly represent vasodilator neurons.

ENTERIC PLEXUSES

In Langley's original classification of the autonomic nervous system, the enteric neurons form the third major division. The cell bodies of enteric neurons are grouped into intramural ganglia that form a vast interconnected system extending the full length of the gastrointestinal tract. Enteric neurons outnumber by far all the rest of the autonomic neurons; there are in the order of 100 million neurons in the enteric nervous system of humans (Furness and Costa, 1987). Delineating the structure and function of the enteric nervous system results in a large and complex area of research. Much of the more recent work has been reviewed comprehensively in several major publications and reviews (Furness, 2000; Furness and Costa, 1987; Johnson, 1987; Kunze and Furness, 1999; Makhlouf and Schultz, 1989; Tache *et al.*, 1994; Wood and Schultz, 1989). The following description is restricted to a summary of some of the important features of the enteric nervous system of humans, with additional information from experimental studies of animals.

The intramural ganglia are grouped into two plexuses: the myenteric plexus, lying between the outer longitudinal and the inner circular muscle layers; and the submucous plexus, which lies in the connective tissue between the circular muscle and the muscularis mucosae. Although the myenteric plexus extends virtually the full length of the gastrointestinal tract, the submucous ganglia are rare or absent in the esophagus and stomach. In general, the neurons of the myenteric plexus are involved in the regulation of the activity of the smooth muscle, whereas neurons in the submucous plexus regulate mucosal secretion and blood flow.

Most enteric neurons are multipolar. Some have relatively short dendrites with irregular shapes and a prominent axon (type I of Dogiel). Others have several long processes that cannot be identified easily as axons or dendrites (type II of Dogiel). Most enteric neurons fall into one of these morphological classes, although many neurons have other shapes, some of which are intermediate between the main classes. Indeed, some classification schemes have recognized many more morphological classes. More importantly, experimental studies on laboratory mammals, especially guinea pigs, but also rats, pigs, dogs, cats, and mice, have clearly demonstrated that neurons with different morphologies

have characteristic projections, connections, transmitter profiles, and functions (Brookes, 2001; Furness, 2000).

The microanatomical and functional complexity of the enteric nervous system is second only to that of the CNS. Although the activity of enteric neurons can be modified by the CNS via inputs through the vagus, pelvic plexus, and prevertebral ganglia (see above), much control of gastrointestinal function can be achieved by the enteric nervous system independent of central influences. Intrinsic neuronal circuits regulate gastrointestinal motility, mucosal secretion and absorption, and local blood flow, largely as a result of activating intrinsic reflexes. Necessary components of these circuits include sensory neurons, associative neurons or interneurons, and final excitatory or inhibitory motor neurons. A great array of potential neurotransmitters has been localized in different classes of enteric neurons. Animal experiments have demonstrated unambiguously that these transmitters, which include ACh, NO, ATP, a wide range of neuropeptides, and probably 5-HT and GABA, are colocalized in combinations that are specific for particular populations of neurons with well-defined cell shapes, projections, and functions (Brookes, 2001; Furness, 2000; Furness and Costa, 1987). The following simplified description of the functional organization of the enteric plexuses applies most closely to the intestine, but the general pattern applies to varying degrees throughout the gut. It is based mostly on data summarized in the reviews already quoted. Specific references refer to details known to be applicable to humans.

Intrinsic Sensory Neurons Within the Enteric Plexuses

A characteristic feature of the enteric plexuses is that they contain neurons with a primary sensory function (for reviews, see Furness *et al.*, 1998; Kunze and Furness, 1999). Animal studies have shown that these neurons have cell bodies in both the myenteric and submucous plexuses, and have a characteristic morphology, with long dendritic processes that ramify extensively (Dogiel type II; Wattchow *et al.*, 1995). They can respond to chemical stimuli from the lumen of the gut and to mechanical stimuli, such as distention of the gut wall, although it is not yet clear whether different populations of sensory neurons are involved in these responses. The output of these neurons runs in both the oral and anal directions along the myenteric plexus, where they form synapses primarily with interneurons, motor neurons, and perhaps other sensory neurons. Indeed, one feature of these neurons that distinguishes them from sensory neurons located in the dorsal root ganglia is that they normally receive synaptic inputs. Synaptic transmission from the enteric neurons is likely to be mediated in part by ACh, but other noncholinergic transmitters also may be involved.

One class of myenteric neurons that receives input from the intrinsic sensory neurons is the intestinofugal neurons. These neurons occur in the small and large intestines and project out of the gut to neurons in the prevertebral and pelvic ganglia (Gibbins, 1995; Keast, 1995; Mawe, 1995). They are activated primarily by gut distention and participate in a peripheral reflex arc that leads to inhibition of gut activity, perhaps as part of a protective reflex (Fig. 6.7). In most species where they have been studied functionally, the intestinofugal neurons are cholinergic and generally contain a range of peptides, most notably VIP (Gibbins, 1995; Mawe, 1995; Quartu *et al.*, 1993). Some neurons in the distal colon and rectum may project directly to the spinal cord (Neuhuber *et al.*, 1993), but their function is unknown.

Myenteric Plexus and the Regulation of Motility

Most of the intrinsic enteric neurons regulating gastrointestinal motility have their cell bodies within the ganglia of the myenteric plexus (Fig. 6.9). Overall, there are two main functional classes of motor neurons innervating the gastrointestinal smooth muscle: excitatory motor neurons and inhibitory motor neurons. Generally, the excitatory motor neurons are cholinergic (Porter *et al.*, 1996, 1997) and may contain peptides, most commonly substance P (Wattchow *et al.*, 1988, 1997). The inhibitory motor neurons usually contain NOS and VIP (Porter *et al.*, 1997; Wattchow *et al.*, 1997). Both NO and VIP, perhaps together with ATP, contribute to inhibitory transmission to varying degrees in different regions of the gut (Brookes, 1993; Tonini *et al.*, 2000). However, there is some evidence that not all neurons projecting to the muscle that contain VIP necessarily contain NOS and vice versa (Gaumnitz *et al.*, 1995; Matini *et al.*, 1995; Porter *et al.*, 1997). In many regions of the gut, including the esophagus, colon, and appendix, presumed inhibitory motor neurons also contain NPY in addition to other potential transmitters (Ekblad *et al.*, 1989; Nichols *et al.*, 1994; Wattchow *et al.*, 1987b, 1996). A subset of neurons containing NOS and VIP projecting to circular muscle contain galanin, which tends to oppose or limit the inhibitory action of VIP (esophagus: Singaram *et al.*, 1994; colon: Burleigh and Furness, 1990; Gaumnitz *et al.*, 1995)

Whether they are excitatory or inhibitory, motor neurons have a similar morphology, with short

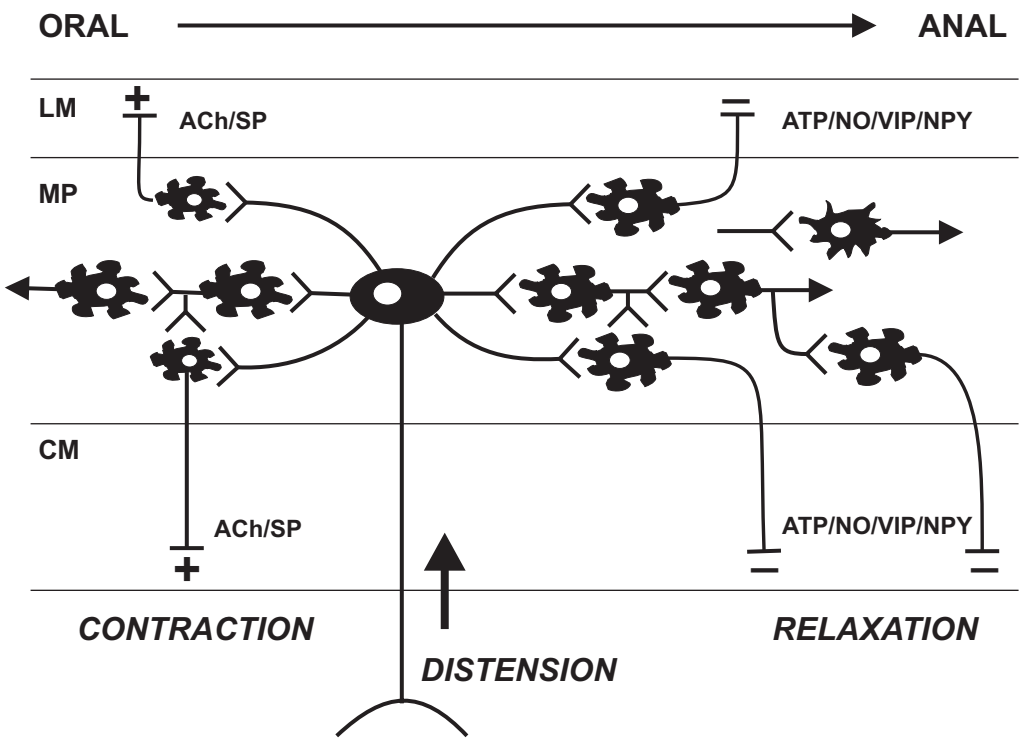

FIGURE 6.9 Simplified diagram of the generalized circuit within the myenteric plexus that underlies the propulsion of intestinal contents in an oral to anal direction. Distention activates intrinsic sensory neurons, either directly or indirectly, with cell bodies in the myenteric plexus (MP). The neurons project in both the oral and anal directions. Some projections in each direction form synapses with interneurons, while others form synapses with motor neurons. All the synapses work primarily via acetylcholine (ACh) acting on nicotinic receptors, although other transmitters are almost certainly involved in specific parts of these pathways. Different populations of motor neurons project to the longitudinal muscle (LM) and the circular muscle (CM). Excitatory motor neurons to the muscle contain ACh and substance P (SP). The inhibitory neurons act via a combination of adenosine 5′-phosphate (ATP), nitric oxide (NO), and vasoactive intestinal polypeptide (VIP); they also often contain neuropeptide Y (NPY). Note that the excitatory neurons project to muscle oral to the distention, while inhibitory neurons project to muscle anal to the distention. This arrangement establishes the polarity of a reflex that can propel gut contents in an oral-to-anal direction. The exact details of the connections and transmitter content of different classes of neurons varies with species and region of the gut. Adapted from Furness and Costa, 1987; Kunze and Furness, 1999.

branched dendrites or lamellar processes (Dogiel type I; Porter *et al.*, 1996; Wattchow *et al.*, 1995). Tracing studies have shown that different populations of motor neurons innervate the longitudinal and circular muscle layers. Some motor neurons project directly to the nearby muscle layers, but others may project for longer distances orally or anally along the myenteric plexus before innervating the muscle. Thus, each muscle layer may be innervated by different populations of excitatory or inhibitory motor neurons that have long or short projections within the myenteric plexuses.

In the esophagus and stomach, and probably the duodenum, some of the final motor neurons receive convergent synaptic inputs from vagal preganglionic neurons (see "Cranial Autonomic Pathways" above). Similarly, some motor neurons in the distal colon and rectum receive synaptic inputs from sacral preganglionic neurons. Most of these inputs are likely to occur onto neurons in the myenteric plexus rather than the submucous plexus (Holst *et al.*, 1997). However, throughout the myenteric plexus, the primary input to motor neurons is from intrinsic sensory neurons or interneurons that also are located in the myenteric plexus. The CNS can inhibit gastrointestinal motility by the activity of noradrenergic sympathetic neurons projecting from the prevertebral ganglia to the motor neurons of the myenteric plexus.

There seem to be several different functional classes of interneurons in the myenteric plexus, particularly those that project in an anal direction. Most interneurons are functionally cholinergic. Some ascending

interneurons contain tachykinins, such as substance P (Wattchow *et al.*, 1997), and some descending interneurons contain various combinations of 5-HT, NOS, GABA, and neuropeptides, including VIP (Gershon, 1999; Krantis *et al.*, 1998; Porter *et al.*, 1997; Wattchow *et al.*, 1997). Consequently, not all transmission between interneurons can be blocked with cholinergic antagonists. Potential transmitters include ATP, 5-HT, NO, and substance P (Galligan *et al.*, 2000; Gershon, 1999).

The basic circuit of the myenteric plexus of the intestine seems to be adapted to provide a mechanism for the propulsion of gut contents (Fig. 6.9; Furness and Costa, 1987). In its simplest version, distention of the intestine at a point results in stimulation of intrinsic sensory neurons that provide excitatory inputs onto interneurons that project orally or anally within the myenteric plexus. The orally projecting interneurons make excitatory synapses with cholinergic excitatory motor neurons, whereas anally projecting interneurons make excitatory synapses with inhibitory motor neurons acting via some combination of ATP, NO and VIP. The excitatory motor neurons themselves project up to 11 mm orally, whereas the inhibitory motor neurons project up to nearly 20 mm anally (colon: Porter *et al.*, 1997). Thus, the gut contracts above a site of distention and relaxes below it to propel the gut contents in an oral-to-anal direction.

Recent experiments in laboratory mammals have shown that the mechanism of motor innervation of the gastrointestinal smooth muscle is much more complex than originally thought. Throughout the myenteric plexus and the circular muscle layers, there are networks of cells known as the "interstitial cells of Cajal." It is now becoming increasingly clear that these cells function both as pacemakers for smooth muscle contractile activity (Huizinga *et al.*, 1997) and as intermediaries for at least some aspects both inhibitory and excitatory transmission to the muscle (Burns *et al.*, 1996; Ward *et al.*, 1998, 2000).

Submucous Plexus and the Control of Secretion

The neurons in the submucous plexus of the intestine tend to be smaller than those in the myenteric plexus and contain fewer functional cell types. Nevertheless, the anatomical arrangement of the plexus is complicated, and naming of its various possible subcomponents has been a source of argument for many years (see Furness and Costa, 1987; Wedel *et al.*, 1999). The ganglia include multiple populations of secretomotor neurons projecting to the gut mucosa, as well as vasodilator neurons innervating the local microcirculation (Vanner and Surprenant, 1996). The submucous ganglia probably also contain some intrinsic sensory neurons with receptive endings projecting to the mucosa and with outputs projecting to other submucous neurons or to the myenteric plexus. About two-thirds of submucosal neurons are likely to be cholinergic, whereas both secretomotor and vasodilator neurons are likely to contain some combination of VIP and NOS (Bosshard *et al.*, 1989; Crowe *et al.*, 1992; Porter *et al.*, 1996, 1999). Other submucous neurons contain 5-HT or substance P (Crowe *et al.*, 1992). At least in the colon, some neurons in the submucous plexus project to the deeper layers of the circular muscle. These neurons are located closer to the circular muscle layer; some of them contain NOS and VIP and may mediate relaxation of the muscle (Domoto *et al.*, 1990; Porter *et al.*, 1999); the possible functions of other submucosal neurons projecting to the muscle are unknown.

As in the myenteric plexus, activity of the motor neurons in the submucous plexus are tonically inhibited by sympathetic neurons projecting from the prevertebral ganglia. Experiments in guineapigs have shown clearly that the sympathetic neurons responsible for tonic inhibition of secretomotor neurons in the submucous plexus form a population that is separate from those responsible for a low level of tonic inhibition of myenteric motor neurons (Furness and Costa, 1987; Mawe, 1995).

ADRENAL MEDULLA AND PARAGANGLIA

The adrenal medullary cells are derived from the neural crest and are a major source of circulating catecholamines, particularly adrenaline. Adrenaline and noradrenaline are secreted from different populations of cells (Coupland and Fujita, 1976). Adrenal medullary cells receive cholinergic preganglionic inputs directly via the splanchnic nerves traveling through the celiac ganglion (Parker, 1996). In addition to catecholamines, some of the adrenal medullary cells contain proenkephalin-derived peptides and NPY, often coexisting (Linnoila and Diaugustine, 1980; Lundberg *et al.*, 1979; Osamura *et al.*, 1987). A small number of other cells contain VIP or somatostatin (see Kondo, 1985). These peptides may function locally within the adrenal gland to modulate secretion or local blood flow, or they may enter the circulation and have a hormonal role.

Small ganglia occur close to the adrenal medulla and they may be the source of VIP axons abundantly distributed through the adrenal medulla (Kondo, 1985;

Linnoila and Diaugustine, 1980). These neurons may influence secretion and blood flow in the adrenal gland.

An additional source of circulating catecholamines and peptides is likely to be the paraganglia, consisting of small groups of extraadrenal chromaffin cells. Paraganglia are associated mainly with the prevertebral and pelvic plexuses. They also occur along the vagal nerve and to a much lesser extent in the paravertebral ganglia (Hervonen *et al.*, 1976, 1978a). The cells are morphologically and neurochemically heterogeneous. In organs such as the carotid and aortic bodies, they are involved in arterial chemoreception, and this function may extend to chromaffin cells outside these areas (Kummer, 1996). Their functions in other locations are unknown but may involve local paracrine or endocrine roles (see Böck, 1982; Kummer, 1996).

CONCLUDING REMARKS

This chapter illustrates that peripheral autonomic neurons are organized into a complex system of pathways controlling a multitude of visceral functions. Most of these pathways can be activated independently of each other by their central inputs as part of a coordinated motor response along with appropriate somatic motor and neuroendocrine outputs. The net result is an integrated and coordinated regulation of effector tissues by autonomic pathways. Some of this coordination must take place in the ganglia themselves, primarily as a result of the arrangement and transmitter repertoire of the preganglionic inputs. Interneurons clearly exist in the enteric nervous system, and some sympathetic neurons innervate (and inhibit) other final motor neurons in the parasympathetic, pelvic, and enteric ganglia. Within the prevertebral and pelvic ganglia, final motor neurons receive and integrate inputs from both central preganglionic neurons and peripheral enteric neurons.

There are few general rules that distinguish the functions of sympathetic and parasympathetic pathways. Tonic activity can occur in both (e.g., parasympathetic innervation of the iris; sympathetic innervation of cutaneous blood vessels), and both can have excitatory and inhibitory neurons projecting to the same effector (e.g., vagal innervation of the airways; sympathetic innervation of skeletal muscle vasculature). Although in some effector tissues the sympathetic and parasympathetic neurons tend to oppose each other (e.g., heart, blood vessels), in others they cooperate (e.g., male genital tract).

Most tissues receiving autonomic innervation are also innervated by unmyelinated primary sensory neurons. Neuropeptides released from the peripheral terminals of these neurons by axon reflexes can modify the autonomic control of peripheral tissues either by exerting direct effects on the targets or by interacting with the autonomic neurons themselves. These effects have been ignored here, but they are almost certain to play a crucial role in the modulation of autonomic motor control in a wide range of pathophysiological conditions.

Most peripheral autonomic neurons contain several different potential transmitters. The exact combinations of transmitters in individual neurons are highly correlated with their projections (see Furness *et al.*, 1989; Gibbins, 1995). These results imply that there is scope for multiple levels of autonomic regulation of peripheral effector tissues with a degree of precision and specificity far greater than has been suspected until now (Morris and Gibbins, 1992). The details and functional consequences of neurotransmitter coexistence in human autonomic neurons remain to be determined in most cases. However, the scope for the development of new therapeutic interventions based on knowledge of these interactions is potentially enormous.

Spinal Cord: Cyto- and Chemoarchitecture

JEAN SCHOENEN
Department of Neuroanatomy and Neurology
University of Liège, Liège, Belgium

RICHARD L. M. FAULL
Department of Anatomy with Radiology
The University of Auckland, Auckland, New Zealand

Our present knowledge on the detailed anatomical organization of the mammalian spinal cord is derived mainly from nonhuman animal studies. There have been many studies on the anatomy of the mammalian spinal cord in the rat, cat, and monkey, with the most comprehensive and authoritative accounts being those provided by Rexed (1952, 1954, 1964) on the cytoarchitectonic organization, and by Scheibel and Scheibel (1966a, b, 1968, 1969a, b, 1970a) on the dendroarchitecture of the cat spinal cord. However, there has been no detailed overall analysis of the anatomical organization of the human spinal cord. In an attempt to redress this, we present here a detailed account of the cytoarchitectural, dendroarchitectural, and myeloarchitectural features of the human spinal cord that is based on the examination of Nissl-, Golgi-, and myelin-stained material of the developing and mature human spinal cord from 93 cases. We will also describe the general chemoarchitecture as seen in the normal spinal cord, and consider the regional chemoarchitecture as well as some functional implications as demonstrated, in part, from the study of human pathological cases.

CYTO- AND DENDROARCHITECTURE

The laminar cytoarchitectonic scheme, described by Rexed in the cat, has been extended *de facto* to mature and immature spinal cords of other animals, e.g., the dog (Buxton and Goodman, 1967), monkey (Chambers and Liu, 1958; Kuypers, 1964; Kuypers and Brinkman, 19670; Kuypers *et al.*, 1962; Miller and Strominger, 1973), and rat (Brichta and Grant, 1985). However, the presence of such a cytoarchitectural organization has been formally demonstrated only in mice (Sidman *et al.*, 1971). Truex and Taylor (1968) have suggested in an abstract that the laminar cytoarchitectonic scheme might be applied to the human spinal cord and their results are mentioned in Carpenter's *Human Neuroanatomy* (1976). In contrast, several authors do not refer to the laminar scheme and prefer to classify spinal neurons

according to one of the classical anatomical organizational schemes (Bossy and Ferratier, 1968; Waibl, 1973). Nevertheless, Rexed's schema has been adopted by most neuroanatomists and neurophysiologists because it offers a more comprehensive and uniform view of the spinal organization. In addition, it has some physiological and functional correlates.

In order to verify the presence of a laminar cytoarchitectural organization of the human, we have studied 46 adults and 12 immature spinal cords, using thick (100 μm) and fine (10 μm) Nissl- and myelin-stained transverse and longitudinal sections. The functional significance of Rexed's lamination was placed in doubt because it is based on a purely cytoarchitectonic approach, neglecting one of the principal morphological attributes of the neurons, the dendritic tree. It is justified to consider dendritic tree geometry as an important parameter in all neuronal classifications with functional perspectives (Leontovich, 1975). Golgi's analysis of the spinal cord, practically abandoned since Ramón y Cajál (1909), was revived in the 1960s. Most of these analyses were performed in newborn kittens (Gobel, 1975a, b; Scheibel and Scheibel, 1966a, b, 1968, 1969a, b). A few concentrated on the adult cat (Leontovich and Zhukova, 1963; Proshansky and Egger, 1977; Szentágothai, 1964; Szentágothai and Rethelyi, 1973) or monkey cord (Beal and Cooper. 1978). Certain authors have examined human spinal cords, but their results, other than those of Pearson (1952) on the substantia gelatinosa and those of Abdel-Maguid and Bowsher (1979) on motoneurons, have not been published in detail. Golgi studies have partially validated the laminar cytoarchitectural schema of Rexed by demonstrating that each of laminae I–IV of the dorsal horn (Beal and Cooper, 1978; Gobel, 1975a, b, 1978a, b; Scheibel and Scheibel, 1966b, 1969b, 1970a, b; Sterling and Kuypers, 1967b) are dendroarchitecturally distinguishable. However, the neurons of the intermediate gray matter were regrouped into an entity, called the "isodendritic core," and linked on a structural basis to the reticular formation of the brain stem, of which it would simply be a caudal extension (Ramon-Moliner and Nauta, 1966; Szentágothai and Rethelyi, 1973).

Since Sholl's work (1953, 1956) on the cerebral cortex it has been known that morphometric analyses of Golgi-impregnated material, although fastidious and therefore little exploited, are indispensable to discern certain details of the dendritic morphology (Ramon-Moliner, 1967). The rare quantitative dendroarchitectural studies of the nonhuman cord indicate some differences between the large and small neurons of the ventral horn (Aitken and Bridger, 1961; Gelfan *et al.*, 1970). Dendritic studies of human cord are sparse and purely qualitative (Laruelle, 1937, 1948; Pearson, 1952; Ramón y Cajál, 1909; van Lenhossek, 1895). The work of Abdel-Maguid and Bowsher (1979) on motoneurons is the only morphometric study completed on human material until the present. On the basis of dendritic field size and dendritic branching pattern, these authors have described two types of a and two types of γ motoneurons. However, Golgi studies have hardly brought forward any criteria permitting better identification of laminae V, VI, VII, and VIII neurons or even motoneurons belonging to different columns. One problem is that they fail to consider the spatial polarization of dendritic trees. This is indeed a major dendroarchitectural parameter that relates closely to the connection of neurons, as already defined by Ramón y Cajál's (1909) "Loi de la polarisation dynamique" and as confirmed by studies of the cerebellum (for a review, see Rakic, 1975), visual cortex (Valverde, 1968, 1970), and laminae IV–VI of the cat spinal cord (Proshansky and Egger, 1977).

We have performed qualitative and quantitative Golgi analyses on 23 human spinal cords taken at autopsy from patients free of any detectable neurological diseases. Our work is based largely on the rapid Golgi technique and therefore on specimens of fetal (26–38 weeks of gestation) or young infant (1 day to 7 years old) tissue. Adult material (22–92 years of age) was studied with different variants of the slow Golgi method. Certain steps of the ontogenesis of spinal dendritic organization could thus be analyzed. The morphometric methods used on camera-lucida-drawn impregnated cells has been described elsewhere (Schoenen, 1981b, 1982a, b). The results of morphometric analyses were compiled from the examination of drawings of 542 neurons distributed in the cytoarchitectural laminae of the gray matter and identified in spinal cord of different ages.

General Laminar Organization

The general organization of spinal neurons was examined on thick transverse sections of the lumbar enlargement. As is shown in Figure 7.1, several groups of neurons can be easily recognized. The tip of the dorsal horn is cuffed by gray matter with a low neuronal density. Neurons in this region are medium sized and some of them lie in close contact with Lissauer's tract. Ventral (deep) to this first neuronal group is a region with very high neuronal density. These neurons are small and spread throughout the width of the dorsal horn. This easily recognizable portion of gray matter corresponds to the "substantia gelatinosa" of Rolando. Several neurons of larger caliber occupy the whole width of the dorsal horn ventral to Rolando's substance. The transition zone between the

FIGURE 7.1 Photomontage of transversely cut (100 μm) human spinal gray matter at the L5 level. Cresyl violet–stained section of a normal 60-year-old. Magnification: ×28. C, D-L, and V-L are the central, dorsolateral, and ventrolateral columns of motoneurons, respectively; imm, intermediomedial nucleus.

substantia gelatinosa and these large neurons is occupied by a portion of gray matter where neurons are larger but fewer than in Rolando's substance. In the ventral horn, motoneurons, which are easily identified, are clustered in three columns: dorsolateral, central, and ventrolateral. On the medial aspect of the ventral horn, there is a crescent-shaped group of neurons of varying sizes. The space between this group and the motoneuronal columns is occupied by smaller cells. In the rest of the gray matter, precise delineation of neuronal groups is more difficult. Figure 7.1 shows that the base of the dorsal horn contains many neurons which, tend to segregate into a medial and lateral group. Small, densely packed neurons predominate in the medial portion, while larger and less densely packed neurons appear in the lateral region. The most laterally located neurons of the lateral group are intermingled with the longitudinal fiber fascicles of the "formatio reticularis." The base of the dorsal horn is not clearly demarcated from the central core of the spinal gray matter. However, the latter is characterized by a lower neuronal density and by differently shaped neurons. Finally, the central canal is surrounded by small neurons, in the vicinity of which a clustering of cells can be recognized on some sections, corresponding to the intermediomedial nucleus.

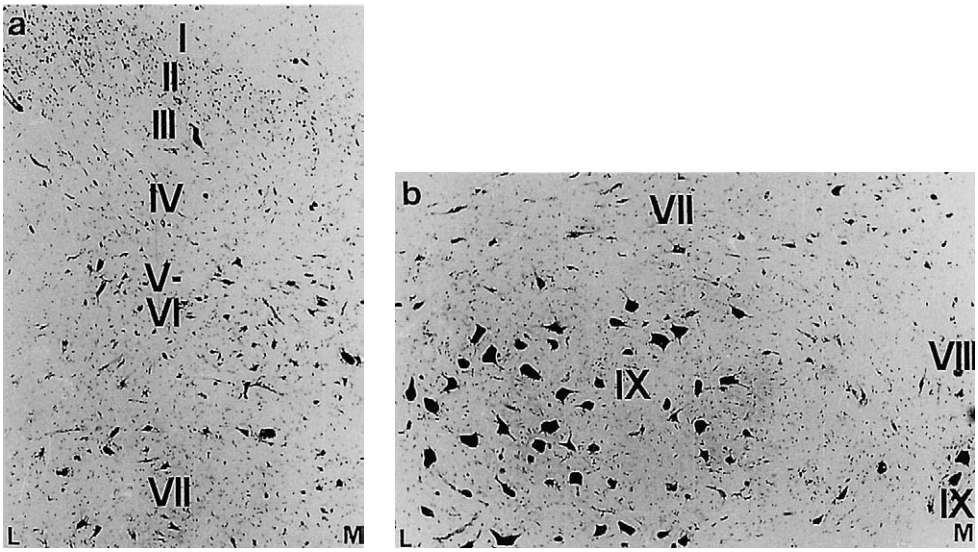

FIGURE 7.2 Transverse 10-µm Nissl-stained sections of a normal 72-year-old of the dorsal **(a)** and ventral **(b)** horns of human spinal segment L4. L, lateral, M, medial. Magnification: ×73.

Low-power examinations of thick transverse sections of the human spinal cord thus reveal a general cytoarchitectural organization that is fundamentally similar to that described by Rexed in the cat. The layer of marginal neurons cuffing the dorsal horn corresponds to lamina I. The substantia gelatinosa of Rolando and the region of large neurons in the center of the dorsal horn correspond to laminae II and IV, respectively. The transition zone between these two laminae is lamina III. The neurons located in the base of the dorsal horn correspond to laminae V and VI of Rexed's scheme. As described previously, these two laminae cannot be readily distinguished in the human spinal cord and contain neurons, which are cytologically similar. They can, however, be separated into a medial portion and a larger lateral portion. According to Rexed (1952), the asymmetries of medial and lateral portions can be used in the cat as a criterion for distinguishing lamina V from lamina VI, in addition to their different position in the dorsoventral axis. This criterion is not applicable to the human cord, so we have decided to call this region of the spinal gray "laminae V–VI." Ventral to laminae V–VI, the center portion of the spinal gray matter corresponds to lamina VII, which at the level of the cervical and lumbar enlargements extends up to the ventral border of the ventral horn. The group of neurons located medially in the ventral horn is lamina VIII. Finally, the columns of motoneurons form lamina IX and the neurons surrounding the central canal form lamina X.

The laminar cytoarchitectural organization described above is not limited to lumbar segments. Longitudinal sagittal sections indicate that the neuronal laminae extend throughout the rostrocaudal axis of the spinal cord. When the cord is cut sagittally, some neuronal laminae may not be in the plane of section because of their particular location (cf. Fig. 7.3). The cytoarchitectural organization of the cervical enlargement is similar to that of the lumbar enlargement. Segmental variations may occur at other levels and will be described. On thin histological sections, lamination of spinal neurons can be seen, but the borders between laminae are difficult to determine (Fig. 7.2).

The laminar organization of spinal gray matter occurs early during ontogenesis. It can be recognized as soon as neuroblasts migrate from the germinal plate laterally and differentiate. In the 6-week-old embryo, differentiated motoneurons can be identified in the ventral horn of the lumbar cord. In addition, neurons cluster on the medial aspect of the ventral horn to form lamina VIII. In the 10-week-old embryo, laminae V–IX can be readily recognized. Neuronal differentiation is less advanced in dorsal parts of the spinal gray, where the alar plate of the germinal zone remains present and laminae I–IV cannot be distinguished. From the age of 26 weeks *in utero* and onward, the cytoarchitectural organization of the spinal gray matter is similar to that of the adult cord except for greater neuronal density and development of myelinated structures. As illustrated in Figure 7.3, there is a clear laminar organization of spinal neurons in the sagittally cut cord of the 26-week-old fetus, although in this plane of section laminae VIII and X are not visualized. In the 5-month-old infant, neuronal density has declined in the gray matter and, as in the adult, the exact delineation of spinal laminae is difficult on thin sections (Fig. 7.3).

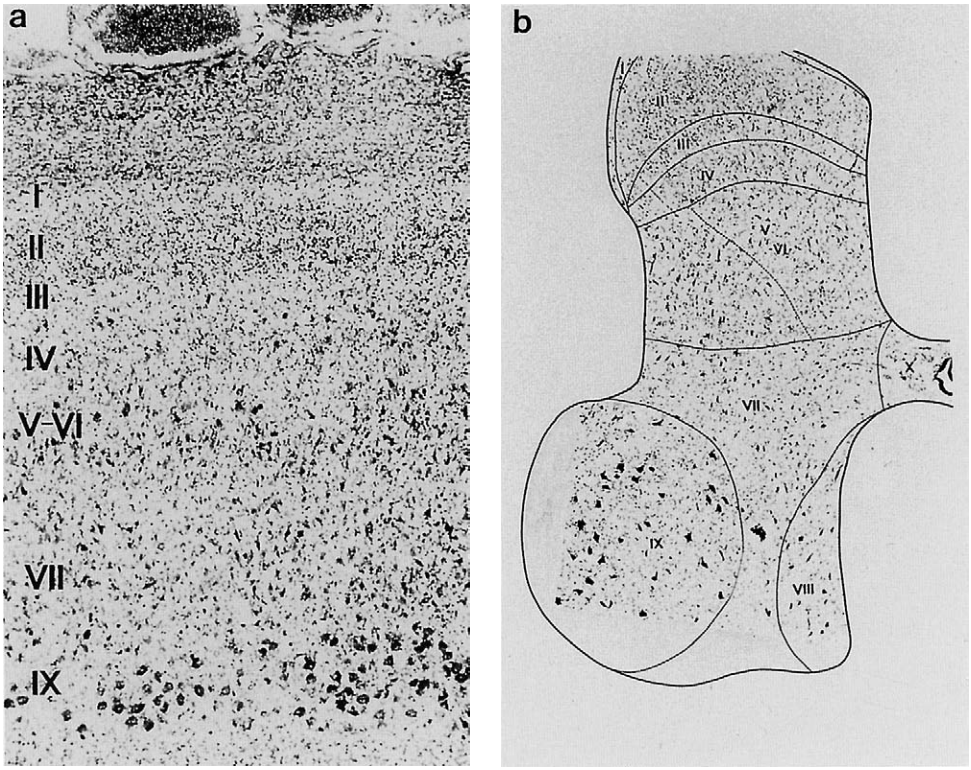

FIGURE 7.3 Spinal cytoarchitecture during development. **(a)** Sagittal Nissl-stained section at the lumbar level of a 26-week-old fetus. Note that laminae VIII and X are not in the plane of section. Magnification: ×48. **(b)** Photomontage of 10-µm transverse cresyl violet–stained sections of segment L5 of a 5-month-old neonate. Magnification: ×20.

Detailed Laminar Characteristics

Cell density and topography within the gray matter, as determined on thick histological section, are not the only criteria to identify cytoarchitectonic laminae. As already mentioned by Rexed, each lamina has in addition its own cytological characteristics. These can be most properly analyzed on Nissl-stained sections. The following cytological characteristics are derived from transverse and longitudinal sections of human spinal cord at the level of the enlargements. Moreover, for each lamina we will describe the dendroarchitectural features as well as morphometric data on dendritic trees.

Lamina I

Lamina I, which is horseshoe shaped and cuffs the tip of the dorsal horn, does not have a uniform thickness. It is thicker at the level of Lissauer's tract and on the lateral border of the dorsal horn. The neuropil of lamina I is loosely organized. Neuronal density is low, and most cells are found in the dorsolateral part, close to Lissauer's tract. Neurons are of variable sizes. Some are fusiform and tangentially oriented, but in the thicker part of the lamina most cells have a stellate, multipolar shape. Nissl bodies are inconspicuous in lamina I neurons.

In lamina I, the majority of dendrites are oriented tangentially to the edge of the dorsal horn. Besides transverse branches, the neurons have longitudinal dendrites that also follow the contour of the dorsal horn. Dendrites are not, however, restricted to the tangential plane; most cells also possess ventral dendrites. These are rami of longitudinal branches curving ventrally; in some cells, the majority of dendrites immediately take a ventral direction. The ventral dendrites which are found in both immature and adult material penetrate deeply into lamina II and can even reach lamina III and IV. Some neurons located in the lateral portion of lamina I have dendrites that penetrate into the white matter of the dorsolateral funiculus. Lamina I neurons are moderately covered with sessile or pedicled dendritic spines, which appear more numerous on the ventral dendrites.

Morphometric analyses confirm the tangential orientation of dendritic trees, but also show that the ventral orientation is far from negligible, since dendritic

spread in the ventral direction is comparable to that in the medial or lateral direction. Dendritic trees of lamina I neurons are poorly branched, and the ramification index (i.e., maximal number of dendritic intersections with 20-µm distant concentric circles from the perikaryon divided by the number of primary dendrites) of 1.60 is the lowest found in the human spinal cord. In adult material, the maximal dendritic extension (radius of the outermost circles crossing a dendrite) is 440 µm.

The tangential orientation of dendrites in lamina I is a classical finding from animal experimentation (Waldeyer, 1888; Ramón y Cajál, 1909; Scheibel and Scheibel, 1968; Gobel 1978a); it was described in humans by von Lenhossek (1895). In our study of the human spinal cord, dendrites perpendicular to the edge of the dorsal horn are a prominent finding. They may outnumber tangential dendrites and penetrate deeply into lamina II, some even reaching laminae II and IV. By contrast, Falls and Gobel (1976) reported that perpendicular dendrites do not exist in lamina I of the adult cat cord, but Ramón y Cajál (1909) pointed out their presence in the cord of the chick embryo and in the medulla of newborn rabbits. Gobel (1978a) thus suggested that they might be immature structures, disappearing during postnatal development. This is not the case in the human cord, where they can be found in fetal as well as in adult material. Lamina I contains projection neurons of the spinothalamic tract as well as proprioneurons (for a review, see Willis and Coggeshall. 1978). In humans, spinothalamic neurons can be identified in lamina I in cases of ventrolateral cordotomy; however, these neurons represent only a small percentage of the total cell population (Schoenen, 1981b; Smith 1976; see Chap 8). Input to this lamina is chiefly from peripheral nociceptors through A-delta and C fibers (for a review, see Cervero and Iggo, 1980; Lynn and Hunt, 1984). These afferents form a dense, tangentially oriented terminal plexus (Rethelyi, 1981) that should favor multiple contacts with dendrites, but not spatial discrimination of inputs. There is evidence from animal experiments that lamina I also contains polymodal neurons, i.e., cells responding to noxious as well as to innocuous tactile stimuli conveyed by A-beta fibers (Willis and Coggeshall, 1978). The latter are distributed mainly to the deeper laminae of the dorsal horn (Lynn and Hunt, 1984). In the human cord, at least, one has to consider the possibility that A-beta fibers might contact laminae I neurons on their ventral dendrites which penetrate deeply into laminae II, III, and IV. Moreover, these ventral dendrites lie within the rich neuropil of lamina II, where part of the control exerted by the substantia gelatinosa on nociceptor-driven projection neurons may be localized.

Lamina II

Lamina II occupies most of the head of the dorsal horn. On transverse section, it has a ventral concavity. It is thickest in its lateral portion, where it covers lamina III. Neuronal density is highest in lamina II, which accounts for the dark appearance of this lamina on Nissl-stained sections. In the human spinal cord there is no clear separation between an outer zone and an inner zone, whereas such a separation was described by Rexed in the cat. The neuronal population of lamina II appears homogeneous. Neurons are small, the largest diameter of their perikaryons reaching 20 µm. They contain only a few Nissl bodies located at either pool of the soma (Fig. 7.4). Horizontal sections indicate that most lamina II neurons are fusiform and oriented along the rostrocaudal axis.

Based on dendritic geometry and axonal course, lamina II contains four types of neurons (islet, filamentous, curly, and stellate cells; their dendroarchitecture is described in detail below (see Fig. 7.6).

Islet Cells These neurons are mainly found in the central parts of lamina II. They have primary dendrites only on a limited surface of the perikaryon. In the most characteristic samples, the first-order dendrites originate from tightly grouped points on the soma, then diverge by branching on diametrically opposite directions. The shape of the dendritic tree resembles a parasol pine. Recurrent dendrites are numerous. Other cells of this class have primary dendrites on two opposite poles of the soma. This cell type, exclusively oriented in the rostrocaudal axis of the cord, closely resembles the islet cells identified by Gobel (1975a, b) in the spinal trigeminal nucleus of the cat. Islet cells represent about 30% of the lamina II neuronal population in humans. They have sparse, irregularly distributed dendritic spines. The axon usually originates on the proximal segment of a primary dendrite. After a short course in the rostral or caudal direction, the axon bifurcates repeatedly at obtuse angles in the immediate vicinity of the neurons. Most axonal branches run longitudinally. Some of them are recurrent collaterals so that the axonal network extends to both sides of the perikaryon. Numerous "boutons en passant" and a few terminal boutons, sometimes grape shaped, can be observed. Rarely, islet cells emit two axons, one originating on the cell soma and the other on a dendrite.

Filamentous Cells These cells are located either in the inner or in the outer portion of lamina II. They are small and have two to three large-caliber dendrites which branch out into a limited number of daughter branches. The main characteristic of these cells is the presence of fine expansions of varied lengths,

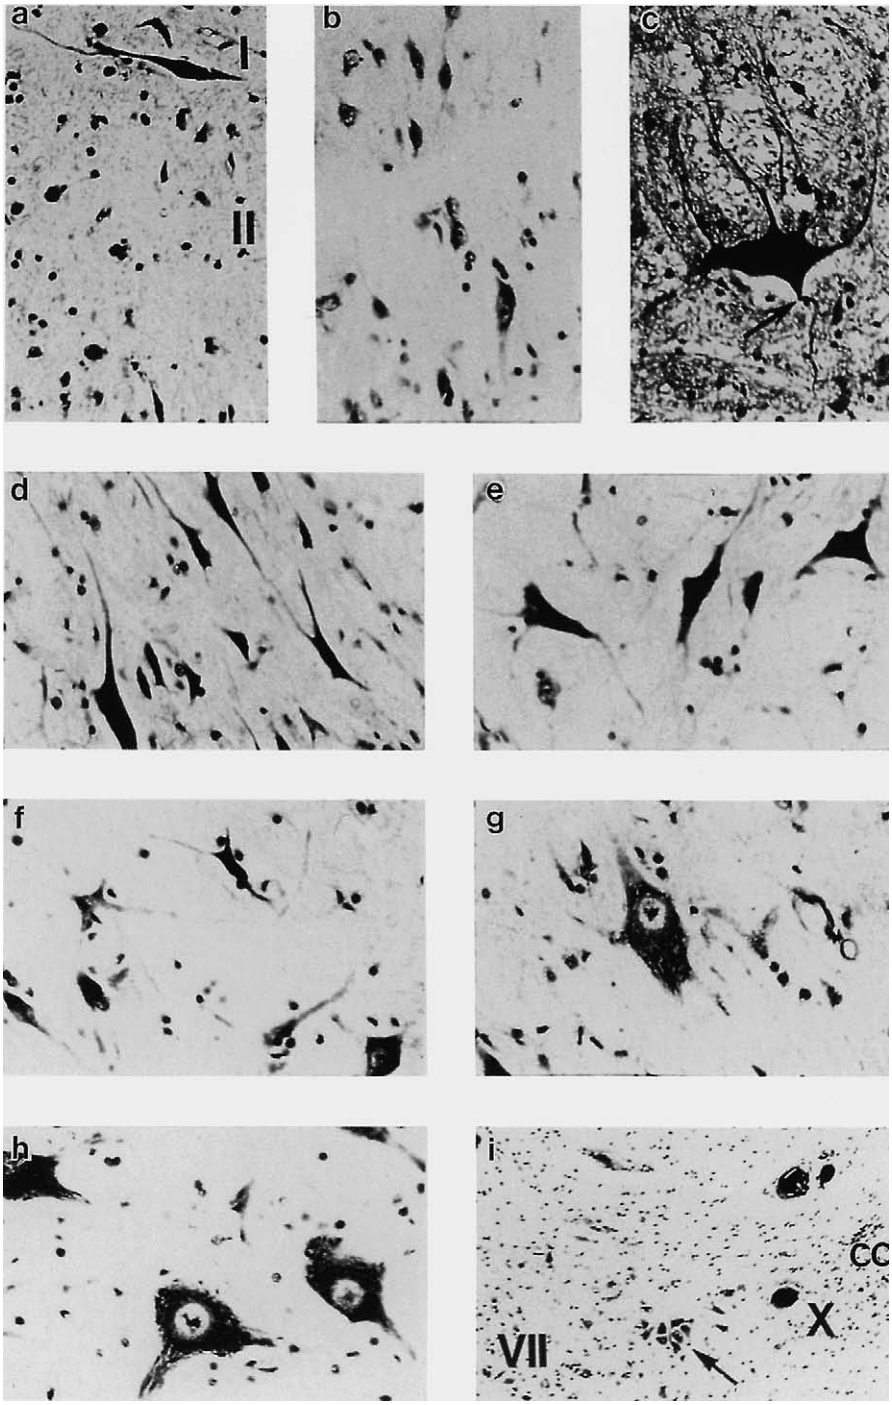

FIGURE 7.4 High-power photomicrographs of poorly differentiated Nissl-stained sections illustrating the cytological characteristics of neurons located in the 10 laminae of human spinal gray matter. **(a)** Transverse section of laminae I and II. A large, fusiform, tangentially oriented lamina I neuron can be seen. Magnification: ×455. **(b)** Horizontal section of lamina II. Note the rostrocaudal orientation of most perikarya. Magnification: ×500. **(c)** Transverse section of lamina IV. Note the large "antenna-like" neuron with a ventral axon *(arrow)*. Magnification: ×500. **(d)** Transverse section of the medial portion of laminae V–VI. Most neurons are fusiform. Magnification: ×455. **(e)** Transverse section of the lateral portion of lamina V–VI. Most neurons are multipolar. Magnification: ×455. **(f)** Transverse section of laminae VII. Neurons are multipolar, but smaller than in laminae V–VI. Magnification: ×455. **(g)** Transverse section of laminae VIII. Note the large neuron. Magnification: ×455. **(h)** Transverse section of lamina IX. Large motoneurons can be seen. Magnification: ×455. **(i)** Transverse section of lamina X. Glial and neuronal elements surround the central canal (cc). The intermediomedial nucleus *(arrow)* is located ventrally at the border between laminae VII and X. Magnification: ×125.

garnishing the entire dendritic tree and conferring the "filamentous aspects" to the cell. In most neurons, the dendritic tree is clearly asymmetrical, predominantly developed on one side of the cell soma. Certain neurons, however, have a bipolar dendritic organization. The orientation of filamentous neurons is always vertical. They represent approximately 20% of the neuronal population impregnated in lamina II. Dendritic spines are more numerous on the filiform branches than on the thick dendrites. The axon issues from the pole opposite to the dendritic tree, gives off a few local branches, then leaves lamina II to penetrate into lamina I or into Lissauer's tract. The axon has a dorsal direction both in dorsally and ventrally located cells.

Curly Cells Among human lamina II neurons, this cell type displays the most complex dendritic tree. Primary dendrites, few in number, give off large-caliber branches, coated with short filiform branches and stalk-like appendages. Most dendrites curve toward each other and thus intermingle to give the "curled" aspect that characterizes this cell type . Curly cells are the least numerous of the four cell types, representing about 10% of lamina II neurons. They are generally located in the outer substantia gelatinosa. Curly cells have abundant dendritic spines that are thin and stubby necked. The axon emerges from a first-order dendrite, runs straight toward the margin of the dorsal horn, and can often be seen to penetrate into lamina I or Lissauer's tract.

Stellate Cells These cells are characterized by a simple dendroarchitecture. Numerous primary dendrites issue from the entire surface of the perikaryon and branch in a rectilinear fashion in many directions within the sagittal plane. These neurons are of the isodendritic type while the other cells in lamina II belong to the allo- or idiodendritic class. The dorsoventral dendrites of stellate cells may cover the entire depth of lamina II and even penetrate a short distance into laminae I and III. Stellate cells preferentially occupy the inner portion of lamina II and represents about 40% of impregnated neurons. Dendritic spines are numerous and spread irregularly over the dendritic tree. The axon issues from the cell soma or, more rarely, from a primary dendrite; it has a ventral direction and one or several collaterals that penetrate deeply into underlying laminae III and IV. Within lamina II, there are some longitudinal axon collaterals.

Morphometric Analyses These confirm the distinct dendritic geometry of each of the four cell types. All lamina II neurons are small, the largest diameter of their perikaryon being around 20 µm. Islet neurons of the adult cord cover a longitudinal territory of 700–800 µm in the rostrocaudal axis. Their dorsoventral or mediolateral extension, however, is less than 50–80 µm. The vertical dendritic extension of filamentous cells can reach 300 µm. Their dendritic spread is greater in the sagittal (50–80 µm) than in the transverse plane (10–30 µm). This explains why, on the transverse plane of section, the visible portion of the dendritic tree is minimal. The dendrites of curly cells occupy a circular territory in the sagittal plane. Because of the curved trajectory of the majority of dendrites, the territorial diameter is low (less than 300 µm). The mediolateral expansion is negligible. The dendritic tree of stellate cells spreads radially in the sagittal plane. Maximal dendritic extension reaches 400 µm in the longitudinal axis, 300–350 µm in the vertical axis. All lamina II neurons have a high ramification index (3.75–4.42), but this is in part due to the presence of recurrent dendritic branches, particularly in islet and curly cells.

Ramón y Cajál (1909) was the first to call attention to the existence of two cell types in the substantia gelatinosa: the "cellule limitrophe" and the "cellule centrale et antérieure." In lamina II of the macaque spinal cord, Beal and Cooper (1978), using the Golgi–Cox method, described a large variety of neurons with different dendritic morphologies. They also proposed a subdivision of the substantia gelatinosa into three differently organized zones: the external zone, or the external portion of lamina II in the cytoarchitectural map of the cat (Rexed, 1964), which is characterized by numerous oblique and ventral dendrites; the middle zone, containing the internal portion of lamina II and the dorsal portion of lamina III, characterized by longitudinal dendrites; and the internal zone, corresponding to the ventral portion of lamina III in the cytoarchitectural scheme and containing principally oblique dorsal dendrites. In our human material, such a stratification of lamina II was not found. However, the four neuronal types described above (Fig. 7.6) do not have an identical topographic distribution. Gobel (1975a, b) described four cell types in lamina II of the cat spinal trigeminal nucleus. Islet cells are identical in his report and in our human studies. Gobel's "border cells" resemble stellate cells in lamina II, except that the axon of "border cells" branches within laminae I, II, and III, while the axon of stellate cells provides collaterals to lamina II and extends into lamina III and IV. The last two neuronal types described by Gobel in the cat, the "stalked cell" and the "abnormal cell" have not been found as such in humans. However, the stalked cell can be compared to the curly cell because of the short, stalk-like dendritic appendages, and the vertical orientation of dendrites is common to both the arboreal cells in the cat and the filamentous cells in

the human cord. Nevertheless, the dendritic tree of the latter is much less extensive, and its axon gives collaterals only to laminae I and II.

Finally, both Gobel's (1975b) results and our human studies have shown the presence of two axons on some lamina II islet cells. The existence of short-axoned Golgi type II neurons in lamina II is controversial. Golgi (1890) pointed out their abundance in the substantia gelatinosa. This observation was challenged by Ramón y Cajál (1909), who found that these neurons were very rare in this location, a finding supported by all subsequent studies of Rolando's substantia gelatinosa using the Golgi method in cats or monkeys (Beal and Cooper, 1978; Scheibel and Scheibel, 1968; Sugiura, 1975; Szentágothai, 1964). In the human cord, the dense axonal network of islet cells occupies the same territory as the dendritic tree. Therefore, unlike other neuronal types identified in lamina II, these cells probably correspond to Golgi type II neurons. This is in agreement with findings in the spinal trigeminal nucleus of the cat (Gobel, 1978b) but not of the monkey (Beal and Cooper, 1978). Interestingly, both the "gate control" (Wall, 1980) and the "reciprocal sensory interaction" theories (Cervero and Iggo, 1980) of modulation of nociceptive transmission in the dorsal horn assume the presence of inhibitory interneurons in lamina II.

Lamina III

Lamina III is poorly demarcated from adjacent laminae II and IV. However, it differs from lamina II by a lower neuronal density and by the occurrence of larger neurons. Conversely, its neuronal density is higher than that of lamina IV, where neurons are larger. Lamina III also presents a distinct myeloarchitecture, which will be described below.

Lamina III contains two neuronal types, which differ in size and dendritic geometry. The majority of impregnated neurons possess an asymmetrical dendritic tree, of which the dorsal branches are more developed. These branches rise vertically from the cell soma and penetrate deeply into the overlying lamina II, reaching 400 μm in length. Ventral dendrites are few and short. In its antenna-like dendritic geometry, this cell type resembles lamina IV neurons but distinguishes itself by its smaller size (perikaryal diameter of 30–50 μm).

The second neuronal type is characterized by a radial dendritic tree and a smaller size (perikaryal diameter of 20 μm or less). Most of its dendrites are located in the transverse and sagittal planes, with a slight preference for a ventrodorsal spread. This cell type is more abundant in the dorsal portion of lamina III, where it may be confused with lamina II stellate cells. It can, however, be distinguished from the latter by a less ramified dendritic tree, fewer dendritic spines, and a greater mediolateral spread.

In the cat, laminae II and III were together referred to as the "substantia gelatinosa" (Szentágothai, 1964) or "gelatinosal complex" (Scheibel and Scheibel, 1968). In the human spinal cord, the dendroarchitecture of lamina III is clearly distinct from that of lamina II. The suggestion that, in humans, laminae II and III are separated entities is also supported by the experimental work of Matsushita (1969) and Ralston (1968a, b, 1979), which showed that laminae II and III differ by their connections and ultrastructure.

Lamina IV

Lamina IV is thicker than lamina III but contains only a small number of neurons of varying size. The characteristic cell type of lamina IV antenna-like neurons (Szentágothai, 1964) can be readily recognized in poorly differentiated Nissl-stained sections (Fig. 7.4c). These larger neurons have the majority of their dendrites oriented dorsally while their axons originate from the ventral region of the perikaryon.

All impregnated neurons in this lamina possess the typical antenna-like dendritic organization, already described in the cat (Szentágothai and Rethelyi, 1973). Most dendrites originate on the dorsal face of the cell and spread dorsally toward the overlying lamina II and III (Fig. 7.5). The dendritic tree extends in both the transverse and sagittal planes. However, morphometric studies show that the mediolateral spread dominates the rostrocaudal spread. Lamina IV neurons can be separated into two groups: medium cells (25–40 μm), which are the most numerous, and large cells (50–75 μm). The length of dorsal dendrites exceeds 1000 μm in the large cells; therefore, these dendrites may cross lamina II out to its dorsal border. The average ramification index for lamina IV neurons is 7.28, which is slightly lower than that of lamina III neurons (7.36). Lamina IV neurons are richly covered with dendritic spines, which are most numerous on dorsal dendrites. When the axon hillock is visible it is always located at the ventral pole of the soma.

As in the cat (Leontovich and Zukova, 1963; Szentágothai and Rethelyi, 1973), all lamina IV neurons in humans, though differing in size, have the typical antenna-like morphology (Figs. 7.6 and 7.7). The mediolateral spread of dendritic trees is not symmetrical but is more marked in lateral directions. A similar asymmetry is found in the cat lamina IV (Proshansky and Egger, 1977) and may be related to the somatotopic organization of peripheral afferents in the dorsal horn where proximal fibers from large cutaneous receptive fields terminate most laterally (Sprague and Ha, 1964; Sterling and Kuypers, 1967a). The predomi-

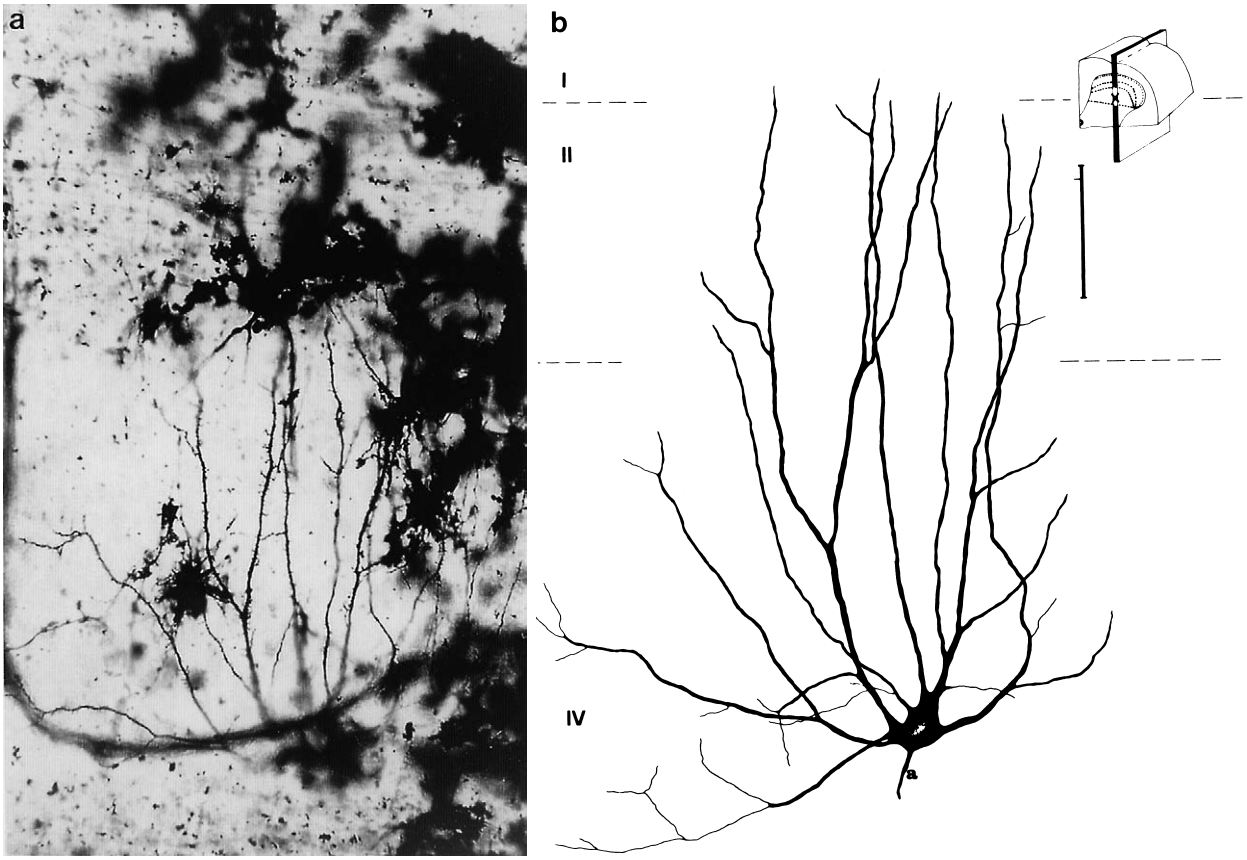

FIGURE 7.5 Large antenna-like neuron in lamina IV. Photomicrograph of Golgi preparation **(a)** and corresponding camera-lucida drawing **(b)** of a sagittal section at the lumbar level of a 1-day-old neonate. The perikaryon *(arrowhead)* is not in the plane of section. Dendritic spines are not drawn.

nantly lateral direction of horizontal dendrites may also provide for an input from corticospinal and lateral reticulospinal afferents, which may enable these effects to exert a powerful descending control on sensory mechanisms in the dorsal horn (Willis and Coggeshall, 1978; see Chapter 8). In animals, the axons of most lamina V neurons enter the spinocervical tract (Willis and Coggeshall, 1978). This tract is merely vestigial in humans (Truex *et al.*, 1970) and most projection neurons in human lamina IV are probably spinothalamic cells, as suggested by the findings in cordotomy cases (Schoenen, 1981b; Smith, 1976; see Chapter 8). The dorsal dendrites of large lamina IV neurons penetrate deeply into lamina II, some reaching the lamina I neuropil. A direct control on lamina IV projection neurons may thus be exerted by lamina II interneurons.

Laminae V and VI

Laminae V and VI occupy the base of the dorsal horn and have different characteristics in their medial and lateral portions. The medial portion contains fusiform or triangular-shaped neurons. These are medium sized and mostly dorsoventrally oriented (Fig. 7.4d). Neurons are less densely packed dorsally in laminae V and VI. Neuronal density is highest in the ventral parts of the medial portion.

The lateral portion of laminae V and VI is not well demarcated from the white matter of the dorsolateral funiculus. This part of the gray matter, corresponding to the "formatio reticularis," has its largest extension in the cervical enlargement. Most neurons are medium sized and multipolar (Fig. 7.4e).

Laminae V and VI have a very similar dendroarchitecture and therefore will be considered together. In transverse sections, neurons of laminae V and VI have a common vertical orientation of the dendritic tree. Dorsal and ventral dendrites extend symmetrically on both sides of the perikaryon in most neurons. According to the position of the soma, dorsal dendrites may cross lamina IV and extend as far as laminae III or II, while ventral dendrites may reach lamina VII. On frontal sections, only a few proximal dendritic stumps are visible, indicating that neurons in laminae V–VI have hardly any longitudinal branches.

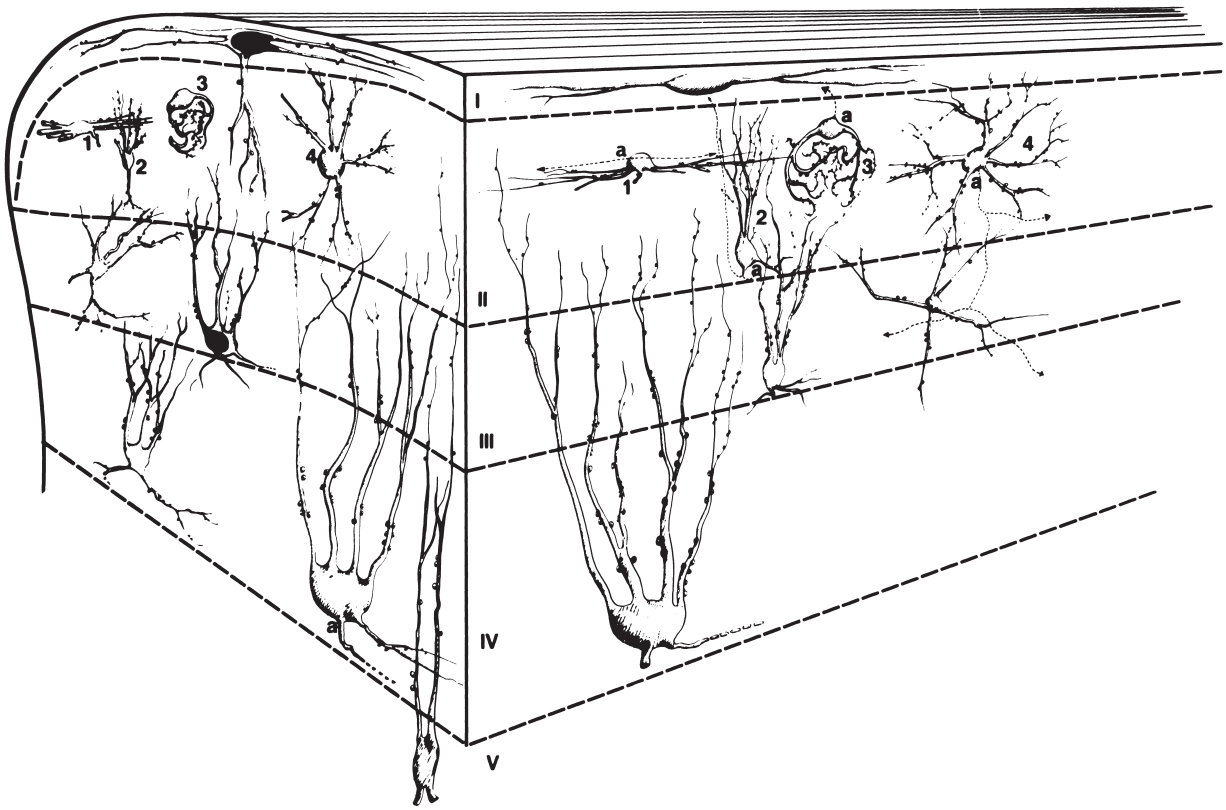

FIGURE 7.6 A representation of the various cell types identified on Golgi-impregnated transverse and sagittal sections in the dorsal horn of human spinal cord. 1, Islet cells; 2, filamentous cells; 3, curly cells; 4, stellate cells; a, axon. From Schoenen (1982a).

In addition to the general verticotransverse orientation of dendrites, some regional dendroarchitectural peculiarities need to be mentioned. There is a narrow mediolateral spread of dendritic trees in medial laminae V–VI neurons. Conversely, laterally located neurons possess a large number of horizontotransverse dendrites, some of which may reach the white matter of the dorsolateral funiculus. The mediolateral spread of dendrites is more marked in lamina VI, especially in its lateral portion. The neuronal population of lamina V is heterogeneous. In the central part of the lamina, the dorsal dendrites of some neurons may cluster and run in parallel with bundles of myelinated afferents penetrating the dorsal horn (Fig. 7.6). In its medial portion, lamina V contains cells that have a dendritic geometry reminiscent of lamina IV antenna-like neurons. Neurons of laminae V–VI have only a few dendritic spines; the initial axonal segment originates mostly from the ventral or lateral poles of the cell body.

Morphometric analyses confirm the preferential verticotransverse orientation of dendrites in these laminae. Mediolateral dendritic spread of the lateral cell population is greater than that of the medial neurons. The dorsoventral spread of medial neurons is greater than that of the lateral cells, while the dorsoventral extension of lamina VI neurons exceeds that of lamina V neurons. In the vertical axis, the total length of the dendritic tree of certain neurons can reach 1300 µm in adult material; its width in the transverse plane reaches 400 µm. The size of laminae V and VI neuronal perikarya varies between 30 and 60 µm. The ramification index is comparable in lateral (7.1) and medial (7.13) neurons, but lateral cells have fewer primary dendrites.

A similar general dendroarchitecture was thus found in laminae V and VI. Therefore, these laminae may comprise a single morphological entity, as suggested by cytoarchitectural studies of the human cord. However, the geometry of dendritic trees differs between medial and lateral portions of lamina V and VI. Mediolateral spread of dendrites is significantly larger in lateral neurons than in medial neurons. This is in accordance with the observations of Proshansky and Egger (1977) in the L6 segment of the cat and with the anatomical subdivision of Ramón y Cajál (1909).

Magnification: ×73. **(c)** Sagittal section of the ventrolateral motoneuronal column at L5 of a 22-year-old adult. Note the loosely meshed longitudinal dendritic plexus. Magnification: ×50. **(d)** Horizontal section of a lateral motoneuron of the ventrolateral column at the lumbar level of a 1-year-old baby. Note the dendritic geometry characterized by rostral, caudal, and lateral branches, the latter penetrating the ventrolateral funiculus. Magnification: ×115. **(e)** Horizontal section at the lumbar level of a 36-week-old fetus. Shown are border cells of the dorsolateral column, forming short transverse bundles which reach the dorsolateral funiculus. Magnification: ×125. **(f)** Horizontal section of the dorsolateral motoneuronal column at the lumbar level of a 2-month-old infant. Note that most dendrites are transversely oriented. Magnification: ×115. Dl, Dorsolateral funiculus; vl, ventrolateral funiculus. From Schoenen (1982b).

From animal experiments it is known that laminae V and VI receive an important contingent of primary afferents of which the terminal arborizations are verticotransverse and avoid the longitudinal axis of the cord (Brown, 1977; Ramón y Cajál, 1909; Scheibel and Scheibel, 1969a; Sprague and Ha, 1964; Sterling and Kuypers, 1967a). The preferential dendritic orientation, as described above, could therefore be parallel to primary afferent terminals, which would favor spatial discrimination of peripheral inputs. In animals, primary afferents of the dorsal horn undergo a dual somatotopic organization. Fibers originating distally terminate in the medial portions of the cord while proximal afferents project onto the lateral portion (Sprague and Ha, 1964). In addition, in the dorsoventral axis of the dorsal horn, there is a progressive enlargement of peripheral receptor fields, with the most ventral neurons displaying the largest cutaneous territory (Applebaum *et al.*, 1975; Brown and Fuchs, 1975; Bryan *et al.*, 1973; Price and Mayer, 1974; Wall, 1967). In accordance with this somatotopic organization, Proshansky and Egger (1977) found in the cat a larger mediolateral dendritic spread in lateral laminae V–VI neurons as compared to medial neurons, and in lamina VI neurons as compared to lamina V cells. Lateral neurons also differ from medial neurons by a large supraspinal and propriospinal input in addition to peripheral afferents, as demonstrated in the cat (Kuypers, 1964; Liu and Chambers, 1964; Nyberg-Hansen and Brodal, 1963; Sterling and Kuypers, 1968) and in humans (Schoen, 1964; Schoenen, 1981b). The greater diversity of afferents could thus be responsible for the more radial morphology of dendritic trees, if one accepts such a causal relationship (Ramón-Moliner, 1967).

Lamina VII

Lamina VII has poorly defined borders. It differs from adjacent laminae V–VI by its lower neuronal density. All neurons are medium sized but vary widely in shape (Fig. 7.4f). Fusiform, mediolaterally oriented neurons predominate in lateral lamina VII, which lies close to the dorsolateral column of motoneurons. Multipolar cells are more frequently found in the central and dorsal regions of lamina VII, while triangular-shaped cells are more numerous in the ventral portion of lamina VII at the level of the enlargements.

In transverse sections, lamina VII is formed by an apparently homogeneous population of medium-sized multipolar neurons. Although these neurons are similar to neurons in laminae VI and VIII, the lamina VII neurons are characterized by a larger number of horizontal or oblique dendrites. These dendrites are the only branches visible in frontal sections; longitudinal dendrites are virtually absent (Fig. 7.8).

Regional dendroarchitectural differences are also found in lamina VII. There is a gradual modification of dendroarchitecture in passing from the lateral to the medial portion of the lamina. Some lateral neurons, adjacent to the dorsolateral column of motoneurons, possess a bipolar dendritic tree that is obliquely oriented in the transverse plane. Neurons located in

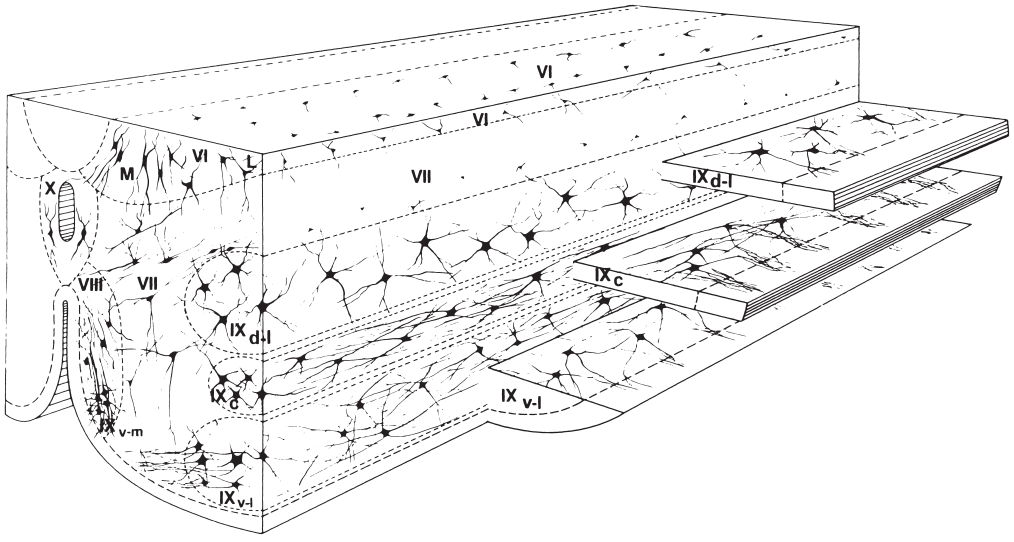

FIGURE 7.8 Three-dimensional representation of spinal dendroarchitecture in the intermediate gray matter and the ventral horn. $IX_{v\text{-}m}$. Ventromedial; $IX_{v\text{-}l}$, ventrolateral; IX_c, central; and $IX_{d\text{-}l}$, dorsolateral columns of motoneurons; M, medial; L, lateral. From Schoenen (1982b).

the central and ventral portions of lamina VII have, in addition, long though scarce ventral dendrites. On the contrary, medial cells X present a rich dorsal dendritic arborization. The dendritic spine density of lamina VII neurons lies between that of motoneurons, which have the lowest spine density, and neurons of overlying laminae. The position of the initial axonal segment is variable.

Morphometric data computed for the entire cell population of lamina VII indicates that dendrites extend mainly in medial and lateral directions. In addition, they show that on average, polarization of dendritic trees occurs along a slightly oblique horizontal transverse axis with a ventromedial and a dorsolateral pole. This is clearly distinct from dendritic polarization in laminae VI or VIII. The territory covered by transverse dendrites can be considerable, certain dendrites extending over the entire width of the gray matter from lamina X to the white matter of the dorsolateral funiculus, i.e., up to 2 mm. The ramification index of lamina VII neurons is 7.45, which is higher than that of lamina VIII or IX neurons.

Lamina VII receives a small contingent of primary afferents, originating chiefly from muscles and joints (Eccles *et al.*, 1954; Menetrey *et al.*, 1977). These afferents are concentrated in the medial portion, where they form small vertical bouquets corresponding to the "collatérales du noyau gris intermediaire" of Ramón y Cajál (1909; Sterling and Kuypers, 1967b). Interestingly, the dorsal dendritic tufts of lamina VII neurons in the human cord have a similar morphology and orientation. Supraspinal and propriospinal afferents terminate massively in lamina VII (see Chapter 8). Again, the preferential dendritic orientation of lamina VII neurons, oblique in the transverse plane, corresponds to the axis through which the major afferents penetrate this lamina: ventromedial course for dorsolateral afferents (i.e., lateral cortico- and reticulospinal, dorsolateral propriospinal) and dorsolateral course for ventromedial afferents (i.e., ventral cortico- and reticulospinal, ventromedial propriospinal).

Lamina VIII

Lamina VIII has, in contrast to the previously described laminae, a dorsoventral extension. It is characterized by cytological heterogeneity as it contains small-, medium-, and large-sized neurons of varying shapes. The larger multipolar neurons differ from motoneurons only by finer appearance of their Nissl bodies (Fig. 7.4g).

In transverse section the dendritic tree of lamina VIII neurons is predominantly vertically oriented. Most dendrites originate from either the ventral or dorsal pole of the soma. Dorsal dendrites are directed toward the ventral gray commissure without crossing the midline, or toward lamina VII. Ventral branches run toward the ventromedial tip of the ventral horn. A few dendrites penetrate into the white matter of the anterior funiculus. Lamina VIII neurons have no longitudinal dendrites. Dendritic spines appear more numerous than in lamina VII or IX and predominate on proximal dendrites. When impregnated, the axon hillock has a dorsal orientation.

Morphometric analyses confirm the dorsoventral polarization of dendritic trees in lamina VIII. In most neurons the vertical dendritic extension is symmetrical on either side of the soma, with minimal mediolateral spread. The vertical transverse territory covered by the dendritic tree may be more than 1 mm in the largest neurons. These large neurons have a perikaryal diameter of up to 80 µm, but small cells with a diameter not exceeding 30 µm are also found. The ramification index (3.12) of lamina VIII neurons is among the highest found in human spinal neurons.

According to observations in animals, most afferents to lamina VIII are oriented vertically in the transverse plane and thus parallel to the preferential orientation of dendritic trees found in the human cord. This is the case for the propriospinal fibers (Matsushita, 1969; Ramón y Cajál, 1909; Sterling and Kuypers, 1968), medial vestibulo- and reticulospinal fibers (Kuypers *et al.*, 1962), and primary afferents to the dorsal portion of the lamina (Scheibel and Scheibel, 1969a; Sterling and Kuypers, 1967a).

Lamina X

Lamina X corresponds to the periependymal gray matter and is characterized by the dense structure of its neuropil and a low cell body density. The lamina X neurons are small in contrast to those of adjacent laminae V–VI, VII, and VIII.

As shown in Fig. 7.4i, a cluster of small neurons may be seen at the border between lamina VII and lamina X. These form the intermediomedial nucleus. This nucleus does not form a continuous column along the rostrocaudal axis of the cord, but has a beaded structure, so that it is not identifiable on all sections.

Despite the low number of neurons impregnated on Golgi stains in this lamina, two cell types can be recognized. The first type is found in the mid- and dorsal portions of lamina X. These cells have a bipolar appearance with a fan-shaped dendritic tree branching from one, or rarely, two, primary dendrites located at the ventral and dorsal pole of the soma. Dorsal dendrites may reach the medial part of lamina VI, whereas ventral branches penetrate into lamina VIII. Dendritic spines are spare. The axon is frequently impregnated:

it is directed first laterally, then bifurcates into a dorsal branch crossing laminae VI and V and a ventral branch penetrating lamina VII. On morphometry, dendritic spread is clearly dorsoventral and limited to the transverse plane. Dorsoventral extension of dendritic trees does not exceed 600 µm in adult human material. The high ramification index of 4.16 underlines the richness of dendritic branching.

The second neuronal type is located is in the ventral portion of lamina X. Its dendritic tree is morphologically simple and poorly ramified. Primary and secondary dendrites are oriented along the rostrocaudal axis of the cord, parallel to the central canal. Dendritic spines are sparse and only the axon hillock is impregnated. Morphometric analyses show that this cell type is also bipolar, but dendritic polarization is longitudinal, in contrast to the first neuronal type. The total extension of the dendritic tree is considerable, reaching 1.5 mm in adult human material. The ramification index (7.3) is distinctly lower than in the first neuronal type. The perikarya of both lamina X cell types are of comparable size (30–35 µm).

The two cell types found in human lamina X can be compared to the "neurone fusiforme ou triangulaire" and the "cellule étoilée" described by Ramón y Cajál (1909) in the cat. Until recently, lamina X has received little attention from neuroanatomists and neurophysiologists. Interest in this lamina has been revived by the demonstration of a large number of afferents containing various neuropeptides (for a review, see Honda and Lee, 1985). Lamina X probably receives a strong visceral input and has a role in autonomic function.

Lamina IX (Motoneurons)

Lamina IX contains the motoneurons, which are grouped in several columns. Motoneurons are easily recognized by their large size, multipolar shapes, and abundance of large Nissl bodies (Fig. 7.4h). In accordance with the work of Massazza (1922, 1923, 1924), we have identified three columns of motoneurons at the L5 level: a dorsolateral, a ventrolateral, and a central column (Fig. 7.1). In addition, a ventromedial column of motoneurons is found at the L4 level, occupying the ventromedial tip of the ventral horn (Fig. 7.2). Motoneurons have been counted in the human lumbosacral cord by two research groups. The total number of motoneurons in segments L1 to S5 lies between 52,000 and 62,000, with segment L5 frequently containing the largest number of cells (around 10,000) and segment S1 showing the highest density of motoneurons per section (Irving *et al.*, 1974; Tomlinson *et al.*, 1973). In the L5 segment, the size distribution of lamina IX neurons is approximately as follows: 65% large-diameter cells (35–60 µm), 25% intermediate-diameter cells (25–35 µm), and 10% small-diameter cells (less than 25 µm) (Kawamura *et al.*, 1977). The number of motoneurons decreases with age, chiefly around 60 years (Tomlinson and Irving, 1977). It has been estimated that about 200 lamina IX neurons are lost per decade.

Laruelle (1937, 1948) was the first to call attention to the particular dendroarchitectural organization of motoneurons. Using the Bielchowski–Reumont silver impregnation technique in longitudinal sections of the cord, he showed that in various species the majority of motoneuron dendrites are rostrocaudally oriented. Unknown to earlier authors whose studies were exclusively based on transverse sections, this dendritic organization was later confirmed in the cat with the Golgi technique (Balthasar, 1952; Scheibel and Scheibel, 1966a, 1969b; Sterling and Kuypers, 1967b).

In 1970, the Scheibels (1970a, b) renewed interest in the anatomy of motoneurons by showing that their dendrites are gathered into bundles and suggesting that these dendritic bundles might play a role in certain motor programs in the cat. The Golgi method and morphometric analyses of dendritic orientation reveal distinct dendroarchitecture for each motoneuronal column.

Ventromedial Column On transverse sections, the ventromedial motoneurons present a characteristic configuration. One or two primary dendrites of large diameter arise from the dorsal surface of the neurons. These apical dendrites and their daughter branches cross lamina VIII toward the ventral gray commissure or, rarely, toward lamina VII. The ventral, or basal, pole of the perikaryon emits a large number of primary dendrites (three to five), which ramify entirely in a fanlike arrangement. On longitudinal sections, several dendrites from the ventral perikaryon are oriented rostrocaudally, but they are fewer and shorter than longitudinal branches in other motoneuronal columns. Dendritic spines appear most numerous on ventral dendrites. The axon generally arises from the basal pole of the perikaryon.

Ventromedial motoneurons form vertical and longitudinal dendritic bundles. Vertical bundles are composed of 10–30 dendrites, mostly secondary branches belonging to adjacent motoneurons. They are oriented dorsally, and penetrate lamina VIII to reach the ventral gray commissure, but do not cross the midline. During their course through lamina VIII they may receive dorsal or ventral dendrites from neurons within this lamina. The vertical dendritic bundles of ventromedial motoneurons are among the longest and thickest observed in the human cord. They may extend over

2–3 mm in the ventrodorsal axis and their thickness varies from 30–100 µm.

The longitudinal dendrites of ventromedial motoneurons intermesh within the rostrocaudal axis of the cord to form a dendritic plexus which is continuous over the entire length of the motoneuronal column and contains dendritic "microbundles." The latter are formed by five or less dendrites and do not exceed 5–10 µm in width and a few tens of micrometers in length. The dendrites are of variable thickness and order, belonging to neighboring or distant neurons. They may pass from one microbundle to another within the longitudinal dendritic plexus. Both vertical and longitudinal dendritic bundles of the ventromedial motoneurons are already well developed in the 26-week-old fetus.

Morphometric analyses of dendritic spread, i.e., vector analysis (for details, see Schoenen, 1982b), show that the ventromedial motoneurons are preferentially oriented in dorsal, rostral, and caudal directions, with a predominance of dorsal spread. The total length of longitudinal dendrites does not exceed 500–800 mm, even in adult material, which is much lower than in other motoneurons.

Central Column On transverse sections, motoneurons of the central column present a radial, multipolar dendritic tree. The characteristic dendroarchitecture of central motoneurons appears in longitudinal sections. The majority of dendrites are oriented along the rostrocaudal axis of the cord (Fig. 7.7 a).

After a short trajectory, dendrites arising from the medial surface of the perikaryon curve at right angles and spread into the longitudinal axis. In contrast, dendrites on the lateral face of the soma extend perpendicular to the longitudinal dendrites toward the lateral border of the ventral horn, penetrating, with few exceptions, into the white matter of the ventrolateral funiculus. Dendritic spines are scarce. The position of the initial axonal segment varies.

The central motoneuronal column is characterized by transverse and longitudinal dendritic bundles. The lateral dendrites of central motoneurons gather to form large dendritic bundles, which head toward the ventrolateral funiculus. These are formed at first- and second-order dendrites of adjacent motoneurons that join the bundles only at a distance of 50–100 µm from their soma of origin. These laterally oriented bundles contain several tens of dendrites and reach a thickness of 80 µm and a length of 2 mm. Unlike the vertical bundles of the ventromedial column, the lateral dendritic bundling of central motoneurons is inconspicuous in the 26-week-old fetus (Fig. 7.7a), but easily recognized from 36 weeks of fetal age onward.

Longitudinal dendrites of central motoneurons intermesh within the rostrocaudal axis of the cord to form a longitudinal dendritic plexus with microbundles comparable to that described in the ventromedial column. Longitudinal microbundles can be readily identified as early as 26 weeks *in utero* (Fig. 7.7a).

On morphometric analyses of the central column, lateral dendritic spread predominates in the transverse plane, while rostral and caudal spread is prominent in the sagittal plane, confirming the triple polarization of the dendritic tree. Lateral dendrites reach a length of 1300–1500 µm in the adult and penetrate the white matter of the ventrolateral funiculus. The length of longitudinal dendrites nears 900 µm in adult material; thus, the global span of the dendritic tree in the rostrocaudal axis can reach 1800 µm or more.

Ventrolateral Column Dendritic trees of ventrolateral motoneurons are radial in the transverse plane. In the lateral portion of the column, most dendrites are laterally oriented whereas their orientation in the medial portion is medial. Sagittal and frontal sections show that longitudinal dendrites are numerous and long. They run along the rostrocaudal axis as soon as they originate at the antipodes of the cell body (Fig. 7.7d).

Like motoneurons of the central column, those of the ventrolateral column form dendritic bundles in the transverse (Fig. 7.7b) and longitudinal planes (Fig. 7.7c). The morphological features, architecture, and ontogenesis of these bundles are comparable in central and ventrolateral motoneurons. The ventrolateral column is distinguished by the existence of both laterally and medially oriented bundles, in its lateral and medial portions, respectively (Fig. 7.7b), while only lateral bundles are present in the central column.

The vector analysis shows that longitudinal dendritic spread is very pronounced. The territory covered by longitudinal dendrites is the most extensive dendritic domain in human spinal gray matter, since it can reach a total length of 3 mm in the adult. In the transverse plane, vector analyses give varying results, depending on whether the medially or laterally situated neurons are studied. Medial dendritic spread dominates in the former, lateral extension in the latter. There are differences between the morphometric data obtained from ventrolateral motoneurons and those pooled from the other motoneuronal columns. For instance, ventromedial motoneurons have a lower number of primary dendrites and are less ramified, their ramification index (1.70) being lower than that of the other motoneurons (7.13). As a consequence, the radial distance from the soma to the maximal number of dendritic intersections (and thus the perisomatic volume containing most of the dendritic membrane area) is reduced in ventrolateral

motoneurons (60 μm) compared to other motoneurons (100 μm).

Dorsolateral Column In contrast to other motoneurons, those of the dorsolateral column mostly branch out in the transverse plane, showing a rich and multipolar dendritic tree. In frontal sections the dendritic tree is also radial without clear polarization (Fig. 7.7f). In the sagittal plane, the majority of dendrites have a ventrodorsal orientation. There are a few exceptions to the multipolar dendritic organization of dorsolateral motoneurons. These are found in the cervical enlargement, where some neurons bordering the white matter have a longitudinal orientation, and in segment S1, where some ventromedially located neurons may have a similar dendroarchitecture to that of neighboring cells of the central column.

Dendritic bundling is inconspicuous in the dorsolateral column. So-called spinal border cells, located in the vicinity of the dorsolateral funiculus, give rise to short (150–200 μm or less), laterally oriented dendritic bundles, which may penetrate several tens of micrometers into the white matter (Fig. 7.7e).

On morphometry, there is a predominance of dorsal and lateral dendritic spread on transverse sections, dorsal and lateral spread on sagittal sections, and a slight preference for the rostrocaudal axis on frontal sections.

Figure 7.8 is a three-dimensional representation of spinal dendroarchitecture in the intermediate gray matter and the ventral horn. Each motoneuronal column of human spinal cord has a distinct dendroarchitecture. The dendritic tree of *ventromedial* motoneurons has a pyramidal shape resembling that of cerebral cortex pyramidal cells. Apical, dorsally oriented dendrites are the longest; longitudinal dendrites are the most numerous, although shorter. The dendritic tree of *central* column motoneurons forms a T, the base of which is planted on the lateral border of the ventral horn. The majority of dendrites are oriented along the rostrocaudal axis of the cord. Longitudinal spread of dendrites is also dominant in the *ventrolateral* column. Schematically, the dendritic tree of these motoneurons can be compared to a cross in the frontal plane, of which the longest branch is oriented along the rostrocaudal axis of the cord. The *dorsolateral* motoneurons differ from other motoneurons by their multipolar dendritic morphology. Differences in the dendritic branching pattern have been reported between human α and γ motoneurons (Abdel-Maguid and Bowsher, 1979). Our morphometric analyses, based on a greater number of large neurons than small neurons, reveal a similar dendritic organization for small (30–50 μm) and large (50–80 μm) cells. Although there may be species differences, the general somatotopic arrangement of motoneurons is well known. Motoneurons innervating proximal musculature are found in a medial and ventral position, with the ventromedial column innervating axial muscles. On the other hand, the neurons for distal muscles occupy a lateral and dorsal position in the ventral horn (Burke *et al.*, 1977; Elliott, 1944; Romanes, 1951, 1964; Sharrard, 1955; Sprague, 1948, 1951; Sterling and Kuypers, 1967b). In the cat and monkey, it is well established that motoneurons innervating a single muscle are grouped into a single longitudinal column, and columns corresponding to synergic muscles line up in the rostrocaudal axis of the cord. Within a motoneuronal column of which the preferential dendritic orientation is longitudinal, the dendritic trees overlap over a long distance. Such a dendritic organization would thus favor spatial summation along the longitudinal axis of a motoneuronal column and, consequently, synchronization and synergy. The results in the human lumbosacral cord suggest that longitudinal dendritic spread is common to motoneurons of axial, proximal, and calf muscles. These muscles have primary functions in the maintenance of posture and upright position, where synchronization and synergy are required properties. These functional properties are reinforced by the parallel orientation to dendrites of most propriospinal and supraspinal afferents (Scheibel and Scheibel, 1966a, b; Sterling and Kuypers, 1968). In contrast to longitudinal motoneuronal columns, the radial dendritic organization of the dorsolateral column only allows slight interactions between motoneurons, since only dendrites of adjacent neurons are close to each other. This column innervates distal muscles involved in fine, delicate movements of the extremities, so that it is not surprising that its dendritic organization favors precise and selective contacts with afferents.

The literature concerning motoneuronal *dendritic bundles* and differences in these between species has been reviewed elsewhere (Schoenen, 1982b). It is worth mentioning that specialized contacts resembling "puncta adherentia" have been demonstrated at the ultrastructural level within dendritic bundles of human motoneurons (Schoenen, 1981a). The exact role of dendritic bundles is still unknown. However, they are eminently favorable structures for dendrodendritic interactions and ephaptic transmission or electrotonic coupling. It has been suggested that electrotonic contacts between dendrites, transmitting a particular type of information, would constitute within a group of neurons a network of local circuits (Horcholle-Bossavit, 1978) that could serve for central programming (Scheibel and Scheibel, 1975). One can hypothesize that the functional role of the longitudinal dendritic

plexus and microbundles of motoneurons is to favor synchronization within a motoneuronal pole and also synergy between motoneurons of agonist muscles. Moreover, these structures could form a network of local circuits for electrotonic currents that would influence the excitability and tonic activity of the motoneuronal column. Synchronization and synergy are favorable in axial and antigravity muscles, which also possess an important tonic activity. It is therefore interesting to note that the longitudinal plexus is tightest in ventromedial and central columns innervating axial and antigravity muscles, respectively. In contrast to longitudinal bundles, the transverse dendritic bundles clearly have a local, intrasegmental organization, since only adjacent motoneurons in the longitudinal axis participate in a given bundle. Therefore, they could act in phasic, focal modulation of the excitability of a motoneuronal pool. In this respect, it is noteworthy that the motoneurons of an antigravity muscles, where longitudinal as well as transverse dendritic bundles are found, function tonically in maintaining posture, but discharge phasically in other activities such as locomotion (Grillner, 1975). Another peculiarity of transverse dendritic bundles is their topography and orientation within the ventral horn. They are in a close spatial relationship with two principal groups of afferents, namely, the medial system of the brain stem (Kuypers, 1981) and the propriospinal system (Barilari and Kuypers, 1969; Nathan and Smith, 1959; Sterling and Kuypers, 1969; Szentágothai, 1964). These two systems play an important role in adjusting the center of gravity and in locomotion (Delwaide, 1977; Grillner, 1975; Grillner and Zangger, 1979; Kuypers, 1973). It is therefore tempting to attribute to the transverse dendritic bundles of motoneurons a function in centrally programmed activities, such as walking. In line with this hypothesis, one would expect a parallelism between the ontogenic development of these bundles and that of certain motor activities. Such a parallelism has already been established in the kitten (Scheibel and Scheibel, 1970b). In the human lumbar cord, transverse dendritic bundles of central and ventrolateral motoneurons cannot be identified before the fetal age of 36 weeks, while bundling in the ventromedial motoneurons is easily recognizable in the 26-week-old fetus. It is worth relating this anatomical observation to the development of motor function in the fetus. Automatic walking is well developed in the 36-week-old premature infant, whereas it is absent in the 26- to 28-week-old premature infant. In contrast, primitive reflex activities with a predominantly tonic component, such as an incomplete Moro reflex, are already elicitable by 26 weeks (Sher and Brown, 1975). This would thus suggest a developmental synchronism between the different types of motoneuronal dendritic bundles and specific motor programs.

Segmental Variations

In the previous sections, we have described the laminar cytoarchitectural organization of the spinal gray matter at the level of the enlargements. However, it is well known, that the volume and the shape of the spinal gray matter vary along the length of the cord. These variations are commonly used to identify specific spinal segments on histological sections. We have studied regional and segmental variations of spinal cytoarchitecture from C1 to the conus terminalis on serial sections of the spinal cord from a 45-year-old person.

All the neuronal laminae described previously are present throughout the length of the cord down to the lower sacral segments. However, certain laminae undergo important size variations according to the segmental level. As a consequence, the topography of other laminae may be modified. In addition, some neuronal groups such as the central cervical nucleus, the dorsal nucleus of Clarke, the intermediolateral nucleus, and the parasympathetic sacral nuclei, which are easily recognizable, are present only at certain segmental levels. For this reason, they are not included in the general lamina cytoarchitectonic scheme. Only the most significant segmental variations of spinal cytoarchitecture will be described below.

The volume of laminae V–VI is markedly reduced at the thoracic level due to the appearance of Clarke's column in its ventromedial portion (Fig. 7.10). Extension of lamina VII is maximal at the level of the enlargements where this lamina reaches the ventral border of the gray matter between lamina VIII and IX. This ventral portion of lamina VII disappears at thoracic levels. At these levels, lamina VIII, while confined to the medial aspect of the ventral horn in the enlargements, occupies the whole width of the central part of the ventral horn (Fig. 7.9). From thoracic level T1 to the lumbar segment L1, the intermediolateral nucleus can be found in the lateral tip of lamina VII. The central cervical nucleus is found lateral to lamina X at caudal levels of the pyramidal decussation and at cervical levels. It is evidenced by its acetylcholinesterase-clear background marked by stained vascular elements.

Lamina IX is most developed at the level of the enlargements, but the various motoneuronal columns are not found in all segments. The ventromedial column, for instance, can be identified from segments C1 to segment L4; it is the only motoneuronal column identifiable in superior cervical and thoracic segments.

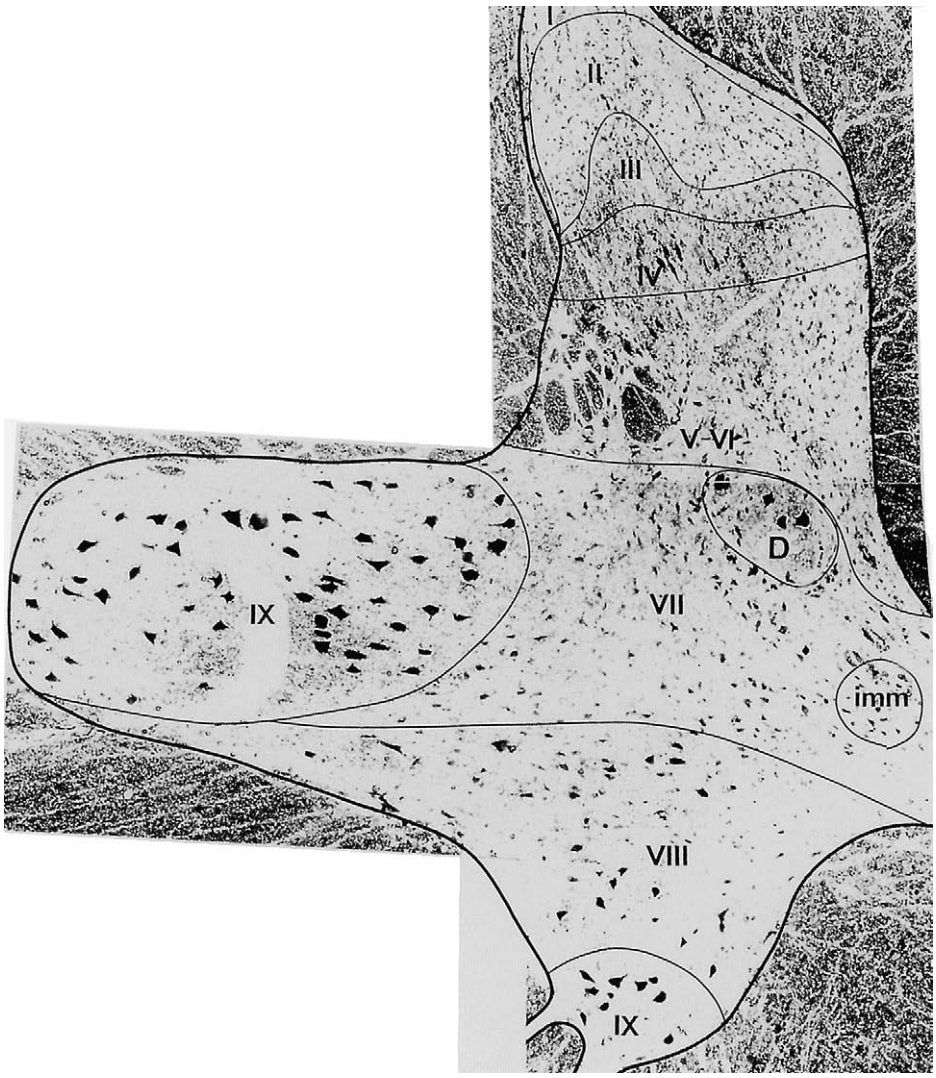

FIGURE 7.9 Photomontage of transverse cresyl violet–stained sections at level T1 illustrating the segmental variations of spinal laminar cytoarchitecture. The T1 segment belongs to the "transitional" cytoarchitectural type. It has features in common with the "thoracic" type [dorsal nucleus of Clarke (D), lamina VIII occupying the width of the ventral horn] and with the "enlargement" type (voluminous dorsolateral column of motoneurons); imm, intermediomedial nucleus. Magnification: ×13.5.

Below the fourth lumbar segment, the ventromedial column of motoneurons disappears.

Below the fourth sacral segment, the cytoarchitectonic laminae progressively vanish. From segment S3 on, there is a midline fusion of the gray matter of the dorsal horns. In addition, the last sacral segments are characterized by the parasympathetic nuclei. The conus terminalis only contains a few cells of glial morphology surrounding the terminal ventricle. At the opposite extremity of the cord, the laminar cytoarchitectural organization extends into the lower medulla where laminae I–IV can be identified in the caudal trigeminal complex. However, rostral to the spinomedullary junction these laminae rotate 90° around the central canal, so that their orientation becomes dorsoventral.

Figure 7.10 is a schematic illustration of the regional surface variations of the first nine cytoarchitectonic laminae from segment C1 to segment S4. From these studies, one may infer the existence of three main region-dependent cytoarchitectural types in the human spinal cord (detailed below) that are comparable to those described by Rexed in the cat:

1. *Enlargement type.* The enlargement type (C4–C8; L4–S2) (see Figs. 7.1 and 7.2) is characterized by expansive dorsal and ventral horns, a large lamina V–VI, a

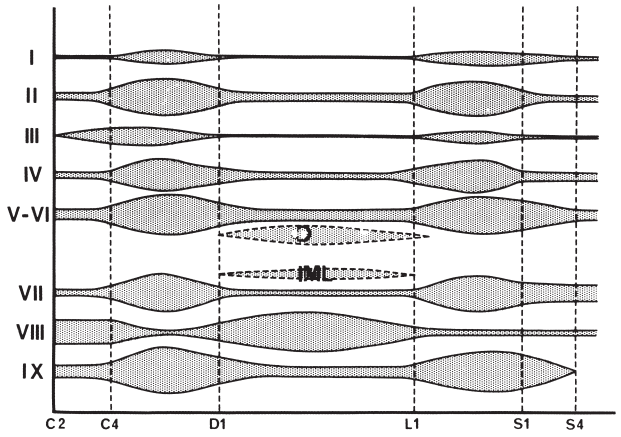

FIGURE 7.10 The surface variations of cytoarchitectural laminae from segment C2 to the sacral level. D, Dorsal nucleus of Clarke; IML, intermediolateral column.

ventrally extended lamina VII, a medially confined lamina VIII, and an extensive lamina IX comprising several motoneuronal columns.

2. *Thoracic type.* The thoracic type (T2–T12) is characterized by a much reduced gray matter, absence of large antenna-like neurons in lamina IV, partial replacement of laminae V–VI by Clarke's column, the presence of the intermediolateral nucleus, the spread of lamina VIII from the medial to the lateral border of the ventral horn, and the sole persistence of the ventromedial motoneuronal column.

3. *Transitional type.* The transitional type is characterized by an intermediate cytoarchitectural organization. This type is found in segments C1–C3, T1, L1–L3, S3, and S4. Figure 7.9 illustrates the cytoarchitectural organization of segment T1, which resembles the thoracic type by the presence of Clarke's column and the topography of laminae VII and VIII but, similar to the enlargement type, contains a well-developed dorsolateral column of motoneurons. From S1–S2 to S4, a supplementary column of motoneurons appears in the ventral horn. This is Onuf's nucleus, which lies at the most ventral border of the ventral horn medial to the other motoneuronal columns. Onuf's nucleus is divided into a dorsomedial cell group innervating the bulbocavernosus and ischiocavernosus muscles and a ventrolateral group innervating external anal and urethral sphincters. A sexual dimorphism has been found in the dorsomedial portion of Onuf's nucleus, which contains significantly more motoneurons in males than in females (Forger and Breedlove, 1986).

The various segmental types of the spinal cytoarchitecture can be readily recognized on high-resolution nuclear magnetic resonance (NMR) images (Solsberg *et al.*, 1990). Some regional variations are illustrated in the 3-Tesla NMR images of formalin-fixed spinal cords shown in Figure 7.11.

CHEMOARCHITECTURE

General Chemoarchitecture

This account of the general chemoarchitecture of the human spinal chord is based on results obtained by histochemical (including immunohistological) methods, receptor autoradiography, and topographical biochemical analyses. Because of obvious methodological problems, human data are still incomplete. We will therefore refer to results of animal experiments whenever appropriate. However, it must be kept in mind that species differences do occur in the spinal chemoarchitectural organization. Such differences are clearly evident when using histoenzymological methods (Schoenen, 1973, 1981). For instance, FRAP, the fluoro-resistant isoenzyme of acid phosphatase that characterizes a subpopulation of spinal ganglion cells in rats and mice, is not found in human spinal chord. Glutamate and succinate-semialdehyde dehydrogenase, which play a role in the metabolism of γ-aminobutyric acid (GABA), are heavily concentrated in lamina II of humans, but not of monkeys.

Acetylcholine

Cholinergic mechanisms appear to play a ubiquitous role in the spinal gray matter. However, the histoenzymological reaction for acetylcholinesterase, the hydrolyzing enzyme of acetylcholine, is strongest (Schoenen, 1973, 1977, 1981; R.L.M. Faull, unpublished observations) and the enzymatically determined levels of choline acetyltransferase, its synthesizing enzyme, are highest (Aquilonius *et al.*, 1981) in dorsal horn laminae I and II, in lamina IX of motoneurons, and in autonomic nuclei such as the intermediolateral nucleus or the sacral parasympathetic nuclei. Muscarinic cholinergic receptors are densely concentrated in laminae II and IX (Scatton *et al.*, 1984; Villiger and Faull, 1985; Whitehouse *et al.*, 1983). As reported in the rat, muscarinic receptors in the human spinal chord are predominantly of the M1 type in lamina II, but significant densities of both M1 and M2 receptor subtypes are present in the motoneuronal columns (Fig. 7.12) (Villiger and Faull, 1985). Therefore, motoneurons that use acetylcholine as a transmitter at the neuromuscular junction receive an important cholinergic input. This input has various origins, including recurrent collaterals from adjacent motoneurons and supra- and propriospinal fibers. Moreover, axon collaterals of motoneurons are the main afferents of Renshaw cells, which are responsible for recurrent

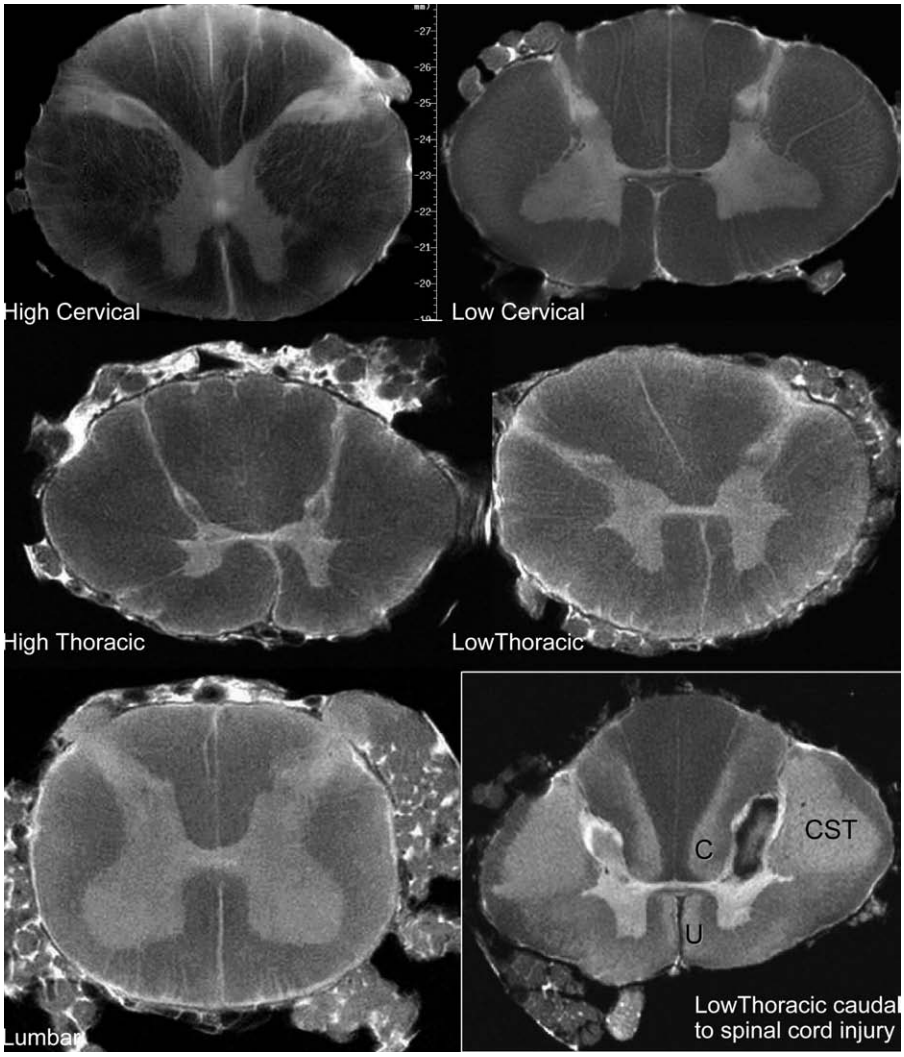

FIGURE 7.11 3T NMR images of formalin-fixed human spinal cords at high and low cervical and thoracic levels, and at the lumbar level. Myelin-rich white matter appears dark, while gray matter is lighter. In the dorsal horns, myelin-poor laminae I–II and Lissauer's tract contrast with surrounding white matter and underlying laminae III and IV. The lower right image shows demyelination in crossed (CST) and uncrossed (U) corticospinal tracts, and in Schultze's comma tract in a segment just caudal to a spinal cord injury. A necrotic lesion can be seen in the right dorsal horn. (Courtesy of Drs Kakulas-Univ of Perth-Australia, Martin & Scholtes-Univ of Liège-Belgium and Gelan-Univ of Limburg-Belgium.)

inhibition and possess cholinergic nicotinic receptors (for a review, see Krnjevic, 1979).

Monoamines

The monoaminergic projections to the spinal cord are well known in animals (for reviews, see Hunt, 1983, and Lindvall and Bjorklund, 1983). Noradrenaline-containing fibers to the dorsal horn and to the ventral horn originate, respectively, in the lateral tegmentum (A5 and A7 groups) and in the locus ceruleus and subceruleus. Serotonergic input to the dorsal horn comes from the raphe magnus nucleus, whereas the raphe obscurus and pallidus nuclei innervate the intermediate gray matter and the ventral horn. Dopamine-containing fibers are chiefly concentrated in the dorsal horn and originate from the diencephalic A11 cell group. There is also evidence in primates for a histamine-containing descending pathway (Ninkovic *et al.*, 1982). Cell bodies immunoreactive for histamine have been localized in the pons and medulla, and H1 histamine receptors have been found in dorsal and ventral horns but also over dorsal root ganglion cells.

In humans, the organization of spinal monoaminergic systems is poorly known. Topographical

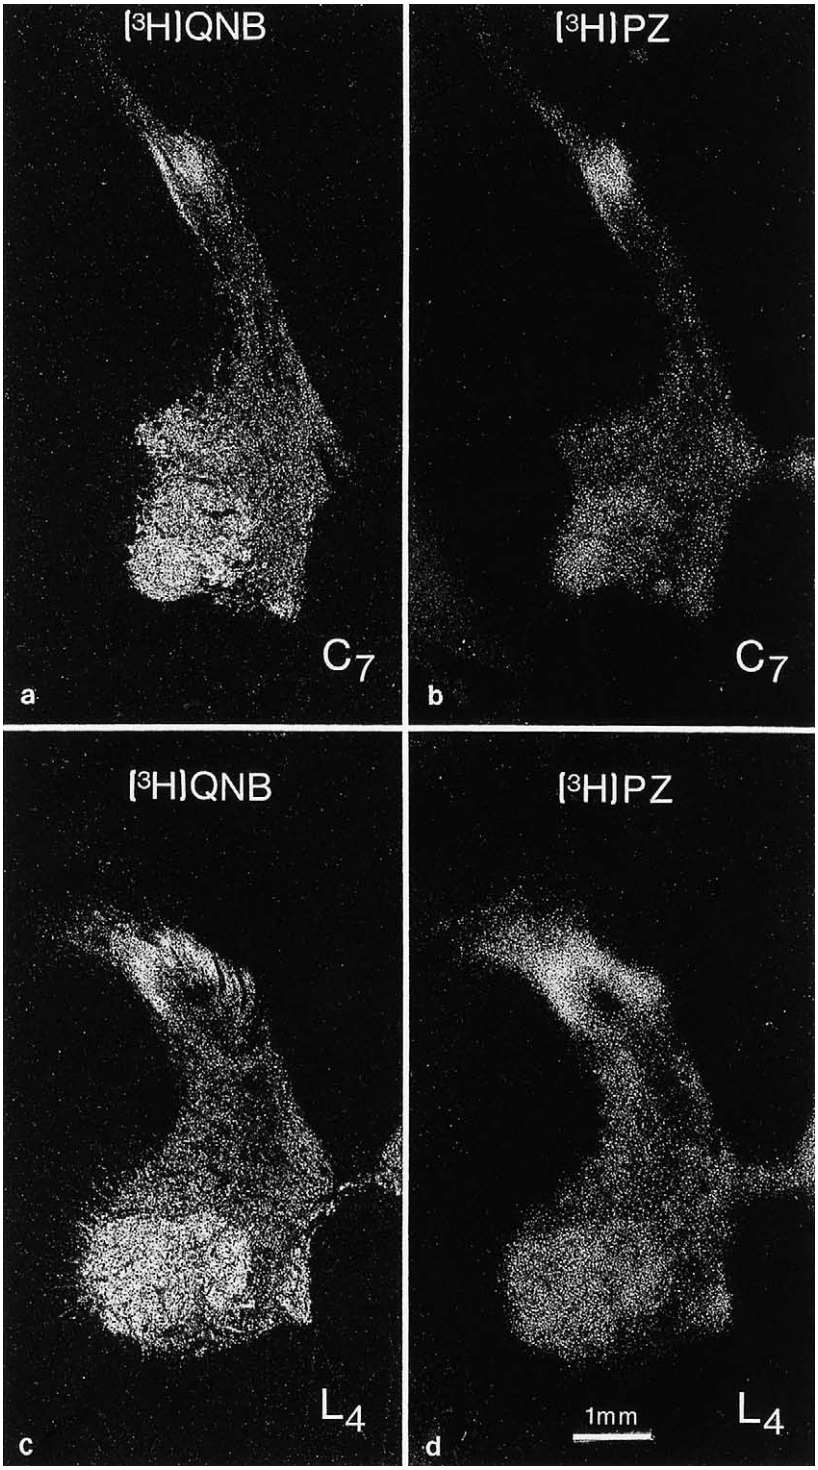

FIGURE 7.12 Autoradiograms showing the distribution of muscarinic cholinergic receptor subtypes (M1 and M2) in transverse hemisections of the human spinal chord at segment levels C7 (**a** and **b**) and L4 (**c** and **d**). **a** and **c** show the distribution of [^{3}H]quinuclidinyl bezilate ([^{3}H]QNB; a ligand with a high affinity for both M1 and M2 receptors) binding sites; **b** and **d** show the distribution of [^{3}H]pirenzepine ([^{3}H]PZ; a ligand with a high affinity for M1 sites and a low affinity for M2 sites) binding sites. The distance between sections a and b and that between sections c and d is 64 µm. In the autoradiograms, the region of dense labeling in the dorsal horn of the gray matter is located within lamina II, and the regions of moderate to heavy labeling in the ventral horn are localized to the regions of lower motor neuron nuclei which constitute lamina IX. Comparison of the density of [^{3}H]QNB and [^{3}H]PZ binding in laminae II and IX suggests that lamina I contains a high proportion of M1 receptors while lamina IX contains both M1 and M2 receptors. From Villiger and Faull (1985).

biochemical studios, using radioenzymatic assays or chromatography, have shown that the spinal levels of serotonin are much higher than those of noradrenaline and dopamine (Bennett *et al.*, 1986; Scatton *et al.*, 1986). Serotonin and noradrenaline are more abundant in the ventral horn, whereas dopamine predominates in the dorsal horn (Scatton *et al.*, 1986). Fibers immunoreactive for serotonin are most numerous in laminae I, II, VIII, and IX of human cord. They can be found in close contact with motoneuronal somata or proximal dendrites. Up to now, cell bodies containing serotonin, which have been described in lamina X of the monkey cord (LaMotte *et al.*, 1982), have not been identified in human materials. α2-Adrenergic receptors are very dense in lamina II and the intermediolateral nucleus (Unnerstall *et al.*, 1984). They have a low density in the ventral horn, as have β-adrenergic receptors (Hayashi *et al.*, 1981).

Amino Acids

Experimental data in animals suggest that amino acids such as glutamate, aspartate, glycine, and GABA are of paramount importance in spinal neurotransmission. Unfortunately, these substances are rapidly autolyzed after death, and this is a major obstacle to their study in human autopsy material.

Glutamate and Aspartate These amino acids are excitatory in spinal gray matter. There is some incomplete evidence from animal experiments that aspartate is the transmitter of certain peripheral afferents and interneurons, whereas glutamate may be used by Ia afferents and corticospinal fibers (see Krnjevic, 1979). In ventral gray matter of the human spinal cord, levels of aspartate exceed those of glutamate (Patten *et al.*, 1982).

Glycine Glycine is thought to be the principal inhibitory neurotransmitter in the ventral horn. It is known from studies in animals that Renshaw cells are glycinergic. These cells project on motoneurons but also on Ia interneurons and on other Renshaw cells. Ia interneurons, which inhibit antagonistic motoneurons when they are activated by Ia afferents coming from agonist muscles, might also use glycine as a neurotransmitter.

In the human spinal cord, glycine is detected biochemically at appreciable levels in the ventral gray matter (Boehme *et al.*, 1976; Patten *et al.*, 1982) Moreover, glycinergic receptor levels are high in homogenized ventral horns (Hayashi *et al.*, 1981). However, with *in vitro* autoradiography, glycinergic receptors appear more dense in lamina II than in lamina IX (J. Schoenen, unpublished observations).

γ-Aminobutyric Acid GABA is an inhibitory transmitter that has been implicated in presynaptic inhibition. Concentrations of GABA are high in the entire spinal gray matter, but especially in the dorsal horn. In the rat, neurons immunoreactive for glutamic acid decarboxlase (GAD), the synthesizing enzyme of GABA, are most numerous in the ventral horn (McLaughlin *et al.*, 1975).

In human autoradiographic studies, selective labeling of lamina II occurs with the use of tritiated muscimol, a preferential agonist of $GABA_A$ receptors (Fig. 7.13a and a'). Similarly, tritiated baclofen demonstrates that $GABA_B$ receptors have a higher density in this lamina (Fig. 7.13b and b') and this extends results obtained in the rat (Price *et al.*, 1984). Both $GABA_A$ (Whitehouse *et al.*, 1983) and $GABA_B$ receptors are scarce in human ventral horns, but they exist in appreciable amounts in lamina X (Fig. 7.13). Benzodiazepine receptors, which are linked to the $GABA_A$ receptor–chloride ionophore complex (Haring *et al.*, 1985; Schoch *et al.*, 1985), are very dense in lamina II (Fig. 7.14); in particular, as shown in Figure 7.14, the highest density of benzodiazepine receptors is localized in the inner segment of lamina II (Iii), and this region is flanked by moderate densities of receptors in the outer segment of lamina II (IIo) and in the immediately adjacent region of lamina III (Faull and Villiger, 1986.) Our autoradiographic studies and biochemical assays of membranes prepared from the lumbosacral cord show that these [^{3}H]flunitrazepam binding sites have high affinity and satisfy the pharmacological characteristics of the "central" type II benzodiazepine receptors (Faull and Villiger, 1986). Although the precise synaptic localization of benzodiazepine receptors in the human spinal cord has not been determined, physiological evidence from animals shows that benzodiazepines act by enhancing GABA-mediated presynaptic inhibition on primary dorsal root afferent terminals (Haefely *et al.*, 1983).

Neuropeptides

We have studied the differential distribution of 12 neuropeptides using immunocytochemical methods in spinal cords from 20 patients (25–70 years old) without neurological disease (Schoenen *et al.*, 1982, 1983, 1985a). We have also examined the spinal cord from a 32-week-old premature fetus. In half the cases, the sampling had to be limited to the lumbosacral enlargement. The unlabeled peroxidase–antiperoxidase complex method of Sternberger (1970) and the indirect fluorescent method of Coons (1958) were used. All primary antisera were tested for specificity using liquid- and solid-phase absorption tests. The methodology has been described elsewhere (Schoenen *et al.*, 1985a). Opiate receptors were studied with quantitative

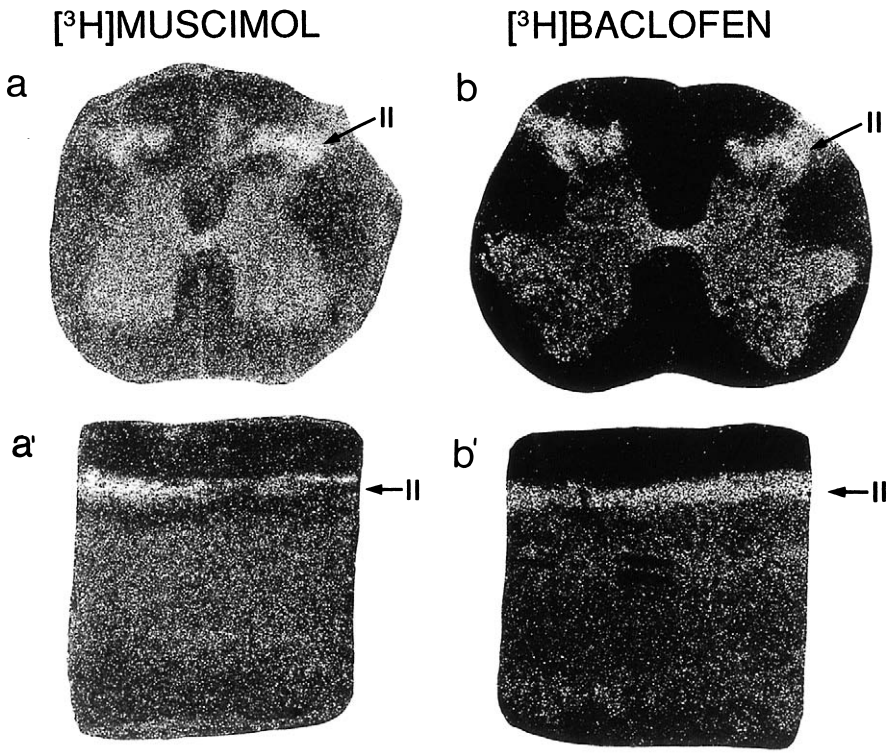

FIGURE 7.13 Autoradiographic localization of GABA receptor subtypes in the lumbar enlargement of human spinal cord using [^{3}H]muscimol (GABAA agonist) for a and a′ and [^{3}H]baclofen (GABAB agonist) for b and b′ as ligands. a and a′ transverse and sagittal sections at L4; b and b′, transverse and sagittal sections at S1. Magnification is ×10.

autoradiographic methods and [^{3}H]diprenorphine as a ligand in six cases aged 7–41 years. Preliminary results on localization of calcitonin gene–related peptide (CGRP) were obtained in two cases using ^{125}I-labeled CGRP. The results on the distribution of peptide immunoreactivities in the human spinal cord are summarized in Tables 7.1 (dorsal horn) and 7.2 (ventral horn.)

Substance P All spinal laminae contain substance P (SP)–positive, medium sized fibers with varicosities. A few fine fibers are also present. Lamina I shows the greatest immunoreactivity (Faull and Villiger, 1986, 1987; Schoenen *et al.*, 1985a). Fibers tend to cluster in dense bundles that are rostrocaudally oriented (Fig. 7.15). Dorsoventral fibers are numerous in the lateral part of lamina I neurons (Fig. 7.15b). Longitudinal and oblique fibers are seen in Lissauer's tract, some dividing into ascending and descending branches (Fig. 7.15b). Positive fibers are less densely packed in lamina II, where they are most numerous in its inner portion (IIi). These fibers are also longitudinal. The number of obliquely running fibers increases in deep lamina II (IIi) and lamina III (Fig. 7.15d). In their medial portions, laminae I to IV are crossed by dorsoventral bundles of SP-positive afferents (Fig. 7.15a). In contrast to lamina IV, laminae V–VI contains many fibers, most of which are oriented obliquely in the transverse plane. SP-positive fibers are less abundant in laminae VII, VIII, and IX but can be easily identified in all cases.

Some SP terminals appear in close association with the perikarya or the proximal dendrite of motoneurons. Lamina X contains a moderate number of positive fibers, with prominent commissural fibers dorsal to the central canal. There is a dense distribution of SP fibers to the intermediolateral column and the sacral parasympathetic nuclei. In the 38-week-old fetus, SP innervation is evident in the dorsal horn.

Cell bodies immunoreactive for SP can be identified in lamina III. Their dendrite are confined to the sagittal plane but spread in several directions, suggesting that they correspond to the "radiate" cell types described in Golgi material in the opening section (Fig. 7.19). SP receptors have been demonstrated in lamina II of the rat spinal cord (Danks *et al.*, 1986).

Opiates Substantial evidence indicates that the spinal cord is an important site for the action of

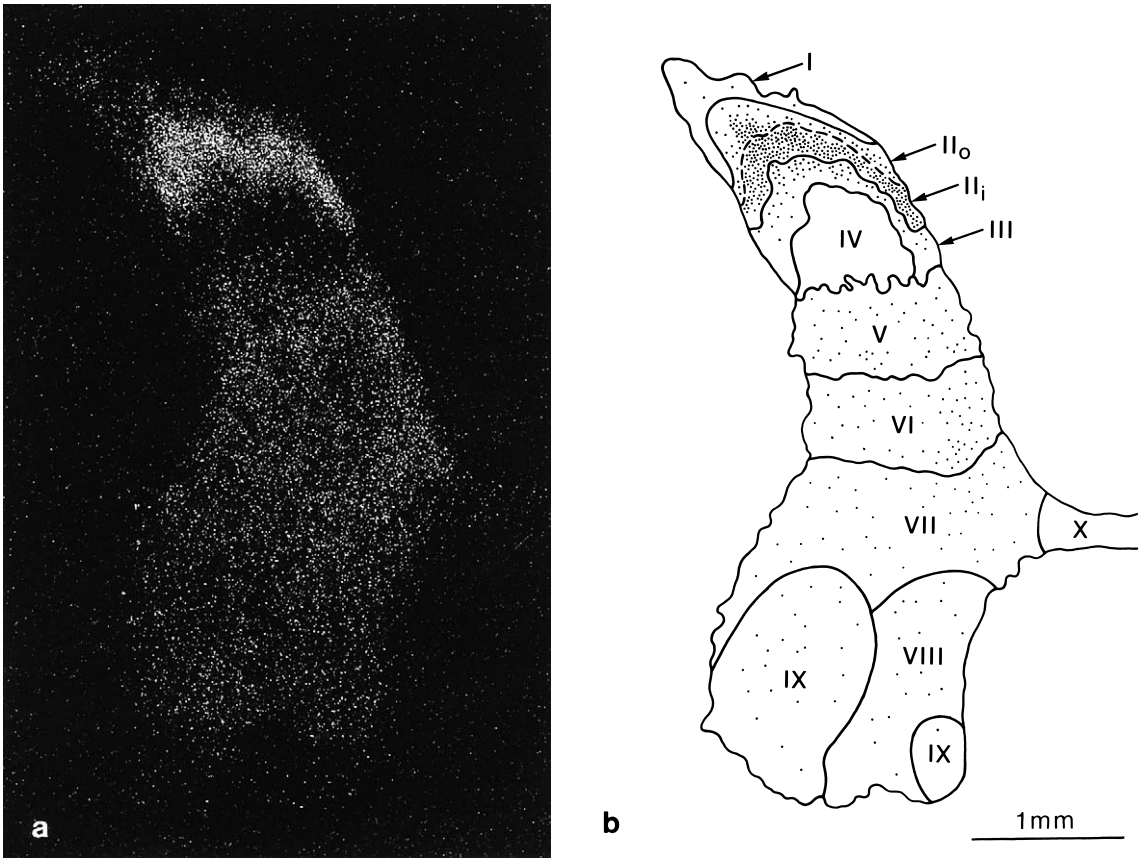

FIGURE 7.14 The distribution of benzodiazepine receptors in the third lumbar segment of the human spinal cord. **(a)** Autoradiogram of [^{3}H]flunitrazepam binding sites; **(b)** a detailed charting of this pattern of labeling on a diagram depicting the laminar subdivision of the spinal gray matter as demonstrated in sections stained for myelin, Nissl substance, and substance P (see Section and Villiger, 1986, for details). The highest density of benzodiazepine receptors is localized within the inner portion of lamina II (IIi) lying immediately adjacent to lamina III, whereas the remaining laminae of the spinal gray show a moderate to low level of receptor labeling. From Faull and Villiger (1986).

exogenous and endogenous opiates. Both methionine (M-ENK) and leucine (L-ENK) enkephalin immunoreactivies are found in small fibers with fine varicosities in the dorsal horn and in medium-sized, irregularly beaded fibers in the remaining gray matter (Fig. 7.16a). Since the density of M-ENK and L-ENK-immunoreactive fibers differs only in two laminae, medial V–VI and VII, the following description will account, with few exceptions, for both peptides. A moderate number of enkephalin-positive fibers is seen in lamina I, most of them running in the rostrocaudal direction (Fig. 7.16c, g). Immunoreactive dots, possibly representing terminal boutons, closely surround the soma and proximal dendrites of lamina I neurons (Fig. 7.16g.) Enkephalin immunoreactivity is much denser in lamina II, mainly in its outer zone (IIo) (Fig. 7.16c). Fiber density decreases markedly in laminae III and IV. Laminae V–VI contain various enkephalin-positive fibers which differ from those in the superficial laminae of the dorsal horn by their thicker caliber and their dorsoventral orientation. The lateral portions of laminae V–VI receive a very dense projection of enkephalin fibers, apparently coming from the dorsolateral funiculus (Fig. 7.16b). The medial portion contains chiefly L-ENK-positive fibers, which are also more numerous in lamina VIII. A substantial number of enkephalin fibers are found in lamina IX; these are in close contact with motoneuronal membranes (Figure 7.17); others can be followed deeply into the ventral white matter. Immunoreactivity for both enkephalins is very dense in lamina X and the intermediolateral column (Fig. 7.16b). In the 32-week-old fetus, enkephalin immunoreactivity is easily identified in the dorsal as well in the ventral horn (Fig. 7.16h).

A few faintly stained cell bodies have been identified only with the M-ENK antiserum. They are located in laminae I and II. Lamina I cells (Fig. 7.16f) present the characteristic ventral orientation of some dendrites. Labeled neurons in lamina II are bipolar and dorsoventrally oriented in transverse sections (Fig. 7.16d, e). This is the typical appearance of stellate cells in Golgi material (see introductory section and Fig. 7.19).

Syn-enkephalin (SYN) comprises 70 residues at the amino terminal of proenkephalin and was isolated

from bovine adrenal medulla and brain. In the human cord, the distribution of SYN immunoreactivity is comparable to that of M-ENK (Fig. 7.17b). However, its overall density is slightly lower and up to now no SYN-positive cell bodies have been detected (Schoenen *et al.*, 1986).

The high concentration of enkephalin immunoreactivity in laminae I and II of the dorsal horn closely correlates with the laminar distribution of opiate receptors in the human spinal cord, as demonstrated by our quantitative autoradiographic studies on the distribution of [^{3}H]diprenorphine (a ligand which binds to most of the opiate receptor subtypes; Chang *et al.*, 1981; Pfeiffer and Hertz 1982; Pfeiffer *et al.*, 1982) binding sites in six human cases aged 7–41 years (Faull and Villiger, 1987). As shown in Fig. 7.18, in these detailed anatomical studies covering 25 of the 31 segmental levels of the human spinal cord (Faull and Villiger, 1987), opiate receptors were found to be localized mainly within laminae I, II, and III of the dorsal horn and in Lissauer's tract, with the highest density of receptors localized within the inner portion of laminae II (see Fig. 7.18). These receptors appear to be principally of the k subtype (Faull and Villiger, 1987).

Cholecystokinin Cholecystokinin (CCK)–immunoreactive fibers are small to medium sized with regular varicosities. They are found in all spinal laminae. The distribution of CCK is comparable to that of SP, except for a heavier innervation of laminae VII and VIII. Fibers in lamina I are numerous and mainly longitudinal. Dorsoventral orientation predominates in the lateral portion of the lamina. Some fibers penetrate into lamina I from Lissauer's tract. Perisomatic terminals on marginal neurons are a frequent finding. CCK immunoreactivity is more dense in the inner than in the outer zone of lamina II. A moderate number of CCK fibers distributes to the medial portion of laminae V–VI and the dorsal part of lamina X. Innervation of lateral laminae V–VI is denser and thicker fibers are involved. A strong CCK immunoreactivity is found in lamina

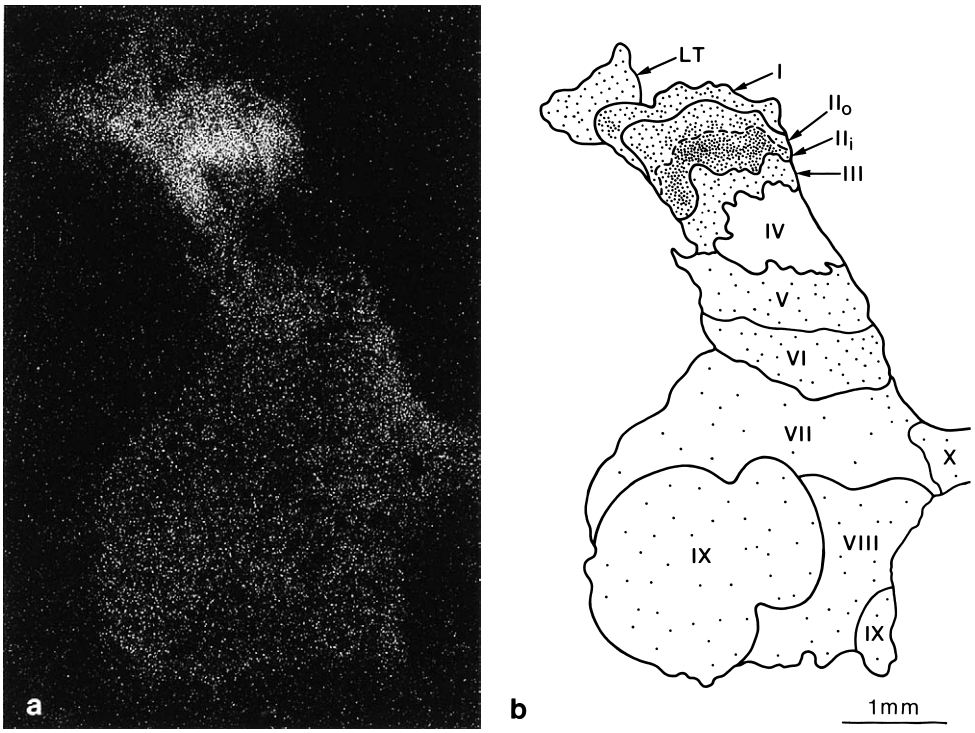

FIGURE 7.18 The distribution of opiate receptors in the fourth lumbar segment of the human spinal cord. **(a)** An autoradiogram of [^{3}H]diprenorphine binding sites; **(b)** a detailed charting of this pattern of labeling on a diagram depicting the laminar subdivision of the spinal gray matter as demonstrated in sections stained for myelin, Nissl substance, and substance P (see Sec. I and Faull and Villiger, 1987 for details). Opiate receptors are localized mainly within laminae I–III of the dorsal horn and in Lissauer's tract (LT), with the highest density of receptors localized within the inner portion of lamina II (IIi) lying immediately adjacent to lamina III; the remaining laminae of the spinal gray show much lower levels of receptor labelings. From Faull and Villiger (1987).

VIII, mainly in its dorsomedial part, at the level of enlargement (Fig. 7.17d). Scattered fibers can be seen in lamina IX in close association with motoneurons or penetrating the ventral funiculus.

It has recently been suggested that part of spinal CCK immunoreactivity may be due to the presence of CGRP (Ju *et al.*, 1986). This specificity problem is relevant mainly for peripheral afferents to the dorsal horn but awaits confirmation in humans.

Calcitonin Gene–Related Peptide CGRP is contained in medium-sized and thick fibers of the human gray matter. Characteristically, these fibers are confined to laminae I–IV of the dorsal horn, lamina X, the intermediolateral nucleus, and the sacral parasympathetic nuclei. In the dorsal horn, distribution of CGRP immunoreactivity is comparable, though not identical to that of SP. Indeed, CGRP fibers are most numerous in laminae I and II. In these laminae, they are chiefly longitudinal, whereas in deeper laminae III and IV they are oblique or dorsoventral in the transverse plane. Double-staining procedures indicate that strong staining for CGRP extends more ventrally in the dorsal horn than that for SP.

CGRP is until now, the only peptide identified within the perikarya of motoneurons. Only weak CGRP immunoreactivity can be found in motoneurons of the human cord. Demonstration of CGRP within motoneurons is easier in rat and other mammals (Gibson *et al.*, 1984). It has been demonstrated recently that CGRP may have a trophic action on cholinergic receptors of skeletal muscle (Fontaine *et al.*, 1986.)

CGRP receptors are most dense in lamina II, lamina X, and the intermediolateral column.

Neuropeptide Y Neuropeptide Y (NPY)–positive fibers are found in all laminae of human spinal gray matter. Dotlike immunoreactivity characterizes the superficial dorsal horn, whereas fibers are medium sized and beaded in other laminae. The densest NPY innervation is seen in laminae I and IIo, in the motoneuronal columns, and in the autonomic nuclei.

Somatostatin Somatostatin (SOM)–positive fibers are small with irregular varicosities. They are confined to the three superficial laminae of the dorsal horn, the motoneurons, lamina X, and the autonomic nuclei. The strongest concentration of SOM immunoreactivity is found in inner lamina II as a dense reticulum of longitudinal fibers. Several fibers in deep lamina II have a dorsoventral direction, penetrating into lamina III.

The greatest number of immunoreactive cell bodies demonstrated in our material contain SOM. These neurons are located in lamina II. Their dendritic organization (longitudinal polarization, few primary dendrites originating on one side of the perikaryon, presence of recurrent branches) suggest that they are of the islet cell type identified in this lamina with the Golgi method (Fig. 7.19).

Thyrotropin-Releasing Hormone Thyrotropin-releasing hormone (TRH) immunoreactivity is limited to certain specific regions of the human spinal gray matter: laminae II, VII, IX, X, and intermediolateral nucleus. TRH-positive fibers are small and punctiform in laminae II. Scattered beaded fibers are found in the other laminae. Some of these are closely opposed to the perikaryon or proximal dendrites of lamina VII neurons or motoneurons (Fig. 7.17). TRH receptors are dense in lamina II but less dense in lamina IX (Manaker *et al.*, 1985).

Other Peptides Oxytocin (OXY)–positive fibers have been detected only in four spinal laminae. Single elongated fibers run rostrocaudally in lamina I. In laminae III, IV, and IX, fibers are short and dorsoventrally oriented. OXY immunoreactivity in lamina IX is peculiar in that it is concentrated mainly in the dorsolateral motoneuronal column. Scattered vasopressin (VASO)–positive fibers are restricted to laminae II, III, IV, and medial V–VI.

As has been described in other mammals (Basbaum and Glazer, 1983) and in humans (Anand *et al.*, 1983), vasoactive intestinal polypeptide (VIP)–containing fibers are chiefly restricted to the lumbosacral cord. These thick, irregularly beaded fibers run tangentially in lamina I, mediolaterally in lamina X, and project to the intermediolateral column and the sacral parasympathetic preganglionic neurons.

During ontogenesis, peptidergic fibers appear early in the human spinal cord. Substance P and enkephalin-immunoreactive fibers can be identified in the dorsal horn as early as 12 weeks *in utero* (Charnay *et al.*, 1983, 1984).

VIP has a distinct distribution in the spinal gray matter. In humans, its concentration is very high in the lumbar and even more so in the sacral regions of the spinal cord (Anand *et al.*, 1983). VIP-containing fibers are mainly distributed to lamina I, IML, sacral parasympathetic preganglionic neurons, and lamina X (Table 7.2). There is good evidence from animal experiments that VIP is the transmitter in visceral afferents (for a review, see Basbaum and Glazer, 1983). Since VIP is also found within neuronal cell bodies in the IML and IMM nuclei in the monkey spinal cord (LaMotte, 1987), this peptide may have important functions in visceral autonomic reflex activities. VIP-containing lamina X neurons have been found to contact the cerebrospinal fluid along the surface of the

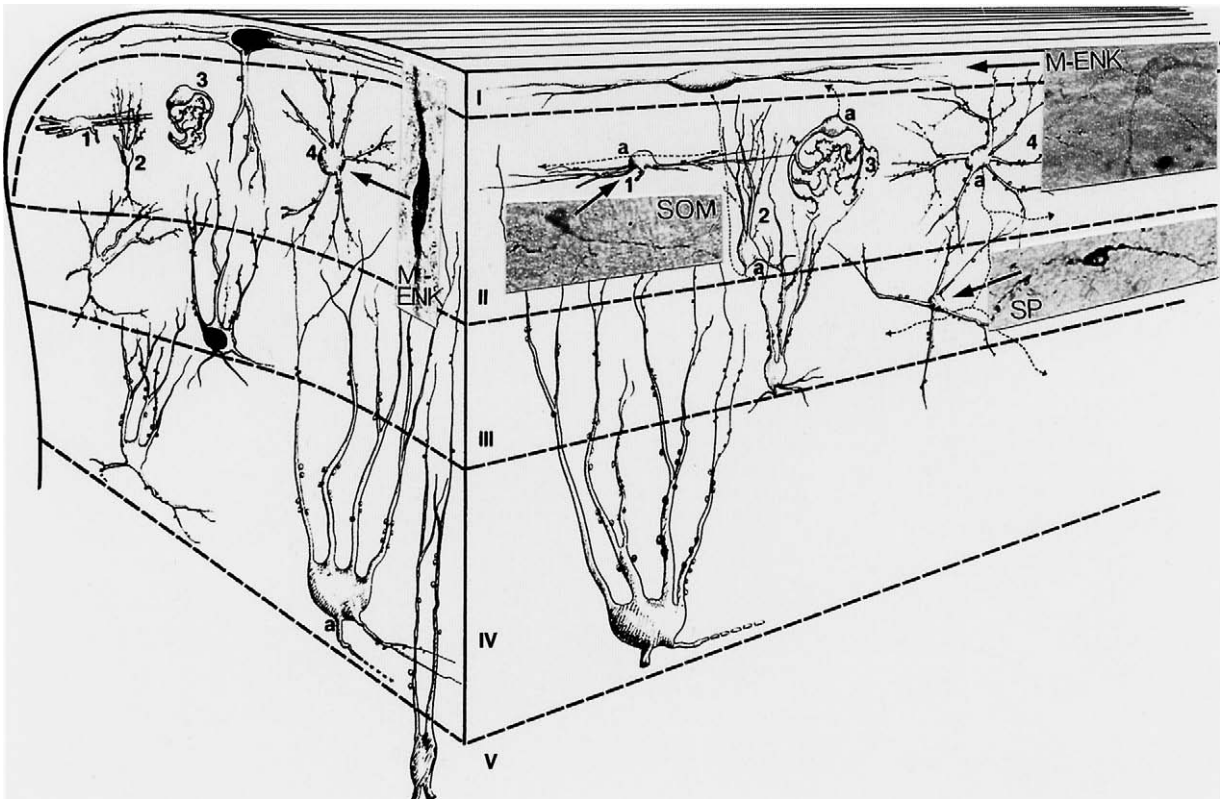

FIGURE 7.19 The dendritic cell types in human dorsal horn (see Schoenen and Faull, chapter 2) with superimposed photomicrographs of peptide-containing neurons. Comparison of dendritic geometries suggests that M-ENK-positive neurons correspond to marginal cells with ventral dendrites and to lamina II stellate cells (4), SOM-positive neurons correspond to lamina II islet cells (1), and SP-positive neurons correspond to lamina III radiate cells. 2, Filamentous cells; 3, curly cells; a, axon.

central canal in the cat and monkey (LaMotte, 1987). The biological role of these neurons remains obscure.

Others

Other chemicals characterize fibers and nerve cells in the human spinal cord. For examples, calcineurin is highly concentrated in small nerve cells and fibers of the substantia gelatinosa, whereas another Ca^{2+}-binding protein, synaptophysin, is distributed throughout the spinal gray matter with highest concentrations in the anterior horn, Clarke's column, and lamina II (Goto *et al.*, 1990; Zhang and Rosenblum, 1996).

Insulin-like growth factor-1 receptors have a concentration that is highest around the central canal and decreases from dorsal to ventral horns and white matter (Adem *et al.*, 1994). They are up-regulated in spinal cords from amyotrophic lateral sclerosis patients.

Glial-derived nemotrophic factor and neurotrophins as well as their receptor tyrosine kinases have been indentified in dorsal horn and motor neurons (Josephson *et al.*, 2001).

Regional Chemoarchitecture and Functional Considerations

We will now outline the overall chemical anatomy of the major functional subdivisions of the gray matter, i.e., the chemical characteristics of the "sensory" dorsal horn (laminae I–IV), the mixed "sensory–motor" intermediate gray (laminae V–VIII and X), and the "motor" ventral horn (laminae IX). Furthermore, from a functional viewpoint, it is interesting to consider how these chemicals may be involved in the processing of neuronal information in the spinal cord.

Dorsal Horn (Laminae I–IV)

From a functional point of view, the most interesting finding emerging from the studies reviewed above is that each of the laminae and the sublaminae of the dorsal horn has a distinctive chemoarchitecture (Table 7.1). The peptide-containing cell bodies, which are visualized in human autopsy material, are localized in the superficial spinal laminae (Fig. 7.19), with the exception of CGRP-positive motoneurons.

[a]Shown are modifications of various putative neurotransmitter immunoreactivities in case of limb amputation, descending tract lesions, and amyotrophic lateral sclerosis (ALS): =, no change; ↓, slight reduction; ↓↓ massive reduction of immunoreactive fibers; ↑, slight increase of ENK immunoreactivity (only in a case of recent amputation).

In human material, information concerning the organization of transmitter systems can be gained by the study of selected pathological cases. Using immunocytochemistry, we have studied spinal cords from four patients who died at varying intervals after amputation: a below-knee (2 weeks delay), a below-hip (6 months delay), an arm (1 month delay), and a thumb (3 months delay). In all four cases, SP immunoreactivity was reduced but not abolished in the ipsilateral dorsal horn of the corresponding spinal segments (Table 7.3). Reduction was most pronounced in laminae I and II and especially in the medial portion of these laminae. Mediolateral extension of SP reduction was proportional to the deafferented peripheral territory; it was greatest in the case of the below-hip amputation and limited to a very narrow medial portion of the dorsal horn in the case of a thumb amputation. SP innervation of the intermediate gray and the ventral horn appeared normal. SOM and CCK immunoreactivities were also reduced in laminae I and II, but to a lesser degree. In contrast, enkephalin immunoreactivity was increased in these laminae but only in the case of a leg amputation performed 2 weeks before death. No asymmetries were observed in the staining for VASO, OXY, TRH, or serotonin.

These results confirm those obtained by Hunt *et al.* (1982) in two amputees and extend them to other neuropeptides. Reduction of peptide immunoreactivities is probably due to "transganglionic degeneration," which was first illustrated by the disappearance of FRAP in rat laminae II after transection of the sciatic nerve (Schoenen *et al.*, 1968). The data obtained in human pathological cases suggest also that the somatotopic arrangement of peripheral afferents to the dorsal horn is similar in humans and in animals, i.e., medial projection of distal afferents, lateral projection of proximal afferents.

On the other hand, we have studied immunocytochemically the lumbar enlargement in four pathological cases where most of the descending fibers had been interrupted at the cervical or thoracic level: two cases of complete traumatic section of the cord at C7 and T2 autopsied 2 and 5 years after the trauma, and two cases of transverse thoracic myelitis autopsied 2 and 5 months after the beginning of symptomatology. In all four cases, VASO- and OXY-immunoreactive fibers were absent in the lumbar gray matter. TRH- and serotonin-containing fibers were slightly reduced in the dorsal horn, whereas SP, SOM, CCK, or enkephalin fibers were unchanged in the dorsal laminae (Table 7.3).

It may be concluded from these studies that, as in the spinal cord of animals (Hökfelt *et al.*, 1975), most SP fibers to human laminae I and II originate from spinal ganglion cells. In contrast, there is no indication for a peripheral origin of enkephalinergic fibers to the dorsal horn. It remains to be determined why enkephalin immunoreactivity may increase after amputation. This may be due to accumulation of the neurotransmitter in terminals following the peripheral deafferentation, but our results suggest that this phenomenon could be

transitory. Parts of the SOM- and CCK- (or CGRP?) containing fibers in the human dorsal horn have a peripheral origin, whereas the totality of OXY and VASO immunoreactivity is provided by descending afferents. It is not clear at present whether the modifications of dorsal horn neuropeptides described above may play a role in the pathophysiology of phantom limb pain of amputees. The observation of a marked reduction of lamina II SP and synaptophysin immunoreactivities in patients suffering from familial dysautonomia or Riley-Day syndrome, who have a profound analgesia (Pearson *et al.*, 1982; Goto *et al.*, 1990), favors the hypothesis that SP is important for transmission of nociceptive input.

Intermediate Gray Matter (Laminae V–VIII, X, and Autonomic Nuclei)

It is well established that the intermediate gray matter as defined here contains neurons which are involved in the processing and relay of somatosensory information (nociceptive and deep-muscle mechanoreceptive functions—laminae V–VI), in the control of somatic motor functions (laminae V–VI, VII including the dorsal nucleus of Clarke, and VIII), and in autonomic sensory and motor functions (lamina VII including the intermediomedial nucleus, the intermediolateral nucleus, the sacral parasympathetic nucleus, and lamina X).

If one excludes the neuronal groups implicated in autonomic functions (intermediomedial nucleus, intermediolateral nucleus, sacral parasympathetic nucleus, periependymal gray matter), the distribution of the various putative neurotransmitters and their receptors that have so far been studied is rather nonselective. An interesting chemoarchitectural–functional correlation can be established from the findings of TRH innervation of medial lamina VII. It has been shown in human volunteers that TRH at low intravenous doses modifies excitability of motoneurons through an action on interneurons of the flexor reflex pathway (Delwaide and Schoenen, 1985). These interneurons are probably located in the medial portion of lamina VII, i.e., in a region where TRH terminals have been identified. Lamina VIII is characterized by a dense network of CCK- and serotonin-containing fibers. The functional significance of these findings is not known, but it is worth mentioning that lamina VIII contains interneurons and propriospinal neurons as well as some long projection neurons, which are implicated in the motor control of axial musculature. SP and enkephalin levels in laminae V–VI appear unchanged after lesions of peripheral (amputation) or descending (cord transection) afferents. In contrast, SP immunoreactivity in lamina VII is reduced below the spinal transection, whereas enkephalin immunoreactivity remains unchanged (Table 7.3). This suggest that, in laminae V–VI, SP and enkephalins are mainly of intrinsic origin, while in lamina VII the origin of SP is supraspinal and that of enkephalins is intrinsic.

The dorsal nucleus of Clarke is characterized by high levels of acetylcholinesterase (Schoenen, 1973) and muscarinic cholinergic receptors (R. L. M. Faull and J. W. Villiger, unpublished observations). These findings suggest that acetylcholine has a role to play in the dorsal spinocerebellar pathway. Furthermore, SP- and CGRP-containing fibers are found in close contact with neurons in the nucleus of Clarke, whereas other neuropeptides are virtually absent in this nucleus. This would indicate that Clarke's nucleus receives some small C or A delta peripheral afferents in addition to the large input by thick myelinated afferents.

The autonomic nuclei of the intermediate gray matter have a specific chemoarchitecture. The intermediolateral, intermediomedial, and sacral parasympathetic nuclei as well as lamina X are indeed characterized by high levels of muscarinic cholinergic receptor binding and high concentrations of several neuropeptides (SP, enkephalins, CCK, NPY, and VIP); with the exception of lamina X, acetylcholinesterase is also present in these structures. In addition, GABA and glycine receptors are found in lamina X. A similar profuse peptidergic innervation of autonomic nuclei and lamina X has been shown in animals (Honda and Lee, 1985; Hunt, 1983) and serotonin-containing lamina X neurons have been identified in the monkey (LaMotte *et al.*, 1982) and rat (Newton *et al.*, 1986). The high concentrations of muscarinic receptors and acetylcholinesterase in both autonomic sensory (IMM) and autonomic motor (IML) regions of the intermediate gray matter parallel their high concentration in somatic sensory (lamina II) and somatic motor (lamina IX) regions of adjacent dorsal and ventral horns, respectively. Acetylcholine and neuropeptides thus appear to have a major role in both sensory and motor autonomic functions.

Motor Nuclei (Lamina IX)

In agreement with numerous previous findings in animals suggesting that acetylcholine has a major role in lower motor neuron function. In the human, this region contains high concentrations of acetylcholinesterase (Engel, 1969; Schoenen, 1973), choline acetyltransferase (Aquilonius *et al.*, 1981), and muscarinic cholinergic receptor binding (Villiger and Faull, 1985). The latter is a mixed population of the M1 and M2 subtypes, contrasting with the high concentrations of M1 receptors in human lamina (Fig. 7.12). This suggests that M1 and M2 cholinergic receptors may be differentially involved in sensory and motor

TABLE 7.4 Reported Changes of Neurotransmitters and Their Receptors in ALS

[a] ↓, Slight reduction

functions in the human spinal cord (Villiger and Faull, 1985). Following degeneration of lower motoneurons in amyotrophic lateral sclerosis (ALS), there is a simultaneous reduction of acetylcholinesterase (Friede, 1969), choline acetyltransferase (Gillberg *et al.*, 1982; Nagata *et al.*, 1981), and muscarinic cholinergic receptors (Whitehouse *et al.*, 1983) in the ventral horn (Table 7.4). These findings are consistent with the concept that lower motoneurons utilize acetylcholine as a transmitter and also receive a cholinergic innervation. The latter may be provided by recurrent collaterals of motoneurons, and/or by supra- and propriospinal afferents.

Most of the inhibitory actions on motoneurons are probably mediated by glycine, the transmitter released by Renshaw cells and presumably Ia interneurons. The finding that motoneuron degeneration due to ALS results in the reduction of glycinergic receptors in the ventral horn (Hayashi *et al.*, 1981; Whitehouse *et al.*, 1983) provides further evidence that these receptors are located on motoneurons (Table 7.4).

Numerous animal studies have demonstrated that serotonin has a role in motor function in the ventral horn (for a review, see Krnjevic, 1979). Spinal reflexes and locomotor activity are facilitated in the spinal cat after injections of the serotonin precursor 5-hydroxtryptophan. This effect has been attributed to inhibition of inhibitory interneurons, but other mechanisms might be relevant. The finding of numerous serotonergic fibers in lamina IX of human spinal cord (Fig. 7.20) suggests that serotonergic neurons may also play a role in the control of spinal motor activity in humans. Since almost all these fibers disappear below spinal transections (Table 7.3), these neurons probably have a supraspinal localization. In addition to serotonin, noradrenaline has an action on motoneurons. Despite the high levels of noradrenaline in human ventral horn (Scatton *et al.*, 1986), its effect on motor functions is presumably mediated through an action on interneurons, since adrenergic receptors remain unchanged after degeneration of motoneurons in ALS (Hayashi *et al.*, 1981).

Finally, although the density of peptide-immunoreactive fibers in the ventral horn is relatively low in comparison to the dorsal horn, the fact that all peptides studied, except for CGRP, VASO, and VIP, are found in terminals closely apposed to motoneurons and that peptide receptors are also localized in this region suggests that various peptides may be involved in aspects of lower motor neuron control (Schoenen and Delwaide, 1985). Immunocytochemical studies in human pathological material have demonstrated the origin of some of the peptidergic fibers innervating lamina IX (Table 7.3). For example, a supraspinal origin for OXY, TRH, and, in part, SP and SOM fibers is indicated by the study of spinal transection cases. Conversely, the finding that enkephalins and CCK-immunoreactive fibers in this region are unaffected by descending tract degeneration suggests a predominantly local and/or dorsal root origin for these peptides in the human.

The modifications of spinal peptidergic innervation observed in ALS are especially interesting. In four cases of typical ALS, we have found a severe reduction or a total disappearance of SP-immunoreactive fibers in lamina IX (Fig. 7.20) (Schoenen *et al.*, 1985b). This reduction is obvious even at segmental levels where motoneuronal degeneration is inconspicuous, e.g., in the cervical enlargement of a patient with a lumbar

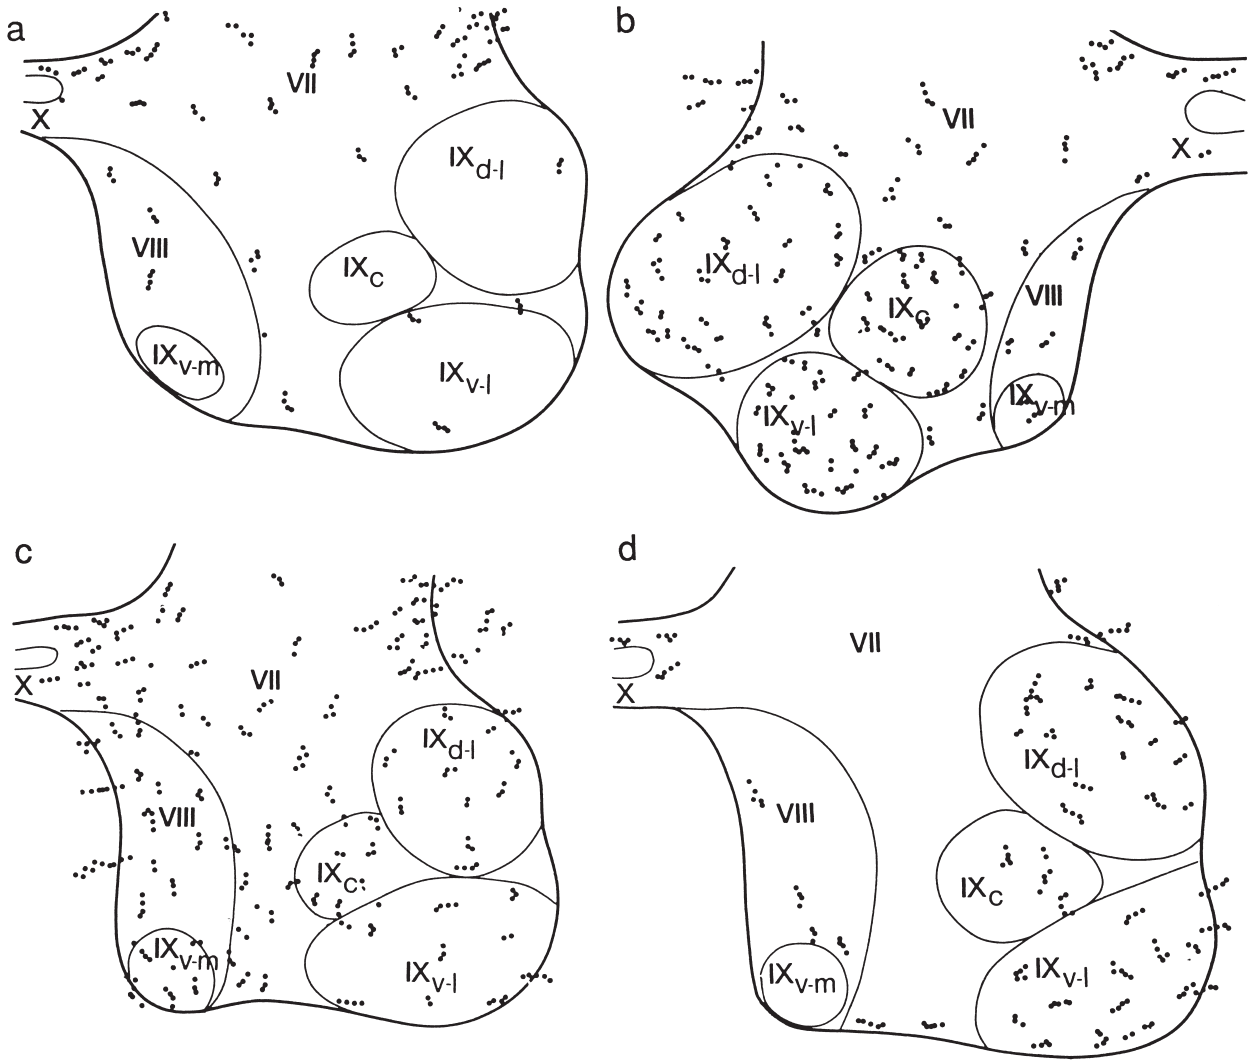

FIGURE 7.20 Camera-lucida mapping of immunoreactive fibers on three consecutive 30-mm-thick sections at L5. **(a)** ALS case, substance P; **(b)** normal case, substance P; **(c)** ALS case, metenkephalin; **(d)** ALS case, serotonin. form of the disease. SP innervation remains normal, not only in the dorsal horn, but also in laminae VII and VIII. SP fibers are also normal in the entire spinal gray matter, including lamina IX in a case of motor neuron disease without pyramidal lesion. In the four ALS cases, immunoreactivity for other peptides (enkephalin, SOM, CCK, VASO, OXY, TRH) and for serotonin remained normal (see Fig. 7.20). This is of particular interest since there is evidence from animal experiments that SP, TRH, and serotonin can be colocalized in supraspinal afferents to lamina IX. Unlike other neurotransmitter changes, which are probably secondary to motoneuronal degeneration (Table 7.4), early loss of supraspinal SP afferents to motoneurons in ALS might be relevant to the pathogenesis of this disease, in which there is also an increase of IGF-1 receptors in cervical and sacral gray matter (Adem *et al.* 1994). For additional information on the distribution of receptors in the spinal cord, see Faull *et al.* (1991).

MYELOARCHITECTURE

There has been no previous detailed study on the myeloarchitecture of the gray matter in the human spinal cord. In our studies, the myeloarchitecture of the human spinal cord has been examined using 50-µm sections stained with osmium tetroxide (Fig. 7.21) and

FIGURE 7.21 The myeloarchitecture of the spinal gray matter in the fourth lumbar segment of the human spinal cord as demonstrated in a 50-µm section stained with osmium tetroxide.

10-µm sections stained using the Weigert method (Fig. 7.22). The myeloarchitectural characteristics of the various laminae in the spinal gray are described in detail below, followed by a general description of the major features in the white matter.

Dorsal Horn (Laminae I–IV)

The dorsal horn of the human spinal cord shows a very distinctive myeloarchitecture. In our studies on the human spinal cord, the myeloarchitectural characteristics of the dorsal horn are best seen in "thick" sections stained with osmium tetroxide (Fig. 7.21).

Lamina I

Lamina I caps the dorsal horn and is traversed by small numbers of quite finely myelinated fibers which give it a fine reticulated appearance in myelin-stained material (Fig. 7.21). It is generally easily distinguished from the surrounding white matter and the underlying lamina II.

Lamina II

Lamina II is the most distinctive lamina in myelin-stained material (Figs. 7.21 and 7.22). It is characterized and distinguished from adjacent laminae by the almost total lack of myelinated fibers, which results in its distinctive gelatinous appearance in fresh unfixed material. As shown in Figures 7.21 and 7.22, lamina II is so conspicuous in myelin-stained material that such preparations provide the best basis for accurately defining the precise boundaries of this lamina and for demonstrating its general morphological characteristics. Its ventral border describes an irregular serrated outline and is more clearly delineated than the dorsal border. The lamina shows considerable variation in size and shape from one level of the spinal cord to another. As can also be seen from Figures 7.21 and 7.22, lamina II is most extensive in the region of the cervical and lumbosacral enlargements (Fig. 7.22a, c, d) and is considerably thinner and more attenuated in the thoracic region (Fig. 7.22b). In the cervical (Fig. 7.22a) and lumbosacral (Figs. 7.21 and 7.22c ,d) enlargements, this myelin-poor lamina is frequently traversed by fascicles of heavily myelinated fibers passing in the dorsoventral direction to reach deeper laminae of the spinal gray.

Lamina III

Lamina III is also best distinguished by its myeloarchitecture (Fig. 7.21). It contains moderate numbers of myelinated fibers which clearly distinguish the lamina from the more superficial, nonmyelinated lamina II and the deeper, more heavily myelinated lamina IV.

Lamina IV

Lamina IV is characterized by an especially high concentration of myelinated fibers, the highest of any lamina in the spinal gray matter (Fig. 7.21). In osmium-stained material the myelinated fibers appear to be as densely packed as those in the adjacent spinal white matter, and in these preparations it is easy to delineate this lamina from the adjacent less densely myelinated laminae III and V.

Conclusions

The marked differences in the concentration of myelinated fibers in the laminae of the dorsal horn provide a sound basis for defining the precise boundaries between these laminae in the human spinal cord. Similar myeloarchitectural differences in other mammals have been used to assist in the delineation of the laminae of the dorsal horn (Hunt, 1983; Rexed,

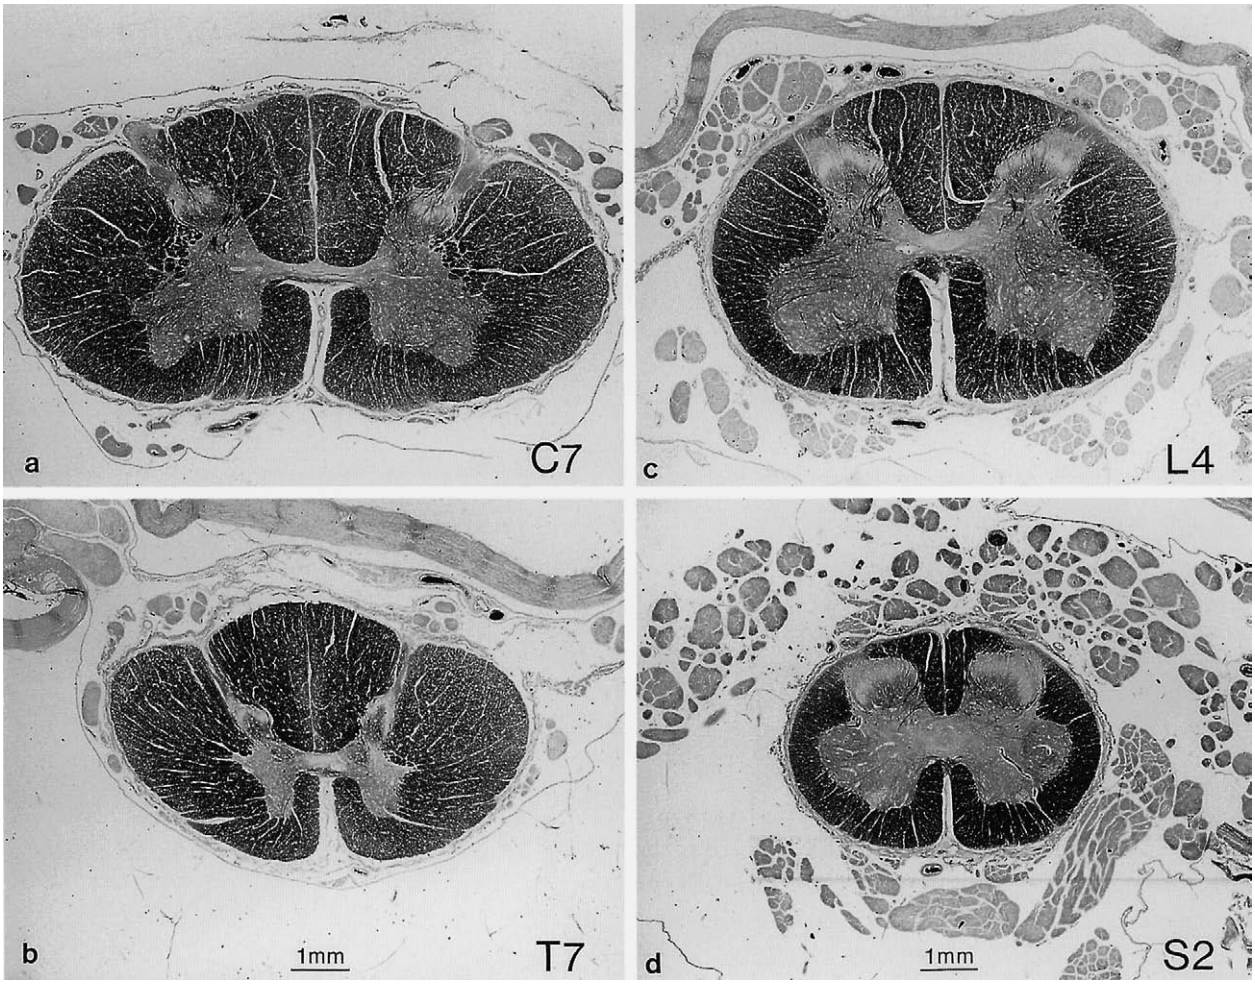

FIGURE 7.22 The myeloarchitecture of the human spinal cord at spinal levels **(a)** C7, **(b)** T7, **(c)** L4, and **(d)** S2, as demonstrated in 10-µm sections stained according to the Weigert procedure.

1964), particularly to show the border between laminae II and III (Molander *et al.*, 1984; Ralston, 1979; Rexed, 1964; Snyder, 1982) However, the laminar myeloarchitectural differences described in other mammals are generally not as marked or distinct as those observed in our osmium-stained "thick" sections of the human spinal cord (Fig. 7.21; see also Faull and Villiger, 1986, 1987). In particular, the subtle differences that we have observed in the myeloarchitecture between laminae III and IV in the human have not been reported in other mammalian species.

Intermediate Gray Matter (Laminae V–VIII and X)

Lamina V

On myeloarchitectural criteria, lamina V is easily separated from the more densely myelinated lamina IV but merges imperceptibly with lamina IV (Fig. 7.21). Within the lateral one-third of lamina V, longitudinally coursing bundles of myelinated fibers disrupt the gray matter and give it a distinctive reticulated appearance (Fig. 7.21); this is especially obvious at cervical levels of the human spinal cord (Fig. 7.22a). This reticulated lateral region of lamina V appears to be equivalent to the region designated as the lateral zone in the cat by Rexed (1952, 1964) and as the processus reticularis or formatio reticularis by earlier workers (see Rexed, 1964, for details). The larger remaining medial region of lamina V is characterized by the presence of heavily myelinated fiber bundles arching dorsoventrally from the dorsal funiculus to terminate either within this lamina or to reach the more ventrally located laminae of the spinal gray (Figs. 7.21 and 7.22). These fibers are presumably branches of the heavily myelinated fibers in the medial division of the dorsal root.

Lamina VI

Lamina VI is myeloarchitecturally similar to lamina V. It shows a comparable lateral reticular zone and a larger medial region where the dorsoventrally oriented fibers appear more dispersed (Figs. 7.21 and 7.22)

Lamina VII

Lamina VII shows a moderate concentration of myelinated fibers. Here the fibers generally have no preferred direction but are present in the form of an interlacing network of multidirectional myelinated biers (Fig. 7.21). Nevertheless, transversely directed fiber bundles are often clearly distinguished in lamina VII of the cervical and lumbar spinal enlargements (Fig. 7.22a, c, d). In the ventral region where lamina VII borders lamina IX, increased numbers of myelinated fibers are often present and here they skirt the lamina IX border, emphasizing and delineating the lamina VII/IX boundary (Fig. 7.21). Finally, in the dorsomedial region of lamina VII in the thoracic and upper lumbar segments, the round to oval dorsal nucleus of Clarke is conspicuously marked in myelin-stained material by the presence of a dense fine plexus of myelinated fiber terminals (Fig. 7.22b).

Lamina VIII

Lamina VIII is continuous with and myeloarchitecturally similar to lamina VII. Here the fibers are often oriented in the dorsoventral direction (Fig. 7.21).

Lamina X

Lamina X is distinguished by the relative lack of myelinated fibers. Thus, in myelin-stained material, it is easily distinguished from lamina VII laterally and from the anterior white commissure ventrally (Figs. 7.21 and 7.22).

Motoneurons (Lamina IX)

Lamina IX

Lamina IX generally shows a lower concentration of myelinated fibers than the adjacent laminae VII and VIII. In particular, as depicted in Fig. 7.21, the various component subnuclei of lower motoneurons which constitute this lamina are clearly demarcated by bordering fascicles of myelinated fibers. In addition, the neuropil of lamina IX is marked by the myelinated axons of lower motoneurons coursing ventrally toward the white matter; those myelinated fibers coalesce to form fascicles that traverse the adjacent white matter to form the emerging ventral rootlets of the spinal cord (Figs. 7.21 and 7.22).

White Matter

The white matter of the spinal cord consists of closely packed nerve fibers surrounding the gray matter (Fig. 7.21). It is divided into right and left halves by the posterior median septum and the anterior median fissure. At the base of the anterior median fissure the white matter on both sides of the cord is continuous via a slender lamina of decussating nerve fibers forming the anterior white commissure. Although the anterior white commissure is easily recognized at al spinal levels (Fig. 7.22), it appears to be most extensive at lumbosacral levels (Figs. 7.21 and 7.22c, d).

Because the number of nerve fibers in the ascending and descending spinal tracts is greatest at cervical levels, the white matter is best developed in the cervical segments (Fig. 7.22a) and progressively decreases in size at successive caudal levels of the spinal cord (Fig. 7.22b–d). These changes in the size of the white matter, together with variations in the gray matter, result in the spinal cord varying in size and shape from one region to another. Thus, the spinal cord is largest in the cervical region, where it is oval shaped (Fig. 7.22a), and smallest at sacral levels, where it is more circular in outline (Fig. 7.22d).

A sexual dimorphism in the relative proportion of white matter at the C5 level was described by Yuan *et al.* (1999), the area ratio of the white matter to the whole segment area being larger in males. The same authors found that with age, the area of gray matter decreased faster in males, but the area of white matter decrease faster in females.

The white matter is subdivided into three compartments: posterior, lateral, and anterior funiculi. The white matter between the posterior median septum and the attachment of the dorsal rootlets forms the posterior funiculus. The lateral funiculus lies between the attachment of the dorsal and ventral rootlets, and the anterior funiculus is formed by the white matter lying between the emerging ventral rootlets and the anterior median fissure. Rostral to midthoracic levels, the posterior funiculus and a lateral cuneate fasciculus (Fig. 7.22a); at levels caudal to T6 the posterior funiculus is represented only by the gracile fasciculus (Fig. 7.22b–d). The localization of the various fiber tracts in the spinal white matter is outlined by Schoenen and Grant in Chapter 11.

Spinal Cord: Connections

JEAN SCHOENEN
Department of Neuroanatomy and Neurology, University of Liège, Liège, Belgium
GUNNAR GRANT
Department of Neuroscience, Karolinska Institutet, Stockholm, Sweden

Thanks to modern tracing methods (antero- and retrograde transport labeling), which have complemented the classical fiber degeneration techniques, our knowledge of connections in the mammalian spinal cord has greatly expanded. Important contributions in this field have also been provided by electrophysiological experiments in animals using orthodromic or antidromic electrical stimulation. Extensive and competent reviews of the results of these experiments have been published by Willis and Coggeshall (1991), Kuypers (1981), Fyffe (1984), and Tracey (1986).

With human material, where the modern tracing methods are not applicable, one has to rely on data from the study of selected pathological cases with circumscribed lesions. In such cases, tracing of axons and identification of their terminals can be achieved by anterograde degeneration labeling (Marchi and Nauta techniques). Cells of origin of fiber systems can be detected by utilizing the chromatolytic changes that occur in neuronal cell bodies after transection of their axons (retrograde chromatolysis). The results of these human studies are often difficult to interpret and sometimes of limited value because of the low sensitivity of the methods used and the complexity of neurological pathology. Nevertheless, valid conclusions can be made about some of the important fiber connections in the human spinal cord. These will be reviewed below, but where appropriate, references will also be made to experimental findings in nonhuman mammalian cords. Indeed, it is known that certain spinal connections differ markedly between different species (e.g., corticospinal connections), while others have roughly the same organization in all mammals (e.g., descending brain stem pathways). In the following section we describe the intrinsic connections of the spinal cord, which are mainly represented by the propriospinal system. The second and third sections are devoted to afferent and efferent spinal pathways, respectively.

PROPRIOSPINAL PATHWAYS

Contrary to what has frequently been assumed, short-axoned neurons that distribute their fibers only through the gray matter to neighboring neurons are rare in the spinal cord. Such neurons probably only exist in the substantia gelatinosa (lamina II). The great majority of spinal neurons, especially those located in laminae V–VIII, are propriospinal in nature. On their way to the funiculi, they may establish connections with adjacent cells via collaterals of their main axons. Propriospinal neurons have a paramount role in spinal functions. For example, descending pathways are differentially distributed to subgroups of propriospinal neurons, which relay their action to motoneurons or other spinal cells.

White Matter Localization

The anatomy of the fasciculi proprii of the spinal cord in humans has been extensively reviewed by Nathan and Smith (1959). The portions of the spinal white matter bordering the central gray matter contain most of the axons of propriospinal neurons. According to Nathan and Smith, the following bundles of fibers need to be considered.

Ground Bundles

Anterior Ground Bundle The anterior ground bundle is present throughout the spinal cord, containing most fibers at the levels of the enlargements. It contains both ascending and descending fibers; these fibers vary in length, with some extending through the cord, and others covering one segment or less. The shortest fibers immediately surround the gray matter and the longer fibers are situated more peripherally. Most of the fibers are fine, with diameter of less than 3 μm. The cells of origin are poorly known, although they are probably located in the more medial and dorsal parts of the ventral horn, in the intermediate gray matter, and possibly in the dorsal horn. The fibers terminate in the ventral horn throughout the spinal cord, predominantly in their ventromedial portion. The anterior ground bundle is the first tract of the spinal cord to myelinate during ontogenesis.

Lateral Ground Bundle The lateral ground bundle is situated between the most lateral part of the ventral roots and the dorsal roots. It is also present throughout the cord and is most developed in the cervical and lumbar enlargements. It has both ascending and descending fibers; the fibers vary in length, and their cells of origin are mostly ipsilateral and located in the intermediate gray matter, the dorsal horn, and some in the ventral horn. Fibers in the lateral ground bundle have many collaterals and terminate throughout the gray matter. Most of the bundle is myelinated in the 5-month-old fetus.

Posterior Ground Bundle The posterior ground bundle designates the fine fibers of the fasciculi proprii scattered throughout the whole area of the dorsal columns. The presence of these propriospinal fibers is disputed. They probably arise from neurons in the medial parts of the dorsal horn, are short, and distribute to the gray matter of the medial part of the dorsal horn. These fibers are unmyelinated and small (0.5–2 μm).

Lissauer's Tract

Lissauer's tract is bound anteriorly (or ventrally) by lamina I and posteriorly (or dorsally) by the subpial neuroglia and the entering posterior roots. It is present throughout the cord, and is most developed in the upper cervical region and least developed in the thoracic cord. It is mainly composed of unmyelinated fibers but also contains fine myelinated fibers. The tract contains both ascending and descending fibers and both types extend for a few segments. In the monkey, the majority of these fibers have been found to be dorsal root afferents. The remaining fibers are intrinsic. The cells of origin of these intrinsic fibers and the cells around which they terminate are marginal neurons and neurons of the substantia gelatinosa. These neurons also receive terminals from the dorsal root afferent fibers.

Cornucommissural Tract

This tract, which is most developed in the lower lumbar region, lies against the medial aspect of the dorsal horn and along the dorsal commissure. It consists mainly of ipsilaterally running propriospinal ascending and descending fibers, which seem to connect the regions of subjacent gray matter to similar areas at other levels. It is apparently one of the earliest parts of the dorsal columns to show myelination during development.

Comma Tract

This comma-shaped collection of fibers lies in the cervical and upper thoracic cord between the fasciculi cuneatus and gracilis. Whether it consists of the descending division of dorsal root fibers or of intrinsic fibers has been a matter of discussion. According to Nathan and Smith (1959), the bulk of evidence indicates that the comma tract consists of the descending division of the cervical and upper thoracic dorsal roots.

Septomarginal Tract

This tract is situated along the posterior periphery of the cord but has a different location at different segmental levels. In the lumbar enlargement it extends along the median septum and may abut against the posterior commissure. It contains a mixture of both descending divisions of dorsal roots and intrinsic cord fibers. However, the evidence with respect to the latter is inconclusive.

Cells of Origin

While little is known regarding the distribution of propriospinal pathways in humans, a considerable number of data have been gathered in other mammals, especially in the cat and monkey, by means of the anterograde degeneration, retrograde degeneration, and the retrograde horseradish peroxidase (HRP)

transport techniques. The bulk of these data comes from the work of Barilari and Kuypers (1969) and Molenaar *et al.* (1974) and has been summarized by Kuypers (1981). The propriospinal neurons may be subdivided according to the length of their fibers into long, intermediate, and short propriospinal neurons. The long propriospinal neurons distribute their axons throughout the length of the spinal cord, mainly through the ventral funiculus and the ventrolateral fasciculus. They are concentrated in lamina VIII and the dorsally adjacent part of lamina VII. The fibers from the long propriospinal neurons in the cervical cord descend bilaterally, but those from the corresponding neurons in the lumbosacral cord ascend mainly contralaterally. The intermediate propriospinal neurons extend over shorter distances. They are located in the central and medial portions of lamina VII and project bilaterally but with an ipsilateral preponderance. The short propriospinal neurons that distribute their fibers over a distance of only six to eight segments are the main occupants of the lateral part of laminae V–VII; their fibers course primarily ipsilaterally through the lateral funiculus.

Distribution

The propriospinal fibers in the different parts of the ventral and lateral funiculi are distributed preferentially to different parts of the spinal gray matter. Recipient areas consist of both the intermediate gray matter and the motoneuronal columns. Propriospinal fibers in the dorsolateral fasciculus terminate mainly in the dorsal and lateral parts of the intermediate gray matter and in the dorsolateral motoneuronal column. These propriospinal fibers are thus distributed specifically to motoneurons of intrinsic hand and foot muscles. Conversely, propriospinal fibers in the ventral part of the ventrolateral fasciculus distribute to the central and medial parts of lamina VII and to ventromedial motoneurons, which innervate proximal extremity and girdle muscles. The third contingent of propriospinal fibers, those which run in the ventral funiculus, terminate mainly in the ventromedial part of the gray matter (lamina VIII and medial lamina VII), which contains long propriospinal neurons, and in the ventromedial motoneuronal column, which innervates axial and girdle muscles (Fig. 8.1).

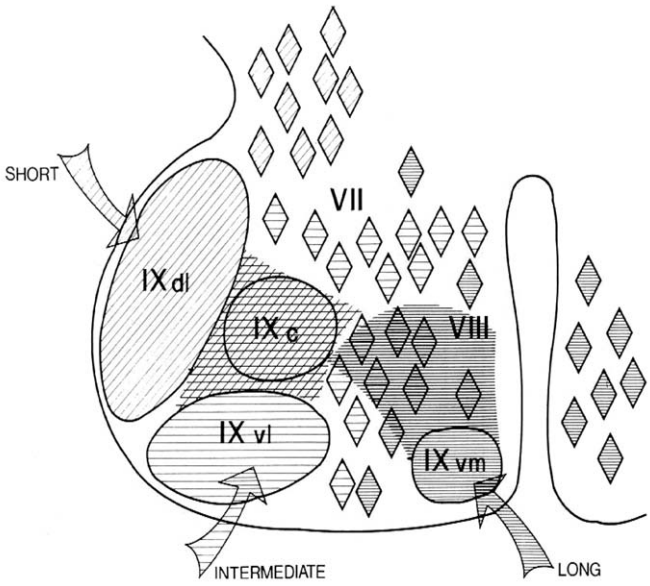

FIGURE 8.1 Cells of origin and terminal distribution area in ventral horn of long *(dark-shaded)*, intermediate *(horizontally shaded)*, and short (obliquely shaded) propriospinal neuron groups.

AFFERENT PATHWAYS

Primary Afferents

Primary afferent fibers reach the spinal cord via the dorsal roots. The question of whether some afferents also enter via the ventral roots has attracted interest in recent years, after unmyelinated sensory fibers were found in the ventral roots of various mammals including (probably) humans (see Coggeshall, 1986; Willis and Coggeshall, 1991). The cells of origin of these afferent fibers, like those of dorsal root afferents are in the dorsal root ganglia. Some of these fibers seem to be afferents making loops in the ventral root. They do not enter the spinal cord from its ventral side. Others are sensory afferents innervating the pia or the ventral surface of the spinal cord. They use the ventral roots on their way to reach the dorsal root ganglia. A third group may be afferents that actually enter the spinal cord from its ventral side, but conclusive evidence for this proposition is lacking.

The cells of origin of the primary afferent fibers are located in the dorsal root ganglia. These cells are unipolar and give rise to peripheral branches that are contained in the spinal nerves and to central branches entering the spinal cord. Peripherally, primary afferent fibers are usually related to different types of receptors; alternatively, they ramify as free nerve endings in skin, joints, muscle, and viscera. The central branches give rise to terminal ramifications in the dorsal column nuclei and/or the spinal gray matter.

Both myelinated fibers of different sizes and unmyelinated fibers are found among the primary afferents. Electron microscopic studies, carried out mainly in rats, have revealed that about two-thirds of

the afferent fibers are unmyelinated. It seems reasonable to assume that the situation would be similar in humans.

Cutaneous fibers are composed of the myelinated Aα/β and Aδ fibers, and of the unmyelinated, fine, slowly conducting C fibers. Joint and visceral afferents are classified in the same way as the cutaneous afferent fibers. In muscle nerves, however, the myelinated fibers are divided into groups I, II, and III, which have successively smaller diameters and slower conduction velocities, and group IV afferents, which are unmyelinated and have the slowest conduction velocities (see Chapter 5). The functional classes of afferent fibers and receptor types, both for cutaneous and for other types of afferents, have been reviewed by Kaas (Chapter 28; see also Willis and Coggeshall, 1991). They will therefore not be dealt with here. It should only be pointed out that methods are now available to characterize response properties of afferents in humans, using so-called microneurography, and to evoke sensations by electrical stimulation in nerves, thereby increasing our knowledge about sensory mechanisms in humans (see, e.g., Chapter 28). Such studies have led to the detection of specific C-fiber receptors for itch (Schmelz *et al.*, 1997) and also of tactile C afferents of a hitherto unknown type in humans (Vallbo *et al.*, 1999). Recently, in a unique patient lacking large myelinated afferents, it was found that activation of tactile C afferents produced a faint sensation of pleasant touch, suggesting their involvement in emotional aspects of tactile stimulation (Olausson *et al.*, 2002).

Dorsal Roots

The dorsal roots are segmentally arranged along the spinal cord. Peripherally, this segmental arrangement is reflected in the dermatomes. For humans, several extensive dermatomal maps have been published, constructed on the basis of different approaches. They are discussed by Kaas in Chapter 28 and will therefore not be dealt with further in this section (see also Dykes and Terzis, 1981). Suffice it to mention that, as a consequence of the anatomical arrangement, lesions affecting dorsal roots result in sensory loss within corresponding dermatomes.

In humans, there are usually 31 pairs of roots (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal), the largest being those of the lumbar and cervical enlargements. Occasionally, the first cervical dorsal root, which is normally very small, is missing. Because of the difference in length between the spinal cord and the vertebral column, the nerve roots of the lumbosacral spinal cord have a much longer distance to travel prior to reaching their respective foramina of exit from the vertebral canal. They are therefore much longer than those of the thoracic and cervical spinal cord. Each dorsal root fans out from the central end of the dorsal root ganglion into several rootlets that enter the spinal cord along the posterolateral sulcus.

About 1 million dorsal root fibers have been found on each side in the human adult. This figure is based on studies in which the silver impregnation technique was used (Arnell, 1933; see also Kjellgren, 1944). Although this technique reveals a higher number of fibers than myelin stains, the figure is certainly much too low. Considering the fact that about two-thirds of the afferent fibers may be unmyelinated, a more realistic number of dorsal root fibers should 2–2.5 million.

Caliber spectra of dorsal roots have been investigated in humans postnatally (Rexed, 1944). This was done with the Alzheimer–Mann–Häggqvist technique, which is used to stains myelinated fibers. A distinct development was found to take place that persisted for up to 5–9 years of age. There was one fine-caliber and one thick-caliber group, which in the adult had maximum diameters of 2–4 and 8–9 μm, respectively. In old persons, distinct signs of diminution in the number of the thick fibers were found commencing at the age of 50 years.

The myelin sheath of dorsal root fibers is produced by two types of cells, which meet at a transitional node. Peripherally, the myelin is produced by Schwann cells, centrally by oligodendrocytes. The transitional region which has several unique features, including astrocytic processes, has been studied in detail ultrastructurally in the cat (Carlstedt, 1977; see also Chapter 9), but not in humans.

A controversial question has been whether dorsal root fibers become segregated on the basis of their fiber diameter just before their entry into the spinal cord (Fyffe, 1984; Snyder, 1977). Early studies at the light microscopic level were not well suited for answering this question. In a comprehensive electron microscopic study, however, Snyder (1977) demonstrated convincingly that a reorganization of the fibers in the rootlet takes place central to the transitional region in the macaque monkey. In this species, as in the cat, small-caliber axons are randomly distributed in the peripheral part of the rootlet (as they are in the peripheral nerve). Centrally, however, in the monkey, but not in the cat, the small-caliber axons take a ventrolateral course in the rootlet and, as this merges with the dorsal columns, these axons form a single bundle on the ventral and lateral surface of the rootlet, which then merges with Lissauer's tract. These findings therefore indicate that a lateral division of the dorsal root is present in the monkey, but not in the cat. The situation in humans has been analyzed at the light microscopic level (Sindou *et al.*, 1974) but not electron microscopi-

cally, which would be necessary for disclosing all the unmyelinated fibers in the rootlet.

Dorsal Root Ganglia

The dorsal root ganglia (spinal ganglia) are usually located within the intervertebral foramina, immediately outside the points where the nerve roots perforate the dura mater. However, the C1 and C2 ganglia lie on the vertebral arches of the atlas and axis, those of the sacral nerves are inside the vertebral canal, and that of the coccygeal nerve is within the sheath of dura mater. The C1 ganglia are missing in some individuals. On the other hand, aberrant ganglia consisting of groups of nerve cells are sometimes found on the dorsal roots of the upper cervical nerves between the spinal ganglia and the spinal cord.

The ganglia are derived from the neural crest, and they contain the cell bodies of nearly all neurons conveying somatic and visceral input from the body to the spinal cord. The ganglion cells vary in diameter between about 10 and 100 μm. Each such cell is surrounded by satellite cells. These are also derived from the neural crest. They seem to be modified Schwann cells. The ganglion cell population has been divided into two groups, one group of large cells, which appear light in Nissl stains, giving rise to large-caliber fibers, and one group of small dark neurons, giving rise to small-caliber fibers. In recent years, attempts have been made, mainly in rats, to classify the two populations further in physiological, anatomical, and immunocytochemical terms (e.g., Dodd and Jessel, 1985, Lawson *et al.*, 1985, 1987; Lawson 1995, 2002; see also Chapter 9).

The ganglion cells are unipolar and are usually reported as giving rise to a single process that bifurcates into a peripheral and a central branch. Not infrequently, the proximal segment is highly coiled and this is then referred to as the glomerular segment. Some studies, mainly in the rat, suggest that one single dorsal root ganglion cell may in fact give rise to more than one peripheral branch, and also to more than one centrally projecting branch (see, e.g., Coggeshall, 1986). Evidence emanates mainly from studies in which two different labeling substances have been applied peripherally at different nerves and later both these substance were detected in the same dorsal root ganglion cells, and from studies in which axon counts have been made and compared with results of ganglion cell counts. In the first instance, only a small percentage of ganglion cells show both labels, indicating that double branching is infrequent. With respect to the counting studies, which have indicated a relationship of up to 2:1 between axons and ganglion cells, the results are critically dependent on the methods that have been used. Studies in the rat (Schmalbruch, 1987) indicate that previous investigations have given values for the number of dorsal root ganglion cells that are too low and that, in fact, the ganglion cell numbers compare well with the number of dorsal root axons. However, further investigations are necessary to answer this question, which is of interest also from a clinical point of view because the possible branching of peripheral axons has bearing on the problem of referred pain (Coggeshall, 1986).

Central Terminations

The termination of the primary afferent fibers in the spinal cord and dorsal column nuclei has been dealt with by Kaas in Chapter 28 (see also Chapters 7 and 9). Furthermore, the ascending dorsal column fibers have been discussed in the present chapter in connection with the ascending pathways. Therefore, only a few points will be made with regard to the primary afferent terminations, and they will be restricted to the spinal cord.

On the basis of studies across mammalian and nonmammalian species (Cervero, 1986; Fyffe, 1984; Grant, 1995), it seems justifiable to conclude that humans would also display two principles of organization for the spinal termination of primary afferent fibers. First, there is a somatotopic organization of incoming afferents mediolaterally in the dorsal horn. Distal parts of the limbs are "represented" medially and proximal parts laterally. For the thoracic region of the body, ventral parts are represented medially and dorsal parts laterally. Second, there is a ventrodorsal modality–related segregation principle superimposed on the somatotopic pattern. Fine-caliber fibers related to pain and temperature terminate in superficial parts of the dorsal horn (laminae I and II), whereas coarse-caliber fibers terminate in deeper parts, with some coarse-caliber proprioceptive afferents terminating in the ventral horn (Figs. 8.2 and 8.5). Furthermore, it seems from studies which have been made mainly in cats and rats that in the dorsal horn, the substantia gelatinosa (lamina II) receives primary afferent fibers almost exclusively from cutaneous receptors. Visceral afferents, as well as muscle afferent fibers, seem to have their terminations mainly in laminae I and V (see, e.g. Cervero, 1986; Molander and Grant, 1987; Sugiura *et al.*, 1993; Sugiura and Tonosaki, 1995).

Descending Pathways

The present knowledge on descending pathways in the human spinal cord is still fragmentary to the extent that the 1955 review by Nathan and Smith is still current. Most of the available data concern the corticospinal

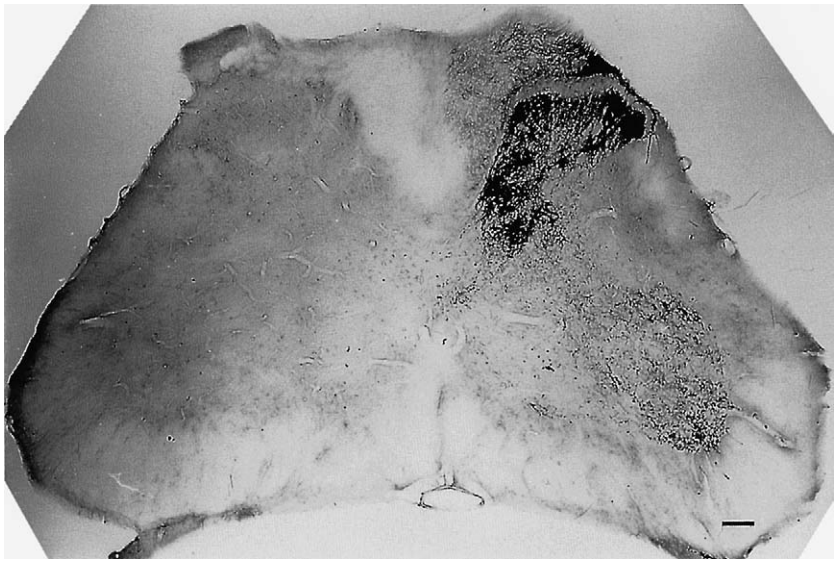

FIGURE 8.2 Distribution of coarse-caliber dorsal root fibers in the L4 segment of the spinal cord of the rat, following unilateral L4 dorsal root ganglion injection of horseadish peroxidase conjugated to the nontoxic B fragment of cholera toxin. Bar = 100 µm.

tract and have been obtained by the anterograde degeneration technique in selected pathological cases. Major contributions in this area have been made by Barnes (1901), Holmes and May (1909), Jane *et al.* (1967), Luhan (1959), Minckler *et al.* (1944), and Schoen (1964, 1969, 1972). Moreover, studies on the fiber composition and course of the pyramidal tract have been performed by Armand (1984), Bumke (1907), Fulton and Sheehan (1935), Giok (1956), Häggqvist (1937), Holstege and Kuypers (1982), Lankamp (1967), Lassek (1942a, b), Nyberg-Hansen and Rinvik (1963), and Swank (1934). An extensive review and analysis of all major work, as well as a compilation of experimental data on the corticospinal tract, has been published by Phillips and Porter (1977). Several comprehensive reviews of descending pathways to the spinal cord in mammals have been made by Kuypers (1964, 1973, 1981). We will first consider the corticospinal system, which has the highest level of development in higher primates, especially in humans. Subsequently, the other descending pathways, for which species differences are less pronounced, will be examined.

Corticospinal Tract

Cells of Origin The cells of origin of the corticospinal tract are located in the precentral gyrus, mainly in its upper two-thirds, and in the paracentral lobule. Brodmann's areas 4 (primary motor cortex) and 6 (nonprimary motor cortex) contribute 80% of the pyramidal tract fibers (see Chapter 27 for diagrammatic and pictorial representation of cortical regions, e.g., Fig. 27). In contrast to other mammals, contribution of corticospinal fibers from the postcentral gyrus is sparse in the human. Corticospinal fibers are not derived exclusively from the large lamina V Betz cells of area 4.

Number of Axons The number of axons in a pyramid is roughly proportional to body and brain weight. The corticospinal tract contains more axons in animals in which the pathway extends the entire length of the cord, compared to those species in which it terminates either at cervical or thoracic levels. In humans, there are approximately 1 million axons in each pyramid. Of these, 80% measure less than 2 µm in diameter and 90% range from 1 to 4 µm. The maximal fiber diameter may be as high as 20 µm. Thick fibers occur especially in species (such as humans) that possess many direct corticomotoneuronal connections.

Postnatal Development During postnatal development, myelination starts in the internal capsule and peduncles, where it is present in the 10- to 14-day-old neonate. Myelination is completed in the second year. It proceeds simultaneously in the lateral and ventral divisions of the tract. The axons from the paracentral lobule and from the upper third of the precentral gyrus myelinate before those from the middle third of this gyrus. Furthermore, a postnatal increase in diameter of corticospinal fibers has been observed in the human (Lassek, 1942b; Verhaart, 1950). In the

newborn rhesus monkey, virtually no cortical fibers are distributed to the motoneuronal cell groups, the full complement of corticospinal connections appearing around the age of 8 months. The increasing wide distribution of cortical fibers in the spinal gray matter with increasing age probably represents a true outgrowth of cortical fibers (Kuypers, 1962).

Trajectory and somatotopy The trajectory and somatology of corticospinal fibers is well known and will not be reviewed in detail here. After decussating in the caudal medulla, the bulk of corticospinal fibers continue in the dorsolateral fasciculus of the spinal cord as the lateral corticospinal tract. Some fibers do not cross in the medulla but continue into the cord in the ventral funiculus and then cross in the ventral white commissure. This is referred to as the ventral (uncrossed) corticospinal tract. The following features have been emphasized for corticospinal tracts in man (Nathan *et al.*, 1990). In the cervical cord, the lateral corticospinal tract covers an area of the white matter that extends anteriorly beyond the level of the central canal. At lower cervical cord levels, fibers separate from the main mass of the tract and reach the periphery of the anterolateral sector of the cord. There is a close anatomical relationship between the lateral corticospinal tract and the denticulate ligament in cervical segments. In most necropsy specimens the anterior uncrossed corticospinal tract is smaller on the left side because a greater number of corticospinal fibers cross to the right side. This accounts for the asymmetry of the two halves of the cord. Inconsistently, a small group of axons remains in the medulla and joins the lateral corticospinal tract. It must be emphasized that the pyramidal tract is subject to much anatomical variation from individual to individual. For instance, in some subjects, the ventral tract may be absent or not project into lumbosacral regions; the pyramidal decussation may be absent; a ventrolateral pyramidal tract may exist, or a Pick's bundle may be found, i.e., recurrent pyramidal fibers which, after decussating in the medulla, ascend in the bulbar lateral tegmental field.

Terminal Distribution The terminal distribution of corticospinal fibers in the human spinal gray matter has been determined by classical fiber degeneration methods in spinal cords of patients who died after suffering circumscribed central nervous system lesions such as cerebrovascular accidents (Schoen, 1964, 1969; Schoenen, 1981). Corticospinal fibers distribute mainly contralaterally to the lateral parts of laminae V–VI, VII, the dorsolateral motoneuronal column, and the lateral parts of the central and ventrolateral motoneurons (Fig. 8.3a, b). Terminals are also found contralaterally in the medial parts of lamina VII and bilaterally in lamina VIII (Schoen, 1969). A few cortical fibers are distributed to lateral lamina IV of the dorsal horn. This distribution pattern is similar throughout the length of the spinal cord, although it is more profuse in the enlargements.

Although at spinal levels fibers originating in different cortical areas are intermingled in the corticospinal tract, there is a clear difference in the terminal distribution of precentral and postcentral cortical fibers. Thus, the few fibers from the postcentral gyrus are distributed mainly to the dorsal gray matter (lamina IV, lateral part of laminae V–VI and VII) (Fig. 8.3c, d), while those from the precentral cortex project in a topographically organized fashion to the intermediate gray matter and the motoneuronal cell groups. According to studies in the monkey, the cortical areas carrying representations of axial and proximal limb movements give rise to few fibers to motoneuronal cell groups and characteristically project to those parts of the gray matter that contain propriospinal neurons with long axons (lamina VIII, medial lamina VII). In contrast, areas where distal extremity movements are represented, project to motoneuronal cell groups of distal extremity muscles and to those portions of the gray matter that mainly contain short and intermediate propriospinal neurons (laminae V–VI, lateral lamina VII) (Kuypers, 1981). The terminal distribution of corticospinal fibers in humans is clearly different from that observed in several other mammals. In more primitive species, such as elephants and marsupials, the corticospinal tract terminates in rostral cord segments and in the dorsal horn, suggesting that it chiefly has a sensory function. In more evolved species, such as rodents and carnivores, the corticospinal tract terminates at more caudal levels of the cord and in more ventral regions of the gray matter. In primates, and especially in humans, there is in addition a heavy projection of corticospinal fibers to the ventromedial part of gray matter containing long propriospinal neurons and to motoneuronal cell groups innervating distal and proximal extremity muscles. From a functional point of view, it is known from lesion experiments in which freely moving monkeys were used that the corticospinal pathway amplifies the motor control exerted by descending brain stem pathways (see below). Specifically, the direct corticomotoneuronal connections make possible the high degree of fractionation of movements such as individual finger movements (see Kuypers, 1981).

The motor deficits occurring after lesions of varying extent of the corticospinal tracts have been assessed in 44 patients having cordotomies for relief of cancer pain (Nathan, 1994). Only surgical incisions extending more posteriorly than the anterior quadrants of the cord

caused motor disturbances. A large unilateral lesion dividing most of the lateral corticospinal tract, and the descending fibers anterior to it, caused flaccid paralysis of the ipsilateral lower limb, but voluntary movements started to return within hours. A thoracic incision cutting one lateral corticospinal tract and most of the opposite tract and reticulospinal fibers anterior to that tract caused total paraplegia; after 2 months, however, the patient was able to walk though with a severe spastic paraparesis. A unilateral division of the lateral corticospinal tract in the upper cervical cord was followed within 6 h by recovery of some ipsilateral finger and toe movements. Lesions of the anterior fibers of the lateral corticospinal tract above the cervical enlargement did not affect motility of the ipsilateral upper limb, suggesting that in more cranial segments fibers destined to the upper limb are in the more posterior part of the tract.

Descending Brain Stem Pathways

Most of the evidence regarding the cells of origin and the terminal distribution of these pathways comes from animal experiments (for recent studies, see Holstege, 1987a, b; Holstege and Kuypers, 1982; Holstege and Tan, 1987; see also Chapters 36 and 9). With few exceptions, only the white matter localization of some of the tracts descending from the brainstem to the spinal cord has been verified in human pathological material (for a review, see Nathan and Smith, 1955; Nathan *et al.*, 1996).

In the human spinal cord, reticulospinal fibers in general are scattered throughout the anterior and lateral columns. Contrary to their animal counterparts from which the description below is largely derived, they do not seem to form well-defined tracts. The following features characterized degenerating reticulospinal fibers in patients with brain stem lesions or anterolateral cordotomies (Nathan *et al.*, 1996). Reticulospinal fibers move posterolaterally as they descend and lie anterior to the lateral corticospinal tract. Their number decreases caudal to the cervical enlargement, their place being taken by propriospinal fibers, but some of them reach the sacral segments in the sulcomarginal fasciculus.

Medial Reticulospinal Tract The medial reticulospinal tract originates in the dorsal and central parts of the medulla and central pontine, medial tegmental field. Its fibers descend ipsi- and contralaterally in the ventral funiculus and ventrolateral fasciculus. These fibers give off multiple collaterals so that two-thirds of the reticulospinal neurons that distribute fibers to the cervical ventral gray also project to the lumbosacral cord. The terminal distribution of these reticulospinal fibers is especially dense in the enlargements and bilaterally involves the ventral gray matter, i.e., medial and central parts of lamina VII, lamina VIII, and the ventromedial motoneuronal column (Fig. 8.3e, f). The medullary reticulospinal fibers probably establish direct connections with motoneurons of neck and back muscles.

Vestibulospinal Tract

The vestibulospinal tract can be subdivided into a lateral component coming from the lateral vestibular (Deiters') nucleus and a medial component from the medial vestibular nucleus (see Chapter 33). Deiterospinal fibers descend ipsilaterally in the ventrolateral fasciculus at cervical levels and then shift into the medial part of the ventral funiculus at lower spinal levels. This population of neurons is somatotopically organized such that the fibers to the cervical cord are derived mainly from neurons in the rostroventral part of Deiters' nucleus, while those to the lumbosacral cord originate from neurons in its dorsocaudal part. Deiterospinal fibers terminate ipsilaterally in the ventromedial part of the gray matter, i.e., lamina VIII and medial part of lamina VII. A few fibers distribute contralaterally. It has been shown in cats that deiterospinal fibers establish polysynaptic excitatory connections with motoneurons of extensor muscles, monosynaptic connections with Ia inhibitory interneurons, and monosynaptic excitatory connections with motoneurons of neck and back muscles.

Medial vestibulospinal fibers pass via the medial longitudinal fasciculus in the spinal ventral funiculus. They descend bilaterally in the spinal cord with an ipsilateral dominance. Their termination area is more restricted than that of the deiterospinal fibers and comprises mainly lamina VIII and the dorsally adjoining part of lamina VII. Medial vestibulospinal fibers establish monosynaptic inhibitory connections with many motoneurons of neck and back muscles. For more details on the vestibulospinal pathways, see Chapter 33.

Interstitiospinal Tract

The interstitiospinal tract comprises fibers from the interstitial nucleus of Cajál that descend mainly ipsilaterally in the ventral funiculus of the spinal cord as far caudally as the sacral segments. These fibers distribute to the dorsal part of lamina VIII and the dorsally adjoining part of lamina VII.

Tectospinal Tract

The tectospinal tract originates in the deeper layers of the superior colliculus and distributes contralaterally only to the upper cervical cord. Its fibers descend in the ventral part of the ventral funiculus and terminate in the medial and lateral portions of the cervical ventral

horn. They establish multisynaptic connections with neck muscle motoneurons that are excitatory to contralateral muscles and inhibitory to ipsilateral ones.

Rubrospinal Tract

The rubrospinal tract is probably less developed in humans than in lower mammals. The cells of origin are located in the caudal magnocellular part of the red nucleus, which is extremely small in humans. According to findings in the cat and rat, the projections are somatotopically organized. Rubrospinal fibers cross in the ventral tegmental decussation of the midbrain and descend in the dorsolateral fasciculus of the spinal cord just ventral to the lateral corticospinal tract. They distribute to the lateral part of laminae V–VI and the dorsal part of lamina VII and, in the cat and monkey, to the dorsal part of lamina IX (Holstege, 1987a). Orthodromic electrical stimulation findings in the cat show that rubrospinal fibers excite flexor motoneurons and inhibit extensor motoneurons. In the rhesus monkey, rubrospinal fibers establish some direct connections with motoneurons of distal extremity muscles. In contrast to those of vestibulo- and medial reticulospinal fibers, the collaterals of rubrospinal fibers are largely restricted to specific levels.

Lateral Reticulospinal Tract

The lateral reticulospinal tract originates in the ventrolateral pontine tegmentum. Its fibers cross in the brain stem, descend through the dorsolateral fasciculus, and terminate in the spinal gray in laminae I and V (Holstege and Kuypers, 1982).

Other Descending Tracts

Fibers from solitary and retroambiguous nuclei descend mainly contralaterally in the ventrolateral and ventral white matter of the spinal cord, innervating phrenic motoneurons and thoracic motoneuronal cell groups. These pathways subserve respiratory activity, as exemplified by the fact that bilateral transection of the upper cervical ventrolateral fasciculus abolishes rhythmic respiration (Nathan, 1963; see also Chapter 15).

In man, the descending sympathetic fibers supplying preganglionic vasomotor and sudomotor neurons of the body caudal to the head and neck are located in the medial part of the white matter along the equatorial plane extending from the base of the posterior horn and the lateral horn. Projections are bilateral and fibers for vasomotor control probably leave the cord cranial to the Th 7 segment (Nathan and Smith, 1987).

According to animal experiments, catecholaminergic innervation of the spinal gray matter is provided by two pathways: (1) the cerulospinal noradrenergic projection, originating in the locus ceruleus and subceruleus and distributing to all parts of the gray matter (see Holstege and Kuypers, 1982); and (2) the tegmentospinal noradrenergic system originating from lateral pontine groups A5 and A7 and projecting to the intermediolateral column (adjoining parts of the intermediate gray) and the dorsal horn (Lindvall and Björklund, 1983).

Serotonergic fibers to the dorsal horn, considered to convey supraspinal control of nociception, come from the raphe magnus nucleus via the dorsolateral fasciculus and project to laminae I and V. The more caudally located nuclei raphe obscurus and pallidus innervate the intermediate and ventral horn via the ventral and ventrolateral white matter (Holstege and Kuypers, 1982; Hunt, 1983).

Conclusion

To summarize, Kuypers (1981) has proposed the subdivision of the descending brain stem pathways into two large groups on the basis of their terminal distribution and functional properties (Fig. 8.4).

Group A Group A (medial reticulospinal tract, vestibulospinal tract, interstitiospinal tract, tectospinal tract) is characterized by location in the ventral and ventrolateral white matter and, frequently, bilateral termination in the ventromedial part of the gray matter (an area that contains long and intermediate propriospinal neurons). These fibers display high degree of collateralization and have some direct connections with motoneurons of neck, back, and proximal extremity muscles. The cell groups of origin of group A pathways receive fibers mainly from cortical areas rostral to the precentral gyrus. Functionally, the system is concerned with the control of posture, synergistic whole-limb movements, and orientation movements of body and head. The distribution area of group A afferents overlaps mainly with that of ventral corticospinal fibers.

Group B Group B pathways (rubrospinal tract, pontospinal tract from the ventrolateral pontine tegmentum) comprise contralaterally descendings fibers which are situated in the spinal dorsolateral fasciculus and characterized by their termination in the dorsal and lateral parts of the intermediate gray matter, an area containing short propriospinal neurons. Group B pathways establish monosynaptic connections with motoneurons of distal extremity muscle in primates and cats. These pathways show a low degree of collateralization in contrast to group A pathways. Their area of termination overlaps chiefly with that of the lateral corticospinal or pyramidal tract. The cells of group B pathways, e.g., the red nucleus, receive mainly

Jean Schoenen and Gunnar Grant

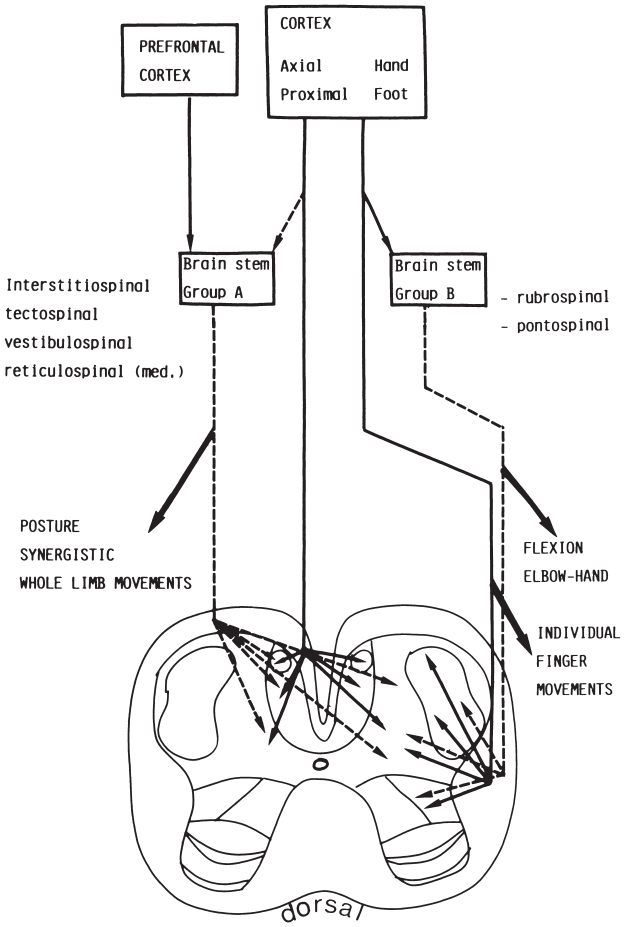

FIGURE 8.4 The major descending pathways to the spinal cord, their terminal distribution in the spinal gray matter, and their main functional roles.

cortical afferents from the precentral gyrus. In view of these anatomical data and functional findings in the freely moving monkey, group B brain stem pathways seem to supplement the control exerted by the group A pathways and provide the capacity for independent, flexion-biased movements of the extremities and the shoulder, but in particular of the elbow and hand.

Considering the pattern of spinal distribution of noradrenergic and serotonergic descending fibers from the brain stem, these pathways probably have a functional role in sensory processing in the dorsal horn, in autonomic activity, but also in motor control. In this respect, it is interesting to recall that electrical stimulation of the nucleus raphe magnus produces an analgesic effect as well as inhibition of interneurons in the spinal flexion reflex arc. Further research is needed to clarify the precise functions of the monoaminergic pathways to the spinal cord.

Finally, as illustrated in Figure 8.5, it is worth mentioning that within the spinal gray matter the majority of afferents are roughly parallel to the preferential dendritic orientation of spinal neurons (see above).

EFFERENT PATHWAYS

The well-known spinal output by somatic motoneurons and autonomic preganglionic cells will not be discussed here (see Chapter 5). We will review below the available data concerning the localization and the trajectory in the human spinal cord of so-called long projection neurons, which give rise to ascending pathways to supraspinal structures. Information in this field chiefly comes from the study of patients who had had ventrolateral cordotomies for the release of intractable pain or localized traumatic or inflammator spinal lesions. Since in such cases there is inevitably involvement of several white matter tracts, it is not possible to precisely determine the cells of origin of any given pathway. However, information can be obtained concerning the funicular localization of ascending axons from spinal neurons.

Ascending Pathways in Humans

Smith (1976) studied retrograde cell changes in 23 human spinal cords after ventrolateral cordotomies. She found that some fibers arising from all gray matter laminae, except laminae II and III, ascend the cord in the lateral funiculus. A larger proportion of fibers arises from laminae I, IV, V, and VII. The majority of those from lamina I have a course contralateral to that of their cells of origin, but a few have an ipsilateral course. More of the fibers arising from lamina I run in the ventrolateral than in the dorsolateral sector. The fibers arising from laminae IV and V run in both the ventrolateral and dorsolateral sectors, both contralateral and ipsilateral to their cells of origin. The major contributing fibers originating in lamina VII come from the nucleus dorsalis of Clarke. The fibers are located both in the dorsolateral and the ventrolateral fasciculi. Most of them are ipsilateral to their cells of origin. Some fibers arise from other cells in laminae V–VI and VII; they ascend both ipsilaterally and contralaterally in the ventrolateral fasciculus. Some neurons in laminae VIII and IX emit axons that run contralaterally in the ventrolateral fasciculus. In a study of five cases of ventrolateral cordotomy performed at upper cervical or thoracic levels between 3 weeks and 8 months before death, we have found (Schoenen, 1981) a low number of chromatolytic neurons contralaterally in

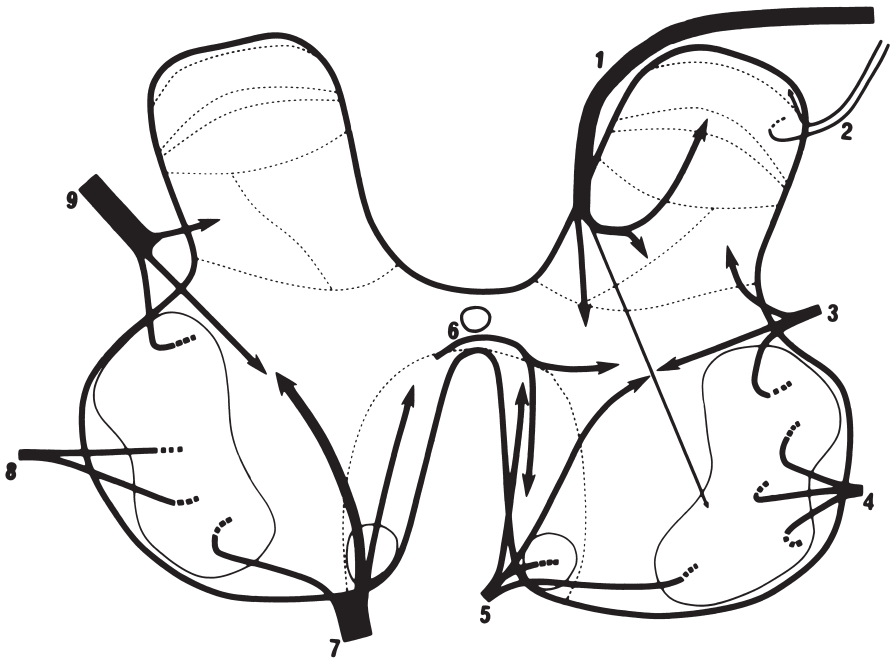

FIGURE 8.5 Illustration of the termination area and orientation of the main afferents to the spinal gray matter. Descending afferents are represented on the left, peripheral, and propriospinal afferents on the right. Fibers taking a longitudinal course are indicated by dashed lines. 1, Large-caliber dorsal root afferents; 2, small-caliber dorsal root afferents; 3, dorsolateral propriospinal afferents; 4, ventrolateral propriospinal afferents; 5, ventromedial propriospinal afferents; 6, commissural propriospinal afferents; 7, vestibulo- and medial reticulospinal afferents (brain stem group A); 8, rubro- and pontospinal afferents (brain stem group B); 9, lateral (crossed) corticospinal afferents.

laminae I and IV of the lumbar enlargement (Fig. 4.5). Conversely, in three patients dying after an acute transverse thoracic myelitis, chromatolytic neurons at the lumbar level were distributed bilaterally in laminae I and IV as well as in laminae VII and VIII and in the marginal part of the dorsolateral motoneuronal column (Fig. 8.6).

It is important to recall that ventrolateral cordotomies damage ascending fibers other than those of the spinothalamic tract, e.g., spinocerebellar, spinoreticular, spinomesencephalic, and propriospinal fibers. Nevertheless, the findings described above and those made by Kuru (1949) in three cordotomy cases suggest that in humans most of the cells of origin of the spinothalamic tract are located in contralateral laminae I and IV. This is at some variance with the results obtained in the cat and monkey, where spinothalamic neurons have been found in laminae I, V, and VII–VIII (Albe-Fessard *et al.*, 1975; Carstens and Trevino, 1978; Trevino and Carstens, 1975; Willis *et al.*, 1979; Apkarian and Hodge, 1989; Craig *et al.*, 1989). It may be surprising that such a low number of spinal neurons show retrograde changes in human cordotomy cases. This might be due to the low sensitivity of the retrograde degeneration method. Another explanation might be the existence of collaterals of the spinothalamic fibers in the spinal cord (Smith, 1976); on the other hand, it must be kept in mind that, as in the cat, the majority of lamina I neurons might be propriospinal in nature and not project into the spinothalamic tract (Cervero *et al.*, 1979) Regarding pain pathways in the human spinal cord, it is interesting to note that commissural myelotomy, another operation performed for relief of intractable pain, produces sensory changes that are not explicable on the basis of previous anatomical knowledge (Cook *et al.*, 1984). Although the purpose of this procedure has been to produce a loss of pain sensibility by dividing the spinothalamic and spinoreticulothalamic fibers as they decussate in the ventral commissure of the cord, this result is not always obtained. The patterns of sensory loss in this case have suggested that the lesion might involve intraspinal polysynaptic, i.e. propriospinal, pain-conducting pathways. Recent studies seem to have shed light on this problem, presenting evidence for a pathway in the posterior funiculus in humans responsible for the

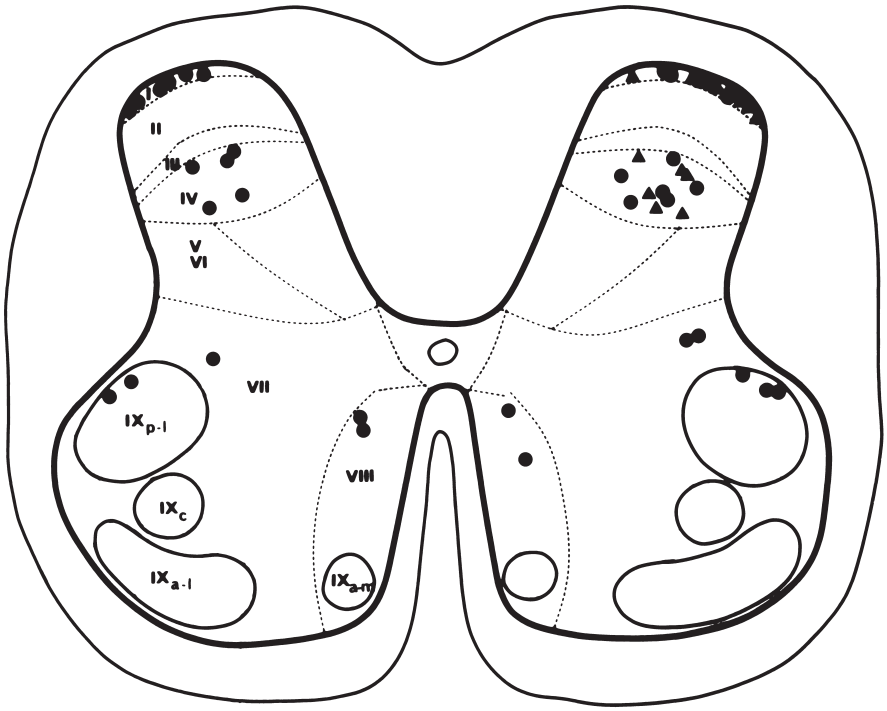

FIGURE 8.6 The distribution of chromatolytic neurons identified on five consecutive 15-mm sections of the lumbar enlargement in two cases of left ventrolateral cordotomy *(triangles)* and two cases of thoracic transverse myelitis *(solid circles)*. IX_{a-l}, Anterolateral; IX_{a-m}, anteromedial; IX_c, central; IX_{p-l}, posterolateral columns of motoneurons.

signaling of visceral pain (Hirschberg *et al.*, 1996). Axons in the medial part of the posterior funiculus at T10 seem to convey ascending nociceptive signals from pelvic visceral organs. This has stimulated a series of experimental studies in rats and monkeys giving evidence for a visceral nociceptive postsynaptic dorsal funiculus pathway, originating from cells in the spinal gray matter around the central canal and terminating in the dorsal column nuclei (Al-Chaer *et al.*, 1998, 1999; Wang *et al.*, 1999; see Willis and Westlund, Chapter 30).

According to Smith (1976), most of the spinocerebellar fibers, whether dorsolateral or ventrolateral, arise from the nucleus dorsalis of Clarke in humans. However, by analogy with experimental findings in the rat (Matsushita and Hosoya, 1979), cat (Burke *et al.*, 1971; Hubbard and Oscarsson, 1962; Matsushita *et al.*, 1979; Grant *et al.*, 1982), and monkey (Lafleur *et al.*, 1974; Petras, 1977; Sprague, 1953), some of the chromatolytic neurons found in laminae VII and VIII and the dorsolateral motoneuronal column ("spinal border cells"; Cooper and Sherington, 1940) after transverse myelitis (Fig. 8.6) may be cells of origin of the ventral spinocerebellar (Gowers') tract.

Ascending Pathways in Experimental Animals

Thanks to modern anatomical tracing methods and to electrophysiological experiments, data concerning the spinal ascending pathways are much more extensive and precise in animals than in humans. Findings have been comprehensively reviewed by a number of authors among whom are Willis and Coggeshall (1991), Clark (1984), Cook *et al.* (1984) and Tracey (1995). They are summarized below with emphasis on functional considerations. See also Kaas (Chapter 28) for the somatosensory system and Voogd *et al* (Chapter 11) for the spinocerebellar tracts.

Dorsal Columns

The dorsal columns comprise short, intermediate, and long systems of fibers. These fibers are from dorsal root afferent but also from second-order sensory neurons of the dorsal horn and the area around the central canal (see above). Less than 25% of the dorsal column fibers belong to the long system. The dorsal column pathway includes the gracile fasciculus, containing ascending branches of afferents supplying the lower part of the body and hindlimb, and the laterally located cuneate

fasciculus, which contains afferents from the upper part of the body and forelimb. The topographical anatomy of the dorsal columns in the human spinal cord has been studied by Smith and Deacon (1984). These authors conclude that the gracile and cuneate fasciculi should be considered as separate anatomical entities. The shape of each fasciculus is different in, and characteristic of, each of the upper thoracic and cervical segments. A certain degree of segmental lamination is present in the gracile fasciculus, but with extensive overlapping of fibers from different segments. The pattern of lamination in the cuneate fasciculus and the degree of overlapping of fibers resembles that in the caudal gracile fasciculus. The latter synapses in the gracile nucleus and the cuneate fasciculus in the cuneate nucleus (see Chapter 10). A small proportion of long ascending primary afferent fibers terminates in the dorsal horn at various segmental levels. Most of the axons of the second-order neurons, whose cells of origin are found mainly in laminae IV–V in the cat (but more dorsally in the rat and monkey) and also in the area around the central canal (see above), terminate in rostral portions of the ipsilateral dorsal column nuclei. It is interesting to note that large myelinated axons from muscle and joint receptors of the hindlimbs may leave the gracile fasciculus at lower lumbar levels and ascend through other systems (e.g., the dorsolateral fasciculus). This particular hindlimb projection terminates in nucleus Z, which is located immediately rostral to the gracile nucleus (see Kaas, Chapter 28).

Functional considerations regarding the dorsal column pathways have been revised dramatically over the past few years. It now appears that the dorsal column pathways are not particularly important for vibratory and joint sensations. Surgical lesions of the dorsal columns in humans can produce only minimal sensory deficits but affect visceral nociception, as discussed above. There is evidence that these pathways are involved in highly complex discriminative sensory tasks, such as two-point discrimination, judging the magnitude of cutaneous pressure, and the ability to detect the speed and direction of moving stimuli.

Ventrolateral Ascending Pathways

These pathways include portions of both the lateral and ventral funiculi. They contain spinothalamic and spinoreticular projections and convey pain, temperature, touch, and pressure information. The ventrolateral system is not compactly organized, but somewhat diffusely structured, intermingling with other ascending pathways. There is a general somatotopic tendency such that axons arising from lower segments are located in a more dorsolateral position and those from higher levels are more ventromedial in location.

Spinothalamic Tract

The spinothalamic tract in experimental animals originates from neurons in mainly contralateral laminae I, V, VII, and VIII. In the monkey, the majority of spinothalamic neurons are located in laminae I and V, while in the cat, spinothalamic neurons are more numerous in laminae VII and VIII. It has not been settled whether the decussation of spinothalamic tract axons is only in the ventral commissure of the cord or also in the dorsal commissure. Spinothalamic neurons in the human and monkey terminate in the ventral posterolateral thalamic nucleus (see Chapter 28) as well as in the central lateral nucleus of the intralaminar complex (see Chapter 20) and in the recently distinguished posterior ventromedial nucleus of the posterior group of nuclei (see Chapter 28). This latter nucleus has been identified in man as a specific pain and temperature relay receiving input from lamina I spinothalamic neurons (Craig *et al.,* 1995). In other mammals, e.g., cat, spinothalamic neurons terminate mainly in the posterior thalamic nuclear complex and the intralaminar nuclei. In a recent study in this animal species, evidence was presented for lamina I cells having different thalamic projection patterns for thermoreception and nociception (Craig and Dostrovsky, 2001).

Functionally, it has been demonstrated in humans that the spinothalamic tract conveys the accurate localization of pinprick and thermal stimuli. However, recovery of pain sensation after ventrolateral cordotomy indicates the potential for pathways in other parts of the cord (spinocervicothalamic tract, spinoreticular tract, intersegmental polysynaptic systems) than the ventrolateral fasciculus to transmit pain information. Division of the anterolateral pathways after cordotomy relieves pain and itch, but alters no form of tactile sensibility except for possible disturbance of discrimination (Nathan, 1990). A human case with a transection of all of the spinal cord except a superficial part of one ventral quadrant shows that this part of the cord carries sufficient information to permit touch and pressure sensation bilaterally, pain and temperature sensations contralaterally, and position sense at some joints ipsilaterally (Willis and Coggeshall, 1991). For the pain system, Chapter 30.

Spinoreticular Tract

The spinoreticular tract ascends in the ventral and lateral funiculi and ends in a number of nuclei of the reticular formation (see the anterolateral therapeutic cordotomy case in Figure 8.6). Its cells of origin are located bilaterally in the dorsal and the ventral horn. Many of its fibers are collaterals of spinothalamic tract neurons. In the primate, however, there is evidence that the spinoreticular projection is largely uncrossed.

The spinoreticular pathway responds to a wide variety of sensory stimulations.

Spinotectal Tract

The spinotectal tract consists of several components, including projections to the superior colliculus, the central gray, and the midbrain reticular formation. In the monkey, the cells of origin appear to be located in laminae I and IV–VII.

Spinocervicothalamic Tract

The lateral cervical nucleus, which is consistently found in lower mammals, is present only inconsistently in human cords (see Chapter 28). Afferent fibers to the lateral cervical nucleus arise at all cord levels from the ipsilateral dorsal horn, primarily from lamina IV. The axons travel in the dorsolateral fasciculus dorsally to the dorsal spinocerebellar tract. They synapse in the lateral cervical nucleus, which in turn projects through the contralateral medial lemniscus to the ventral posterolateral nucleus and the posterior nuclear complex of the thalamus. This system responds to a variety of sensory stimuli, primarily from cutaneous receptors. It seems to contribute to tactile conditioned reflexes, two-point discrimination, tactile and proprioceptive placing, and size discrimination. Recent studies indicate that it may be involved in nociception.

Spinocerebellar Tracts

The dorsal and the ventral spinocerebellar tracts project sensation related primarily to the lower extremities. For a more detailed account of the origin, route to the cerebellum, and lobular and zonal distribution, see Chapter 11.

Dorsal Spinocerebellar Tract

The dorsal spinocerebellar tract is located at the periphery of the dorsolateral fasciculus and arises from the ipsilateral nucleus dorsalis of Clarke. This nucleus is present from the first thoracic through the second lumbar spinal segments in humans, but is largest in the lower thoracic and upper lumbar segments. The pathway projects via the inferior cerebellar peduncle to the vermis and paravermal region of the cerebellum in the hindlimb regions. Functionally, the dorsal spinocerebellar tract conveys information from muscle spindles, Golgi tendon organs and joints, as well as from touch and pressure receptors of the lower extremities.

Ventral Spinocerebellar Tract The ventral spinocerebellar tract is located at the periphery of the ventrolateral fasciculus. Its cells of origin are distributed in laminae V and VII of the lumbosacral segments. The tract enters the superior cerebellar peduncle to terminate in the vermal and paravermal regions of the anterior lobe of the cerebellum. As a result of its numerous polysynaptic inputs and large receptive fields, the ventral spinocerebellar tract appears to relay information regarding the status of muscle groups and the entire extremity.

Cuneocerebellar Tract and Rostral Spinocerebellar Tract The cuneocerebellar tract and the rostral spinocerebellar tract are the upper extremity equivalents of, respectively, the dorsal and the ventral spinocerebellar tracts for the lower extremity.

Spinovestibular and Spinoolivary Tracts

These tracts are of uncertain existence in primates. An exception to this seems to be ascending fibers to group Z (nucleus Z) of the vestibular nuclear complex. As discussed in Chapter 28, this is a pathway for muscle spindle afferents from the hindlimb which projects further to the contralateral thalamus and cortex (see also Willis and Coggeshall, 1991).

It was thought previously that Helweg's tract, a small bundle of fine fibers located peripherally in the ventral part of the cervical ventrolateral fasciculus, contained spinoolivary fibers. This has been denied by Smith and Deacon (1981), who concluded that in the human cord Helweg's tract comprises a majority of descending fibers.

There are profound differences between spinal cord and peripheral nerves in terms of their development, normal structure, organization and function, as well as in reactions to injury. The general principles in organization of the spinal cord and peripheral nerves differ with regards to the structure of the nerve–glia cell units and their surrounding extracellular space. In contrast to the quite arbitrary distribution of nerve fibers with different functional modalities in the peripheral nerves (Sunderland, 1945; see also Chapters 4–6), there is a clustering of nerve fibers according to function, modality, and somatotopy in the spinal cord (see Chapters 7 and 8). The condensed and advanced functional neuronal arrangements in the spinal cord are therefore quite different from the situation in the peripheral nerve.

All nerve fibers in the peripheral nervous system (PNS), except for those extending from postganglionic autonomic neurons, are also in part located in the central nervous system (CNS). Given the large differences in organization between the two compartments, most nerve fibers in the PNS show profound transformations when entering the CNS compartment. Although the conversion in cellular and histological organization from the peripheral nerve to the spinal cord occurs abruptly at the peripheral–central nervous interface in the transitional region (see below), somatotopic and functional characteristics change more gradually. Thus, there is a nerve fiber segregation by modality in the human nerve trunk (Hallin *et al.*, 1991). Closer to the spinal cord, in the spinal nerve roots, there is an even higher level of organization compared to the peripheral nerve trunk. The afferent sensory nerve

fibers are separated from the efferent fibers according to the law of Magendie (Cranefield, 1974), so that in principle, dorsal roots contain afferent nerve fibers, while efferent motor fibers are found in the ventral roots. At the junction between spinal cord and roots, there is a profound redistribution and reorganization of nerve fibers as well as of endoneural vessels.

THE SPINAL CORD-SPINAL NERVE ROOT JUNCTION

Gross Morphology

When approaching the spinal cord, the nerve root is at some distance split into several thinner components called rootlets, which in turn separate into still thinner minirootlets before joining the spinal cord. These entities are separated by pia and root sheath derivates. The rootlets and minirootlets of the dorsal root merge to form a socket of white matter at the junction with the spinal cord in the dorso-lateral sulcus, whereas in the ventral root, the minirootlets are less closely packed and enter the ventral aspect of the spinal cord as separate units (Fig. 9.1).

The segment of the spinal nerve root situated closest to the spinal cord, i.e., the root-spinal cord junction, contains a specific and specialized part of the nervous system where most of the translations between the peripheral nerve and spinal cord occurs (Carlstedt, 1977; Fraher, 1992, 2000). This part constitutes the PNS–CNS transitional region (TR). This region is characterized by the presence of a projection of CNS tissue from the spinal cord together with PNS tissue in the most proximal part of the root. The contour of the CNS projection is usually dome shaped with a peripherally oriented convexity (Berthold and Carlstedt, 1977). In cervical ventral roots the PNS–CNS interface is situated beneath the surface of the spinal cord (Fraher, 1978). A short length of the CNS projection into the rootlet makes its convexity less marked. The farther the CNS tissue extends into the root the more pointed it becomes. This CNS part of the root becomes longer in a caudal direction along the spinal cord. The CNS outgrowth is particularly conspicuous in the first sacral dorsal root (Tarlov, 1937). As a rule, the CNS part of the root is longer in sensory than in ventral roots.

Thus, the TR is the most proximal free part of the root which in one and the same cross-section contains both CNS and PNS tissue (Fig. 9.2).

The term transitional region has been chosen rather than "entry zone," "junction," or "border" because it gives greater emphasis to the conceptual importance of the structural changes that take place in association

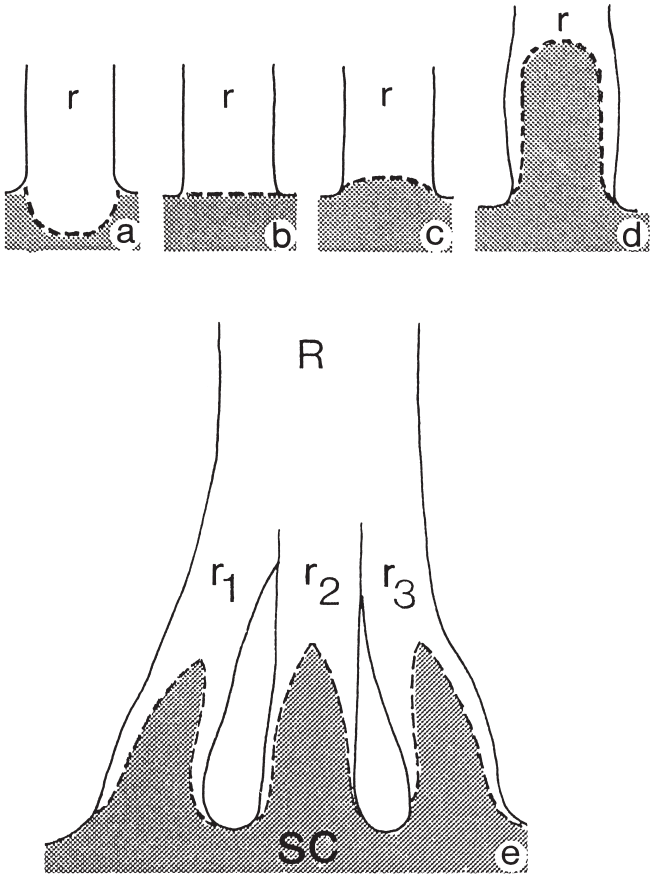

FIGURE 9.1 Schematic representation of the root–spinal cord junction with different PNS–CNS arrangements. **(a–c)** Concave, inverted flat, or slightly convex transitional region (TR) in cervical ventral roots. **(d)** Convex, dome-shaped, or pointed TR in dorsal roots in the caudal part of the spinal cord. The root splits into rootlets (r), each with its own TR and attaching separately to the spinal cord (SC; **e**). From Berthold, C. H., Carlstedt, T., Cornetrusson, O., Peripheral Neuropathy. 73–91, 198, 1993

with a more extended and spacious structure than is indicated by the other terms. When comparing PNS and CNS tissue, the PNS tissue is characterized by axon–Schwann cell units demarcated by a basement membrane suspended in a collagen-rich extracellular space, the endoneurial space. This is in contrast to the CNS tissue, in which the extracellular space is exceedingly small, collagen is lacking, and the axons are embedded in a complex network of oligodendrocyte and astrocyte processes. The interface between the axial CNS compartment and the surrounding PNS compartment is refered to as the CNS–PNS borderline, which is penetrated by nerve fibers. In this way, nerve fibers in the PNS extend into the CNS or vice versa and thus traverse the TR. This region therefore holds a position of conceptual importance with regard to neuronal organization as well as a model system for experi-

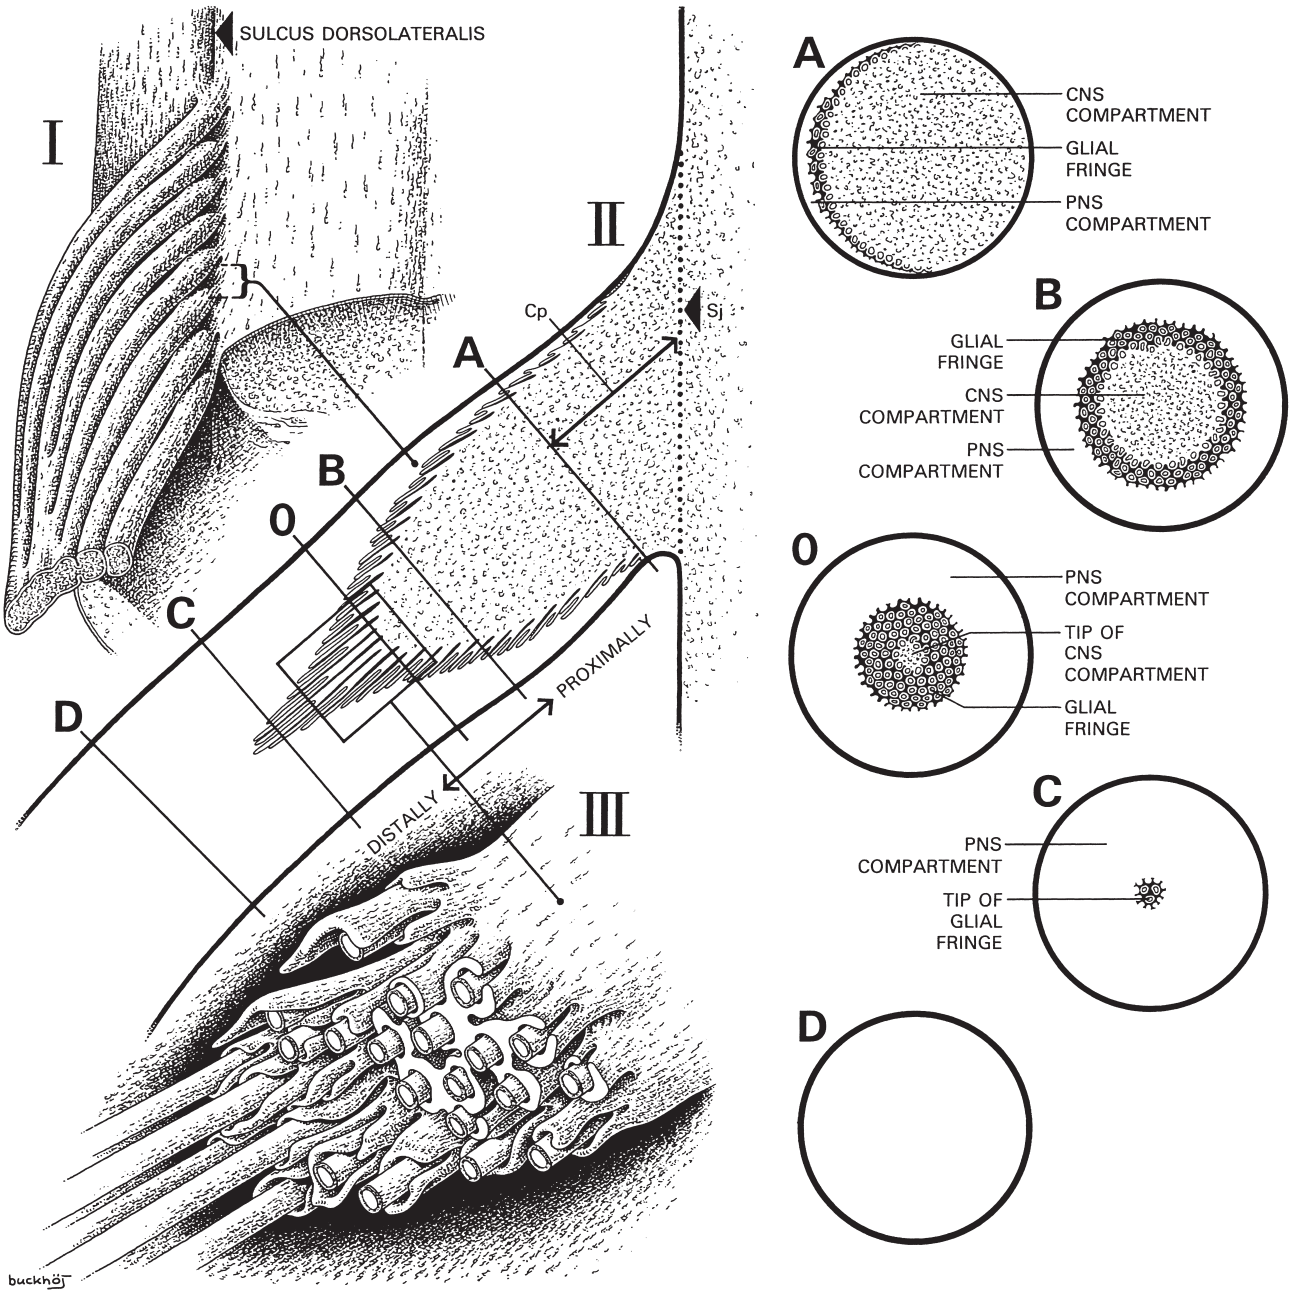

FIGURE 9.2 Schematic drawings showing the S1 dorsal root (I), a frontal section through the transitional region of a S1 doorsal rootlet (II), and the distal part of the glial fringe (III). **I.** The dorsal root S1 and part of its spinal cord segment as viewed from behind.The rootlet marked out by the bracket is present at higher magnification in II. **II.** Frontal section through the TR. The proximal and distal directions as well as the longitudinal axis of the rootlet are indicated. Five reference cross sections levels (A, B, C, D, and O) through the proximal part of the S1 dorsal rootlet are marked. The transitional region extends between levels A and C. The dotted line indicates the spinal cord–rootlet junction (Sj). The wedge shaped part of the rootlet situated between level A and the spinal cord–rootlet junction (Sj) is denoted the connecting piece (Cp). The tip of the cone-shaped CNS compartment is situated at level O. The tip of the glial fringe is located at level C. Level D runs through the stereotype part of the rootlet some 200–400 µm distal to the TR. The picture is not drawn to scale. **III.** Artistic view of glial fringe. Only myelinated fibers are indicated. From T. Carlstedt, Thesis 1977.

mental investigations regarding differences in reaction patterns within one and the same neuron in the two main parts of the nervous system.

Structural Elements in the PNS–CNS Transitional Tegion

The PNS compartment contains up to 100-µm-long extensions of fibrous astrocytic processes. These extend from the CNS compartment forming a fringe among the nerve fibers. The individual parts of this fringe are demarcated from the endoneurial space by a basement membrane. Similar to the organization in the glia limitans membrane, desmosomes, tight junctions, and gap junctions are common between individual astrocytic processes in the fringe. Closer, about 5–20 µm distal to the CNS compartment (the PNS–CNS borderline), the fringe becomes thicker, separating or enclosing individual myelinated nerve fibers in a tube- or holster-like fashion. In this way the most proximal PNS part of the myelinated nerve fiber, the paranode, is situated in an endoneural cul-de-sac that at the bottom contains a node of Ranvier. There is a hybrid transitional PNS–CNS node of Ranvier as the myelinated nerve fibers pass the TR (Fig. 9.3). The basement membrane coating the glial fringe is reflected over to the nerve fibers at the bottom of the various cul-de-sacs and continuous with the Schwann cell basement membrane. Here, there is a unique apposition between astrocytes and Schwann cells (Fig. 9.3). In the glial fringe there is an occurrence of a small uncharacterized cell type. Since such cells are invested by a basement membrane, they suggest an epithelial origin or may represent some sort of aberrant Schwann cells (see "Developmental Aspects").

The CNS compartment is dominated by fibrous astrocyte cell bodies and a dense network of astrocytic processes. The occurrence of astrocytes is about 10 times as high as for the white matter or the glia limitans. They seem to be concentrated at the transitional nodes of Ranvier for the larger myelinated fibers. Oligodendrocytes and microglia are rare. There are no vessels in the CNS compartment. The capillaries in the endoneural space of the PNS compartment do not cross the PNS–CNS borderline with the nerve fibers but deviate out from the rootlets to join vessels in the pia mater. Nor are there any vessels from the spinal cord proper in the CNS compartment. This indicates that the different permeability properties of vessels in the nerve and the spinal cord maintain different types of barriers, e.g., blood–nerve and brood–brain barriers, with different permeability properties. The lack of blood vessels means that the CNS compartment has to rely on diffusion of nutrients and waste products for a distance of sometimes more than 1 mm for a proper metabolism.

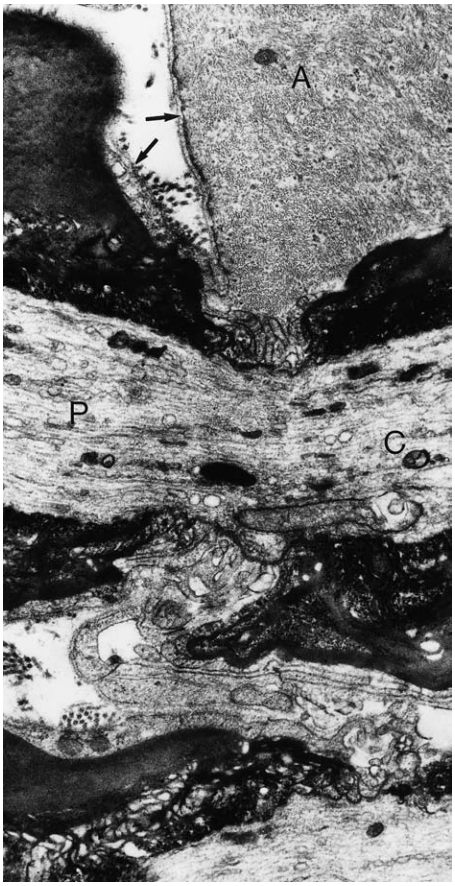

FIGURE 9.3 Electron micrograph of a longitudinal section through a transitional node of Ranvier. The proximal end of a part of the glial fringe surrounding the proximal peripheral paranode is seen outside the node gap. The Schwann cell basement membrane is continuous with that outlining the astrocyte outside the node gap (×25,000). From Berthold, C.H. and Carlstedt, T. *Acta Physiol Scand. Supp.* 446, 1977

Passage of Nerve Fibers through the Trasitional Region

There is an extensive reorganization particularly of dorsal root nerve fibers in the PNS compartment as they approach the CNS compartment. This part of the root seems to act as a sieve, organizing fibers according to size and function in preparation for their entrance into different fiber tracts of the spinal cord. The largest fibers become directed to the center of the root. The larger myelinated fibers in the dorsal root are known to project mono- or disynaptically to the motoneurons and to join the lemniscus pathways; some of them enter the posterior horn of the spinal gray matter and ramify.

The thinly myelinated and unmyelinated fibers are repositioned at the periphery of the root, aggregating just deep to the surface of the rootlet sheath and concentrated to the ventro-lateral zone of the rootlet. They therefore enter into the CNS close to the spinal cord. These fine fibers are aiming for the superficial layers of the dorsal horn, a segregation according to function occurring in the TR for adaptation of the peripheral nerve to the spinal cord. This segregation of the thin fibers, which mainly are concerned with pain, is the anatomical basis for the neurosurgical pain treatment of superficial rhizotomy (Sindou *et al.*, 1974; Berthold and Carlstedt, 1977). The myelinated fiber change from PNS to CNS type of organization occurs in a transitional node of Ranvier situated at the proximal end of a glial fringe cul-de-sac at the PNS–CNS borderline (Fig. 9.3). This node is a composite PNS–CNS node consisting of PNS components in its distal half, and CNS components in the proximal half. There is no change in size at the borderline passage. The larger unmyelinated fibers in the PNS part (>0.6 μm) become small myelinated fibers when crossing into the CNS compartment because of the different axon dimensions that initiate myelination in the PNS and the CNS, respectively. Thus, among the afferent nerve fibers there is conceptually a third group of nerve fibers being a hybride of a myelinated and unmyelinated axon. Fine unmyelinated fibers become invested by astrocyte processes rather than Schwann cells at the PNS–CNS crossing.

DEVELOPMENTAL ASPECTS

During early embryonic development the peripheral nerves and roots are formed by neurite outgrowth from neural tube and neural crest cells (Hamilton *et al.*, 1972; Horstadius, 1950; Pannese, 1974). Axons enter and exit the vertebrate spinal cord at specialized regions along the neuraxis. With a location at prospective exit and entry sites of the neural tube, just before axons arrive, a population of cells appear that have migrated from the neural crest. These cells form "boundary caps" delineating the site of presumptive exit–entry points (Golding *et al.*, 1997). They express a cell adhesion molecule, which is thought to be important for the adherence of these cells to the neural tube as well as to each other. The establishment of these exit–entry sites along the neural tube could be initiated by restricted domains of the neural tube basal lamina defining where the migrating boundary cap cells arrest and conglomerate or, alternatively, specific groups of neuroepithelial cells differentiate at the presumptive exit–entry points (Lumsden and Keynes, 1989). These cells would degrade the basal lamina by secreting proteases and create the attachment of neural crest cells. The boundary cap cells are acting as a potential source of chemoattractant, guiding early sensory axons to entry sites or motor axons to exits points (Guthrie and Lumsden, 1992; Niederlander and Lumsden, 1996). Schwann cell–astrocyte interfaces at the surface of the spinal cord are generated as a result of these interactions. Mostly these interfaces are segregated into distinct dorsal (afferent) entry and ventral (efferent) exit points. This segregation of the function of the dorsal and ventral nerve roots is often referred to as the law of Magendie (Cranefield, 1974). However, in addition to motor axons and preganglionic axons, ventral roots also contain unmyelinated or thin myelinated sensory axons and postganglionic sympathetic axons. Human ventral roots have been shown comprise a proportion of sensory axons (Phillips *et al.*, 2000), including some 15–30% unmyelinated axons (Coggeshall *et al.*, 1975). Many of these appear to represent pain transducing axons (Hosobuchi, 1980). It has therefore been assumed that ventral roots channel sensory axons to the CNS. However, observations in the cat indicate that these axons end blindly, enter the pia mater, or loop and return toward the periphery, and that these units reach the CNS via dorsal roots (Risling *et al.*, 1984). Thus, as it stands now, it seems that the law of Magendie still gives an accurate description of the function of the ventral and dorsal roots (see Hildebrand *et al.*, 1997). However, it cannot be excluded that these sensory axons may have a role in radicular root pain mechanisms since they seem to provide both the ventral roots and the ventral pia mater with mechanosensitive pain fibers (Frykholm *et al.*, 1953; White and Sweet, 1955).

Preceding the establishment of a Schwann cell–CNS glia, i.e., astrocyte, interface during early embryonic life, there is an outgrowth of neurites. Motoneuron axons leave the ventral horn in intramedullary bundles that cross the ventral white matter of the spinal cord. Dorsal root nerve fibers grow through the dorsal root to enter the spinal cord (Smith, 1983; Altman and Bayer, 1984; Mirnics and Koeber, 1995). Subsequently, there are different mechanisms governing the patterning of the central projections within the spinal cord (Fitzgerald *et al.*, 1993; Sharma *et al.*, 1994; Messersmith *et al.*, 1995; Puschel *et al.*, 1996; Redmond *et al.*, 1997). The first dorsal root nerve fibers to enter the spinal cord are the NT-3-dependent muscle sensory afferents.

The PNS–CNS border is initially situated at the very junction of the root to the spinal cord surface and there is no transitional region. Clusters of primitive Schwann or boundary cells cling to bundles of axons that pass through openings in the external glia limiting membrane of the spinal cord (Carlstedt, 1981) (Fig. 9.4). Schwann cell processes extend to the cord surface. The basement

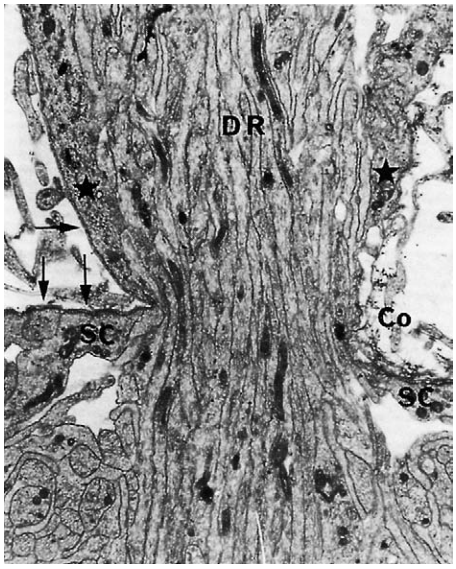

FIGURE 9.4 Electron micrograph of longitudinal section through the dorsal root (DR)–spinal cord (SC) junction during early embryonic life. There is not yet a TR developed. Bundles of immature neurites pass through an opening in an early glia limitans. The basement membrane of dorsal root satellite cells (*) is in continuity with that of the spinal cord *(arrows)* (×5000). Reproduced from T. Carlstedt, *J. Neurol. Sci.* **50,** 357–372, 1981, with permission from Elsevier Science.

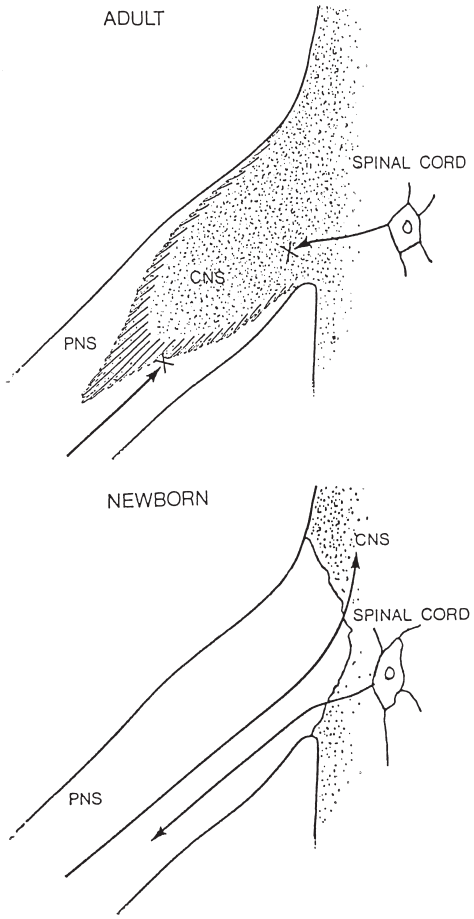

FIGURE 9.5 Schematic drawings. In the adult situation growth of lesioned dorsal root axons as well as intrinsic spinal cord neurites is impeded in the TR. A dorsal root injury that occurs before the TR has started to develop results in axon growth into as well as out from the spinal cord. Reproduced from T. Carlstedt *et al. Brain Res. Bull.* **22,** 93–102, 1989, with permission from Elsevier Science.

membrane of the root is continuous with that of the spinal cord. After nerve fiber separation by migrating Schwann and glia cells and the subsequent initial myelination, the first shallow "glia dome" is formed in the root. Since a CNS protrusion is in conflict with the already established PNS type of myelination of the nerve fibers a profound reorganization follows. Thus, there is a demyelination and disintegration of the most proximal PNS internodes, and a redistribution of detached Schwann cells to unmyelinated fibers as well as aberrant cells. The initial "PNS territory" is occupied by the rapidly extending CNS tissue until a cone of CNS tissue is formed and a TR is established in the most proximal part of the root. (Berthold and Carlstedt 1977, Carlstedt, 1981).

EXPERIMENTAL STUDIES OF THE TRANSITIONAL REGION

General aspects on regeneration through the Transitional Region

Historically, interest in the anatomy of the TR was derived from its involvement in various pathological processes, such as syphilis, acustic neuroma, amyloidosis, poliomyelitis, Werdinger–Hoffman disease, and herpes simplex virus infection. The segregation of axons that takes place in the TR has also served as a basis for certain neurosurgical procedures aimed at alleviation of pain (Sindou *et al.*, 1986). The TR is now used as a model to study the differentiated neuronal regenerative capacity in the PNS and CNS, respectively, as this region offers the unique opportunity to analyze within a limited area the same nerve fiber as it appears in the PNS and CNS.

In the mature mammal, neurons cannot negotiate an elongation across the transitional region and grow into or out of the spinal cord (Oorschot and Jones, 1990; Fig. 9.5). The astrocyte-rich CNS compartment is most effective in preventing regeneration. The lack of appropriate tissue components in the CNS, such as nerve growth factors and extracellular matrix molecules together with growth inhibitory molecules within the CNS are thought to be important in this failure

(Korsching, 1993; Schwab *et al.*, 1993). Thus, regenerating afferent axons are arrested, forming terminal enlargements or synaptoid endings indicating contact inhibition (Carlstedt, 1985). After dorsal root lesion, the astrocytes of the TR form a fibrous astrocytic scar to the same extent as after mechanical injury in the CNS compartment, but depending on the characteristics of the regrowing neurons, the astrocytes express different phenotypes, as well as disintegrate if regeneration of PNS neurites to the CNS root segment is prevented (Carlstedt *et al.*, 1989). Extension of neuronal processes from the spinal cord neurons into the root does not occur after a root lesion.

In the immature mammal, regrowth of severed root neurites as well as new growth from intrinsic spinal cord neurons may occur before the TR has been established. There is a rather sharp cutoff time limit coinciding with the establishment of astrocytes as the earliest CNS compartment in the root (Carlstedt, 1988). Thus, it has been claimed that reconnection between the spinal cord and the peripheral nerve is possible only before the TR has been established in early life (Carlstedt, 1988). However, in recent years regeneration between the CNS and PNS compartments have also been demonstrated in the adult stage. The first demonstration of this possibility came with the study of axon regeneration in spinal cord neurons after providing cut axons with a peripheral nerve graft (David and Aguayo, 1981). In this situation, new axons traversed the demarcation zone between CNS and PNS tissue and entered the denervated PNS graft. In another type of animal experiment, a remarkable regenerative capacity of motoneurons after a cut lesion in the ventral funiculus of the spinal cord with an ingrowth of axons through the lesion and into ventral roots could be demonstrated (Risling *et al.*, 1983). With these findings as a basis, a strategy to explore the possibility of repairing lesions where roots are avulsed from the spinal cord surface has been introduced.

Motoneuron Regeneration after Proximal Axon Injury

Like all other nerve cells, the motoneuron is dependent on interactions with its environment for its well-being and survival. Such interactions can be performed at synapses, between glial elements and the cell soma and dendrites in the CNS, but also along the peripheral axonal pathway. Special attention has been given to the relationship with the myelinating cells in the PNS, i.e., the Schwann cells, and the target muscle fibers in the skeletal muscles. By searching for molecules in these cell types, a number of putative substances with beneficial effects on motoneuron survival and regeneration have been identified. It is beyond the scope for this chapter to discuss the actions of these molecules, but it may be sufficient to conclude that the large number of molecules identified so far poses "an embarrassment of riches" (Oppenheim, 1996).

With the notion that spinal motoneurons are dependent on substances produced by Schwann cells and target muscle fibers for survival and axon regeneration, it may appear peculiar that an axotomy of the motor axon in a peripheral nerve does not seem to have any large influence on motoneuron survival if the lesion is induced in the adult stage (e.g., Schmalbruch, 1984; Lowrie and Vrbová, 1992). A similar lesion in young animals, such as rats in the early postnatal period, has a much more deleterious influence on the motoneurons, with virtually total elimination of motoneurons after a sciatic nerve transection at birth (e.g., Schmalbruch, 1984). Thus, it seems as if the immature motoneuron is much more vulnerable to a lesion of its axon than its adult counterpart, which may reflect a stronger dependency of extrinsic factors during early development. A situation that also appears to have a much more devastating effect on the motoneuron in the adult stage is the ventral root avulsion lesion. This lesion is followed by an extensive cell death (up to 90%) among affected motoneurons, with an occurrence mainly from 1 to 3 weeks post lesion (Koliatsos *et al.*, 1994; Novikov *et al.*, 1997; Piehl *et al.*, 1998). It is plausible to believe that the total lack of trophic support from target muscle fibers and Schwann cells in this case is a major cause of cell death. Another type of lesion in the adult mammal that seems to have a less harmful influence on the motoneuron than ventral root avulsion is, surprisingly, the central axotomy induced by an incision in the ventral funiculus of the spinal cord (Fig. 9.6). This axotomy is even more proximal than that produced by ventral root avulsion, but is followed by a larger proportion of motoneurons that survive (about 50%; Lindå *et al.*, 1993) and indeed also regenerate with new axons passing through the lesion area (Risling *et al.*, 1983). This unexpected regenerative activity may in part be a result of effects exerted by nearby denervated ventral roots and special properties of the motoneuron, but properties of the central scar tissue should also be of relevance (Risling *et al.*, 1989; Frisén *et al.*, 1995, 1998).

The potency of the regeneration of motor axons after an intramedullary lesion is illustrated by the fact that lesioned motoneurons may produce more than one myelinating axon-like process through the lesion area, and in some cases such axons may derive from distal dendrites ("dendraxons"; Lindå *et al.*, 1985). Remaining dendrites are reduced in size, and the number of synaptic connections with the lesioned cells

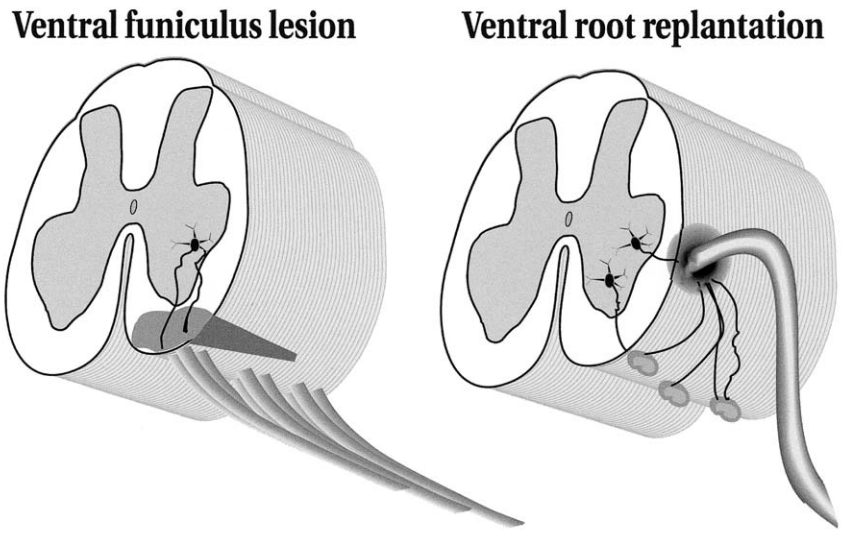

FIGURE 9.6 Schematic drawings of cross-sections through the spinal cord. Regenerative activity in spinal motoneurons is present both after an intramedullary lesion in the ventral funiculus of the cord and after replantation of avulsed ventral roots into the lateral aspect of the cord. From Risling, M. *et al.,* 1993 *Brain Res. Bull.* **30,** 405–411.

is diminished, especially on the cell body and proximal dendrites (Lindå *et al.,* 1992). There also seems to be a preferential loss of excitatory, glutamatergic inputs to the motoneuron in this situation, probably leaving the cells under an inhibitory influence during the repair process (Lindå *et al.,* 2000). These events may mirror a shift in the metabolism of the severed motoneurons from subserving the role for the motoneuron as a commander of muscle activity to a state where the primary goal is to survive and produce new axons.

Repair of Ventral Root Avulsion Lesions in Animals

With the background that spinal motoneurons can survive and regenerate even after a central lesion to their axons, one might expect that motoneurons could be rescued and produce new axons by offering them a peripheral nerve conduit after ventral root avulsion. The simplest and most obvious way to do so is to replant avulsed roots to their original position at the ventral root exit or at least to the spinal cord surface. Thus, after avulsion of lumbar ventral roots supplying the hindleg muscles in rat and cat, and the subsequent replantation of avulsed roots into the lateral part of the spinal cord (Fig. 9.6), it could be demonstrated morphologically after axonal uptake and retrograde transport of a tracer substance (horseradish peroxidase), or after direct intracellular labeling of single motoneurons, that a large number of neurons, presumably motoneurons, are able to let new axons grow out into the implanted roots (Carlstedt *et al.,* 1986; Cullheim *et al.,* 1989). By electrical stimulation of the operated roots it was also possible to show that such regenerating axons can make functional contact with denervated muscle and induce muscle contractions (Fig. 9.7).

A prerequisaite for a meaningful recovery of motor function after ventral root replantation is adequate connection of the motoneurons that reinnervate paralyzed muscles to other neurons. By intracellular recordings from single nerve cells it has been possible to demonstrate that regenerating motoneurons may be positioned in reflex arcs with excitatory and/or inhibitory effects on the motoneurons (Fig. 9.7b–d). With regard to the ability of the motoneurons to find the same muscle that they initially innervated, results from rat and cat studies suggest that there occurred a substantial degree of cross-innervation, with probable negative functional consequences (Carlstedt *et al.,* 1986; Cullheim *et al.,* 1989); (Fig. 9.7e).

The same type of operation in monkey with a change of location for the ventral root avulsion lesion to involve the lower part of cervical spinal cord with projections to the upper limb has shown that regenerating axons from a large number of motoneurons could be found in a small-muscle nerve (Carlstedt *et al.,* 1993). In fact, the number of labeled motoneurons was larger on the lesion side than on the intact side. This could be interpreted as if motoneurons after replantation of a ventral root produce several axons in different nerve branches. However, the most important result from these studies was that the monkeys, after an initial reinnervation phase with synkinesis of antagonistic musculature, with time were able to perform adequate voluntary

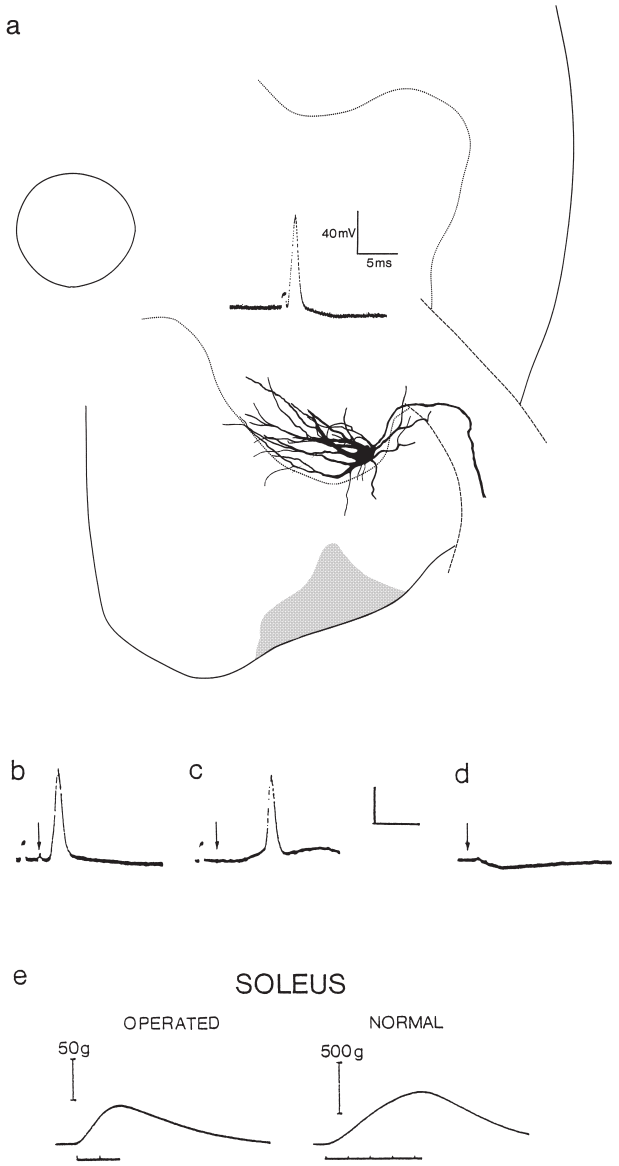

FIGURE 9.7 **(a)** A cat spinal lumbar motoneuron visualized by intracellular staining with horseradish peroxidase. After avulsion and reimplantation of a ventral root laterally a new axon has grown out into the implant. An action potential can be elicited by antidromic electrical stimulation of the ventral root. **(b–d)** Intracellular recordings from different motoneurons with axon outgrowth via implanted ventral roots. In (b) is shown an antidromically evoked action potential after stimulation of the implanted root. In (c) the same motoneuron has been activated orthodromically by stimulation of the tibial nerve in the popliteal fossa. In this way an excitatory postsynaptic potential (EPSP) is produced via primary afferent fibers. The EPSP in turn elicits an action potential. In yet another motoneuron **(d)** an inhibitory postsynaptic potential (IPSP) is elicited after stimulation of the tibial nerve. Scale bars: vertical, 20 mV, horizontal, 2 ms. **(e)** Electrical stimulation of an implanted ventral root gives rise to a contraction in the soleus muscle. The much faster contraction time in the operated animal than in the normal one strongly suggests that reinnervating motoneurons normally support fast-twitch muscle fibers. Reproduced from S. Cullheim, T. Carlstedt, and M. Risling, *Spinal Cord* **37,** 811–819, 1999, with permission from Nature Publishing Group.

movements in primarily proximal muscle groups in the arm (Carlstedt *et al.*, 1993; Hallin *et al.*, 1999).

The described approach rests on the fact that replantation of denervated ventral roots in the vicinity of motoneurons provides a favorable situation for motoneuron survival and regeneration after an axotomy at the CNS–PNS interface. As mentioned above, there is ample evidence that such a strategy may rescue the vast majority of lesioned motoneurons if it is performed within a rather short time from the time of lesion in the rat, but probably much later in the monkey (Hallin *et al.*, 1999). By the administration of substances with known trophic effects on the motoneurons, it may be possible to extend the time interval between lesion and surgery. Thus, it has been shown that intrathecal infusion of brain-derived neurotrophic factor may promote long-term survival of lesioned motoneurons and even induce abundant motor axon regeneration from the avulsion zone along the spinal cord surface, also in the absence of ventral root replantation (Novikov *et al.*, 1997; Novikova *et al.*, 1997). Therefore, a combination of ventral root reconstitution and treatment with neurotrophic factors may be a promising mean for the support of motoneuron survival and motor axon regeneration after ventral root lesions.

Repair of Human Cases of Ventral Root Avulsion Lesions

The technique to repair ventral root avulsion lesions as developed in animal experiments has been applied to humans. Thus, in patients who had sustained several spinal root avulsions, spinal cord implantation of the avulsed roots or nerve grafting was performed. Most patients, who have had spinal cord implantation, show signs of recovery. Electrophysiology has indicated regeneration through the reimplanted roots or nerve grafts by means of muscle reinnervation potentials about 9–15 months after surgery. This has been followed by muscle activity initially noted as muscle twitches (MRC grade 1) that increased in power over a period of 3–4 years (Carlstedt and Norén, 1995; Carlstedt *et al.*, 1995). Among the first 10 operated patients, 3 recovered a useful function due this surgery. In those successful cases there was a final muscle power of grade MRC 4 (Carlstedt *et al.*, 1995, 2000). Recovery occurred mainly in major proximal arm muscles containing large motor units. There was no functional restitution among the hand muscles with small motor units. However, also after a "classical" microsurgical repair of a proximal peripheral nerve injury there is a useful motor recovery limited to proximal arm muscles but rarely any recovery of hand function, probably basically due to a defective neurotropic axonal guidance to the

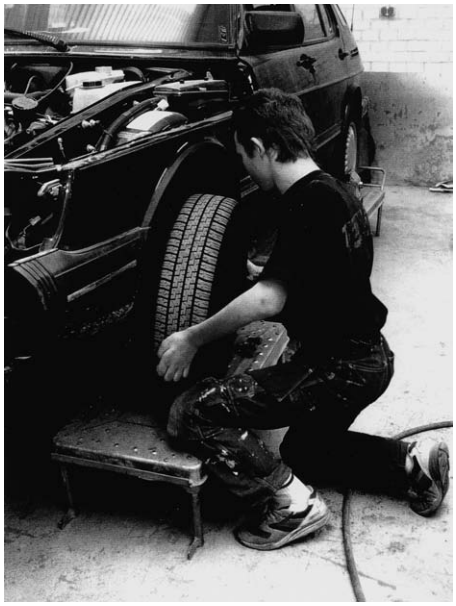

FIGURE 9.8 The first operated human case of ventral root avulsion lesion 2 years after the operation. The lesion engaged all ventral roots from C6 to T1 on the left side and there was initially a total paralysis of elbow and hand muscles. After recovery of especially elbow flexion, the patient could return to his work in a garage. Reproduced from S. Cullheim, T. Carlstedt, and M. Risling, *Spinal Cord* **37,** 811–819, 1999, with permission from Nature Publishing Group.

appropriate targets in the periphery (Brushart, 1988, 1993). Aberrant muscle reinnervation is therefore likely to result in no or poor function in the hand. In spite of this, a recovery of proximal arm function may still be of great value for the patient, exemplified by the first operation, where the recovery of function allowed the patient to go back to working in a garage (Fig 9.8).

A successful outcome occurred only in patients operated early after the injury (Carlstedt and Norén, 1995; Carlstedt *et al.*, 1995, 2000). Patients operated more than a month after the accident recovered little or nonuseful muscle power (MRC grade 1–2). This is consistent with the experimental findings of motoneuron loss after avulsion injury (see above), but also with the fact that cell programs for repair are available for a limited period and are effective if the severed axons are offered a conduit for regrowth (Skene and Willard, 1981; Tetzlaff *et al.*, 1991; Lefcourt *et al.*, 1992; Fawcett *et al.*, 1994). Therefore, if reconstruction is delayed, the growth-associated genes are down-regulated and the neurons become atrophic or die. With delay of repair there is also deterioration of the denervated muscles.

The surgical strategy to repair intraspinal and intramedullary motoneuron lesions does not account for the afferent system. Obviously the motor recovery depends on regrowth of the efferent or motor system only. The reinnervated muscles are probably deficient in proprioceptive innervation as the avulsed dorsal roots cannot be repaired (Carlstedt, 1997). It is difficult to appreciate how afferent sensory function is reintegrated with the motoneurons that have regenerated as a result of this surgical repair of ventral roots only. A central motor program alone may be sufficient to control learned simple movements, such as elbow flexion (Gandeviva and Burke, 1994). However, the afferent feedback system is essential when movements involve small precise contractions, such as finger movements (Gandeviva and Burke, 1994; Wolpert *et al.*, 1995), which do not recover in humans or in animals.

BRACHIAL AND LUMBOSACRAL PLEXUSES

Normal Anatomy

Several hundred thousand nerve fibers from the lower cervical and upper thoracic spinal cord segments interlace from the lateral aspect of the neck to the axilla forming the approximately 15-cm-long brachial plexus. It has the shape of a triangle with the base in parallel with the vertebral column and its apex in the axilla. This is the largest and most complex structure in the peripheral nervous system. It is also one of its most vulnerable parts. There are five components in the brachial plexus: five roots, three trunks, two divisions, three cords, and the nerves. The anterior primary rami of the lowest four cervical nerves (C5–C8) and the first thoracic nerve (T1) unite and branch (Fig. 9.9) in the lower part of the neck in between the anterior and middle scaleni muscles.

The most proximal muscles around the shoulder are innervated from the most proximal branches from the spinal nerves (the dorsalis scapula and the long thoracic nerves) before they started to form the brachial plexus. The trunks of the brachial plexus start at the lateral border of the scaleni muscles (upper trunk from C5 and C6, middle trunk from C7, and lower trunk from C8, and T1). From the upper trunk is the suprascapular nerve given off to innervate the rotator cuff muscles (supra- and infraspinatus). Each trunk splits behind the clavicle into an anterior and posterior division that form the cords that are situated below the clavicle and extend to the axilla. The anterior divisions form the lateral and medial cords—upper and middle trunks to lateral cord and lower trunk to the medial cord. The posterior divisions from all trunks merge into the posterior cord. The lateral and medial pectoral nerves are given off from the lateral and medial cords, respectively. The lateral pectoral nerve (being situated

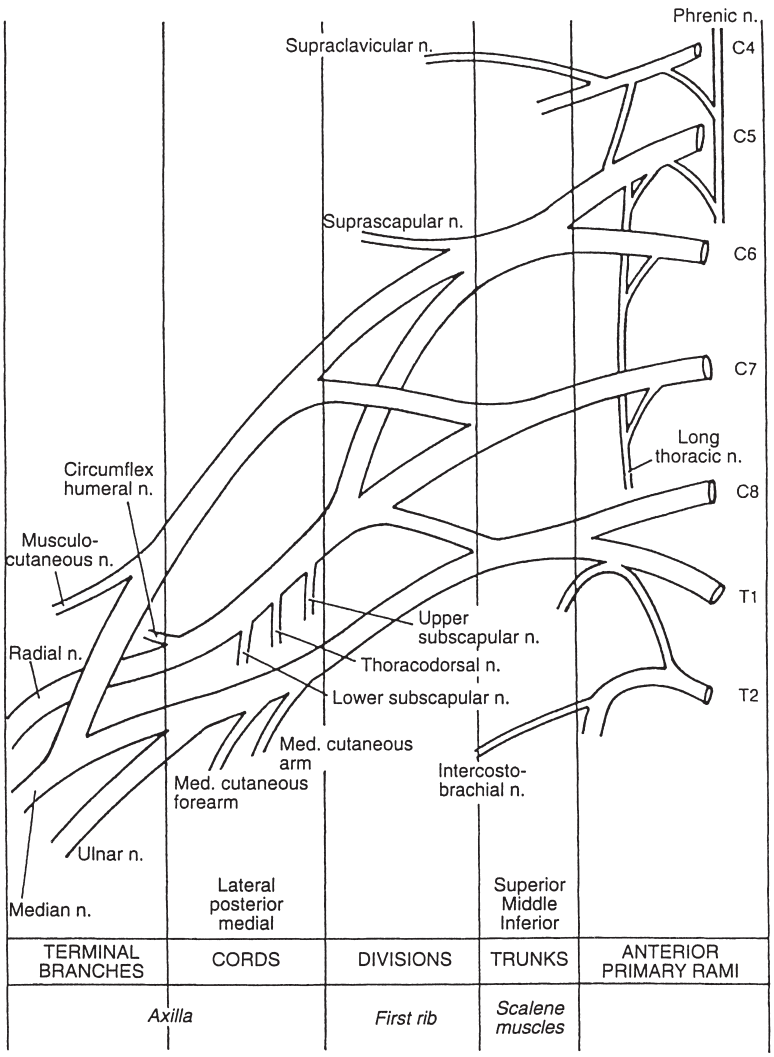

FIGURE 9.9 Schematic drawing of the human brachial plexus. Reproduced from R. Birch, G. Bonney, and C.B. Wynn Perry, "Surgical Disorders of the Peripheral Nerves," Churchill Livingstone, 1998, with permission from Dr. Rolfe Birch.

most medially of the two) is innervating the clavicular part of the pectoral muscle, while the medial pectoral nerve being more lateral innervates the sternal part of this muscle. The thoracodorsal nerve innervating the latissimus dorsi as well as teres and subscapular muscles branches from the posterior cord. At the distal end of the cords the different main nerves to the limb—median, ulnar, musculocutaneous, radial, and axillary are given off.

Thus, trunk and medial shoulder blade muscles are innervated from most proximal branches of the spinal nerves to the brachial plexus even before they have merged to form a plexus. From the trunks and the cords are nerve branches to the shoulder and proximal arm, whereas the muscles of the limb itself are innervated by branches from the main terminal nerves. This anatomical arrangement of nerve branches given off along the course of the length of the brachial plexus makes injury levels quite obvious when testing for muscle function.

The lumbosacral plexus is protected within the pelvic bony ring. Unlike the more exposed brachial plexus it is less subjected to injuries. It is less extensive and complex. Most nerves from the lumbosacral plexus are given off in the posterior abdominal or pelvic wall. The lumbar spinal nerve anterior rami form the lumbar plexus situated within the psoas major muscle in the posterior wall of the abdomen. The first to third sacral nerves form the sacral plexus on the posterolateral wall of the pelvis. Branches from the fourth lumbar ramus

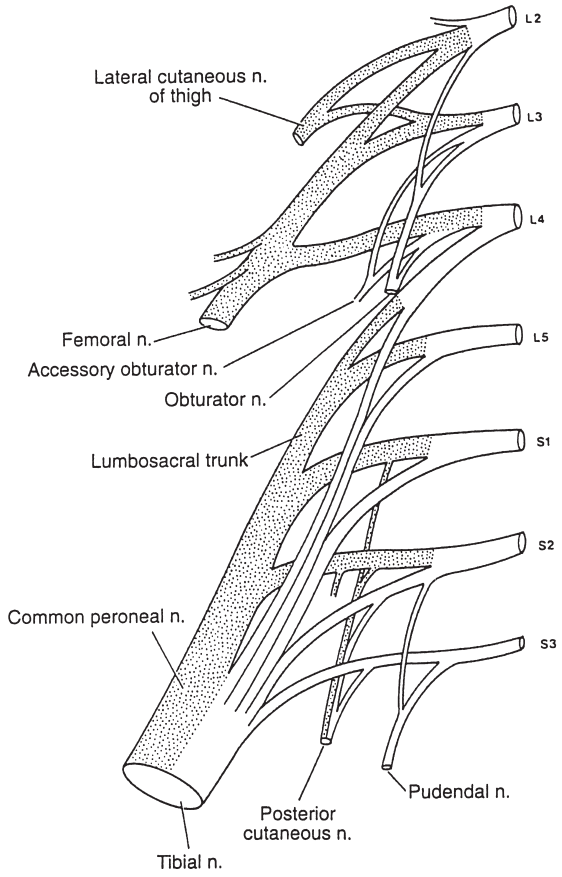

FIGURE 9.10 Schematic drawing of the human lumbosacral plexus. Reproduced from R. Birch, G. Bonney, and C.B. Wynn Perry, "Surgical Disorders of the Peripheral Nerves," Churchill Livingstone, 1998, with permission from Dr. Rolfe Birch.

and the entire fifth ventral ramus join to form the lumbosacral trunk, which emerges medial to the psoas major muscle to enter the pelvis and join the sacral plexus to form the lumbosacral plexus (Fig 9.10). Branches from the lumbar plexus innervate the skin and muscles of the lower part of the abdomen and the thigh.

The femoral nerve (L2–L4), after innervating the iliopsoas muscle, supplies the quadriceps muscle as well as skin of the thigh and the calf through the saphenous nerve. The obturator nerve (L2–L4) innervates medial muscles and skin in the thigh. Muscles in the buttock are innervated from the sacral plexus (superior and inferior gluteal nerves) as are muscles on the dorsal aspect of the thigh as well as in the calf and foot through the sciatic nerve. The organization is much less clear in the lumbosacral plexus than in the brachial plexus. Assessment of injuries as regards level of lesion in the lumbosacral plexus is obviously much more difficult by clinical means.

Plexus Lesions

One of the most devastating nerve injuries is a lesion of the brachial or the lumbosacral plexus. Restoration of limb function and control of pain after such injuries are formidable tasks. Prognosis for spontaneous recovery is often bleak, and several conditions can be recognized that make regeneration difficult (Carlstedt, 1998, Bonney, 1959, Birch *et al.*, 1998). Thus, in an injury like this, located in the most proximal part of the PNS, close to the neuron cell body, could give rise to significant neuronal death. If regeneration takes place, the new neurites would have to elongate for long distances. They would have to find their appropriate targets and form functional contacts without being sidetracked in the complex intrafascicular communications along the peripheral nerves.

The most common plexus lesion is the closed traction injury. It is usually sustained by young males following motor bike injury or children who had a complicated birth (the obstetrical brachial plexus lesion or birth palsy) (Birch *et al.*, 1998). The severity of the plexus lesion depends on the magnitude of the impact and can range from a temporary conduction block (neurapraxia), which recovers spontaneously, to a total severance (neurotmesis, avulsion) with a profound impairment of limb function, or partial lesions, sparing some activity in the limb. With regard to the brachial plexus, the injury is located supra- or infraclavicularly. The supraclavicular lesion is the most common type. In addition, there may be one or several spinal nerve roots avulsed from the spinal cord, root ruptures, or spinal nerve injuries. The birth palsy is usually sustained by a large child (> 4 kg) and located in the supraclavicular part of the brachial plexus. Most patients recover spontaneously, but severe injuries with several root avulsions may also occur. These injuries could have serious implications on the growth and development on the limb.

Detailed anatomical knowledge is the basis for diagnosis and treatment. By knowing the dermatomes and myotomes of different spinal nerves and where the peripheral nerves are leaving the plexus, a precise diagnosis of level and extension of the plexus injury can be reached. The surgical treatment should be swift and include nerve grafting to repair ruptures, as well as transfer of neighboring nerves (such as the accessory, dorsal scapular, and intercostal nerves) to reconstruct and augment function in parts of the plexus that have been severely damaged. In partial plexus lesion where hand function has been spared, it is possible to achive close to normal function with swift surgical reconstruction. In severe total lesions good supportive function and reduction of pain can be obtained by surgery (Birch *et al.*, 1998).

This chapter describes human homologues of nuclei identified in the brain stem of other mammals and attempts to extend to the human the overall organizational schemata that have been proposed for brain stem of other mammalian species. Structures of the brain stem are very diverse with respect to functions they participate in, neuroactive elements they contain, and neural pathways they accommodate. As a reflection, the anatomical organization of the human brain stem is a complex amalgam of compact neuronal groups and dispersed cell areas with varying cytoarchitecture. Many of these neurons, nuclei, and areas are given elaborate descriptions in separate chapters of this book that deal with associated functional networks, whereas the purpose of this chapter is to present an account of human brain stem nuclei and areas with discrete emphasis on the structural organization of the region, rather then functional, chemical, or pathological characteristics. It would have been inappropriate, however, to discount apparent functional characteristics of some brain stem structures, particularly when such characteristics can be used to systematize the diversity of brain stem neuronal groups. This chapter discusses a number of human brain stem structures in relation to autonomic function, vestibular system, visual system, auditory system, motor cranial nerves, or somatosensory system. However, many brain stem structures are not obviously related to a particular function, or are related to a number of functions or better known for their structural characteristics; thus, the reticular formation, precerebellar nuclei, red nucleus, locus coeruleus, and raphe nuclei are distinguished as complex structural entities and discussed in approximate rostro caudal order. This chapter also describes the distribution of some neuroactive chemicals to rationalize the details of structural delineations.

Following the original suggestion of Paxinos and Huang (1995), we also acknowledge that the radial arrangement of the human medulla with reference to the fourth ventricle (as King, 1980, proposed for the cat) is more tenable than the "quilt" pattern proposed by Olszewski and Baxter (1954). Thus, it appears that the human medulla is organized roughly in columns, commencing with a special afferent zone (vestibular nuclei) dorsolaterally and terminating in a general motor efferent zone ventromedially (hypoglossal). Intervening in a dorsal-to-ventral sequence are the somatic afferent column (spinal nucleus of the trigeminal), the visceral afferent column (solitary nucleus and the dorsolateral slab of the intermediate reticular zone), and the visceral or branchial efferent column (dorsal motor nucleus of vagus, ambiguus, and the ventromedial part of IRt). A scheme of organization along these lines was suggested by Herrick (1922) for the cranial nerve nuclei and is now

popularly used in many neuroanatomy text books.

Traditionally, nuclei have been identified using cytoarchitecture, myeloarchitecture, and connectivity. In the last 20 years, researchers have used developmental, functional, and, increasingly, chemoarchitectonic criteria to complement these traditional methods (Heimer and Wilson, 1975; Krettek and Price, 1978; Paxinos and Watson, 1998; Koutcherov *et al.*, 2000). We are of the view that for the establishment of homologies it is necessary that the human and rat brain stem be studied in parallel using the same criteria. The criteria used for establishing homologies in the present study were morphological and involve cytoarchitecture, chemoarchitecture, topography, and subnuclear organization.

Work based on chemoarchitectonic analysis began after Koelle and Friedenwald (1949) developed a simple histochemical method for revealing acetylcholinesterase (AChE), the degradative enzyme for acetylcholine. The application of AChE staining has subsequently proven very useful in distinguishing brain areas. A comprehensive delineation of the rat brain by Paxinos and Watson (1982) was done largely on the basis of AChE reactivity with Nissl staining used as a secondary criterion. In the last 30 years, AChE histochemistry was successfully used for delineation of the brain in many mammalian species. Most importantly, AChE histochemistry works well on the fresh (unfixed) postmortem human brain, which allows this method to be successfully applied to the neuroanatomical delineation of the human brain. For example, AChE staining was used in pathological studies of the brains of patients with Alzheimer's disease (Saper and German, 1987) and was recently employed to reveal the organization of the human hypothalamus (Koutcherov *et al.*, 2000). Because the AChE content of homologous nuclei is reasonably stable across mammalian species, this chapter relies mainly on AChE distribution to illustrate brain stem homologies. We have also considered cell morphology and the distribution of tyrosine hydroxylase (Chapter 14), phenylalanine hydroxylase (Chapter 13), substance P (Halliday *et al.*, 1988a), and neuropeptide Y (Halliday *et al.*, 1988c). Some connectivity data were available to us from therapeutic cordotomies (Mehler, 1974a). All findings reported here concern the human unless otherwise stated.

Abbreviations used in the Figures

10	dorsal motor nucleus of vagus
10Ca	dorsal motor nucleus of vagus, caudal part
10CaI	dorsal motor nucleus of vagus, caudointermediate part
10CeI	dorsal motor nucleus of vagus, centrointermediate part
10DI	dorsal motor nucleus of vagus, dorsointermediate part
10DR	dorsal motor nucleus of vagus, dorsorostral part
10n	vagus nerve
10Tr	vagal trigone
10VI	dorsal motor nucleus of vagus, ventrointermediate part
10VR	dorsal motor nucleus of vagus, ventrorostral part
11	spinal accessory nucleus
12	hypoglossal nucleus
12GH	hypoglossal nucleus, geniohyoid part
12L	hypoglossal nucleus, lateral part
12M	hypoglossal nucleus, medial part
12n	root of hypoglossal nerve
12V	hypoglossal nucleus, ventral part
12VL	hypoglossal nucleus, ventrolateral part
12VM	hypoglossal nucleus, ventromedial part
3	oculomotor nucleus
3n	oculomotor nerve or its root
4	trochlear nucleus
4n	trochlear nerve or its root
4V	fourth ventricle
6	abducens nucleus
6n	root of abducens nerve
7	facial nucleus
7D	facial nucleus, dorsal part
7I	facial nucleus, intermediate part
7L	facial nucleus, lateral part
7M	facial nucleus, medial part
7n	facial nerve or its root
7VL	facial nucleus, ventrolateral part
8vn	vestibular root of the vestibulocochlear nerve
9n	glossopharyngeal nerve
A1	noradrenaline cells A1
A1/C1	noradrenaline cells and/or adrenaline cells A1/C1
A2	noradrenaline cells A2
A2/C2	noradrenaline cells and/or adrenaline cells A2/C2
A5	noradrenaline cells A5
A8	dopamine cells
Acs5	accessory trigeminal nucleus
Acs7	accessory facial nucleus
AlI	alar interstitial nucleus
Amb	ambiguus nucleus
ami	amiculum of the olive
AP	area postrema
APT	anterior pretectal nucleus
Aq	aqueduct (Sylvius)
ar	acoustic radiation
Ar	arcuate nucleus of the medulla

AVC	anteroventral cochlear nucleus
b	beta nucleus of the inferior olive
B9	B9 5-hydroxytryptamine cells
basv	basal vein (drains into cavernous sinus)
bic	brachium of the inferior colliculus
BIC	nucleus of the brachium of the inferior colliculus
bsc	brachium of the superior colliculus
C1	C1 adrenaline cells
Cb	cerebellum
CC	central canal
CDPMn	caudal dorsal paramedian nucleus
CeC	central cervical nucleus
CGPn	central gray of the pons
chp	choroids plexus
CIC	central nucleus of the inferior colliculus
CIF	compact interfascicular nucleus
CLi	caudal linear nucleus of the raphe
CnF	cuneiform nucleus
cp	cerebral peduncle
Crb	cribiform nucleus
csc	commissure of the superior colliculus
CT	conterminal nucleus
ctg	central tegmental tract
cu	cuneate fasciculus
Cu	cuneate nucleus
CuR	cuneate nucleus, rotunda part
CuT	cuneate nucleus, triangular part
Cx	cerebral cortex
das	dorsal acoustic stria
DC	dorsal cochlear nucleus
DCIC	dorsal cortex of the inferior colliculus
DG	dentate gyrus
Dk	nucleus of Darkschewitsch
dlf	dorsal longitudinal fasciculus
DLG	dorsal lateral geniculate nucleus
DLL	dorsal nucleus of the lateral lemniscus
DLPAG	dorsolateral periaqueductal gray
DM5	dorsomedial spinal trigeminal nucleus
DMPAG	dorsomedial periaqueductal gray
dms	dorsomedian sulcus
DMSp5	dorsomedial spinal trigeminal nucleus
DMTg	dorsomedial tegmental area
DpG	deep gray layer of the superior colliculus
DPGi	dorsal paragigantocellular reticular nucleus
DpMe	deep mesencephalic nucleus
DPO	dorsal periolivary region
DpWh	deep white layer of the superior colliculus
DR	dorsal raphe nucleus
DRC	dorsal raphe nucleus, caudal part
DRD	dorsal raphe nucleus, dorsal part
DRI	dorsal raphe nucleus, interfascicular part
DRt	dorsal reticular nucleus of the medulla
DRV	dorsal raphe nucleus, ventral part
DRVL	dorsal raphe nucleus, ventrolateral part
DTg	dorsal tegmental nucleus
dtg	dorsal tegmental bundle
DTgC	dorsal tegmental nucleus, central part
DTgP	dorsal tegmental nucleus, pericentral part
E	ependyma and subependymal layers
EC	epicoeruleus nucleus
ECIC	external cortex of the inferior colliculus
EF	epifascicular nucleus
EL	endolemniscal nucleus
EO	epiolivary lateral reticular nucleus
EW	Edinger–Westphal nucleus
fr	fasciculus retroflexus
frpn	frontopontine fibers
FVe	F-cell group of the vestibular complex
γ	gamma pontine nucleus
g7	genu of the facial nerve
Ge5	gelatinous layer of the caudal spinal trigeminal nucleus
Gi	gigantocellular reticular nucleus
GiV	gigantocellular reticular nucleus, ventral part
Gia	gigantocellular reticular nucleus, alpha part
Gr	gracile nucleus
gr	gracile fasciculus
HIO	hilus of the inferior olive
I3	interoculomotor nucleus
I5	intertrigeminal nucleus
I8Ve	interstial nucleus of the vestibular nerve
ia	internal arcuate fibers
icp	inferior cerebellar peduncle (restiform body)
icv	inferior cerebellar vein
IF	interfascicular nucleus
IFH	interfascicular hypoglossal nucleus
II	intermediate interstitial nucleus of the medial longitudinal fasciculus
IMLF	interstitial nucleus of the medial longitudinal fasciculus
In	intercalated nucleus of the medulla
InG	intermediate gray layer of the superior colliculus
InWh	intermediate white layer of the superior colliculus
IO	inferior olive
IOA	inferior olive, subnucleus A of medial nucleus
IOB	inferior olive, subnucleus B of medial nucleus
IOC	inferior olive, subnucleus C of medial nucleus
IOD	inferior olive, dorsal nucleus
IODC	inferior olive, dorsal nucleus, caudal part
IODM	inferior olive, dorsomedial cell group

IOK	inferior olive, cap of Kooy of the medial nucleus
IOM	inferior olive, medial nucleus
IOPr	inferior olive, principal nucleus
IOVl	inferior olive, ventrolateral protrusion
IP	interpeduncular nucleus
IPA	interpeduncular nucleus, apical subnucleus
IPC	interpeduncular nucleus, caudal subnucleus
IPDM	interpeduncular nucleus, dorsomedial subnucleus
IPF	interpeduncular fossa
IPI	interpeduncular nucleus, intermediate subnucleus
IPL	interpeduncular nucleus, lateral subnucleus
IPo	interpositus
IPR	interpeduncular nucleus, rostral subnucleus
ipt	interpedunculotegmental tract
IRt	intermediate reticular nucleus
IS	inferior salivatory nucleus
jx	juxstarestiform body
KF	Kölliker–Fuse nucleus
LC	locus coeruleus
lcsp	lateral corticospinal tract
LDTg	laterodorsal tegmental nucleus
LDTgV	laterodorsal tegmental nucleus, ventral part
lfp	longitudinal fibers of the pons
ll	lateral lernniscus
LPAG	lateral periaqueductal gray
LPB	lateral parabrachial nucleus
LPBC	lateral parabrachial nucleus, central part
LPBD	lateral parabrachial nucleus, dorsal part
LPBE	lateral parabrachial nucleus, external part
LPCu	lateral pericuncate nucleus
LPGi	lateral paragigantocellular nucleus
LPtg5	lateral pterygoid subnucleus of the motor trigeminal
LR4V	lateral recess of the 4th ventricle
LRt	lateral reticular nucleus
LRtPC	lateral reticular nucleus, parvocellular part
LRtS5	lateral reticular nucleus, subtrigeminal part
lscb	lateral superior cerebellar artery (branch of superior cerebellar)
LSO	lateral superior olive
LT	lateral terminal nucleus of the accessory optic tract
LV	lateral ventricle
LVe	lateral vestibular nucleus
LVPO	lateroventral periolivary nucleus
m5	motor root of the trigeminal nerve
MA3	medial accessory oculomotor nucleus
Ma5	masseter subnucleus of the motor trigeminal
MB	mammillary body
mcp	middle cerebellar peduncle
Me5	mesencephalic trigeminal nucleus
me5	mesencephalic trigeminal tract
MG	medial geniculate nucleus
MGD	medial geniculate nucleus, dorsal part
MGM	medial geniculate nucleus, medial part
MGV	medial geniculate nucleus, ventral part
MHy5	mylohyoid subnucleus of the motor trigeminal
MiTg	microcellular tegmental nucleus
ml	medial lemniscus
mlf	medial longitudinal fasciculus
MnR	median raphe
Mo5	motor trigeminal nucleus
MPB	medial parabrachial nucleus
MPBE	medial parabrachial nucleus, external part
MPCu	medial pericuneate nucleus
MPOl	medial periolivary nucleus
MPtg5	medial pterygoid subnucleus of the motor trigeminal
MRF	mesencephalic reticular fields
MRt	medial reticular nucleus of the medulla
MRtV	medial reticular nucleus of medulla, ventral part
mscb	medial superior cerebellar artery (branch of superior cerebellar)
MSO	medial superior olive
MT	medial terminal nucleus of the accessory optic tract
mtg	medial tegmental tract
MVe	medial vestibular nucleus
MVeMC	medial vestibular nucleus, magnocellular part
MVePC	medial vestibular nucleus, parvicellular part
MVPO	medioventral periolivary nucleus
MZ	marginal zone
MZMG	marginal zone of the medial geniculate nucleus
oc	olivocerebellar tract
ocb	olivocerebellar bundle
ODPMn	oral dorsal paramedian nucleus
Op	optic nerve layer of the superior colliculus
opt	optic tract
P5	peritrigeminal zone
P7	perifacial zone
Pa5	paratrigeminal nucleus
Pa6	paraabducens nucleus
PaP	parapeduncular nucleus
PaR	pararaphales nucleus
PaS	parasubiculum
PaVe	paravestibular nucleus
PBG	prabigeminal nucleus

PBP	parabrachial pigmented nucleus
pc	posterior commissure
PC3	parvicellular oculomotor nucleus
PCRt	parvocellular reticular nucleus
PCRta	parvocellular reticular nucleus, a part
PCuMx	pericuneate matrix
PDTg	posterodorsal tegmental nucleus
Pe5	peritrigeminal nucleus
PF	parafascicular nucleus
pica	posterior inferior cerebellar artery
PIL	posterior intralaminar thalamic nucleus
PlGl	pleioglia periaqueductal gray
PLi	posterior limitans thalamic nucleus
pm	principal mammillary tract
PMn	paramedian reticular nucleus
PMnR	paramedian raphe nucleus
PN	paranigral nucleus
Pn	pontine nucleus
PnB	pontobulbar nucleus
PnC	pontine reticular nucleus, caudal part
pncb	pontocerebellar fibers
PnO	pontine reticular nucleus, oral part
Po	posterior thalamic nuclear group
PoDG	polymorph layer of the dentate gyrus
pof	post-olivary fissure
pola	paraolivary artery
polv	paraolivary vein
pos	preolivary sulcus
PoT	posterior thalamic nuclear group, triangular part
PP	peripeduncular nucleus
PPTg	pedunculopontine tegmental nucleus
PPTgC	pedunculopontine tegmental nucleus, compact part
PPTgD	pedunculopontine tegmental nucleus, diffuse part
Pr	prepositus nucleus
Pr5	principal sensory trigeminal nucleus
PRF	prerubral field
PrH	prepositus hypoglossal nucleus
PSol	parasolitary nucleus
ptpn	parietopontine fibers
Ptx	pyramidal decussation
Pul	pulvinar nuclei
PVC	posteroventral cochlear nucleus
PVM	posterior ventromedial thalamic nucleus
py	pyramidal tract
R7	retrofacial nucleus
Ramb	retroambiguus nucleus
Rbd	rhabdoid nucleus
RC	raphe cap
RDM	red nucleus, dorsomedial part
RIP	raphe interpositus nucleus
RLi	rostral linear nucleus
RMC	red nucleus, magnocellular part
RMg	raphe magnus nucleus
Ro	nucleus of Roller
ROb	raphe obscurus nucleus
RPa	raphe pontis nucleus
RPC	red nucleus, parvocellular part
RPn	raphe pontis nucleus
RPO	rostral periolivary region
RRF	retrorubal field
rs	rubrospinal tract
RtTg	reticulotegmental nucleus of the pons
RVL	rostroventrolateral reticular nucleus of the medulla
S	subiculum
s5	sensory root of the trigeminal nerve
Sag	sagulum nucleus
SC	superior colliculus
scol	supracollicular arterial network
scp	superior cerebellar peduncle
scpd	superior cerebellar peduncle, descending limb
SG	suprageniculate thalamic nucleus
SGe	suprageniculate nucleus
sl	sulcus limitans
smv	superior medullary velom
SNC	substantia nigra, compacta part
SND	substantia nigra, dorsal part
SNL	substantia nigra, lateral part
SNM	substantia nigra, medial part
SNR	substantia nigra, reticular part
SNV	substantia nigra, ventral part
SO	superior olive
Sol	nucleus of the solitary tract
sol	solitary tract
SolC	solitary nucleus, commissural subnucleus
SolD	solitary nucleus, dorsal subnucleus
SolDL	solitary nucleus, dorsolateral subnucleus
SolG	solitary nucleus, gelatinous subnucleus
SolI	solitary nucleus, interstitial subnucleus
SolIM	solitary nucleus, intermediate subnucleus
SolM	solitary nucleus, medial subnucleus
SolPaC	solitary nucleus, paracommissural part
SolV	solitary nucleus, ventral subnucleus
SolVL	solitary nucleus, ventrolateral subnucleus
Sp5	spinal trigeminal nucleus
sp5	spinal trigeminal tract
Sp5C	spinal trigeminal nucleus, caudal part
Sp5I	spinal trigerninal nucleus, interpolar part
Sp5O	spinal trigeminal nucleus, oral part
SPP	subpeduncular pigmented nucleus
spth	spinothalamic tract
SpVe	spinal vestibular nucleus
SSol	subsolitary nucleus
SSp	supraspinal nucleus
Su3	supraoculomotor nucleus
Su3C	supraoculomotor cap

SuM	supramammillary nucleus
SuVe	superior vestibular nucleus
Te5	temporalis subnucleus of the motor trigeminal
ts	tectospinal tract
tth	trigeminothalamic tract (trigeminal lemniscus)
Tz	nucleus of the trapezoid body
VCC	ventral cochlear cap
veme	vestibulomesencephalic tract
VLL	ventral nucleus of the lateral lemniscus
vlmv	ventrolateral medullary vein
VLPAG	ventrolateral periaqueductal gray
VLTg	ventrolateral tegmental area
VPI	ventral posterior inferior nucleus
VPM	ventral posteromedial thalamic nucleus
VPO	ventral periolivary nuclei
VRt	ventral reticular nucleus
vsc	ventral spinocerebellar tract
VTA	ventral tegmental area
vtg	ventral tegmental tract
VTg	ventral tegmental nucleus (Gudden)
VTgI	ventral tegmental nucleus, infrafascicular part
VTgP	ventral tegmental nucleus, principal part
VTgS	ventral tegmental nucleus, suprafascicular part
vtgx	ventral tegmental decussation
X	nucleus X
x4n	decussation of the trochlear nerve
xml	decussation of the medial lemniscus
xscp	decussation of the superior cerebellar peduncle
Y	nucleus Y
Z	nucleus Z
Zo	zonal layer of the superior colliculus

AUTONOMIC REGULATORY CENTERS

Dorsal Motor Nucleus of Vagus

Huang and colleagues (1993a, b) published a combined cyto- and chemoarchitectonic analysis depicting the human homologues of the subnuclei of the dorsal motor nucleus of vagus (10N) (Fig. 10.1–10.8). The caudal pole of the dorsal motor nucleus is found at the pyramidal decussation dorsolateral to the central canal (caudal to Fig. 10.1). At this level, it is a loose group of strongly AChE-positive cells. The cell bodies in 10N are prominent on a background of otherwise medium staining. This is in contrast with the hypoglossal nucleus, where the intense reaction in the neuropil obscures the equally intensely reactive cell bodies. The 10N is separated from the hypoglossal nucleus by the intercalated nucleus. The 10N almost reaches the periventricular gray matter at the level of the area postrema. It recedes from the ventricular surface together with the solitary nucleus, rostral to the hypoglossal nucleus. A cell-poor and AChE-negative fringe flanks the medial aspect of 10N. A few cells can be noticed within this zone, a number of which are pigmented and positive for AChE and tyrosine hydroxylase (A2 cell group). Rostrally, 10N persists as a minor medial companion to the ventrolaterally migrating solitary complex (Figs. 10.6–10.8). The compact rostral tip of the AChE-reactive 10N is succeeded by the salivatory nucleus—a scattering of AChE-positive neurons that persists until the level of the exiting fascicles of the facial nerve (Figs. 10.8 and 10.9).

In resent years several chemoarchitectonic studies demonstrated a high concentration of the somatostatin receptors (Carpentier *et al.*, 1996), cannabinoid receptors (Glass *et al.*, 1997), dopamine β-hydroxylase (Kitahama *et al.*, 1996), D2 and D4 dopamine receptors (Hyde *et al.*, 1996), and bombesin cells (Lynn *et al.*, 1996) in the human 10N.

Solitary Nucleus

The solitary tract is a heavily myelinated fiber bundle that extends from the level of the facial nucleus in the caudal pons to the spinomedullary junction. A large region of the dorsal tegmentum, mostly medial and dorsal to the tract, is the solitary nucleus. Early studies of the solitary tract in humans and experimental mammals have established that the tract is composed of fibers from the trigeminal and facial nerves rostrally (Nageotte, 1906), the glossopharyngeal nerve in the intermediate region and the vagus nerve caudally (Bruce, 1898; Papez, 1929; Pearson, 1947). Evidence from studies in experimental animals revealed the solitary nucleus (Sol) as the initial relay for baroreceptor, cardiac, pulmonary chemoreceptor, and other vagal and glossopharyngeal afferents (see Loewy, 1990). For example, the Sol in the rat is known to contain neurons activated by baroreflex afferents, while Sol projections to ventrolateral medulla are essential for baroreflex-induced sympathoinhibition and cardiovascular stimulation (Guyenet *et al.*, 1989). Further chemoarchitectonic analysis (Benarroch *et al.*,

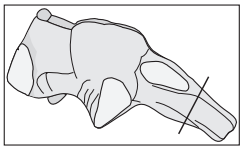

Figure 1

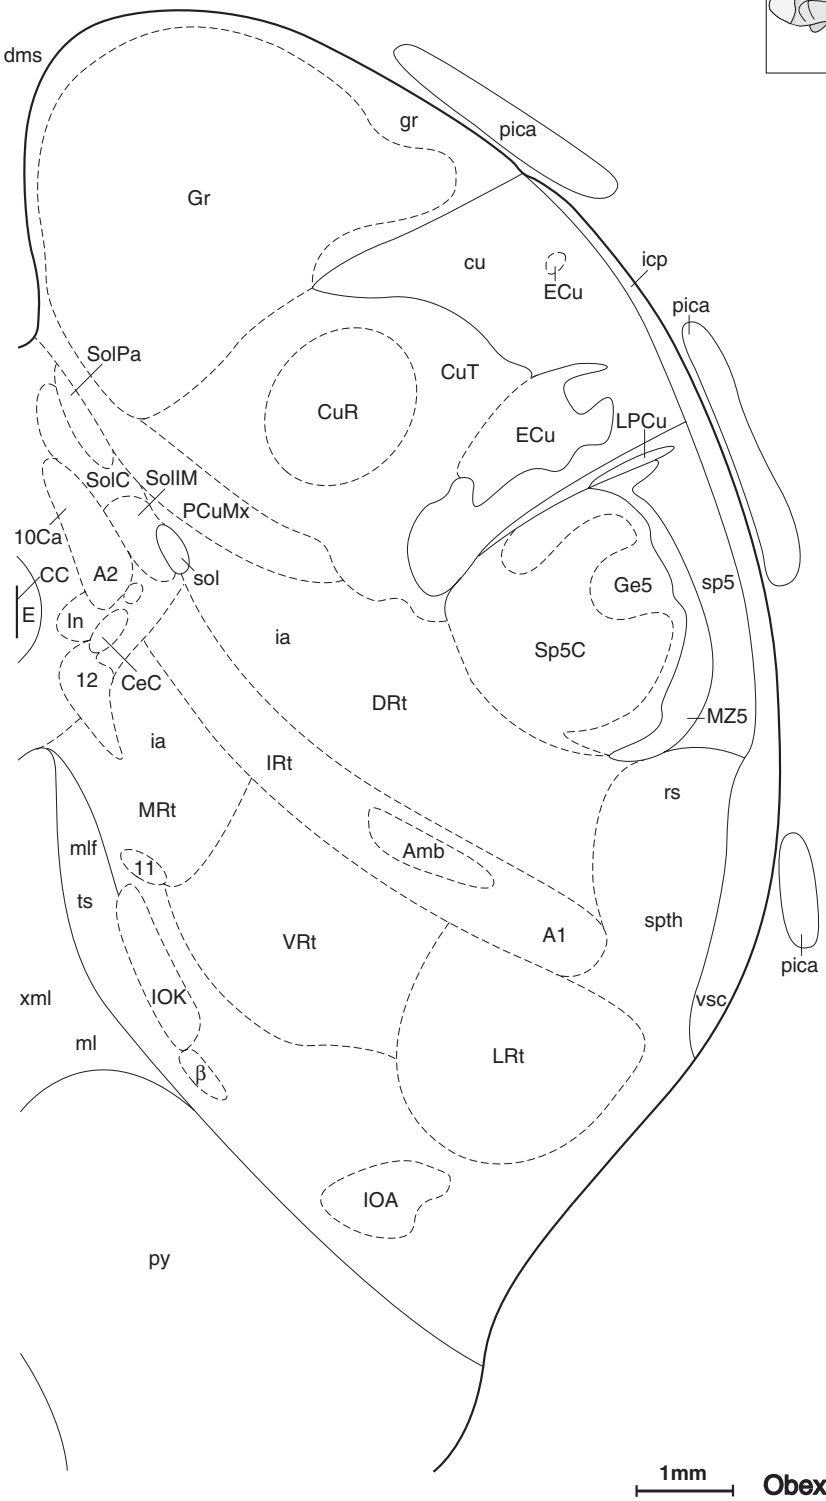

FIGURES 10.1–10.25 Coronal maps of the human brain stem presented in sections at 2-mm intervals. The medullary tissue depicted in plates 1–25 was obtained by Paxinos and Huang (1995) 4 h post mortem from a 59-year-old white male who died suddenly from a heart attack. The donor had no medical history of any neurological or psychiatric disease. The diagrams were reproduced from Paxinos, G., and Huang, X. F. *Atlas of the Human Brain Stem*, Academic Press, San Diego, 1995.

1995) revealed important topographic relationships between catecholamine and nitric oxide-synthesizing neurons, including innervation of intrinsic blood vessels (both tyrosine hydroxylase– and NADPH-diaphorase–reactive processes innervate intrinsic blood vessels in the Sol). Such topographic relationship may be associated with regulation of autonomic reflexes, sympathetic excitatory drive, and intrinsic control of cerebral blood flow in humans (Benarroch *et al.*, 1995). Recent study used postmortem horseradish peroxidase (HRP) tracing method to revealed the human Sol fiber trajectories forming three major bundles: through the intermediate reticular zone, across the dorsomedial reticular formation toward the dorsal raphe, and a ventral one toward the Gi. The terminals were shown within the Sol, dorsomotor nucleus of vagus, and reticular formation (Ruggiero *et al.*, 2000). Using chemoarchitecture, Törk and colleagues (1990), then McRitchie and Törk (1993, 1994) comprehensively delineated the human Sol (Figs. 10.1–10.9). The lowest levels of AChE reactivity are displayed by the ventrolateral, ventral, and intermediate nuclei of Sol. Slightly more reactivity is displayed by the dorsal, dorsolateral, and commissural nuclei. Intense reactivity is displayed by the gelatinous and medial nuclei. Extremely intense reactivity is displayed by the subsolitary and interstitial nuclei.

The paracommissural nucleus (SolPa) is the most caudal representative of Sol (Figs. 10.1–10.3). It appears at the level of the pyramidal decussation and ends with the advent of the gelatinous nucleus. The nucleus is conspicuous by its extremely reach AChE reactivity.

The interstitial nucleus (SolI) commences just caudal to the obex and persists until the accessory motor trigeminal nucleus, caudal to the main mass of the motor trigeminal nucleus; thus, it is the longest and the most rostral representative of Sol (Figs. 10.3–10.9). It is closely associated with the solitary tract, at times enveloping it and at times being enveloped by it. The SolI expands at its rostral pole. It is at these levels in the monkey and human that the nucleus has a gustatory function. Possible gustatory function more posteriorly is suggested by the contributions of the ninth and tenth nerves, but has not yet been confirmed. Pritchard and Norgren, in Chapter 31 provide a comprehensive review of the gustatory role of SolI. The subsolitary nucleus is found at the rostroventral border of the interstitial solitary nucleus. This cell group is characterized by extremely strong AChE reactivity (Paxinos and Huang, 1995). The intermediate, interstitial, ventral, and ventrolateral subnuclei of Sol reportedly contain light bombesin fiber/terminal staining in both the rat and the human brain (Lynn *et al.*, 1996).

Paxinos and Huang (1995) using AChE staining failed to identify the central subnucleus of the Sol in the human despite the prominent appearance of this structure in the rat brain stem. The human homologue of the central subnucleus was nevertheless identified on the basis of strong NADPH-diaphorase reactivity by Gai and Blessing (1996).

The commissural nucleus (SolC) lies ventromedial to the paracommissural nucleus and at its caudal end crosses the midline just dorsal to the central canal (Figs. 10.1 and 10.2). The SolC is composed of very small cells that tend to be mediolaterally oriented.

The gelatinous nucleus (SolG) appears in the lateral part of the solitary complex deep to the area postrema (Figs. 10.1–10.5). It contains extremely small cells that are spindle shaped and possess dendrites that are confined within the nucleus. Most cells are tyrosine hydroxylase positive, but are not pigmented and have been shown to be adrenergic (PNMT positive) (Kitahama *et al.*, 1985). The subnucleus is devoid of bombesin staining (Lynn *et al.*, 1996).

The dorsolateral nucleus (SolDL) (Figs. 10.3–10.6) displays fairly pale and patchy AChE reactivity. It contains small and medium-sized cells arranged in clusters, as well as large, darkly stained cells that are pigmented and tyrosine hydroxylase positive. The dorsolateral nucleus occupies the middle third of Sol rostral to the level of the obex.

The dorsal nucleus (SolD) (Fig. 10.6) is the rostral continuation of the dorsolateral nucleus but is distinguishable by its stronger and homogeneous AChE reactivity. Cytoarchitecturally it is heterogeneous, containing small and large cells. Clusters of bombesin-positive neurons were reported in the dorsal and ventrolateral subnuclei of the human Sol (Lynn *et al.*, 1996). Bombesin coexists with catecholamines in neurons in the dorsal subnucleus, a topographic association that may be relevant to the cardiovascular effects of bombesin.

The medial nucleus (SolM) (Figs. 10.2–10.7) is the strongly AChE-reactive region located between the dorsal, dorsolateral, ventral, and gelatinous nuclei. It is composed mainly of very small cells, although a few larger pigmented cells are also visible. The medial nucleus replaces the commissural nucleus rostrally (Fig. 10.2) and becomes a rectilinear shape as it occupies the full dorsolateral extent of Sol bordering 10 medially (Figs. 10.3–10.5). Further rostrally, it separates 10 from the interstitial nucleus of Sol. The medial nucleus disappears with the loss of 10 (Fig. 10.7). Chemoarchitectonic studies reported strong bombesin fiber/terminal staining in the medial subnucleus of Sol over its full rostral–caudal extent in both rat and human (Lynn *et al.*, 1996). Another study found the dopamine

D2 and D4 receptors to be almost exclusively concentrated in the intermediate and medial subnuclei of Sol (Hyde *et al.,* 1996).

The parasolitary nucleus (PSol) is a conspicuous, AChE-negative, banana-shaped nucleus (with a lateral concavity) featuring small, densely packed cells at the lateral border of Sol. It commences at about the level of the obex caudally and persists until the rostral third of the hypoglossal nucleus (Figs. 10.3–10.5).

Parabrachial Nuclei

The parabrachial nuclei (PB) are pivotal structures in autonomic control because they perform as an interface between the medullary reflex control mechanisms and the forebrain behavior and integrative regulation of central autonomic systems. While 13 distinct subnuclei have been identified in the rat PB (Fulwiler and Saper, 1984; Herbert *et al.,* 1990), only 5 have been discovered thus far in primates (Paxinos *et al.,* 2000). Relative to the rat, the human PB are cell poor and it is not obvious that there are human homologues to the numerous subdivisions described in the rat. Fortunately for the study of homologies, most of the PB subnuclei are chemically specified and project via somewhat distinct chemically coded lines to their terminations in the hypothalamus and medial part of the ventrobasal complex of the thalamus (see Chapter 31). The chemically coded afferent projections to the PB are also instructive in establishing subnuclei or homologies and their projection in the human. For example, consider the known catecholaminergic, cholecystokinin-, galanin-, and corticotropin-releasing hormone immunoreactive projections from Sol to the PB in the rat (Herbert and Saper, 1990; Phillips *et al.,* 2001). Somatostatin binding sites also indicate the presence of somatostatin receptors in PB (Carpentier *et al.,* 1996).

The central part of the human lateral PB contains AChE reactivity, while the dorsal part of the lateral PB is poorly stained for the enzyme. The external part of the lateral PB is also AChE positive and probably corresponds to the pigmented nucleus mentioned by Ohm and Braak (1987). The human homologue of the most medial part of the medial PB has also been identified by AChE staining.

The medial parabrachial (MPB) (Figs. 10.4–10.18) nucleus begins more caudally then the lateral parabrachial and is well displayed at the compact locus coeruleus pars alpha. The intensity of AChE staining varies between cell groups, but sometimes also between species; thus, unlike the rat, the human MPB is strongly AChE positive, especially in its juxtabrachial portion. It is limited rostroventrally by the central tegmental tract before the rostral end of the lateral parabrachial nucleus. The medial part of MPB directly overlies the ventromedial aspect of the superior cerebellar peduncle and is strongly reactive for AChE. The external part of MPB is distinguished by lower AChE reactivity than its medial part.

The lateral parabrachial nucleus (LPB) (Figs. 10.14–10.18) attains its full extent at the caudal pole of the dorsal tegmental nucleus. The AChE-positive central part of LPB succeeds the pedunculopontine tegmental nucleus caudally, which is distinguished by stronger AChE reactivity. The dorsal part of LPB is, in contrast, poorly stained for AChE. The external part of LPB is AChE positive. A quantitative autoradiographic study of human fetuses revealed a sharp decrease in the density of somatostatin binding sites on late stages of gestation (Carpenter *et al.,* 1997).

Calcitonin gene–related peptide (a neuromodulator in efferent projections from PB to the thalamus and amygdala in rats) was recently employed as a marker for ascending visceral sensory pathways in the human brain (le Lacalle and Saper, 2000). As well as in establishing affiliations of the human PB, chemoarchitecture of MPB and LPB may be of value in pathological investigation. For example, a recent study found that the density of somatostatin binding sites was significantly elevated in MPB and LPB in the sudden infant death syndrome (Carpentier *et al.,* 1998).

In the rat, the Kölliker–Fuse nucleus (KF) (Figs. 10.15 and 10.16) was proposed to harbor the most lateral cluster of the A7 noradrenergic group (Paxinos and Watson, 1998). We note, however, that KF does not form a well-circumscribed group in the rat, whereas in the cat, KF has been placed everywhere in the region between the superior cerebellar peduncle, the lateral lemniscus, and the motor trigeminal (see discussion by Berman, 1968). Paxinos and Huang (1995) depicted the location of the nucleus in the human brain stem (Fig. 10.16).

Fix (1980) identified a melanin-containing nucleus associated with the superior cerebellar peduncle. He labeled the nucleus –X, using inverted commas presumably to indicate that he did not wish this to be retained as its name. Ohm and Braak (1987) identified the same nucleus and called it the subpeduncular nucleus. This term can be easily confused with the subpeduncular tegmental nucleus (Paxinos and Watson, 1998); for this reason, Paxinos and Huang (1995) used the term subpeduncular pigmented nucleus, as did Ohm and Braak in the title of their abstract. The subpeduncular pigmented nucleus (SPP) is unmistakably AChE positive in neuropil and cell bodies. It has relatively large, tightly clustered, mostly pigmented cells presenting a globular profile in coronal section. Because SPP is attached to the ventrolateral edge of the

superior cerebellar peduncle, reaching the lateral lemniscus at the pontine surface, it has cell-poor and fibrous regions surrounding it. Caudally, it commences before the lateral parabrachial nucleus as a group of mainly nonpigmented cells ventral to the superior cerebellar peduncle. More rostrally, it is very favorably displayed and appears as a globular nucleus at the ventrolateral edge of the superior cerebellar peduncle with the majority of its cells pigmented. Further rostrally, it drifts dorsally and intrudes into LPB, tapering off as a row of cells on the dorsal part of PB. At this most rostral level, only a few pigmented cells are seen, but the characteristic AChE reactivity is present. The cells of SPP are polygonal with no specific orientation. Ohm and Braak (1987) observed neurofibrillary tangles in this nucleus in brains from Alzheimer's disease patients. Incidentally, considering their pivotal role within central autonomic regulatory systems, the nuclei of the pontine parabrachial region (MPB, LPB, SPP) together with the intermediate zone of the medullary reticular formation (IRt) are thought to be early targets of the Alzheimer's disease–related pathology (Rub *et al.*, 2001). The subpeduncular pigmented nucleus is not the homologue of the Köliker–Fuse nucleus or of any other known nucleus in experimental animals.

Periaqueductal Gray

Recent evidence suggests that the periaqueductal gray (PAG) is an important central relay in cardiovascular and other autonomic control. There is also substantial evidence for human homologies to the PAG subdivisons established in rat and cat (Bandler *et al.*, 1991; Beitz, 1995; see also Chapter 12). Thus, Paxinos and Huang (1995) identified dorsomedial, dorsolateral, lateral; and ventrolateral PAG columns in the human (Figs. 10.19–10.25). Another chemoarchitectonic investigation based on NADPH-diaphorase reactivity (Carrive and Paxinos, 1994) recognized the supraoculomotor cap in the human PAG. The posterior part of this cap was subsequently distinguished by AChE staining (Paxinos and Huang, 1995). Paxinos and Huang (1995) also outlined the human *pleoglial* PAG—a median structure above the rostral levels of the aqueduct. Like the parabrachial nucleus, the PAG forms an interface between the forebrain limbic system and medullary autonomic centers. It receives afferents from the hypothalamus and amygdala and in turn projects to the intermediate reticular zone of the medulla. Carrive *et al.* (1989) showed that the PAG autonomic control is compartmentally organized into PAG columns and coupled to defensive behavior in the rat. Paxinos and Huang (1995) showed a columnar arrangement for the human PAG, which is discussed in detail by Carrive and Morgan (in Chapter 12).

The nucleus of Darkschewitch (M) is found in the periaqueductal gray, dorsomedial to the interstitial nucleus of the medial longitudinal fasciculus at a level posterior to the ascending fasciculus retroflexus. It is nondistinct in AChE preparations. The human PAG displays certain AChE-reactive regions that have no apparent animal homology.

RETICULAR FORMATION

The keystone to the organizational plan of the medullary reticular formation offered in this chapter is the intermediate reticular zone (IRt). Rt is described in detail in Chapter 19 of this book.

Intermediate Reticular Zone

Historical Considerations

In 1986 the intermediate reticular nucleus of the rat was recognized as the zone between the gigantocellular and parvicellular reticular nuclei which contains large, medium, and small cells and is slightly more reactive for AChE than its neighbors (Paxinos and Watson, 1998, Figure 58–71). Presumably, this zone brackets the line separating the alar and basal plate derivatives in development. The line extends radially from the sulcus limitans in the floor of the fourth ventricle to the periphery of the brain stem where the vagal and glossopharyngeal rootlets emerge. Due to its cytoarchitecture and position, the zone was named the intermediate reticular nucleus. Allen *et al*. (1988) found a distinct punctuated distribution of angiotensin II receptors over cell bodies in what they proposed to be the human homologue of the rat intermediate reticular nucleus (see also Allen *et al.*, 1991). Halliday and colleagues (1988b, c), and later Huang and colleagues (1992), showed tyrosine hydroxylase, and neuropeptide Y (NPY) cell bodies and fibers in what in fact is the intermediate reticular nucleus.

Based on the evidence for the existence of the intermediate reticular zone in humans and, following mappings of tyrosine hydroxylase, serotonin, NPY, and substance P in this area, Paxinos and Huang (1995) proposed an extension of IRt boundaries. Given the heterogeneity of this area (see below), they changed its name from "intermediate reticular nucleus" to "intermediate reticular zone" (IRt). The hallmark of the cytoarchitecture of the intermediate reticular zone is the polarity of cell bodies and their major dendrites. These cells are oriented along the dorsomedial to ventrolateral axis, mirroring the shape of the zone in

coronal sections. This orientation predilection distinguishes the IRt from the adjacent gigantocellular and parvicellular reticular nuclei that contain neurons with various orientations.

Position

Caudally, the IRt separates the ventral and medial reticular nuclei from the dorsal reticular nucleus; rostrally, the IRt separates the gigantocellular from the parvicellular reticular nuclei (Figs. 10.1–10.10). The zone commences at the pyramidal decussation and extends to the facial nucleus. It is a convex arc with the convexity facing laterally in the rat but medially in the human (probably due to the enormity of the human inferior olive). Dorsally, outlying tyrosine hydroxylase–positive cells of this zone are found in the cell-poor region that caps the medial pole of the dorsal motor nucleus of vagus. Laterally, it has a variable extent. At caudal levels (Fig. 10.1), IRt reaches the lateral surface of the medulla dorsal to the lateral reticular nucleus (LRt). Somewhat rostrally (Figs. 10.2–10.6), IRt nearly bisects the LRt in its surge to the lateral surface. Further rostrally, it forms a slab dorsal to the lateral paragigantocellular nucleus and together they reach the lateral medullary surface (Fig. 10.9). Caudally, it harbors the retroambiguus, ambiguus, and Al noradrenaline cell groups. Rostrally, it harbors the ambiguus nucleus as well as the Cl adrenaline group.

Catecholamine Cells

Catecholamine cells are found throughout the IRt but are more prominent in the part ventrolateral to the ambiguus nucleus (Al and Cl). These regions of the IRt have been called the caudoventrolateral (CVL) and rostroventrolateral (RVL) reticular nuclei of the medulla (Arango *et al.,* 1988). This cell group is thought to be involved in control of sympathetic cardiovascular outflow, cardiorespiratory interactions, and reflex control of vasopressin release. For example, resent pathology study showed depletion of catecholaminergic tyrosine hydroxylase–positive neurons in patients with multiple-systems atrophy with autonomic failure (Benarroch *et al.,* 1998). The full extent of IRt can be clearly seen in Figure 4 of Arango *et al.,* which depicts tyrosine hydroxylase immunoreactivity in the medulla. This observation was later successfully used by Huang *et al.* (1992) for delimiting IRt on the basis of the distribution of the tyrosine hydroxylase–immunoreactive cells and fibers. The distribution of AChE-positive cells in the IRt resembles the distribution of the catecholamine-containing cells. The most distinct AChE positive neuropil is associated with RVL at levels where the ambiguus nucleus is most prominent. This AChE reactivity in the IRt (RVL) is associated with cell bodies and fibers and it nearly reaches the lateral surface of the brain.

Neuropeptide Y

NPY-reactive neurons are found throughout the rostrocaudal extent of the ventrolateral IRt, particularly at midolivary levels. Expression of NPY mRNA has also been reported in IRt (Pau *et al.,* 1997). Benarroch and Smithson (1997) described typosine hydrozylase (NADPH-diaphorase) distribution in the IRt. The distribution of NPY immunoreactivity overlaps typosine hydroxylase but not NADPH-diaphorase reactivity (Benarroch and Smithson, 1997), suggesting a possibility of further subdivision of human ventrolateral IRt.

Serotonin

Caudally, the lateral part of the IRt contains some serotonin cells intermixed with the catecholamine cells, though differentially concentrated. Many of these cells, particularly serotonin cells, are very close to the surface of the medulla. The more rostral regions of IRt contain only occasional serotonin cells. At rostral levels, most serotonin cells are distributed in the lateral paragigantocellular nucleus, immediately medioventral to IRt (Fig. 10.9).

At times, some chemically specified cell groups do not respect classical nuclear boundaries and no adjustment of boundaries can be made that can accommodate the new elements without violating other delineation criteria. However, the IRt has consistently appeared as an entity in the work of a number of investigators who have used retrograde or anterograde labels or different chemically specific stains. Having obtained an "afterimage" from the pattern of distribution of chemically specified elements, it is possible to detect, in Nissl-stained sections, fusiform cell bodies that are oriented in the direction of the axis that joins the dorsal motor nucleus/solitary complex dorsomedially with the Al/Cl cell groups ventrolaterally. The existence in the IRt of "independent" nuclei that do not share IRt properties prompted us to reclassify this region from a nucleus to a zone.

Substance P

Substance P is differentially distributed in the medullary reticular nuclei. IRt displays more substance P–positive fibers than adjacent nuclei. The distribution of substance P fibers in IRt is nonhomogeneous. Rostrally, IRt displays a band of substance P–positive fibers and cells near its border with the parvicellular reticular nucleus. The ambiguus nucleus is the most substance P–poor region of the IRt. Caudally, the IRt contains a few substance P–positive cell bodies that are larger than the substance P–positive cells in the parvi-

cellular reticular nucleus. All substance P cells in the IRt also contain adrenaline or noradrenaline. However, most (about 95%) of the catecholamine cells do not contain substance P (Halliday *et al.*, 1988a). Ni and Miller Jonakait (1988) have shown that substance P fibers excellently delineate Irt in the developing mouse.

Salmon Calcitonin Binding Sites

The IRt can also be delineated by the salmon calcitonin binding sites (Sexton *et al.*, 1994). It is important to mention, though, that these sites invade some regions of the parvicellular reticular nucleus and the gigantocellular nucleus.

Connections

There is evidence that cells contained in the IRt have both ascending and descending connections. For example, following small HRP injections into the parabrachial region in cats, King (1980) found separate sheets or layers of retrogradely labeled cells in '1ateral tegmental field" (Berman's, 1968) that ran parallel to the long axis of the lower brain stem and radially with respect to the ventricle. The more medial gamma and delta layers of labeled cells of King's (1980) description appear to occupy the medial region of the lateral tegmental fields [or parvicellular reticular formation (PCRt of our terminology)] that we have now incorporated into the IRt. Similarly, HRP injection into the caudal vagosolitary complex produced a comparable sheet of labeled cells extending the length of the cat's medulla in what Mehler (1983) also then called the medial part of the PCRt but which we now consider part of the IRt zone. Interestingly, anterograde tracer injection experiments involving IRt in the rat produce confirmatory evidence of ascending projections to the parabrachial region and descending projections to the solitary nucleus and the phrenic motoneuron pools at C4 (Yamada *et al.*, 1988).

In the monkey, injections of HRP into the cervical vagus nerve result in heavy retrograde labeling of neurons in the ipsilateral dorsal motor nucleus of the vagus and in the ambiguus nucleus. "Additionally, a few neurones are labeled in the intermediate zone between these two nuclei" (Gwyn *et al.*, 1985), i.e., in the IRt.

Retroambiguus and Ambiguus Nuclei

The RAmb commences below the pyramidal decussation as a scatter of AChE-positive cells embedded in the part of the IRt that is separated from the rest by the decussating corticospinal fibers. It extends to the level of the LRt, at which point it is succeeded by the Amb (Fig. 10.1). RAmb is characterized by diffuse spindle-shaped cells. Amb, by contrast, has large multipolar neurons that stain densely for AChE and display large Nissl granules. At area postrema levels the Amb is represented by only a few cells (Fig. 10.3). At the level of the caudal pole of the dorsal accessory olive (Fig. 10.4) it expands ventrolaterally to conform with the arcuate shape of the IRt. Near the level of the rostral pole of the hypoglossal nucleus it becomes a round cluster. It attains maximal size near the level of the roots of the glossopharyngeal nerve (Fig. 10.5). At this level, the AChE reactivity associated with the Amb engulfs the surrounding cell-poor zone.

Unlike other regions of IRt, RAmb and Amb do not possess catecholamine or NPY cells and are not invaded by catecholamine- or NPY-containing processes. On the other hands the human adult Amb contains serotonin immunoreactivity (Halliday *et al.*, 1990) and the human fetus Amb contains high concentrations of somatostatin receptors (Carpentier *et al.*, 1996). In addition, monoamine oxidase A, substance P, and receptors for angiotensin II are scarcest in the RAmb and Amb regions of the IRt (Paxinos *et al.*, 1990). The mode of integration of the RAmb and the Amb with the remainder of IRt is still unclear. A recent case description provided insight into the role of Amb, Sol and neighboring medullary reticular formation as well as the vagal dorsal motor nucleus in central control of swallowing. Thus, lateral medullary syndrome presented with numerous symptoms, including dysphagia, is associated with lesion in the upper medulla (Martino *et al.*, 2001).

Ventral, Medial, and Dorsal Reticular Nuclei

Considering that the existence of the IRt is accepted, the remainder of the reticular formation of the medulla can be subdivided in a scheme that is in harmony with the distribution of neuroactive compounds in this area.

The area ventral and medial to the IRt (previously known as medullary reticular nucleus, ventral part) features two distinct nuclei. These are a ventral nucleus with small and medium-sized cells that Paxinos *et al.* (1990) called the ventral reticular nucleus (VRt), and a medial nucleus with larger cells and greater AChE reactivity, which they called the medial reticular nucleus (MRt) (Figs. 10.1–10.4). The caudal pole of the VRt is found at a ventrolateral position below the retroambiguus nucleus (RAmb). Rostrally, it is displaced medially and dorsally by the advancing epiolivary lateral reticular nucleus (EO), which in turn is displaced medially and dorsally by the lateral paragigantocellular nucleus (LPGi) (Fig. 10.5). All these nuclei border the inferior olive (IO) ventrally and the IRt dorsally. Immunostaining for tyrosine hydroxylase reveals large catecholaminergic neurons in VRt.

The area dorsal and lateral to the IRt (previously known as medullary reticular nucleus, dorsal part [MdD]) contains smaller cells and fewer substance P fibers. To be consistent with the other terms in this region, Paxinos and Huang (1995) called it the dorsal reticular nucleus (DRt). The DRt contains large catecholaminergic neurons distinguishable by strong tyrosine hydroxylase immunoreactivity. It is thought that DRt servers a role of a primary pro-nociceptive center in the pain control system that integrates multiple excitatory and inhibitory actions for nociceptive processing (Lima and Almeida, 2002; Villanueva *et al.*, 2000). The parvicellular reticular nucleus is found dorsal to the IRt and rostral to DRt, from which it is difficult to distinguish.

Lateral Reticular Nucleus

The lateral reticular nucleus (LRt) consists of the lateral reticular nucleus proper, the subtrigeminal division, the epiolivary division, and the pravocellular division.

The LRt proper has AChE-positive neurons in a somewhat dense neuropil that is perforated by negative fibers with longitudinal orientation. It commences caudally at the rostral part of the pyramidal decussation (caudal to Fig. 10.1). According to Paxinos *et al.* (1990), the name "lateral reticular nucleus" is retained only for this part of the nucleus (without qualifiers such as "proper" or "prinicipal").

The subtrigeminal LRt (LRtS5) features large cells, well stained for AChE, in a dense AChE background. It commences caudal to the principal inferior olive (Figs. 10.1–10.3). At its rostral pole it becomes fractionated and discontinuous (Fig. 10.7). The LRtS5 also contains tyrosine hydroxylase–positive neurons. The LRtS5 together with VRt and DRt is thought to play a role of autonomic respiratory centers in the medulla. In support of this view, a recent study reported severe loss of catecholaminergic (tyrosine hydroxylase positive) neurons in LRtS5, VRt, and DRt in patients with myotonic dystrophy who suffered alveolar hypoventilation and respiratory insufficiency (Ono *et al.*, 1998).

The LRt extends medially over the caudal pole of the inferior olive. This epiolivary part becomes separated from the main LRt at the caudal pole of the dorsal accessory olive. Further rostrally, it shifts medially as a compact rectangular group (Figs. 10.1–10.7). Paxinos and colleagues (1990) noticed in the baboon a nucleus in a position similar to the epiolivary LRt that displays large retrogradely filled cells following thoracic HRP injections. This spinally projecting nucleus in the baboon cannot be assigned to LRt because it projects to the spinal cord rather than the cerebellum. Therefore, the epiolivary nucleus may not belong to LRt complex, although the two nuclei are nearly identical morphologically (Paxinos *et al.*, 1990). The similarity of the epiolivary nucleus to LRt was also recognized by Braak (1971).

The parvicellular part of LRt (LRtPC) betrays its presence in the rat by the extremely dense AchE reactivity. In the human, AChE reactivity is found in islets near the surface of the lateral medulla immediately external to LRt (Fig. 10.5). Small compact cells poorly stained for Nissl are associated with this reactivity is the homologue of LRtPC. In humans its size is clearly attenuated in comparision with that in the rat. For further details on LRt, see Walberg (1952).

Gigantocellular, Lateral Paragigantocellular, Gigantocellular Ventral Part, Gigantocellular Alpha Part, and Dorsal Paragigantocellular and Parvicellular Reticular Nuclei

The gigantocellular reticular nucleus (Gi) appears together with Roller's nucleus (Fig. 10.5). It extends to the level of the exiting facial nerve, where it is succeeded by the caudal part of the pontine reticular nucleus (PnC) (Figs. 10.10–10.11). Study of the cytoarchitectonic development of the human Gi suggested that immature Gi neurons appear by 16 weeks of gestation after migration and that the subsequent differentiation and maturation progresses gradually and monotonously during the latter half of gestation (Yamaguchi *et al.*, 1994).

The present description of the lateral paragigantocellular nucleus (LPGi) is based on the distribution of serotonin cells. LPGi first appears lateral to the rostral pole of the epiolivary LRt (Figs. 10.5–10.6). LPGi remains at a lateral position and always ventromedial to the IRt. When the dorsal accessory olive disappears, the LPGi expands medially (Figs. 10.7–10.8), where it persists until the rostral pole of the principal inferior olive. Along its entire length, LM features many fusiform serotonin-containing neurons. Beyond the caudal pole of LM, serotonin cells remain in the region but do not penetrate the epiolivary reticular nucleus; rather, they shift dorsally into the IRt and mingle with the tyrosine hydroxylase–positive cells of this zone. The spread of the LPGi as shown by Nissl staining matches that of the serotonin-positive cell bodies. More than 150 serotonin-positive cells can be seen on each side of a 50-µm section of the medulla. The serotonin-positive cells are larger in the LPGi (27 ± 4 µm) than in the caudal part of the intermediate reticular zone (19 ± 4 µm) (Halliday *et al.*, 1988a).

Substance P is found in many of the serotonin-containing cells in the LPGi (Halliday *et al.*, 1988b). A recent study examined proximal projections of LPGi using a bidirectional lipophilic fluorescent tracer, 1,1′-dioctadecyl-3,3.3′,3′-tetramethylindocarbocyanine perchlorate (DiI), in postmortem human fetuses and reported diffusion of DiI to the arcuate nucleus (Ar), nucleus raphe obscurus, hilus of the inferior olive, bilateral Gi and the intermediate reticular zone (IRt), vestibular and cochlear nuclei, cells and fibers at the floor of the fourth ventricle, medial lemniscus, lateral lemniscus, inferior cerebellar peduncle and cerebellar white matter, central tegmental tract, and capsule of the red nucleus (Zec and Kinney, 2001).

The Gi, ventral part (GiV) is an AChE-ppor area above the dorsal accessory olive. It borders the LPGi and IRt laterally and the Gi dorsally. Unlike the rat, cat, and monkey (see Chapter 8), the human GiV does not have giant cells. It is succeeded rostrally by the gigantocellular α part (Giα).

The Giα forms a cap over the raphe magnus (Figs. 10.9 and 10.10). It has small, medium, and large cells, many of which are oriented mediolaterally. It is bordered laterally by the central tegmental tract as the tract approaches the inferior olive. It is characterized by medium AChE reactivity and has AChE-positive cell bodies. In addition, serotonin-positive cells invade the ventral and lateral part of the GiA (see Chapter 30). The dorsal paragigantocellular nucleus (DPGi) is favorably seen in Fig. 10.10 as an AChE-poor region.

TEGMENTAL NUCLEI

Ventral Tegmental Nucleus

In 1884, von Gudden observed that in the rabbit the majority of the fibers of the mammilotegmental tract terminated in a distinct nucleus of the pontine tegmentum that he named after himself, "das Guddensche Ganglion." This nucleus is now known as the ventral tegmental nucleus (von Gudden, 1884) (VTg) and is a densely packed, conspicuous nucleus in all species studied except the human. On the basis of chemo- and cytoarchitecture, Paxinos *et al.* (1990) and, soon after, Huang *et al.* (1992) delineated VTg in humans as the large, AChE-reactive nucleus that succeeds rostrally the abducens nucleus, after allowing the root of the seventh nerve to interpose itself between the two nuclei. This area is not a rostral extension of the abducens nucleus because both nuclei taper prior to reaching either side of the root of the seventh nerve. The VTg is embedded in the lateral aspects of the medial longitudinal fasciculus (mlf), extending both ventrally into the tegmenturn and dorsally into the central gray of the pons. The extension into the central gray features slightly smaller cells and is slightly less AChE reactive than other portions of VTg. The cells of VTg are mainly large and well stained for Nissl. Its anteroposterior extent is about 2.4 mm. It is succeeded rostrally by the alar interstitial nucleus. The topography of the human VTg, as described by Huang *et al.* (1992) with a suprafascicular and a principal part, more closely resembles the arrangement of the nucleus in the hamster than that in the rat or cat (see Hayakawa and Zyo, 1983, for drawings of the VTg in a number of experimental animal species).

Dorsal Tegmental Nucleus

Caudally, the dorsal tegmental nucleus (DTg) commences at the level of the rostral pole of the reticular tegmental nucleus (Fig. 10.18). It was first identified by von Gudden (1889, cited by Berman, 1968). Chemo- and cytoarchitectonic study of the nucleus in the human (Huang *et al.*, 1992) delineated DTg as a circumscribed, compact, small-celled nucleus conspicuous by its relatively poor AChE reactivity, which contrasts sharply with the dense lateral dorsal tegmental nucleus (Fig. 10.18). It extends to the caudal pole of the pedunculopontine tegmental nucleus (PPTg). The DTg was erroneously considered to be part of the supratrochlear nucleus (dorsal raphe in current nomenclature) by Olszewski and Baxter (1954). The DTg is completely devoid of serotonin cells, and this supports the original classification of von Gudden (1889) that distinguished it from the raphe nuclei.

Posterodorsal Tegmental Nucleus

The posterodorsal tegmental nucleus has been identified by Huang *et al.* (1992) on the basis of chemo- and cytoarchitecture (Fig. 10.16). The nucleus is distinguished within PAG of the pons by strong AChE reactivity.

Lateral Dorsal Tegmental Nucleus

The lateral dorsal tegmental nucleus (LDTg) borders the locus coeruleus and the DTg through some of its course (Figs. 10.16–10.18). It outdistances the DTg caudally and, especially, rostrally where its ventral part persists until PPTg compact part is fully displayed (Fig.10.15). In humans, as in the rat, the ventral part of the LDTg (LDTgV) consists of AChE-positive cells that extend into the fibrous tegmentum ventral to PAG. The LDTgV mingles rostrally with PPTg. (For

the cholinergic nature of these nuclei, see Chapter 33). LDTg cells are extremely AChE positive but are usually concealed by the intense AChE neuropil of the nucleus. Substance P immunoreactivity is displayed by nearly all the large cells of the nucleus (Del Fiacco *et al.,* 1984; Nomura *et al.,* 1987).

Pedunculopontine Tegmental Nucleus

The PPTg contains AChE-positive cells and neuropil and rides the dorsal aspects of the superior cerebellar peduncle. The nucleus has a compact, large-celled part and a diffuse part (Figs. 10.19 and 10.20). It has cholinergic (see Chapter 33) and substance P-positive cells (see Chapter 32). It is likely that the compact part of the human PPTg is the homologue of the rat retrorubral nucleus.

In Figure 10.20, directly medial to the spinothalamic tract there is an area of AChE reactivity. Olszewski and Baxter outlined two nuclei in this position: the subcuneiform and the diffuse pedunculopontine tegmental. We believe that their scheme is not entirely correct, but we cannot at present make another proposal. This region is probably transversed by ascending AChE fibers of the PPTg. Riley (1943), referring to Ziehen (1934), included this region in "area U".

Microcellular Tegmental Nucleus

An extensive parvicellular and AChE-reactive nucleus has recently been identified medial to the parabigeminal nucleus of the rat (Paxinos, 1983, 1985; Paxinos and Butcher, 1986). It has been called the microcellular tegmental nucleus (MiTg). No nucleus of such intense AChE reactivity is found medial to the parabigeminal of the human. However, a parvicellular nucleus of low AChE reactivity is found in a position of the human tegmentum analogous to that occupied by the MiTg in the rat. On the basis of these observations, Paxinos *et al.* (1990) proposed that the MiTg exists in the human but has different AChE properties.

LOCUS COERULEUS

The locus coeruleus (LC) (Figs. 10.13–10.18) is characterized by large AChE-positive cells. Meesen and Olszewski (1949) identified in the rabbit a ventral extension of the LC, which they called LC alpha. This ventral extension included a compact portion and a more extensive diffuse part. In the human, Olszewski and Baxter included the compact portion of the pars alpha in their LC proper and the diffuse part in their subcoeruleus (SubC). Paxinos and Watson (1998) labeled the compact part of the LC that is ventral to PAG (in the fibrous tegmentum) as subcoeruleus alpha (SubCA). However, the cells more closely resemble those of the LC rather than those of the SubC; hence, the term "LC alpha" rather than "SubC alpha" in the present description. Unlike LC, which has relatively few spinal-projecting cells, the LC alpha exhibits numerous descending projections to the spinal cord as well as many ascending projections to the forebrain (W R. Mehler, unpublished observations; Satoh *et al.,* 1977). Resent report showed strong expression of NPY mRNA in the LC (Pau *et al.,* 1998). High concentration of somatostatin binding sites in the area also indicates presence of somatostatine receptors in the LC (Carpentier *et al.,* 1996). In Alzheimer's disease the LC sustains degeneration, but the LC alpha remains unaffected (Marcyniuk *et al.,* 1986a, b).

Epicoeruleus Nucleus

Unlike the rat, LC of humans confines itself to the ventrolateral corner of PAG and does not cling to the full dorsoventral extent of the mesencephalic tract of the trigeminal (Paxinos *et al.,* 1990). In humans, the space dorsal to the LC and medial to the mesencephalic tract of the trigeminal nerve is occupied by a group of medium cells, which Paxinos and Huang (1990) called the "epicoeruleus nucleus" (EC) (Figs. 10.15–10.18). In transverse section this nucleus has the shape of an isosceles triangle, with the base resting on the LC and a small-angle apex pointing dorsally. EC is best seen caudal to the caudal pole of DTg. It remains to be determined whether EC is a separate entity from the medial parabrachial nucleus.

Pathology of major depression was recently shown to be accompanied by altered norepinephrine transporter (NET) function (a membrane protein responsible for termination of the action of synaptic norepinephrine and a site of action of many antidepressants) in LC (Klimek *et al.,* 1997). Chemoarchitectonic evidence revealed the angiotensin II type 1 receptors in the human LC (Benarroch and Schmeichel, 1998) and somatostatin in the fetal human LC (Carpentier *et al.,* 1996), while the differential decrease in the density of somatostatin binding sites observed in the fetal LC during development supported the notion that the somatostatinergic systems in LC as well as in LPB may be involved in maturation of the respiratory control (Carpenter *et al.,* 1997). Recent study also localized strong human cocaine- and amphetamine-regulated transcript (CART) mRNA expression in the human LC (Hurd and Fagergren, 2000). The subcoeruleus nucleus is the AChE-positive area dorsolateral to the central

tegmental tract (ctg). For a description and pictorial representation of LC, subcoeruleus, and the A7 and A5 noradrenergic cell groups, see Chapter 14.

RAPHE NUCLEI

Raphe Obscurus and Magnus Nuclei

The raphe nuclei are described comprehensively in Chapter 13. The raphe obscurus (ROb) possesses AChE-positive cells and dendrites which form two paramedian bands at the divided midline medial to the medial longitudinal fasciculus and the predorsal bundle (Figs. 10.2–10.10).

The raphe magnus (RMg) caps the medial lemniscus and is most prominent at the rostral pole of the inferior olive (Figs. 10.9–10.11). At this level the raphe (the midline) is wide and colonized by two parallel chains of pontine nuclei (pararaphales nucleus). Cells of RMg tend to be oriented mediolaterally. The RMg neuropil shows medium AChE reactivity and is interrupted by the AChE-negative fibers of the medial lemniscus. About half of the raphe magnus cells are positive for serotonin and it is possible that serotonin cells are also AChE positive. Approximately 30% of serotonin cells in RMg and ROb also contain substance P (Halliday *et al.*, 1988a). In the rat, serotonergic cells in the medullary nucleus raphe magnus RMg and adjacent nucleus reticularis magnocellularis Gi are likely involved in modulation of nociceptive transmission, whereas nonserotonergic cells may modulate stimulus-evoked arousal or alerting as well as spinal autonomic and motor circuits involved in thermoregulation and sexual function (Mason, 2001).

Median and Paramedian Raphe Nuclei

In the rat, Paxinos and Watson (1998) used the term median raphe (MnR) to describe the midline nucleus containing large cells that are predominantly serotonin positive. The MnR cells differ from the remaining cells in what was formerly called the central superior medial nucleus (the region between the tectospinal tracts) in terms of morphology, chemoarchilecture, and connectivity. Paxinos and Watson abandoned the term "central superior medial nucleus" because this nucleus actually encompasses two heterogeneous nuclei. Taking Mehler's suggestion, Paxinos and Watson (1998) introduced the term "paramedian raphe nucleus" (PMR) to refer to the more laterally located non-serotonin-positive cells, which are distinct from MnR (see their figures 48–51).

In the human, the distribution of serotonin-positive cells is much more extensive than that of the rat. However, many (but not all) lateral serotonin cells of the human morphologically resemble the remainder of the reticular formation cells and do not present a specific dendritic orientation. The serotonin cells of MnR are characterized by their lack of laterally oriented dendrites. In the rat, an intense AChE-positive zone separates MnR from PMR. In humans, a similar AChE-positive zone shepherds the large median raphe cells rostrally but is invaded by the larger midline cells caudally (Paxinos and Huang, 1995). The shepherding zone, as well as MnR and PMR, display bowed boundaries that collectively give this region the appearance of a barrel with staves.

The MnR is found dorsal and rostral to RTg in the rostral pons and isthmus (Figs. 10.16–10.19). Hornung in Chapter 13 observes that in a narrow sense the raphe pontis nucleus is, in fact, the caudal pole of MnR and proposes to abandon the term "raphe pontis nucleus" as referring to a region harboring serotonin neurons. Rostrally, MnR is limited by the decussation of the superior cerebellar peduncle. Dorsal to the decussation, the nucleus merges with the caudal linear nucleus.

Raphe Pontis Nucleus

Unlike other raphe nuclei, the cells of raphe pontis nucleus are not serotonin positive. Buettner-Ennever and Horn describe this cell group in detail in Chapter 19 of this book.

Dorsal Raphe Nucleus

The dorsal raphe nucleus shows extreme AChE reactivity in the neuropil of its wings (Figs. 10.13–10.22). The median strip of cells is associated with less reactivity in the neuropil; consequently the cells, which display medium reactivity, can be visualized. An autoadiography study showed that neurons of dorsal raphe are characterized by NPY mRNA expression (Pau *et al.*, 1998). Recently, Hurd and Fagergren (2000) reported strong human CART mRNA expression in the dorsal raphe, though it is not clear whether the message is in serotonin-containing cells.

VENTRAL MESENCEPHALIC TEGMENTUM AND SUBSTANTIA NIGRA

Chapter 14 gives a comprehensive pictorial representation of the mesencephalic dopamine groups on the basis of tyrosine hydroxylase immunoreactivity.

Caudal Linear Nucleus

The caudal linear nucleus (CLi) is more extensive in the human than in the rat (Figs. 10.20–10.22). In humans, it extends from the medial longitudinal fasciculus dorsally to the interfascicular nucleus ventrally. Caudally, it rides on the rostral aspect of the decussation of the superior cerebellar peduncle until it joins the rostral tip of MnR. Some CLi cells infiltrate the decussation of the superior cerebellar peduncle to mingle with the median raphe. The caudal linear nucleus consists of a median and two paramedian corridors of cells that are strikingly different in their chemoarchitecture. The median corridor is AChE negative and contains serotonergic neurons, while the lateral corridors are AChE positive and contain numerous tyrosine hydroxylase–positive cells. Paxinos and Huang (1995) named the unpaired midline corridor featuring the serotonin cells—the *azygos* part of CLi. This azygos part succeeds MnR (with which it is continuous through cell bridges blasting through the superior cerebellar peduncle). The AChE-positive catecholaminergic corridor is the *zygos* part of CLi. The paramedian clusters do not extend as far caudally as the median cluster; thus, it is only the median cluster that meets MnR. The CLi borders the rhomboid nucleus and is succeeded rostrally by the rostral linear nucleus at approxi mately the point of the caudal pole of the red nucleus.

Interfascicular Nucleus

The interfascicular nucleus (IF) straddles the interpeduncular nucleus. Laterally, the IF is in contact with the paranigral nucleus. In contrast to rats, cats, and monkeys, in which the IF is a median cluster, the human IF is small and consists of two paramedian clusters that are connected only by cell bridges (Halliday and Törk, 1986). Compared to other nuclei of the ventral mesencephalic tegmentum, it has significantly smaller cells (Halliday and Törk, 1986). Both the cells and the neuropil are densely AChE positive.

Rostral Linear Nucleus

The rostral linear nucleus (RLi) consists of scattered pigmented AChE-reactive cells within and dorsomedial to the superior cerebellar peduncle as the peduncle encapsulates the red nucleus (Figs. 10.23–10.25).

Retrorubral Fields

The dopamine-containing (tyrosine hydroxylase-positive) retrorubral fields are found caudal and dorsal to the caudal pole of the red nucleus, at the level where the third nerve forces its way through the red nucleus. In drawing the borders of the human retrorubral fields it may be useful to consider the map of the pigmented cells in the human brain stem presented by Mai *et al.* (1987).

Paranigral Nucleus

In contrast to the rat, the paranigral nucleus (PN) of humans is extremely AChE reactive and abuts not on the interpeduncular nucleus as in the rat but on the medial pole of the substantia nigra (Figs. 10.20 and 10.21).

Parabrachial Pigmented Nucleus

The parabrachial pigmented nucleus (PBP) occupies the space between the substantia nigra compact part and the red nucleus (Figs. 10.20–10.25). It is characterized by AChE-positive neurons and a neuropil of medium to dense reactivity.

Substantia Nigra

The substantia nigra (SN) displays intense AChE reactivity in the cell bodies and neuropil of its compact (SNC) and lateral (SNL) parts (Figs. 10.20–10.25). In places, SNC divides or envelopes the reticular part. The dopamine-containing neurons are AChE positive but are not cholinergic (Butcher and Talbot, 1978). The reticular part of SN is less reactive than the compact part. For a comprehensive description of SN, see Chapter 31.

Interpeduncular Nucleus

The interpeduncular nucleus (IP) (Figs. 10.20–10.24) displays an AChE-dense zone that straddles a core of medium reactivity. This pattern is not readily comparable to that shown in the rat. As in the rat, the fasciculus retroflexus in humans displays an AChE-dense core surrounded by an AChE-negative area.

CRANIAL MOTOR NUCLEI

Hypoglossal Nucleus

The hypoglossal nucleus (12N) (Figs. 10.1–10.5) is one of the most AChE-reactive nuclei in the staining of both cell bodies and neuropil. Its caudal representative is the ventrolateral division (12VL). This division possesses large AChE-positive neurons found within the fibrous zone ventrolateral to the central canal, at

the medial border of MRt (see above). As in the rat (Krammer *et al.*, 1979), the 12VL disappears as soon as the dorsal division develops. In the rat, the 12VL innervates the geniohyoid muscle (Krammer *et al.*, 1979). The ventromedial division of 12N is the largest, and in the rat it innervates the genioglossus muscle (Krammer *et al.*, 1979). We are not confident about the homology of the dorsal division because another subnucleus (potentially a laterally displaced dorsal division) appears in the human. In the rat, the dorsal division innervates the styloglossus and hyoglossus muscles. The nucleus of Roller accompanies the rostral third of the hypoglossal nucleus.

Facial Nucleus

The facial nerve nucleus (7N) abuts the rostral end of IRt and persists until the level of the exiting facial nerve (Figs.10.10 and 10.11). In humans, as in the rat, the 7N contains AChE-reactive cell bodies and neuropil. Subdivision of the 7N in the human (see Figs. 10.10 and 10.11) (Pearson, 1947; Paxinos and Huang, 1995) is in conflict with this in the monkey (Satoda *et al.*, 1987). The accessory 7N are intensely reactive for AChE. Surrounding the 7N is an AChE-positive zone which was named the perifacial zone in the human and the rat brain (Paxinos and Huang, 1995). For more information on the nucleus, see also Chapter 16.

Accessory Facial Nucleus

The caudal pole of the accessory facial nucleus (Acs7) appears dorsomedial to the caudal third of the 7N. It assumes a compact pyramidal shape at its rostral pole immediately medial to the exiting facial nerve (Fig.10.10).

Motor Trigeminal Nucleus

The caudal pole of the motor trigeminal nucleus (Mo5) is represented by the accessory trigeminal nucleus (Acs5) (Fig. 10.11) and appears medial to the exiting root of the facial nerve. It extends rostrally to the dense caudal pole of LC. The Mo5 is strongly reactive for AChE (cells and neuropil) and the reactivity extends into the cell-poor peritrigeminal zone (Paxinos and Huang, 1995) (Fig. 10.13).

Abducens Nucleus

The abducens nucleus (6N) is located caudal to the horizontal limb of the exiting facial nerve (Figs. 10.10 and 10.11). The 6 has prominent AChE-positive cells but its neuropil is only of medium intensity. Rostrally, it is separated from the more reactive VTg by the horizontal limb of the facial nerve root. The nucleus is also discussed in Chapter 16.

Trochlear Nucleus

The trochlear nucleus (4N) is found in an invagination of the medial longitudinal fasciculus near the level of the junction of the inferior and superior colliculi (Fig. 10.21). Its motoneurons are AChE positive but its neuropil is only moderately reactive. The 4N is separated from the rostrally lying oculomotor nucleus by a small cell-free space. The two nuclei can be distinguished by the fact that 4N is embedded in the fasciculus while the oculomotor nucleus is cradled in it. In addition, unlike 4N, scattered oculomotor nucleus cells infiltrate the fasciculus. For additional details about 4N, see Chapter 16.

At the caudal pole of the trochlear nerve the midline between the two medial longitudinal fasciculi features a dense AChE segment (Paxinos *et al.*, 1990). This may correspond to the parvicellular "compact interfascicular nucleus" (CIF) of Olszewski and Baxter (1954).

Oculomotor Nucleus

Olszewski and Baxter (1954) report that the oculomotor nucleus (Figs. 10.22 and 10.23) is approximately 5 mm long. It extends from the trochlear nucleus to the unpaired anterior portion of the nucleus of Edinger–Westphal (Fig. 10.23). The caudal pole of the oculomotor nucleus is more reactive for AChE than the trochlear nucleus. The nucleus of Edinger–Westphal is reactive for AChE in both its cells and neuropil (Figs. 10.23 and 10.24).

SOMATOSENSORY SYSTEM

Gracile Nucleus

At the level of the pyramidal decussation, the tapering caudal pole of the gracile nucleus (Gr) appears as small clusters of AChE-positive cell bodies. Rostrally, the main body of Gr appears with the characteristic patches of AChE reactivity corresponding to clusters of cells separated by AChE-negative myelinated fibers (see Chapter 24). The Gr persists almost to the rostral pole of the area postrema (Figs. 10.1–10.3).

Cuneate Nucleus

The cuneate nucleus (Cu) first appears at midlevels of the pyramidal decussation (Fig. 10.3) and extends to

the rostral pole of the area postrema (Fig. 10.4). The Cu displays patches of AChE reactivity similar to those of Gr but of higher intensity. Attached to the borders of some compact bundles of the cuneate fasciculus are clusters of large cells that are well stained for Nissl (density near the brain surface on the border with the gracile nucleus in Fig. 10.4). The neuropil of these clusters is extremely reactive for AChE. It seems to correspond to the area reported to contain substance P fibers by Del Fiacco *et al.* (1984).

External Cuneate Nucleus

Unlike other species, the human external cuneate nucleus (ECu) occupies a greater area of the medulla than Cu or Gr (Figs. 10.1–10.6). It features large cells heavily stained for AChE on a pale background. It expands at the level of the obex and becomes the largest of the dorsal column nuclei rostral to the obex (Fig. 10.5). At its rostral pole it narrows and is found between the mediodorsal aspect of the inferior cerebellar peduncle, the spinal vestibular nucleus, and the spinal trigeminal nucleus. It terminates short of the rostral pole of 12 (Fig. 10.6).

Pericuneate, Peritrigeminal, X, and Paratrigeminal Nuclei

Medial Pericuneate Nucleus

At the level of the obex, a narrow zone of pale AChE reactivity appears in the neuropil ventral to the dorsal column nuclei (Figs. 10.2–10.4). Paxinos and colleagues (1990) named this zone the "medial pericuneate nucleus." This basal zone features small, medium, and occasionally large neurons that are AChE positive. The most medial part of this zone interposes itself between EC, solitary, and interpolar spinal trigeminal nuclei. This medial (basal) pericuneate zone (MPCu) was included in Cu by Olszewski and Baxter (1954), even though it can be seen in their photomicrographs to be separate from Cu proper and possess smaller cells (their plates 10 and 11). At levels caudal to the obex, cells in MPCu are diffuse and smaller. Rostral to the level of the area postrema (about 1 mm from the obex) these cells increase in number and become more heterogeneous in size and shape. At one point, MPCu cells appear as a triangular mass that merges rostrally with large, rounder cell clusters (Figs. 10.5 and 10.6). A comparable cell cluster is shown by Olszewki and Baxter in their plates 12 and 13, lateral to the solitary nucleus and medial to the spinal trigeminal nucleus. In AChE-stained sections, other small AChE-positive cells extend into the pale neuropil capping the oral pole of Cu (Fig. 10.5). This basal MPCu is coextensive in length with 12. There is no basal region ventral to the gracile nucleus, except for a few clusters at its oral pole.

Lateral Pericuneate Nucleus

Lateral and ventrolateral to the external cuneate nucleus there are variably shaped aggregates of chiefly large AChE-positive neurons intercalated in the medial edge of the inferior cerebellar peduncle. The most prominent group of these cells frequently forms a wedge separating the cervical dorsal roots surrounding ECu from the dorsal part of Sp5. This chain of cells extends from the level of the obex to the oral pole of ECu (Fig. 10.6), equivalent in length to the hypoglossal cell column. This cell group was described by Ziehen (1934) as the "promontorium" (Latin, "to jut out") and was considered part of the insular nuclei of ECu by Olszewski and Baxter (1954, their plate 10). This nucleus has been confused with nucleus X (described below). Paxinos and colleagues (1990) have called it the "lateral pericuneate nucleus"). Both LPCu and MPCu were identified as separate but related entities by Braak (1971). Braak adopted Ziehen's (1934) term "promontorium" for the lateral group and coined the term "repagulum cuneati" (Greek, *pagus,* "something fixed or fastened together") for the medial group of cells basal to Cu.

Peritrigeminal Nucleus

The peritrigeminal nucleus (Pe5) is in places continuous with LPCu and is found lateral, ventral, and medial to Sp5. Caudally, it commences at the level of the caudal pole of the dorsal accessory olive (Fig. 10.2) and extends to the rostral pole of 12. Olszewski and Baxter (1954) included the lateral segment of Pe5 in their insula cuneati lateralis (their plate 10). The ventral part of Pe5 is usually found between Sp5 and the subtrigeminal LRt. At times, however, it is found ventral or lateral to the subtrigeminal nucleus. A ventromedial cluster that receives anteroventral quadrant fibers has been labeled the paravagal nucleus by Braak (1971) (small-celled nucleus between the labels Amb and IRt). The Pe5 has a medial extension that intercedes between Sp5 and the LRt.

Afferent Connections of the Pericuneate and Peritrigeminal Nuclei

In experimental animals, the pericuneate and Pe5 receive ascending anterolateral spinal quadrant fiber connections (via the inferior cerebellar peduncle) and do not receive dorsal root primary fibers (Mehler, 1969). Nucleus X and the paratrigeminal nucleus (Pa5) project to the cerebellum (Mehler, 1977; Somana and Walberg, 1979). The MPCu cells may receive afferents from the same ascending fiber system that projects to LPCu. Cervical dorsal root connections to the pericuneate

cells cannot be ruled out. Cortical input to the basal dorsal funicular nuclear region has been verified in humans (Kuypers, 1960); rubrobulbar connections with the region have also been described (Holstege and Tan, 1988). The MPCu cells are believed to have connections with the overlying dorsal column nuclei that function as an intermediate zone (Kuypers and Turek, 1964). Differential studies of retrograde cell labeling, following HRP injections into the ventral posterior lateral thalamic nucleus, demonstrated that many cells in the medial basal pericuneate zone (PCu) that convey tactile information also project to the thalamus through the medial lemniscus with gracile and cuneate axons. However, Ostapoff *et al*. (1988) have concluded that what might be the homologues of the PCu cells in the racoon relay deep subcutaneous kinesthetic sensations ending chiefly in the ventral intermediate (Vim)–like shell region rostral to the tactile thalamic nucleus. They also confirmed that the caudally situated cells of subgroup X project to the cerebellum, but cells that they identified as rostrally situated subgroup X, like nucleus Z, also project to the thalamic shell region.

In animal experiments, cells capping the oral pole of Cu project to the cerebellum and do not join the medial lemniscus (Mehler, 1977). Vestibular group F–like cells (FVe) intercalated in the ventral caudal pole of the spinal vestibular nucleus (SpVe) give rise to a third vestibulospinal pathway (see review by Mehler and Rubertone, 1986). The ascending spinal fibers that delineate both the lateral X group and the medial basal dorsal column nuclei also appear to make connections with group F–like cells at this level of transition between the oral pole of the cuneate nuclei and the caudal pole of the vestibular nuclei.

Nucleus X

Sadjadpour and Brodal (1968) identified nucleus X as a cell group related to the dorsal boundary of SpVe, extending from the rostral level of ECu to the caudal level of the dorsal cochlear nucleus. They describe nucleus X as a small triangular area just medial to the inferior cerebellar peduncle, featuring small, lightly stained cells. Paxinos and Watson identified nucleus X in *The Rat Brain in Stereotaxic Coordinates* (Paxinos and Watson, 1998) as the AChE-reactive rostral continuation of ECu. We observed a similar AChE-reactive cluster of small cells in the position described by Sadjadpour and Brodal. Larger cells invade or form a boundary around nucleus X and these cells may belong to SpVe (Sadjadpour and Brodal, 1968). We believe that the ventral part (between the spinal vestibular nucleus and the inferior cerebellar peduncle) is different from SpVe, but we have not grouped it with nucleus X because of the larger cells of this area and its poorer AChE reactivity. Nucleus X can be confused with the insulae cuneati lateralis of Olszewski and Baxter (our lateral pericuneate nucleus). If we accept Sadjadpour and Brodal's view, nucleus X is unlikely to extend this far ventrally (Fig. 10.7). In addition, LPCu has large cells whereas nucleus X, according to Sadjadpour and Brodal, has small cells.

Paratrigeminal Nucleus

In the rat, the paratrigeminal nucleus (Pa5) forms a crescent between the spinocerebellar tract and the spinal tract of the trigeminal, usually invading the latter. The Pa5 of the rat features small cells and is characterized by light AChE and dense substance P reactivity. Some of its cells are substance P positive (Chan-Palay, 1978a, b). While we accept Chan-Palay's definition of this nucleus in the rat, we disagree with her on the human homologue of the Pa5. She considers the insulae cuneati lateralis of Olszewski and Baxter to be the Pa5 of the human. Paxinos and colleagues (1990) have grouped the dorsal insula cuneati lateralis with LPCu and the ventral insula with the peritrigeminal zone. They suggested that the human Pa5 may be, in fact, a string of cells contained primarily within the spinal tract and based their parcellation on the basis that the Pa5 of the rat has small cells in agreement with the parvicellular clusters within the human spinal tract and in contradistinction to the lateral pericuneate zone, which has large cells. An inconsistency in the homology is that the AChE reactivity of the proposed Pa5 of the human is lower than that displayed in the rat.

Spinal Trigeminal Nucleus

The caudal spinal trigeminal nucleus (Sp5) is characterized by strong AChE reactivity in the superficial layers, including the substantia gelatinosa (Figs. 10.1 and 10.2). The marginal zone of the caudal part of Sp5 can be distinguished because it is less AChE reactive than the gelatinous nucleus but more than the spinal tract. Some AChE-reactive cells are found totally within the cuneate fasciculus, yet strong AChE reactivity suggests that they most likely belong to the gelatinous part of the caudal Sp5 rather then to the cuneate system. Also, a recent study revealed NPY mRNA expression within the nucleus (Pau *et al.*, 1998).

The oral Sp5 (Sp5O) has a concentric pattern of AChE reactivity with an extremely AChE dense core (Figs. 10.10 and 10.11). It is succeeded rostrally by the less reactive principal sensory nucleus of the trigeminal nerve. In the principal sensory trigeminal nucleus the AChE reactivity is distributed in small patches adulterated by negative areas.

In the principal sensory trigeminal nucleus the AChE reactivity is distributed in small patches adul-

terated by negative areas. The interpolar nucleus (Sp5I) (Figs. 10.3–10.9) displays moderate AChE reactivity, although there are occasional extremely intense patches that correspond to parvicellular regions. In the ventral part of the nucleus a rodlike structure appears (circular in cross-section), featuring small compact neurones and extremely AChE-dense neuropil. No such structure appears in the rat. Both Sp5O and Sp5I are reported to contain significant number of somatostatin receptors as revealed by somatostatin binding sites (Carpentier *et al.*, 1996).

Mesencephalic Trigeminal Nucleus

The mesencephalic nucleus of the trigeminal nerve (Me5) features prominent AChE-reactive cells and, as in the rat, its cells and axons form a thin sheet that circumscribes the cylindrically shaped periaqueductal PAG from LC almost to the level of the posterior commissure (Figs. 10.12–10.24).

Endolemniscal Nucleus

At caudal medullary levels, long islands of cells strongly reactive for AChE separate dense fascicles of the medial lemniscus. The islands appear just rostral to the caudal pole of the principal nucleus of the inferior olive. Caudally, they are wholly confined within the medial lemniscus. However, rostrally they unite and flank the lateral side of the medial lemniscus. These cell groups resemble the medial accessory olive but are clearly more medial to it. Given their position, Paxinos *et al.* (1990) called them the "endolemniscal nucleus".

B9 and Supralemniscal Nucleus

The B9 is identified as a group of serotonergic cells lying above the medial lemniscus. This cell group also contains a region of extremely strong AChE reactivity that is distinguished as the supralemniscal nucleus (Fig. 10.16).

VESTIBULAR NUCLEI

Medial Vestibular Nucleus

The medial vestibular nucleus (MVe) succeeds the gracile nucleus rostrally at the level at which the gelatinous solitary nucleus is most prominent and persists rostrally to the level of the abducens nucleus (Figs. 10.5–10.10). It has a mottled appearance in AChE. Caudally, embedded in the medial part of MVe, are two clusters of larger cells, the neuropil of which stains strongly for AChE (Fig. 10.5). It is important to point out that a group of large neurons positioned ventrally and medially to the main body of MVe is currently considered to be part of the medial rather then lateral vestibular nucleus, as it was previously thought.

Spinal Vestibular Nucleus

The spinal vestibular nucleus (SpVe) overlaps the rostral pole of the external cuneate and subsequently replaces it (Figs. 10.5–10.9). It is rectangular in cross-section and is located dorsolateral to the solitary and spinal trigeminal nuclei. The SpVe is also characterized by the passage of the lateral vestibulospinal tract which, being AChE negative, contrasts with the medium density of the neuropil of the SpVe. Distribution of somatostatin binding revealed that both MVe and SpVe contain numerous somatostatin receptors (Carpentier *et al.*, 1996). The area above the spinal and dorsal vestibular nucleus is identified as the paravestibular nucleus. Nucleus Y is allocated an area above the inferior cerebellar peduncle prior to ascendance of the peduncle to the cerebellum.

Lateral Vestibular Nucleus

The lateral vestibular nucleus (LVe) replaces SpVe rostrally (Figs. 10.9 and 10.10). It displays large AChE-positive cells and has lighter neuropil than the rest of the vestibular nuclei. The superior vestibular nucleus is not optimally displayed in our plates.

Interstitial Nucleus of the Eighth Nerve

The eighth nerve is AChE negative but its interstitial nucleus displays AChE-positive cell bodies and neuropil.

Nucleus of Origin of Vestibular Efferents

The nucleus of origin of vestibular efferents is a human homologue of the paragenual nucleus of the rat, which was first identified in proximity of the genu of the seventh nerve by Paxinos and Watson (1998) and later by Swanson (1992). In the human, as in the rat, the nucleus is distinguished as a group of AChE-positive neurons riding on top of the horizontal limb of the root of the seventh nerve.

AUDITORY SYSTEM

Ventral Cochlear Nucleus

The ventral cochlear nucleus (VC) displays AChE-positive cell bodies against a light neuropil. It can be

distinguished from the pontobulbar nucleus, which is located more medially and which displays high AChE reactivity in its neuropil. The VC also features a cap that is slightly reactive in the neuropil. The dorsal cochlear nucleus is more reactive in AChE preparations than VC. At the same time the superficial glial zone of the nucleus is less AChE reactive then the nucleus itself.

Superior Olive

The superior olive (SO) is the AChE-poor area rostroventral to the facial nucleus (Figs. 10.10 and 10.11). The most conspicuous feature of SO in Nissl preparations is the medial superior olive (MSO). It consists of medium-sized, slightly AChE-positive cells and is surrounded by AChE-positive vascular elements that are themselves encircled by an AChE-negative zone. The lateral superior olive is extremely negative in AChE preparation but features some moderately stained capillaries. A conspicuous characteristic of the lateral superior olive is its significantly greater size relative to the size of the entire superior olive nucleus in the rat or the mouse.

The periolivary nuclei surround SO. The dorsal periolivary nucleus is the most AChE-reactive structure in the SO complex (Fig. 10.11). The position of the dorsal periolivary nucleus is betrayed by MSO, which points directly to it. The dorsal periolivary nucleus probably contains the bulk of the cells that provide the cochlear efferents. The human homologues of the mediocentral and lateroventral periolivary nuclei are AChE positive.

The human homologue of the superior paraolivary nucleus remains an enigma. In the rat, this nucleus is contiguous with MSO. In the human at this position, we noticed a vertically oriented stream of cells. These cells are medium sized and AChE positive, but do not display the dense AChE neuropil that characterizes the dorsal periolivary nucleus. Judging from the maps of retrogradely labeled cells following HRP injections into the cat cochlea, these cells may also belong to the cholinergic efferent projection. For a comprehensive account of the human auditory system and superior olive, see Chapter 34.

Trapezoid Nucleus

Identification of the human homologue to the trapezoid nucleus (Tz) has been elusive (Chapter 27). Stromberg and Hurwitz (1976) and Richter *et al.* (1983) suggested tentatively that an attenuated homolog of Tz in the human at the level of the exiting trochlear nerves. Indeed, Paxinos and colleagues (1990) found Tz at the level of the exiting sixth nerve in the shape of a golf club, with most of its cells underlying the central tegmental tract and bordering the medioventral periolivary nucleus. The cells of Tz are large, with weak AChE reactivity, and are found among the caudal crossing fibers of the trapezoid body (Figs. 10.11 and 10.12). It has been pointed out by Paxinos and colleagues (1990) that Tz in the human is much less cellular than in the rat.

Nuclei of the Lateral Lemniscus

The ventral nucleus of the lateral lemniscus (VLL) succeeds SO rostrally (Figs. 10.17 and 10.18). The VLL can be distinguished from SO by its slightly larger cells and by the fact that the cell group, after tapering to an elongated rostral pole, becomes larger and more cellular. In addition, the cells of the VLL are slightly more AChE reactive than those of SO. The VLL commences at the level of the oral pole of the motor nucleus of the trigeminal. The nuclei of the lateral lemniscus reach the caudal pole of the pedunculopontine tegmental nucleus. For a quantification of the human nuclei of the lateral lemniscus, see Ferraro and Minckler (1977).

Inferior Colliculus

As in the rat (Paxinos and Watson, 1998), the inferior colliculus (IC) of the human displays light AChE reactivity that features slightly denser patches, especially in the external cortex (ECIC) (Figs. 10.19–10.22). In the central nucleus of IC, blood vessels are visible as wavy lines of some AChE positivity. For more details regarding IC, see Chapter 34.

Nucleus of the Brachium of the Inferior Colliculus

The nucleus of the brachium of the inferior colliculus (BIC) (Figs. 10.21–10.23) shows pale AChE reactivity but is recognizable because the surrounding dorsolateral tegmentum is AChE negative. Rostrally, the subbrachial nucleus is found beneath the BIC.

Medial Geniculate

The medial geniculate (MG) displays weak and blotchy AChE reactivity (Figs. 10.22–10.25). By homology with the monkey (Pandya *et al.*, 1994), Paxinos and Huang (1995) recognized the AChE-negative ventral and the AChE-positive medial subnuclei of MG, as well as the strongly AChE-reactive and large-celled suprageniculate nucleus.

VISUAL SYSTEM

The visual system is covered in detail in Chapter 35 of this book, but some elements of the visual pathways represent integral structural parts of the brain stem and as such are presented in this chapter.

Superior Colliculus

Laemle (1983) has provided a Golgi analysis of the human superior colliculus (SC). Morphologically, SC can be divided into (1) a superficial division consisting of the zonal, superficial, and optic layers; (2) an intermediate division consisting of the intermediate gray and white layers, and (3) a deep division consisting of the deep gray and deep white layers (Figs. 10.22–10.25). The AChE reactivity of the human SC resembles that of the rat. The superficial gray layer is the most intensely reactive. The zonal layer is also reactive except for its most superficial strip. The optic nerve layer shows less reactivity than that of the surrounding superficial and intermediate gray layers and is, as a result, cospicuous. The intermediate gray and white layers show intense reactivity. The intermediate white layer displays periodic patches of AChE reactivity as observed in the rat (Paxinos and Watson, 1998). Lattices of high cytochrome oxidase or succinate dehydrogenase activity have been observed in the human SC (Wallace, 1988). The anterior pretectal area is densely reactive for AChE and so is the subadjacent parafascicular nucleus. A number of enigmatic patches of AChE reactivity appear below SC.

Parabigeminal Nucleus

The parabigeminal nucleus (PBG), while somewhat inconspicuous in Nissl preparations, is all too evident in AChE-stained sections (Figs. 10.20 and 10.21). It is present in the region at which the compact pedunculopontine tegmental nucleus achieves its greatest size.

Medial Terminal Nucleus of the Accessory Optic Tract

The existence of the medial terminal nucleus (MT) of the accessory optic tract is ambiguous in humans. On the basis of observations on the monkey, Fredericks *et al*. (1988) proposed that MT should be present in the human at a position transversed by the lateral rootlets of the oculomotor nerve. MT is an AChE-negative area (as in the rat) transversed by the most rostrally exiting oculomotor fibers.

Alar Interstitial Nucleus

At the caudal pole of LC, fibers from the vestibular nuclei travel rostromedially to gather in the medial longitudinal fasciculus proper (mlf). In these wings of the mlf is found an AChE-reactive nucleus with medium-sized cells. Paxinos *et al*. (1990) called this nucleus the alar interstitial nucleus of the mlf (AIl). It appears rostral to the rostral pole of the ventral tegmental nucleus and is approximately 1.5 mm in length (Fig. 10.14).

The alar interstitial nucleus is succeeded rostrally by the more medially placed interstitial nucleus of Cajal (see Buttner-Ennever and Horn, Chapter 19 of this book), AchE reactive cells and neuoropil wholly embedded in the mlf proper (Fig. 10.15). It is found at levels caudal to the dorsal tegmental nucleus.

PRECEREBELLAR NUCLEI AND RED NUCLEUS

Chapter 11 of this book includes a comprehensive description of the cytoarchitecture and connectivity of the precerebellar nuclei.

Inferior Olive

Medial Accessory Olive

AChE is differentially distributed in the medial accessory olive. The lateral part of the medial accessory olive (IOA) displays some of the densest AChE reactivity found in the medulla (Figs. 10.1–10.3). Both the neuropil and the cell bodies are densely reactive. IOA is the group that appears at the caudal pole of the olive and, rostrally, greatly outdistances the other nuclei of the medial accessory olive. Subnucleus B is slightly less reactive (Fig. 10.4). Subnucleus C is less densely stained in the neuropil and the cell bodies are clearly visible. In this respect, it resembles the beta nucleus that it borders.

Beta Nucleus

The beta nucleus (IOB) in the cat stains poorly for AChE and is confined to the caudal one-third of the olive (Marani *et al*., 1977). In the monkey, IOB disappears prior to the full development of the principal nucleus (Brodal and Brodal, 1981). In our human material, IOB appears as one of the caudal representatives of the olive but vanishes well before the appearance of the rostral division of the dorsal accessory olive (Figs. 10.2 and 10.3).

Dorsomedial Cell Column

The dorsomedial cell column (IODM) is best described as a dorsomedial satellite of IOA in the rostral part of the latter (Figs. 10.6–10.8). The IODM is small and usually ovoid; it is depicted in the monkey by Brodal and Brodal (1981; in their figure 1) and in the cat by Marani *et al.* (1997, in their figure 4A).

Ventrolateral Outgrowth

The ventrolateral outgrowth (IOVL) is actually the nuclei "g" and "h" of Olszewski and Baxter (1954) and of Braak (1970). The alternative term is consistent with the nomenclature now commonly used in studies with monkeys (Bowman and Sladek, 1973; Brodal and Brodal, 1981), cats (Marani *et al.*, 1977), and rats (Paxinos and Watson, 1998). The ventrolateral outgrowth is serpentine in the transverse plane, with its head (nucleus h) pointing dorsomedially (Fig. 10.3). It commences slightly more caudally than IODM and ends considerably short of the rostral pole of IODM. It is parallel to the IOA and interposes itself between IOA and IOPr.

Cap of Kooy

The cap of Kooy (IOK) is present at the caudal pole of the olive and represents the most dorsal extension of the complex at that level. It shows moderate AChE reactivity (Figs. 10.1–10.3).

Dorsal Accessory Olive

Olszewski and Baxter (1954) and Braak (1970) included in the dorsal accessory olive (IOD) two heterogeneous and discontinuous groups of cells. Paxinos and colleagues (1990) reserved the name IOD for the larger eyebrow-shaped rostral part that caps the dorsomedial aspects of the principal olive. This part persists until the frontal pole of the olive, where it has the shape of a comma (Figs. 10.4–10.9). The smaller, caudal subnucleus of the IOD (IODC) is rod shaped (round in cross-section) and, compared with IOD proper, has denser AChE reactivity and features smaller cells. The IODC commences prior to the principal nucleus and continues until the epiolivary lateral reticular nucleus becomes very prominent, at which point it briefly attains a horizontally oriented spindle shape (Figs. 10.2 and 10.3). It is succeeded rostrally by the IOD after a small hiatus. Paxinos and colleagues (1990) called the posterior part "caudal dorsal accessory olive." The inferior olive, including the caudal dorsal accessory olive, was excellently displayed by Kooy (1916).

Principal Olive

The principle subnucleus (IOPr) shows homogeneous medium staining for AChE neuropil and cell bodies (Figs. 10.3–10.9).

Conterminal Nucleus

The conterminal nucleus (Ct) is located on the lateral surface of the amiculum of the olive and displays intense AChE reactivity in cell bodies and neuropil (Figs. 10.2–10.7).

Arcuate Nucleus

The arcuate nucleus (Ar) appears on the anterior surface of the medulla, extending dorsally at the midline and partly surrounding the pyramid (Fig. 10.4). The Ar reacts densely for AChE, as do the pontine nuclei of which it is presumed to be a displaced kin (Mikhail and Ahmed, 1975; Olszewski and Baxter, 1954). A recent pathology study found that sudden infant death syndrome is associated with high-frequency hypoplasia, characterized by a volume reduction and neuronal depletion of Ar (Matturri *et al.*, 2002).

Paramedian and Dorsal Paramedian Nuclei

Brodal and Gogstad's (1957) paramedian groups correspond to the clusters of AChE-positive cells and neuropil seen within the predorsal bundle at the rostral pole of the hypoglossal nucleus. Olszewski and Baxter's dorsal paramedian groups resemble the pontine nuclei in cytoarchitecture and AChE reactivity. The caudal dorsal paramedian (CDPMn) is distinguishable from the subadjacent 12, which is extremely AChE reactive. The CDPMn is most prominent at the rostral pole of the 12 (Figs. 10.7 and 10.8). The CDPMn is succeeded rostrally by its oral companion (ODPMn).

Intercalated Nucleus

The intercalated nucleus (In) commences caudal to the obex and persists until the rostral pole of the hypoglossal nucleus, where it is succeeded by the prepositus hypoglossal nucleus. The intercalated nucleus displays medium AChE reactivity, and some positive cells can be detected through the neuropil. It starts as a narrow wedge between the 12 and the 10 but expands rostrally to fill the vacuum created by the lateral migration of the 10 (Figs. 10.1–10.6). Although In is characterized by small cells, at its rostral pole a dense cluster of larger cells appears at the border with 10. These cells are probably the ones that react for tyrosine hydroxylase (see Chapter 31).

Prepositus Hypoglossal and Interpositus Nuclei

The prepositus hypoglossal nucleus (Pr) succeeds the intercalated nucleus rostrally and displays a light AChE core surrounded by a region of greater reactivity (Figs. 10.7–10.9). A distinct cluster of large cells well stained for Nissl is found in the ventromedial tip of the Pr. The Pr is bordered medially by the oral dorsal paramedian and laterally by the interpositus nucleus (IPo) (Figs. 10.7–10.9). Rostrally, Pr is succeeded by the AChE-dense region found immediately caudal and medial to the abducens nucleus. This AChE-positive region may correspond to the pontine paramedian reticular nucleus involved in horizontal gaze. Dorsal to the 10, Olszewski and Baxter outlined IPo to separate Pr from the medial vestibular nucleus. Dorsal and rostral to the oral pole of Pr the supragenicular nucleus can be detected by medium AChE reactivity.

Cribriform Nucleus

The cribriform nucleus (Crb) was identified by Paxinos and Huang (1995) as the area lateral to the solitary nucleus and medial to the dorsal column nuclei and spinal vestibular nucleus. This area is generally AChE positive while characteristically perforated by AChE-negative fibers (Fig. 10.6).

Pontine Nuclei

The pontine nuclei (Pn) attain their maximal relative size in the human, nearly throttling the dorsal pontine tegmentum. Their outposts are distinguishable by the intense AChE reactivity of cell bodies and neuropil. As in other species, their main mass is found below the medial lemniscus. However, in the human, unlike the rat, there are pontine-like nuclei encircling and bisecting the rostral medulla. The pontobulbar nucleus (PnB) lies outside the inferior cerebellar peduncle and appears caudally at the rostral pole of the external cuneate nucleus, presenting a triangular profile at this level (Fig. 10.6). At more rostral levels, the pontobulbar nucleus spreads to engulf this peduncle laterally and ventrally. Further rostrally, it is broken up into large islands in the ventrolateral aspects of the medulla (Figs. 10.7–10.9). These islands are intermingled with the vestibular division of the vestibulocochlear nerve. The nuclei pararaphales constitute two paramedian chains of islands of pontine-like cells that bisect the medulla at rostral levels (Figs. 10.7–10.9) (see also Olszewski and Baxter, 1954).

The reticular tegmental nucleus (RtTg) is located above the medial lemniscus. It is found immediately rostral to the exiting sixth nerve and it is replaced by MnR rostrally (Figs. 10.11–10.16). The nucleus consists of many scattered tight clusters of cells usually engulfed in AChE-reactive neuropil. Some cell clusters are associated with weak reactivity, though the cell bodies are positive. The cells are distinguishable from those of the pontine nuclei because they are larger and stain more intensely in Nissl preparations.

Olszewski and Baxter (1954) recognized a "processus grisium pontis supralemniscalis." The AChE reactivity in the lateral part of this nucleus is extreme and thus similar to that of the pontine nuclei. However, the AChE reactivity of the medial part is light, resembling some of the lighter clusters of RtTg. The two parts of the processus grisium pontis supralemniscalis are often separated by fiber bundles. Olszewski and Baxter depicted more densely stained and larger cells in the lateral part. For the above reasons, Paxinos and colleagues (1990) allocated the medial part to RtTg and retained "processus grisium pontis supralemniscalis" only for the lateral part.

Red Nucleus

The red nucleus is found at the level of the substantia nigra as a sphere encapsulated within the ascending superior cerebellar peduncle (Figs. 10.22–10.25). Unlike the rat, the magnocellular part of the red nucleus is relatively small in the human, occupying only the caudal pole (Fig. 10.22) (Wollard, 1927, cited by Jerath. 1964). A number of large cells in this region, however, are pigmented and therefore must be ectopically placed cells of the parabrachial pigmented nucleus, of the mesencephalic reticular formation, or of the caudal linear nucleus. At rostral levels, the fasciculus retroflexus penetrates the red nucleus, separating a dorsomedial portion. The dorsomedial portion displays higher AChE reactivity. Recent immunohistochemical studies revealed the presence of parkin (Parkinson disease related protein) (Zarate-Lagunes *et al.*, 2001), somatostatin receptors sst (4) (Selmer *et al.*, 2000), as well as P2Y(1) purinergic receptor (Moore *et al.*, 2000) in the red nucleus of the human. The nucleus is relatively big and current resolution of MRI and PET scans allows depiction of the red nucleus in the brain of the conscious human. For the connections of the red nucleus, see Voogd, Chapter 11.

CONCLUSION

This overview presents a comprehensive classification of the human brain stem structures which include most of neuronal cell groups in the human brain stem.

The most significant conclusion of this overview is a glaring structural similarity of brain stem across species reflected by an impressive number of homologies recognised between the brain stem of the human and that of other animals. While it can be hypothesised that there are human homologues to nearly every nucleus identified in the rat brain stem, species differences and even strain differences occur, and this compels us to establish homologies not by extrapolation but by direct observation of human tissue.

Then again, this overview presents a comprehensive classification of the human brain stem structures which are, at this time, best characterised by trivial structural similarity to corresponding homologues in the brain stem of experimental animals. Functional mechanisms of the human brain stem, on the other hand, remain hidden in connections, chemoarchitecture and physiology of neuronal groups. These characteristics are emerging from encouraging noninvasive imaging studies and expanding creative application of chemical analysis of the human brain. At that, a comparative structural plan of the brain stem forms an excellent fundament to interpret, convey, and compare these findings.

CHAPTER

11

Cerebellum and Precerebellar Nuclei

JAN VOOGD
Department of Neuroscience
Erasmus Medical Center Rotterdam, Rotterdam
and Neuroregulation Group, Department of Physiology
University of Leiden, Leiden, Holland

Recent interest in the nonmotor functions of the human cerebellum (Leiner *et al.*, 1986; Schmahmann, 1997) and the advances made in the molecular biology and physiology of the cerebellum (De Zeeuw *et al.*, 1997; Gerrits *et al.*, 2000) have raised renewed interest in its anatomy. In this chapter I have tried to make the data on the gross anatomy of the human cerebellum and its nuclei more accessible to its users and to emphasize the magnitude of the cerebrocerebellar connections in the human brain. The problem in this approach remains that the recent literature is almost restricted to the anatomy of the rodent and feline cerebellum, with some excursions to nonhuman primates, and that new information on the fiber connections of the human cerebellum is almost completely lacking. During the late 19th century and the first decades of the 20th century, the connections of the human cerebellum were extensively studied with the myelogenetic method (reviewed by Flechsig, 1927) and traced with Marchi staining of degenerated myelin (Marchi and Algeri, 1885) in human pathological material. But these studies stopped and were never resumed. This situation did not improve with the advent of the silver impregnation methods for degenerated axons (Nauta and Gygax, 1951, 1954). Among the hundreds of papers using the Nauta method in experimental studies of the cerebellum there are only a few on the afferent, intrinsic, or efferent connections of the human cerebellum. What is probably the most complete account of the fiber connections of the human cerebellum therefore remains von Bechterew's review of his myelogenetic studies of the human brain *Die Leitungsbahnen im Gehirn und Rückenmark* from 1899. As a consequence, much of the anatomy of the human cerebellum still rests on assumptions and interpretations of animal studies.

This chapter is based on the text as it appeared in the first edition of *The Human Nervous System* (Voogd *et al.*, 1990). Most of the data on connections from studies in rodents and carnivores have been omitted from this new edition. This information is available in

some recent reviews (Voogd, 1995, 1998, Voogd *et al.*, 1996b, Voogd and Glickstein, 1998). Some of the human cases used in this chapter were documented by the late Dr. Jaap Schoen from the Department of Anatomy of the University of Leiden. For details on these cases, the reader is referred to the first edition.

EXTERNAL FORM, DEVELOPMENT, AND SUBDIVISION OF THE HUMAN CEREBELLUM

Introduction

The shape of the human cerebellum differs from that of most other mammals, with the possible exception of the great apes, which have not been studied in great detail (Larsell, 1970). The most obvious features of the human cerebellum are its overall size, the depth of the transverse fissures, and the great mediolateral width and parallel orientation of the folia of the hemisphere. According to Langelaan (1919), "the great obstacle to the study of the morphology of the cerebellum lies in its nomenclature." This problem probably is caused by the nature of the nomenclature of the cerebellum, which is a mixture of purely descriptive names and terms with a comparative anatomical context. Most of the names attributed to the lobules of the vermis and hemisphere by Malacarne (1776; cited by Glickstein, 1987), Meckel (1817; cited by Larsell and Jansen, 1972) and Burdach (1822; cited by Larsell and Jansen, 1972) are still in common use (Fig. 11.1). Different nomenclatures for the human cerebellum, which are mainly of a historical interest, were reviewed by Angevine *et al.* (1961) and tabulated by Schmahmann *et al.* (1999). In the following description of the folial pattern of the human cerebellum, I will use the classical terminology and refer to Larsell's comparative anatomical nomenclature. Introduced for the rat (Larsell, 1952), this nomenclature, which indicates the lobules of the vermis with the roman numerals I–X and the lobules of the hemisphere with the same numbers and the prefix "H", was applied in its final form to the human cerebellum by Larsell and Jansen in 1972. The comparative anatomical and embryological implications of Larsell's nomenclature will be discussed at the end of this section. In a recently published magnetic resonance imaging (MRI) atlas of the human cerebellum in proportional stereotactic space (Schmahmann *et al.*, 1999, 2000) a modification of Larsell's nomenclature was adopted to indicate the lobules. The prefix "H" for the lobules of the hemisphere was discarded, the superior and inferior semilunar lobules (Larsell's lobules HVIIAa and Ab) were indicated as crus I and crus II of Bolk's (1902, 1906) ansiform lobule, and the names of the transverse fissures, as used by Larsell and Jansen (1972), were retained.

Gross Anatomy of the Human Cerebellum

In the descriptive anatomy of the human cerebellum a superior surface (facing the tentorium and indicated as the rostral surface, when the long axis of the brain stem is taken as reference) and an inferior (caudal) surface generally are distinguished. The rostral, caudal and ventral aspects of the cerebellum are illustrated in Figs. 11.2 and 11.3. The folial pattern of the cerebellum is best studied in serial parasagittal sections (Fig. 11.4). MR images from serial sagittal, horizontal, and coronal slices were illustrated by Schmahman *et al.* (1999, 2000). One of their reconstructions of the human cerebellum and one of their slices horizontal slices are reproduced in the Figs. 11.3 and 11.5.

In a midsagittal section (Fig. 11.1C) the primary fissure, which divides the cerebellum into anterior and posterior lobes, can be identified as the deepest fissure on the superior (rostral) surface. The anterior lobe is subdivided into the lingula (lobules I and II of Larsell), the lobulus centralis (lobule III), the culmen (lobules IV and V). The lingula, or its ventral sublobule when present, is embedded in the anterior medullary velum. The ventral surface of the anterior medullary velum is covered with ependyma and forms the rostral wall of the fastigium, the narrow protrusion of the fourth ventricle in the base of the cerebellum. The main fissure in the anterior lobe, which can be recognized in all mammals, is the preculminate fissure between lobulus centralis and culmen. The folial pattern of the lingula/lobulus centralis region and the subdivision of the culmen in lobules IV and V is subject to many variations (Larsell and Jansen, 1972). The subdivision of the region behind the primary fissure into the declive (lobule VI), the folium (lobule VIIAa of Larsell; VIIAf of Schmahmann *et al.*), and the tuber (lobule VIIAb and VIIB of Larsell; lobules VIIAf and VIIB of Schmahmann) can only be appreciated when taking the relations of this part of the vermis with the hemisphere into account. The pyramis (lobule VIII), the uvula (lobule IX), and the nodulus (lobule X), with their intervening prepyramidal, secondary, and posterolateral fissures, are easy to identify. The ependymal roof of the fourth ventricle is attached to the nodulus. Together with the rostral ependymal surface of the nodulus it forms the caudal wall of the fastigium.

The superior (rostral) surface of the cerebellum is relatively flat, with the culmen forming the higest point of the "monticulus," the small hill, which slopes downward as the declive. At the superior surface the

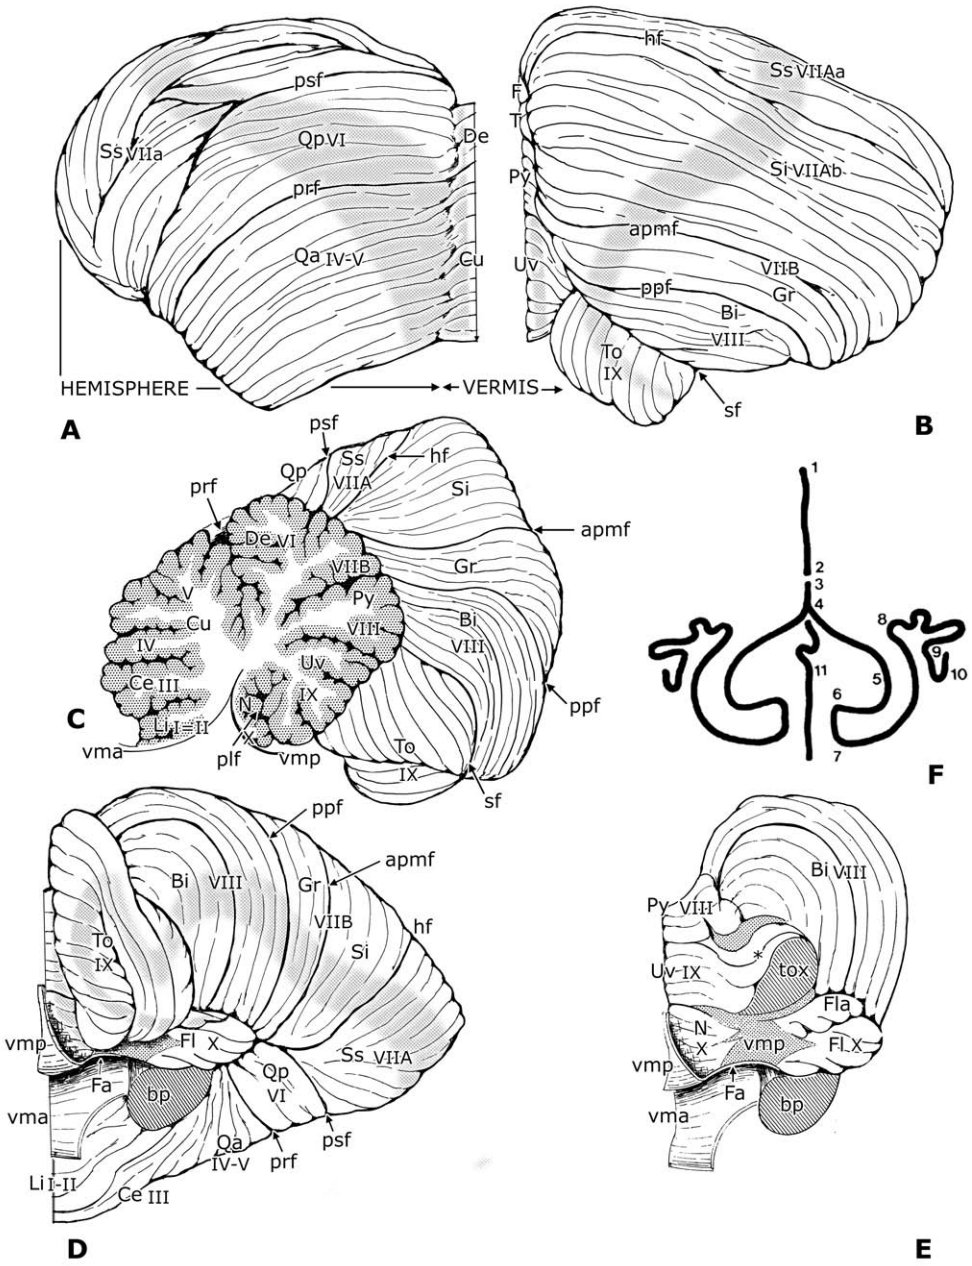

FIGURE 11.1 The human cerebellum. Semidiagramatic drawings of the anterior aspect **(A),** the posterior aspect **(B),** the midsagittal section **(C),** the ventral aspect **(D),** and the region of the nidus avis on the ventral aspect, after removal of the tonsilla **(E).** Bolk's (1906) wire diagram of the groundplan of the mammalian cerebellum is illustrated in **(F).** Areas without cortex in D and E are indicated by dots. The cross-sections of the brachium pontis and the peduncle of the tonsilla are hatched. The connection between the uvula and the tonsilla is indicated by an asterisk. The gray bands indicate the direction of the folial chains of the vermis and the hemisphere. Vermis and hemispheres separate in the posterior lobe. Two loops are present in the folial chain of the hemisphere: one at the level of the semilunar lobulus, one at the level of the tonsilla. This configuration corresponds to Bolk's (1906) groundplan of the mammalian cerebellum (F), which shows loops in the region of the ansiform lobule (4–5–6) and the paraflocculus (6–9). Lobules are indicated by abbreviations of their anatomical names and by Larsell's roman numerals. Abbreviations: apmf, ansoparamedian fissure; Bi, biventral lobule; bp, brachium pontis; Ce, central lobule; Cu, culmen; De declive; F, folium vermis; Fa, fastigium; Fl, flocculus; Fla, accessory paraflocculus of Henle; Gr, lobulus gracilis; hf, horizontal fissure; N, nodulus; plf, posterolateral fissure; ppf, prepyramidal fissure; prf, posterior superior fissure; psf, primary fissure; Py, Pyramis; Qa, anterior quadrangular lobule; Qp, posterior quadrangular lobule; sf, secondary fissure; Si, inferior semilunar lobule; Ss, superior semilinar lobule; T, tuber vermis; To, tonsilla; Tox, cross-section of the peduncle of the tonsilla; Uv, uvula; vma, anterior medullary velum; vmp, posterior medullary velum.

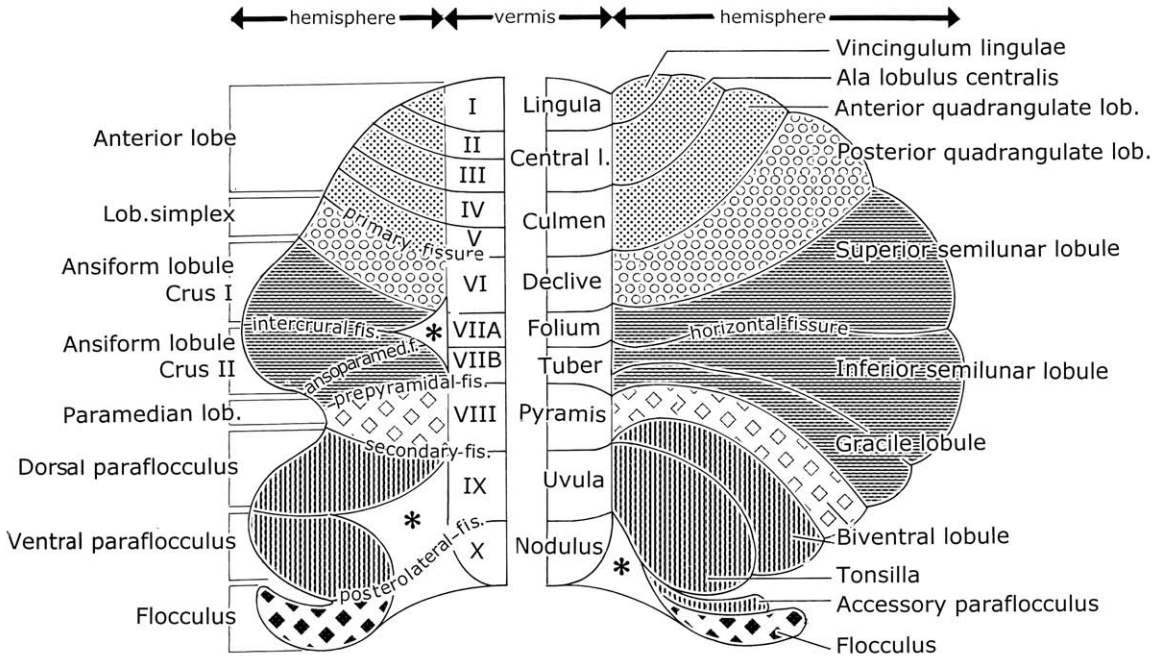

FIGURE 11.2 Comparative anatomical nomenclature of the cerebellum according to Bolk, with Larsell's roman numerals indicated in the vermis **(left),** and the classical nomenclature of the cerebellum **(right).** Possible homologies are indicated by identical hatchings in the two panels.

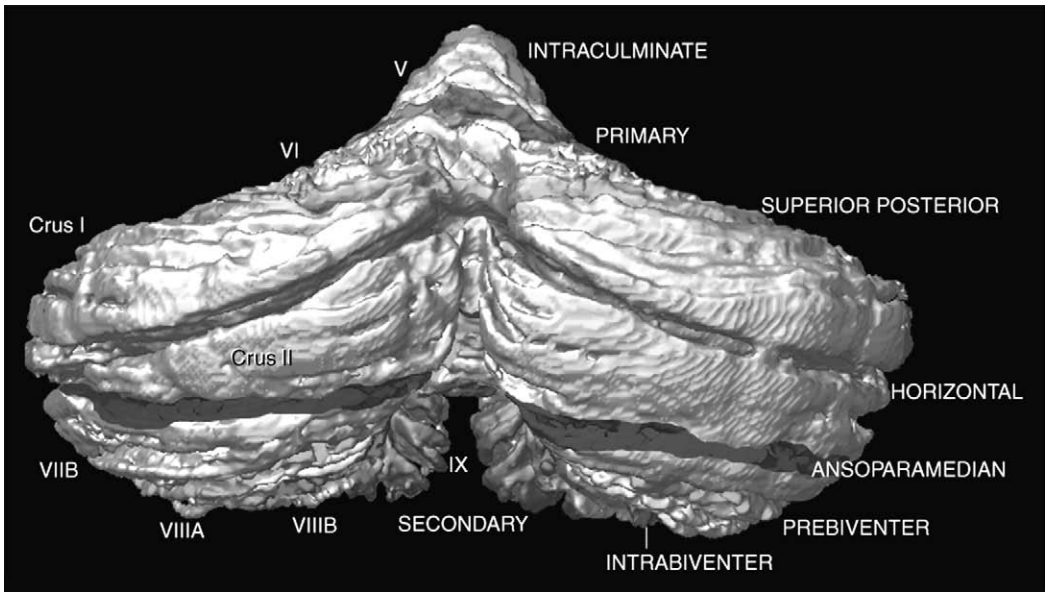

FIGURE 11.3 Three dimensional reconstructions of MR images, of the caudal surface of the cerebellum. The position of the ansoparamedian fissure, between the inferior semilunar lobule (Crus II) and the lobulus gracilis (VIIB), is asymmetric. The original color coding of the fissures has been omitted. Adapted from Schmahmann *et al.* (2000).

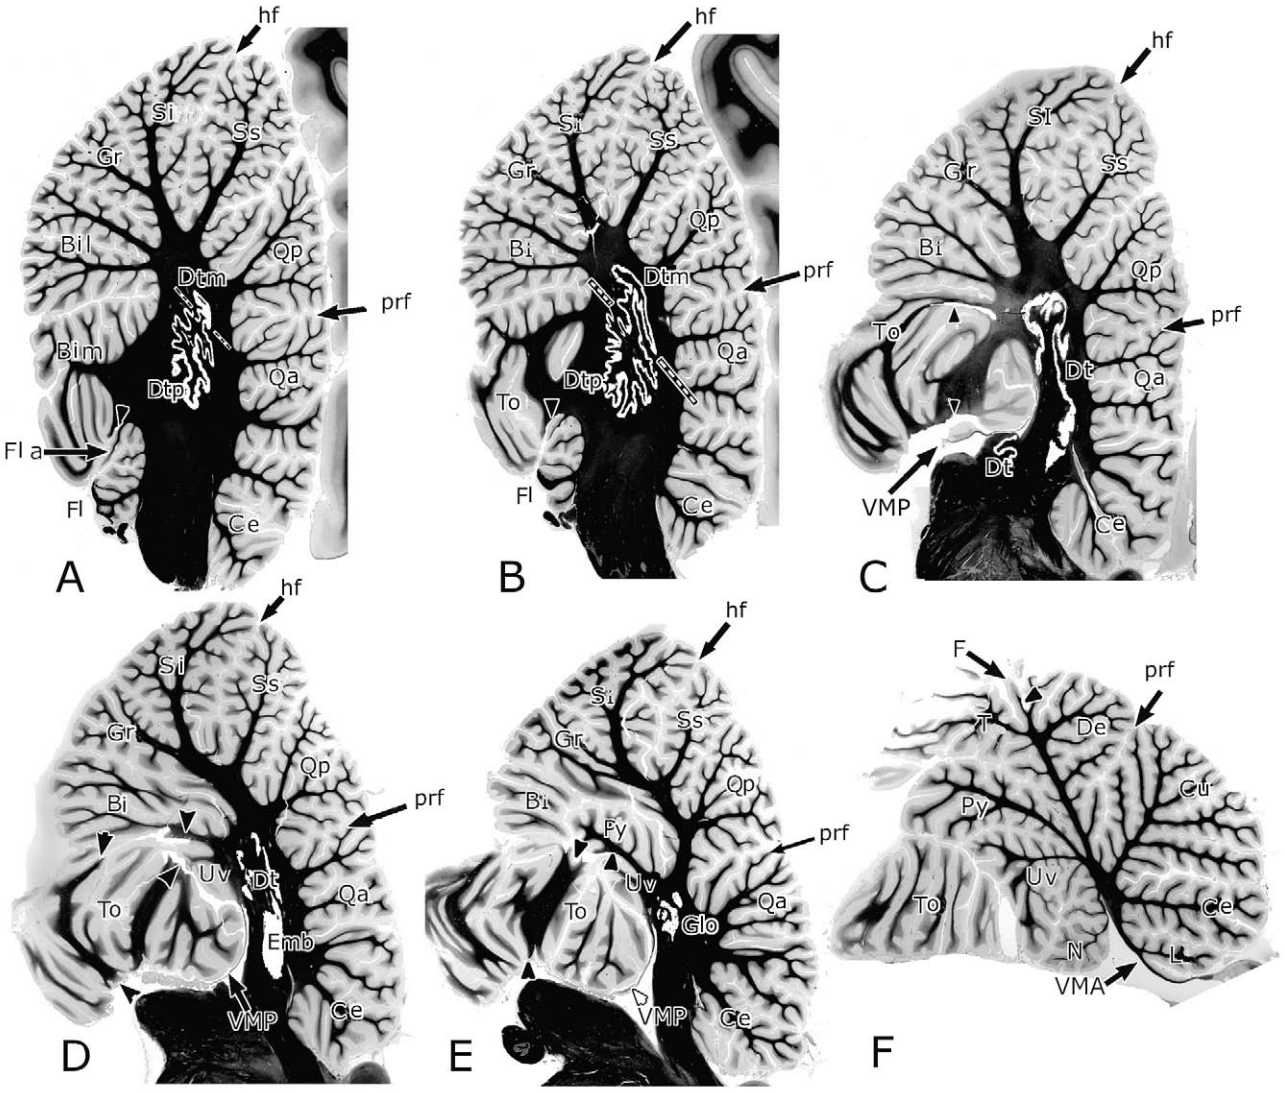

FIGURE 11.4 Six parasagittal sections through the cerebellum. A is the most lateral section, E passes through the paravermal region, F passes through the vermis. Arrowheads indicate areas without cortex between the tonsilla and the accessory paraflocculus/flocculus complex **(A, B),** the dorsal and ventral surface of the tonsilla **(C–E),** the transition from the pyramis into the biventral lobule (D), pyramis and uvula (E), and the base of the folium vermis **(F).** Compare with dissected area of nidus avis in Figure 11.1E. Scans with enhanced contrast from Weigert–Pal–stained sections from the Jelgerma Collection. Abbreviations: Bi, biventral lobule; Bil, lateral belly of the biventral lobule; Bim, medial belly of the biventral lobule; Ce, central lobule; Cu, culmen; De, declive; Dt, dentate nucleus; Dtm, magnocellular, dorsomedial portion of the dentate nucleus; Dtp, parvocellular, ventrolateral portion of the dentate nucleus; Emb, emboliform nucleus; F, folium vermis; Fl, flocculus; Fla, accessory paraflocculus of Henle; Glo, globose nucleus; Gr, lobulus gracilis; hf, horizontal fissure; N, nodulus; prf, primary fissure; Py, Pyramis; Qa, anterior quadrangular lobule; Qp, posterior quadrangular lobule; Si, inferior semilunar lobule; Ss, superior semilinar lobule; To, tonsilla; Tu, tuber vermis; Uv, uvula.; VMP, posterior medullary velum. Courtesy of Dr. Enrico Marani.

vermis is demarcated from the hemisphere by a shallow paramedian sulcus. Most fissures in the vermis of the anterior lobe and in the declive continue uninterruptedly into the hemisphere. A precise demarcation of the anterior vermis in sections is difficult if not impossible (Schmahmann *et al.*, 1999). These authors estimated the width of the anterior vermis at 14–20 mm, depending on the section and the definition of the surface markings. The hemispheral lobules on the superior surface generally can be traced from their vermal counterparts by following the transverse interlobular fissures. In this way the hemisphere of the lingula (the

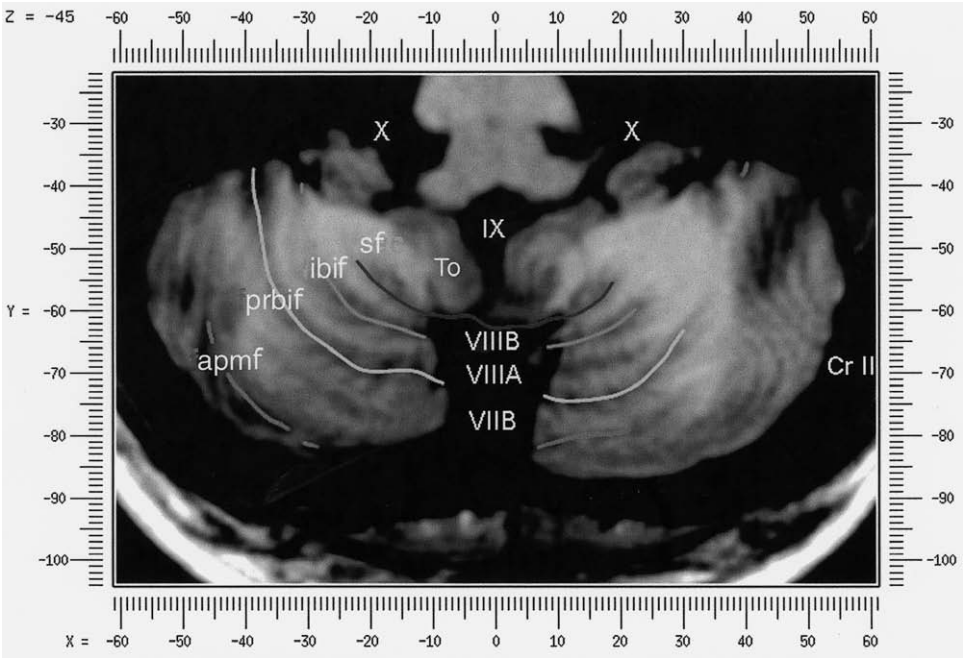

FIGURE 11.5 Horizontal MR image of a section passing through the ventrocaudal pole of the cerebellum. Note position of the tonsilla, as well as the presence of areas without cortex between the tonsilla (To) and the acessory paraflocculus/flocculus complex (X). Abbreviations: apmf, ansoparamedian fissure; Cr II, crus II; ibif, intrabiventral fissure; prbif, prebiventral fissure; sf, secondary fissure; To, tonsilla; VIIb–X, lobules VIIB–X of Larsell. From Schmahmann *et al*. (2000).

vinculum lingulae, Larsells lobule HI and HII), the hemisphere or "alae" of the lobulus centralis (HIII), and the hemisphere of the culmen (lobulus quadrangularis anterior, lobules HIV and HV) and of the declive (lobulus quadrangularis posterior, lobule HVI) can be delineated.

Morphologically the anterior lobe and the declive with its hemisphere form an entity characterized by the lack of a distinct vermis and the continuity of its transverse fissures. For the declive and its hemisphere this was emphasized by Bolk (1906), who coined the name "lobulus simplex" for this ensemble because he was unable to distinguish a clear border between vermis and hemispheres in this part of the cerebellum in most of the mammalian cerebella he examined. There are no stringent reasons to attach more importance to the primary fissure than to any other interlobular fissure. The subdivision of the cerebellum by the primary fissure into anterior and posterior lobes is of historical but not of great morphological significance.

A distinct vermis, bordered by deep paramedian sulci from the hemispheres, makes its appearence caudal to the lobulus simplex. The presence of a paramedian sulcus and the great expansion of the posterior hemisphere makes it more difficult to trace the interlobular fissures from the vermis into the hemisphere in this region. The posterior superior fissure constitutes the caudal border of the lobulus simplex and can be traced far laterally, caudal to the declive and the posterior quadrangular lobule (HVI) on the superior surface of the cerebellum. The deep horizontal fissure runs approximately along the border of the superior and inferior (caudal) surface of the hemisphere. Usually it can be traced into the vermis as the caudal border of the folium (lobule VIIAa of Larsell, VIIAf of Schmahmann). This vermal lobule may consist of a single, unfoliated lamina, caudal to the declive and located in the bottom of the deep cerebellar notch between the protruding hemispheres. Laterally it expands into the superior semilunar lobule (HVIIAa of Larsell, crus I of Bolk and Schmahmann).

At the inferior surface of the cerebellum the prepyramidal fissure forms the border between the tuber (lobule VIIB) and the pyramis (lobule VIII) at the level of the vermis, and between the lobulus gracilis (HVIIB) and the biventral lobule (HVIII) in the hemisphere. According to Larsell and Jansen (1972) and Schmahmann *et al*. (1999), the region of the hemiphere between the horizontal and prepyramidal fissures can be subdivided by the ansoparamedian fissure into the inferior semilunar lobule (lobule VIIAb of Larsell; crus II of Bolk and Schmahmann) and the lobulus gracilis (lobule VIIB of Larsell). However, the position of this fissure and its continuation in the tuber, is highly

variable, as shown by the asymmetry of these lobules in the specimen of the cerebellum illustrated by Schmahmann *et al.* (1999) (Fig. 11.3) and by the variations in the nomenclature for this region in their tabulated summary.

In the serially sectioned cerebellum illustrated in Fig. 11.4, I observed irregularities in the structure of the cerebellar cortex, with small areas where a cortex was completely lacking and white matter came to the surface, at the transition of the folium and the tuber into the hemisphere. Regions without cortex commonly are found in most mammals in the paramedian sulcus at sites of great expansion of the hemisphere, such as in the center of Bolk's ansiform lobule (Voogd, 1964, 1998).

The secondary fissure, located between the pyramis (VIII) and the uvula, laterally separates the biventral lobule (HVIII) from the tonsilla (HIX). The lateral part of the pyramis sometimes expands into a small folial rosette, known as the "Nebenpyramide" of Henle (1871). Laterally, most intralobular fissures of the pyramis become more shallow and disappear. An area without cortex replaces the cortex on the caudal (ventral) surface of the pyramis (Fig. 11.2E). At the junction with the biventral lobule, some folia that bridge the paramedian sulcus connect the rostral (dorsal) pyramis with the biventral lobule. Therefore, the intrabiventral fissure, which separates the lateral belly of the biventral lobule (lobules HVIIIAa and b) from the medial belly (lobules HVIIIAc and VIIIIB), continues into one of the intralobular fissures on the rostral (dorsal) surface of the pyramis.

The folia of the tonsilla (lobule HIX of Larsell) form a medially directed loop, which ends in the flocculus (Fig. 11.2D). Areas without cortex are found in the center of this loop, on the dorsal and the ventral surface of the uvula (Fig. 11.4C–E). In the bottom of the secondary fissure the cortex of the medial belly of the biventral lobule continues into the cortex covering the lateral aspect of the tonsilla. The distal part of the tonsilla is turned inward and is lodged next to the uvula and the nodulus in a deep recess, known as the nidus avis (Fig. 11.2E). The bottom of the nidus avis is formed by a medullary sheet, the posterior medullary velum. The posterior medullary velum is attached to the base of the nodulus medially and to the medullary stalk of the tonsilla and the floccular peduncle laterally. It serves as the attachment (taenia) of the plexus choroideus in the roof of the fourth ventricle and its lateral recess. The folia on the lateral aspect of the uvula taper and disppear. A foliated band (the "furrowed band" of Reil; Larsell and Jansen, 1972) connects the uvula with the tonsilla (asterisk in Fig. 11.2E, asterisk; Fig. 11.4D).

The cortex of the nodulus (lobule X) is not continuous with the flocculus (lobule HX) or the flocculus accessorius of Henle (1871) (lobule HIX of Larsell). Laterally its folia taper and disappear in the posterior medullary velum (Figs. 11.2E and 11.4A, D). Small islands of cerebellar cortex sometimes are present in the velum, between the nodulus and the flocculus. Laterally, the flocculus accessorius and the flocculus are located ventral to the tonsilla. The cortex of the flocculus accessorius remains separated from the cortex of the tonsilla by the area without cortex on the ventral tonsillar surface. The cortex of the flocculus and the flocculus accessorius are continuous in the bottom of the posterolateral fissure, which separates them. Variations in this region were studied by Tagliavini and Pietrini (1984).

Comparative Anatomical Considerations

The revised nomenclature for the human cerebellum, introduced by Schmahmann *et al.* (1999), is a modification of Larsell's nomenclature combined with some of the terms introduced by Bolk (1902, 1906). Bolk and Larsell are representatives of two quite different concepts on the morphology of the mammalian cerebellum, both based on studies of its comparative anatomy. Larsell (Larsell, 1967, 1970; Larsell and Jansen, 1972) emphasized the mediolateral continuity of fissures and the lobules of vermis and hemispheres. His descriptions are precise but rigid, acknowledging the continuity of each lobule of the vermis with its counterpart in the hemisphere. Bolk (1902, 1906; for reviews, see Glickstein and Voogd, 1995; Voogd, 1975) stressed the relative independance of vermis and hemispheres. His scheme is more flexible. Bolk contrasted the morphology of the anterior lobe and the lobulus simplex, where the transverse fissures continue uninterruptedly from the vermis into the hemispheres, and which lack a clearly defined vermis in many species, with the structure of more caudal parts of the cerebellum (Bolk's lobulus complicatus) characterized by a certain independance of the folial chains of vermis and hemispheres (Fig. 11.6). Both Larsell and Bolk acknowledged the classical subdivision of the vermis of the human cerebellum, although they introduced slight modifications and different nomenclatures for the lobules of the vermis in their comparative studies. Larsell subsequently traced the fissures separating the lobules of the vermis into the hemisphere, either during their development or in the adult. Bolk described his observations on adult mammalian cerebella in developmental terms. The anterior lobe and the lobulus simplex constitute a single "growth center"; the posterior vermis and its hemisphere behave as independent centers, which both expand in the sagittal plane. The folial chains of vermis and hemispheres can be subdivided into secondary centers, or segments, by the depth of

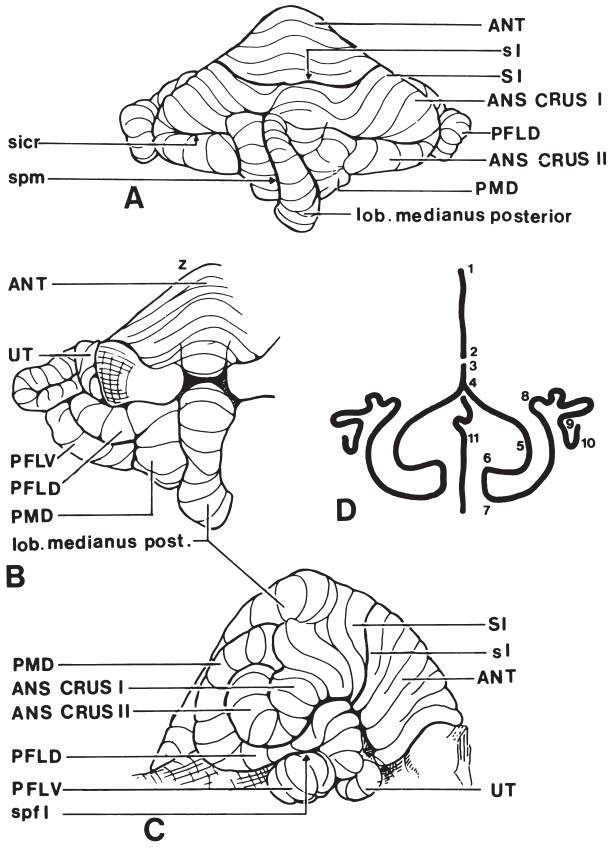

FIGURE 11.6 The cerebellum of *Lemur albifrons*. For the description of his basic plan of the mammalian cerebellum Bolk used the cerebellum of *L. albifrons*. This figure illustrates dorsal **(A),** ventral **(B)** and lateral **(C)** views of this cerebellum. Both the sulcus primarius and many of the intralobular fissures of the anterior lobe and the lobulus simplex can be traced to its lateral margin, and no indication can be found of paramedian sulci delimiting a vermis in these parts. The region behind the lobulus simplex (Bolk's lobulus complicatus) consists of the caudal vermis and the paired hemispheres separated by the deep paramedian sulci. The vermis consists of a long chain of narrow folia. The rostral and caudal segments of the folial chain of the hemisphere are thrown into loops: the lobulus ansiformis and the formatio vermicularis. The intermediate segment, the paramedian lobule, is located parallel to the vermis. The formatio vermicularis by Bolk consists of the paraflocculus (Stroud, 1895; divided into dorsal and ventral limbs, corresponding to the crus circumcludens and the pars floccularis of Bolk) and the flocculus (Bolk's uncus terminalis). The folial chain of the hemisphere, therefore, is "fragmented into secondary centres which differ in growth intensity." The segmentation of the folial chains of vermis and hemisphere is well illustrated in Bolk's wire diagram of the mammalian cerebellum (D:1–2: anterior lobe; 3–4: simple lobule; 4–6: ansiform lobule; 6–7: paramedian lobule; 7–9: crus circumcludens and pars floccularis, or paraflocculus; 10: uncus terminalis or flocculus; 11: caudal vermis). Abbreviations: ANS CRUS 1, Crus I of the ansiform lobule; ANS CRUS II, Crus II of the ansiform lobule; sI, sulcus primarius; SI, lobulus simplex; sicr, sulcus intercruralis; spfl, sulcus interparafloccularis; spm, sulcus ANT, anterior lobe; PFLD, paraflocculus dorsalis; PFLV, paraflocculus ventralis; PMD, lobulus paramedianus; sI, sulcus; UT, uncus terminalis (Bolk), flocculus. Redrawn from Bolk (1902).

the intervening fissures, or changes in the width or the direction of the folia. In the folial chain of the hemisphere Bolk distinguished two laterally directed loops, one in the region of the ansiform lobule and the other in the region of the paraflocculus. These loops also can be recognized in the human cerebellum (Fig. 11.1). The first loop is located in the region of the semilunar lobules, where folia emerge in a feather-like fashion from the horizontal fissure. The second loop is located in the tonsilla, the homologue of the mammalian paraflocculus. It the case of the human cerebellum it is directed medially.

In Bolk's descriptions the continuity within a folial chain (although he never verified the continuity of the cortex histologically) and the varying degrees of independance of vermis and hemisphere are the main elements. The precise location of the boundary fissures of a lobule, or the continuity between the fissures, separating the segments of the folial chain of the hemisphere, with their possible vermal counterparts, clearly is of less importance.The relative independence of vermis and hemispheres in the posterior lobe is supported by the mode of development of the principal transverse fissures and by interruption of the cortex between the expanding folial chains of vermis and hemispheres.

Most fissures, such as the posterior superior, intercrural (horizontal), ansoparamedian, secondary, and the posterolateral fissure develop independently in vermis and hemispheres and only become confluent at a later date. The only fissure in the posterior lobe, which is continuous from the vermis into the hemispheres from the beginning of development, is the prepyramidal fissure (Bolk, 1905a, b; Larsell, 1947; Larsell and Jansen, 1972).

Functionally, vermis and hemispheres are dissociated by the complete interruption of the cortex or the lack of a molecular layer in the center of the loops of the folial chains of the hemisphere (i.e., in the intercrural or horizontal fissure for the cortex between lobule VII and the ansiform lobule, and in the caudal paramedian sulcus for the cortex between the uvula/nodulus and the paraflocculus/flocculus). At these sites the parallel fibers, which represent the only means of transverse communication in the cerebellum, are either absent or reduced in number. The cortex within a folial chain always remains continuous between successive segments (Voogd, 1964, 1998). In most species the cortex of the pyramis is continuous with the hemisphere caudal to the prepyramidal fissure. The cortical bridge between pyramis, caudal paramedian lobule, and dorsal paraflocculus was identified by Ellioth Smith (1902, 1903) as the copula pyramidis. Interruptions of the cortex also were noticed in the human

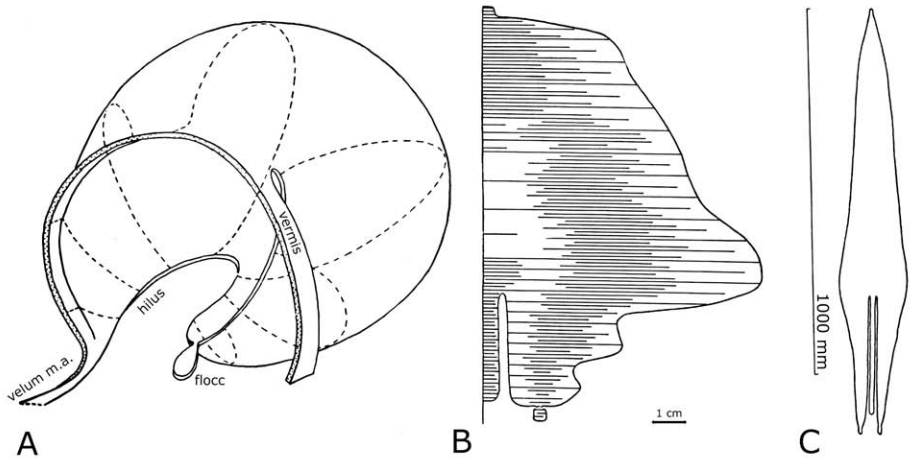

FIGURE 11.7 Braitenberg's graphical reconstructions of the cerebellar cortical sheet (Braitenberg and Atwood, 1958). **A.** Diagrammatic representation of right half of the human cerebellum as viewed from the medial side. For graphic purposes the discontinuous portion of the vermis is bent posteriorly. Dotted lines show direction of folia. The midline margin of the cerebellar sheet is cut. **B.** Plane representation of the right half of the cerebellar cortical sheet. Horizontal parallel lines have the actual measured length of the folia; three lines represent 10 folia. Actual vertical distances in this representation can be obtained by multiplying number of horizontal lines by 10 mm. **C.** Plane representation of human cerebellar cortical sheet, in which maximum length and width of the unfolded cortical sheet are represented in their true proportions (about 7:1).

cerebellum, in the lateral folium and tuber (VIIf and VIIt, Fig. 11.4F), and in the caudal paramedian sulcus in the region of the nidus avis (Figs. 11.2E and 11.4E, F). Striking illustrations of the independent expansion of the folial chains of vermis and hemispheres (which, however, ignore the continuity at the site of the copula pyramidis) were published by Braitenberg and Atwood (1958) (Fig. 11.7) for the human cerebellum and by Sultan and Braitenberg (1993) for many mammalian species. These figures also show to advantage the proportions of the folial chains, with their great length and relatively narrow width.

The nomenclatures of Bolk and Larsell as used in this chapter, are based on the comparative anatomy of the cerebellum. However, this does not guarantee the homology of fissures or fissures indicated with a name or number. These nomenclatures are primarily descriptive tools, based on criteria such as the developmental age and adult continuity of fissures, the general shape of lobules, or the apperence of the arbor vitae. The constancy of the paramedian sulcus and of some of the transverse fissures, such as the preculminate, primary, prepyramidal, secondary, and posterolateral fissures, is indicative of the homology of the intercalated lobules. However, homologies beyond this crude pattern generally remain uncertain. True homologies should be based on essential properties of the lobules, such as their zonal composition or on sound knowledge of the genetics and the developmental biology of the folial pattern (see Hatten and Heintz, 1995; Herrup and Kuemerle, 1997; Ozol *et al.*, 1999 for a discussion of this subject).

Homologies of the region of the biventral lobule, the tonsilla, and the flocculus with the paraflocculus and flocculus of the cerebellum of nonhuman primates have been notoriously difficult to establish. In monkeys (Fig. 11.8C) the cortex in the caudal paramedian sulcus, between uvula (lobule IX) and nodulus (X) and the hemisphere, is completely interrupted. The cortex of the pyramis (VIII) is continuous in the bottom of the paramedian sulcus with the caudal paramedian lobule (corresponding to the copula pyramidis). On the ventral surface (Fig. 11.8B) the cortex of the paramedian lobule is continuous with the folial chain of the dorsal paraflocculus. Rostrally the dorsal paraflocculus forms a laterally directed loop, the lobulus petrosus, which is lodged in the subarcuate fossa of the petrosal bone. At the rostral surface of the cerebellum a narrow bridge of cortex connects the rostral limb of the folial loop of the lobulus petrosus with the ventral paraflocculus (Fig. 11.8A). The deep, subfoliated posterolateral fissure separates the ventral paraflocculus from the flocculus, which includes the caudal 4 or 5 folia of the chain. Flocculus, (dorsal) paraflocculus, and paramedian lobule differ in their intrinsic zonal organization in most mammals (Voogd, 1998; see "Longitudinal Zonation of the Cerebellum" for more particulars). In monkeys the zonal organization of the flocculus and the ventral paraflocculus is very similar, sudden changes are observed at the transitions of the ventral paraflocculus

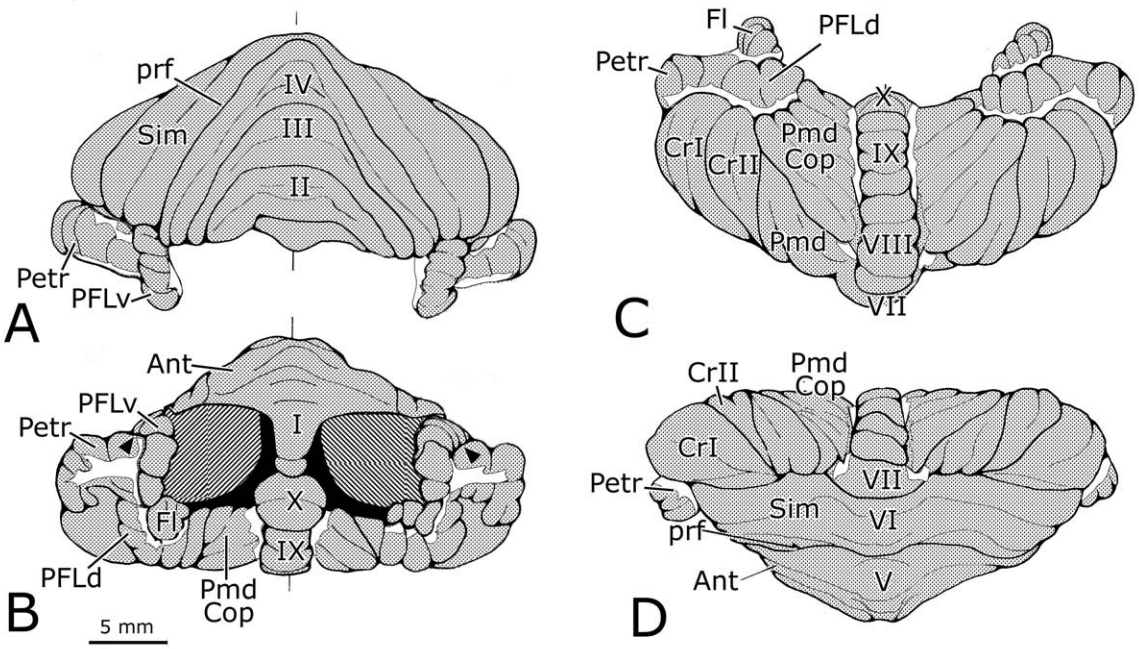

FIGURE 11.8 The cerebellum of *Macaca fascicularis*. **A.** Anterior aspect. **B.** Ventral aspect with cut surface of the cerebellar peduncles *(hatched)*. **C.** Caudal aspect. **D.** Dorsal aspect. Areas covered by cortex are shaded. The folial chains are bordered by white matter coming to the surface. Areas without cortex thus separate the ansiform and paramedian lobules from the caudal vermis, and from the dorsal paraflocculus and the petrosal lobule (in **B, C,** and **D**).White matter separates the rostral and caudal limbs of the petrosal lobule (in **B**) and the ventral paraflocculus with the flocculus from the dorsal paraflocculus (in **B** and **C**). The transition from the petrosal lobule into the ventral paraflocculus is indicated by arrowhead. Abbreviations: I–X, lobules I–X of Larsell; Ant, anterior lobe; Cop, copula pyramidis; CrI, crus I of the ansiform lobule; CrII, crus II of the ansiform lobule; Fl, flocculus; fps, fissura prima; Petr, petrosal lobule; PFLd, paraflocculus dorsalis; PFLv, paraflocculus ventralis; Pmd, lobulus paramedianus; Sim, lobulus simplex.

into the petrosal lobule and of the dorsal paraflocculus into the paramedian lobule (Figs. 11.49 and 11.50). A petrosal lobule and its subarcuate fossa are present in all monkeys of the old and the new world, but absent in homenoids, with the exception of *Hylobates* (Gannon *et al*., 1988).

Data on the gross anatomy of the cerebellum of the great apes are scarce (Larsell and Jansen, 1972), and the zonal organization of their cerebella and that of the human cerebellum has not yet been studied. The homology of the lobules in this region as stated by Bolk (1902, 1906) and Larsell (Larsell and Jansen, 1972) therefore remains uncertain. They maintain that the copula (lobule VIIIA) is represented by the lateral belly of the biventral lobule, the dorsal paraflocculus (lobule HVIIIB) by its medial belly, and the ventral paraflocculus by the tonsilla (lobule HIX). According to Larsell and Jansen (1972), the accessory paraflocculus (HIX; Loyning and Jansen, 1955) is connected to the tonsilla and separated from the flocculus proper (lobule HX). For several reasons these homologies appear unlikely.

In most mammals the dorsal and ventral paraflocculus can be distinguished as the two limbs of a continuous cortical loop, but they are certainly not homologous in different species (Fig. 11.49). In carnivores the dorsal paraflocculus and the proximal part of the ventral paraflocculus (in rodents and lagomorphs represented by the petrosal lobule) display the typical two- or three-zonal architecture of the paraflocculus. The distal part of the ventral paraflocculus [indicated in the cat as the ME, the medial extension of the ventral paraflocculus, by Gerrits and Voogd (1982)], corresponding to folium P in the rabbbit (Yamayoto, 1979), shares its zones with the flocculus. In monkeys these floccular zones extend over the entire ventral paraflocculus. Therefore, it appears unlikely that the huge tonsilla of the human cerebellum would represent the homologue of the ventral paraflocculus of monkeys; a homology with the dorsal paraflocculus seems much more likely. Whether pars of the biventral lobule should be included with the dorsal paraflocculus cannot be decided at present. The accessory paraflocculus probably is the homologue of ventral paraflocculus of monkeys. The

narrow cortical bridge between the ventral paraflocculus and the petrosal lobule in monkeys is not present in the human cerebellum, where white matter separates the accessory paraflocculus from the tonsilla and a petrosal lobule is absent.

CEREBELLAR NUCLEI

The four central cerebellar nuclei were first distinguished by Stilling (1864) in the human cerebellum (Fig. 11.9). Their morphology was extensively reviewed by Ziehen (1934) and more recently by Larsell and Jansen (1972). The cerebellar nuclei border on the fourth ventricle and the vestibular nuclei. The border with the vestibular nuclei is not distinct because the large cells of Deiters' nucleus, which are a prominent feature of this transitional area in lower mammals, are difficult to distinguish in the human brain (see Chapter 33).

The medial or fastigial nucleus is located next to the midline. It consists of several cell groups, which have not been named. Its rostral and dorsal parts are traversed by thick fibers of the uncinate tract, which decussates in between the fastigial nuclei of both sides. Laterally it is delimited by a cellular ridge, which extends in the cerebellar white matter of the vermis (Fig. 11.10B, C). In monkeys this ridge can be considered as part of the interstitial cell groups (Fig. 11.12).

The globose nucleus consists of several cell groups, separated by fiber bundles. It extends far caudally, where these cell groups fuse into a single mass. The emboliform nucleus has about the same rostrocaudal

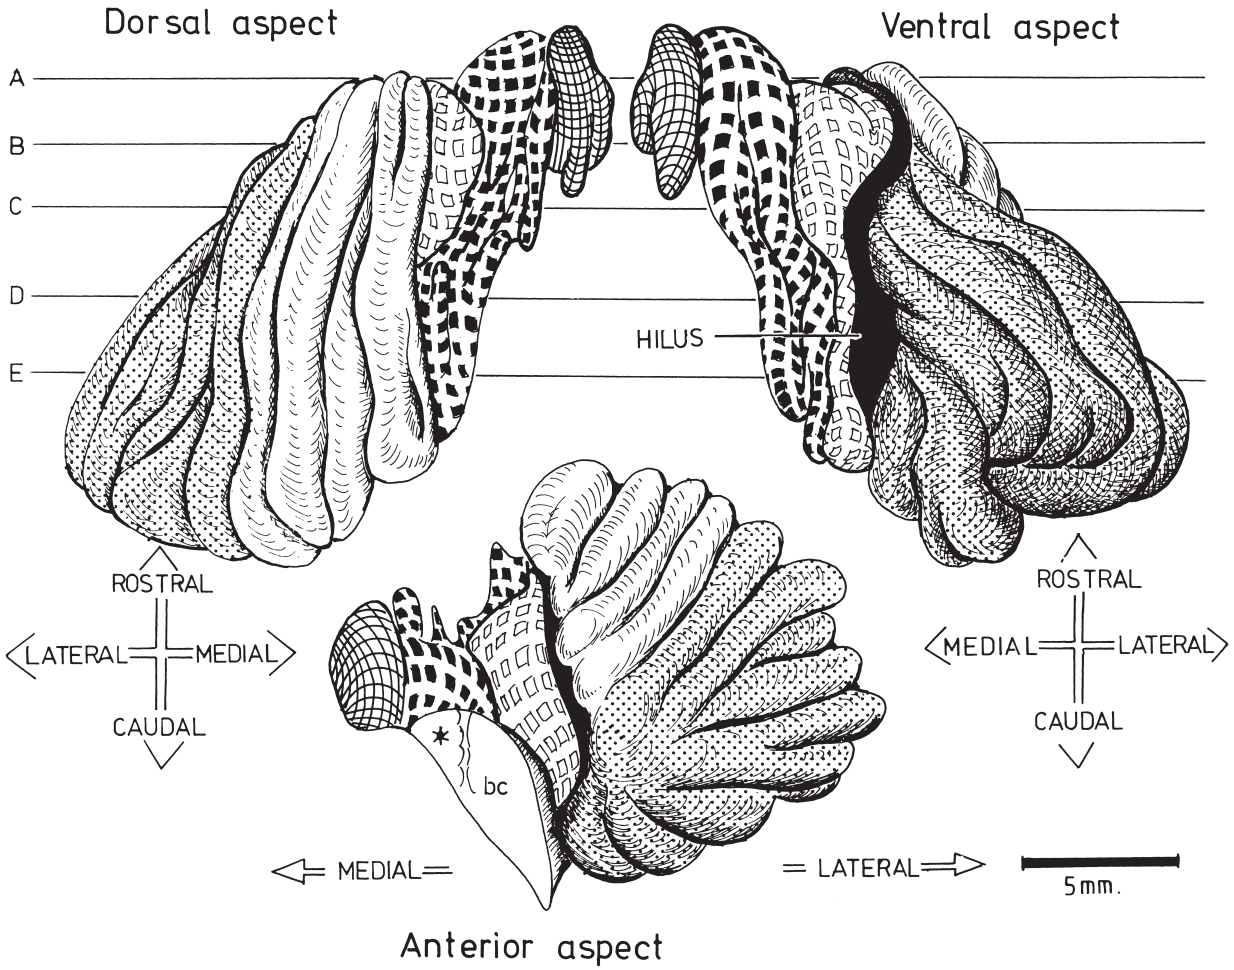

FIGURE 11.9 Graphical reconstructions of the central cerebellar nuclei of the human cerebellum. Dorsal, ventral and anterior views. Fastigial nucleus: double hatched; globose nucleus: filled squares; emboliform nucleus: open squares; the macrogyric, ventrolateral portion of the dentate is indicated by dots. The medial component of the brachium conjuctivum is indicated by an asterisk. The levels of the sections depicted in Figure 1.10A–E are indicated.

extent as the globose nucleus. The two nuclei are completely separated by fiber bundles. The emboliform is a compact nucleus, which tapers caudally and fuses with the medial lamina of the dentate nucleus (Fig. 11.10D, E). The fastigial, globose, and emboliform nuclei contain cells of all sizes, but the larger cells are present in the emboliform nucleus.

The dentate nucleus has the shape of a "crumpled purse" (Chan-Palay, 1977) with its hilus directed ventromedially and rostrally. Two parts of the nucleus can be distinguished (Figs. 11.4A, B, 11.9 and 11.10). Its dorsomedial part is folded in rather narrow, rostrocaudally directed ridges. It is known as the microgyric part of the dentate nucleus. The ridges in the ventrolateral part of the nucleus are broad and subdivided, and the cell band in this part of the nucleus is wider than in the microgyric part. Their direction is obliquely laterally and caudally, and the ridges turn inward and can be followed at he ventral surface of the nucleus. Caudally the hilus is closed by the medial lamina of the dentate. The cells of the microgyric part of the dentate are larger than those in the macrogyric position of the nucleus (Demolé, 1927a, b), but both subdivisions also contain small neurons (Fig. 11.11).

The cerebellar nuclei of mammals can be subdivided according to Brunner (1919) into three mediolaterally arranged nuclei or according to Weidenreich (1899) and Ogawa (1935) in rostrolateral and caudomedial groups. Cytoarchitectonic criteria can be used to subdivide the cerebellar nuclei, but the presence of fiber bundles, and the disposition of their efferents in the nuclear hilus and in their efferent tracts are especially important in this respect. Brunner's (1919) mediolateral subdivision into the medial (fastigial), lateral (dentate), and interposed nuclei is based on the contours of the central nuclear mass. The three nuclei are part of a continuum and the nuclear borders therefore remain arbitrary. Although Brunner's concept of the cerebellar nuclei as a single mass has been disproved, his names for the nuclei have stuck. Weidenreich's (1899) comparative studies in mammals had already shown that fiber bundles subdivide the nuclei into a caudomedial group, which includes the fastigial nucleus and the caudal part of the Brunner's interposed nucleus (the nucleus interpositus posterior of Ogawa, 1935), and a rostrolateral group which is composed of the dentate nucleus and the rostral part of the interposed nucleus (the nucleus interpositus anterior). The nuclei within each group are interconnected by cell bridges. The subdivision of Weidenreich and Ogawa can be readily appreciated in lagomorpha (Ono and Kato, 1938; Snider, 1940), in carnivores (Flood and Jansen, 1961; Voogd, 1964), and in primates (Courville and Cooper, 1970; Chan-Palay, 1977). In rodents and insectivores the separation between the two nuclear groups is less

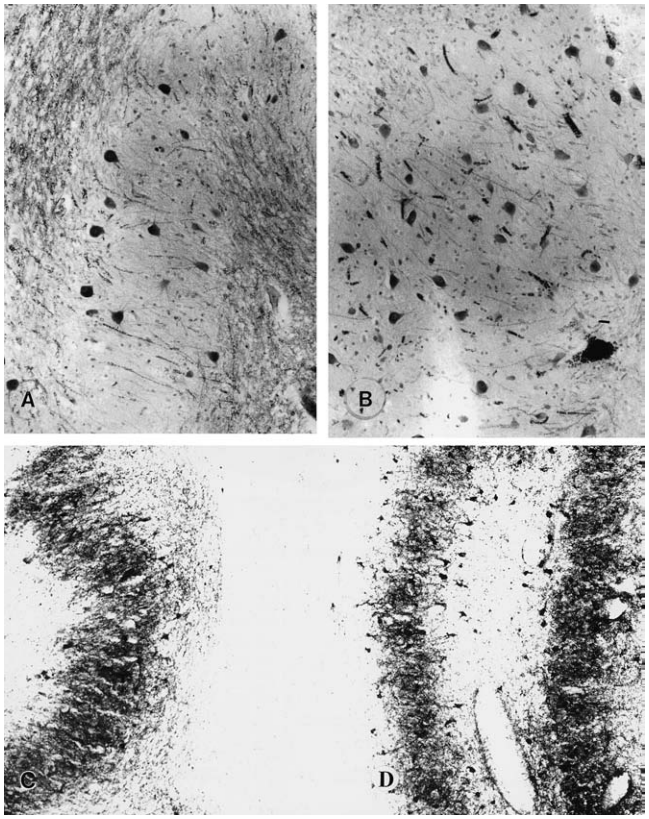

FIGURE 11.11 **A.** The dentate lamella. microgyric (magnocellular) part. Magnification 50×. **B.** Macrogyric (parvicellular) part. distinct and the connections between the nuclei of each group are more extensive (Korneliussen, 1968; Ohkawa, 1957).

The topographical relations of the fastigial, globose, and emboliform nuclei of man resemble those of the fastigial nucleus and the posterior and anterior interposed nuclei of nonhuman primates (Courville and Cooper, 1970). The fastigial nucleus of the monkey is broadly fused with the posterior interposed nucleus. Caudally this connection is U shaped (Fig. 11.12, section 120); rostrally it continues into a lateral "ridge" of the fastigial nucleus and scattered cells in the region between the fastigial and anterior interposed nuclei (Fig. 11.12, section 165). The U-shaped subnucleus probably is identical to the "interstitial cell groups," described by Buisseret-Delmas *et al.* (1993) in the same position in the rat. In the rat it is the recipient of the X zone, one of the Purkinje cell zones of the vermis (Fig. 11.46 in "Longitudinal Zonation of the Cerebellum"). The anterior interposed and dentate nuclei are interconnected in the same way as the emboliform and dentate nuclei in the human cerebellum. The

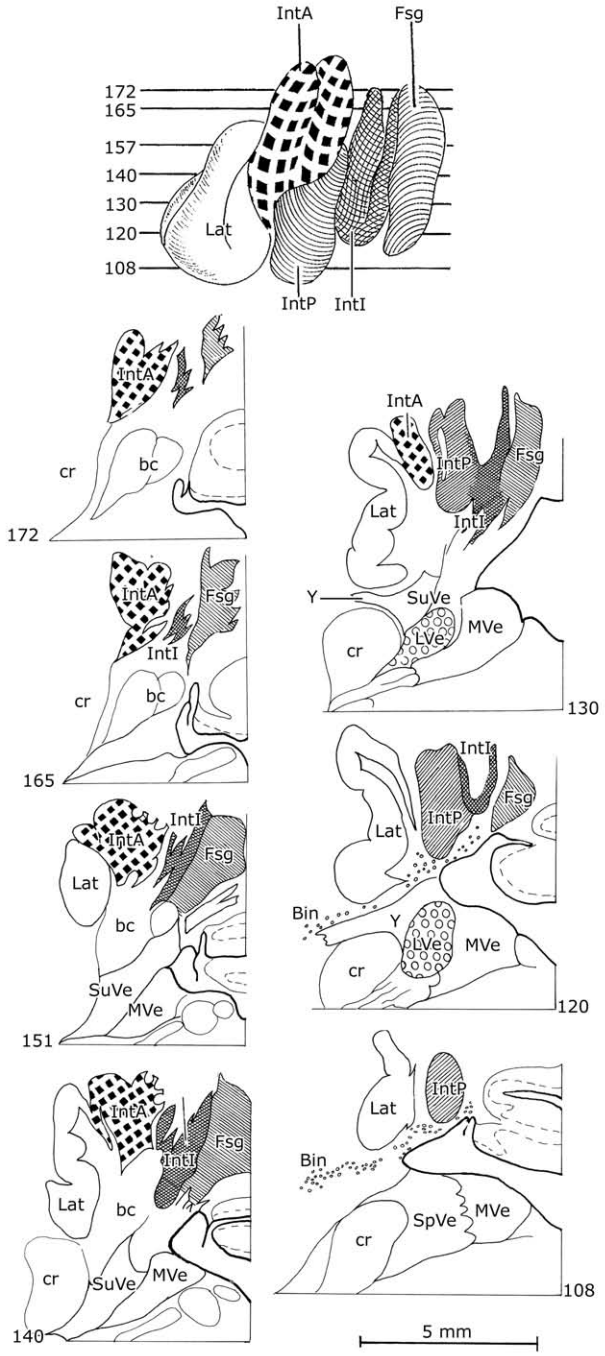

FIGURE 11.12 The cerebellar nuclei of the *Macaca fascicularis*. Upper diagram: graphical reconstruction of the dorsal aspect of the cerebellar nuclei. Levels of the diagrams are indicated by lines. Below are drawings of serial, acetylcholinesterase-stained sections. The U-shaped, intermediate cell group (IntI) located between the fastigial and interposed nuclei is indicated by double hatching. The basal interstitial nucleus of Langer (Bin) is indicated by dots. The medial component of the brachium conjunctivum is indicated with an asterisk. Abbreviations: bc, brachium conjunctivum; Bin, basal interstitial nucleus; bp, brachium pontis; cr, restiform body; Fsg, fastigial nucleus; IntA, anterior interposed nucleus; IntI, intermediate cell group; IntP, posterior interposed nucleus; Lat, lateral cerebellar nucleus; LVe, lateral vestibular nucleus of Deiters; Mve, medial vestibular nucleus; SpVe, spinal vestibular nucleus; SuVe, superior vestibular nucleus; Y, group Y.

anterior and posterior interposed nuclei in the monkey extend over approximately the same rostrocaudal extent (Fig. 11.12): therefore, the adjectives "anterior" and "posterior", are not entirely appropriate; they are derived from the situation in lower mammals, where the two nuclei occupy a rostral and a caudal position. The general shapes of the dentate nucleus and the lateral cerebellar nucleus of the monkey are the same, but a homology of their subdivisions is not yet possible.

One group of small neurons in the rhesus monkey, which was described by Langer (1985) under the name of the basal interstitial nucleus, displays uniform and strong AChE activity. These small cells lie dispersed in the white matter of the flocculus and the nodule and ventral to the dentate and the posterior interposed nucleus, in the roof of the fourth ventricle (Fig. 11.12). The basal interstitial nucleus is reciprocally connected with the flocculus and possibly projects to other lobules of the cerebellum (Langer, 1985). In this respect, it differs from the group Y (Brodal and Pompeiano, 1957), which is a lateral extension of the superior vestibular nucleus, located ventral to the dentate nucleus (Fig. 11.12). The group Y gives rise to projections to the oculomotor nuclei (Graybiel and Hartwieg, 1974; Sato *et al.*, 1984; Stanton, 1980b; Steiger and Büttner-Ennever, 1979; Yamamoto *et al.*, 1986). The group Y is large in monkeys but less conspicuous in the human brain (see Chapter 33). The basal interstitial nucleus has not been identified in the human cerebellum.

Two populations of neurons have been distinguished in all cerebellar nuclei. One consists of small GABAergic neurons, which project exclusively to the inferior olive (Graybiel *et al.*, 1973; Tolbert, 1976, Mugnaini and Oertel, 1981, 1985; see also "Afferent Systems of the Inferior Olive: The Nucleoolivary Projection"). These small GABAergic neurons also has been demonstrated in the human cerebellar nuclei (Mugnaini, personal communication) (Fig. 11.11C). The other population consists of excitatory relay cells with widespread, branching axons, terminating in the brain stem, spinal cord, and thalamus. They constitute a mixed population of cells of all shapes and sizes (Courville and Cooper, 1970). The possible excitatory neurotransmitters of the relay cells were reviewed by Voogd *et al.* (1996b). A third population of small interneurons was identified by Chan-Paly (1977) on morphological grounds in the monkey and by Chen and Hillman (1993) on the basis of their neurotransmitter content in the rat.

In the human cerebellum the dentate nucleus can be subdivided into ventromedial magnocellular and caudolateral parvocellular parts. These two regions also differ in their development, the rostromedial portion differentiating before the caudolateral dentate (De Sanctis, 1898, 1902/1903; Weidenreich, 1899; Vogt and Astzwazaturow, 1912; Brun, 1917/18a–c, 1925a, b), and

in the higher iron content of the caudolateral dentate (Gans, 1924). The latter observation probably constitutes first instance of a neurochemical differentiation within the cerebellum. The caudolateral dentate usually was involved in human cases of "neocerebellar atrophy," which mainly affected the hemisphere and spared the flocculus and the vermal and paravermal cortex and the other cerebellar nuclei, including the rostromedial dentate (Brouwer, 1913, 1915; Brouwer and Coenen, 1920, 1921; Brun, 1917/18a–c, 1925a, b). To express the differential vulnerability of the two parts of the human dentate nucleus they became known as the rostromedial palaeodentatum and the caudolateral neodentatum. The homology of the two parts of the human dentate with possible subdivisions of the dentate nucleus of monkeys is not clear. However, there are indications for a subdivision of the monkey dentate on the basis of the corticonuclear and efferent connections of this nucleus, which will be discussed in later sections of this chapter.

CEREBELLAR PEDUNCLES: TOPOGRAPHY OF PATHWAYS FROM THE HUMAN CEREBELLAR NUCLEI

Cerebellar Peduncles

Superior, inferior, and middle cerebellar peduncles generally are distinguished (Fig. 11.13). The superior peduncle contains a compact, sickle-shaped fiber bundle, the brachium conjunctivum, which consists of fibers from all the ipsilateral cerebellar nuclei. The middle cerebellar peduncle, or the brachium pontis, is located laterally. The middle peduncle is purely afferent. Its origin from the contralateral pontine nuclei was first demonstrated by Vejas (1885) in chronic experiments in the rabbit. The inferior peduncle consists of external and internal divisions: the restiform body and the juxtarestiform body (Stilling, 1846). The fiber bundles of the juxtarestiform body are located medial to the restiform body, within the lateral and spinal vestibular nuclei. They consist of the ascending and descending branches of the vestibular root fibers, intrinsic vestibular connections, crossed and uncrossed efferent pathways from the fastigial nucleus, and Purkinje cell axons that enter the juxtarestiform body from the flocculus and the vermis. The restiform body consists of afferent fibers

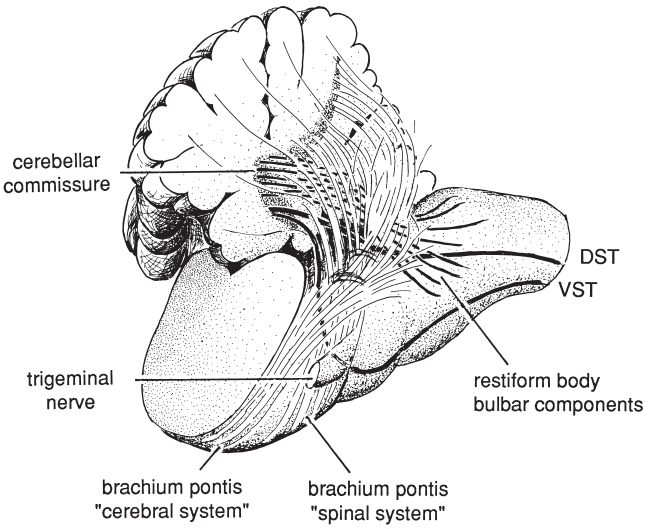

FIGURE 11.13 Diagram of the extra- and intracerebellar course of the main fiber systems terminating as mossy fibers in the cerebellum of the cat. *Thin lines:* pontocerebellar fibers. *Heavy lines:* bulbo- and spinocerebellar systems. The ventral spinocerebellar tract passes rostral to the root of the trigeminal nerve. From Voogd (1967).

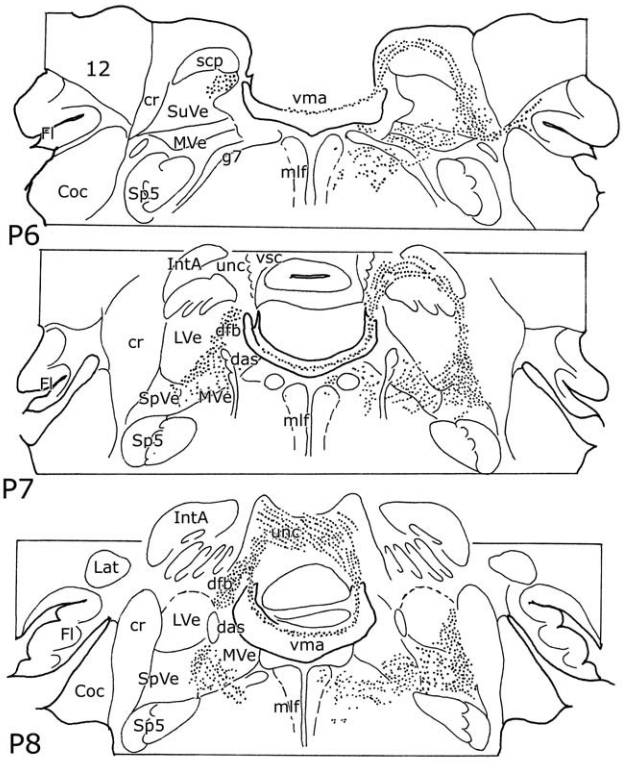

FIGURE 11.14 Diagram of the efferent pathways from the left fastigial nucleus in the cat. course of the direct fastigiobulbar tract **(left)** and the uncinate tract **(right)** in the stereotatic planes P.6–P.8. The situation in monkeys is very similar to the cat. Abbreviations: bp, brachium pontis; Coc, cochlear nuclei; cr, restiform body; das, acoustic striae; dfb, direct fastigiobulbar tract; Fl, flocculus; g7, genu of facial nerve; IntA, anterior interposed nucleus; Lat, lateral cerebellar nucleus; LVe, lateral vestibular nucleus of Deiters; mlf, medial longitinal fascicle; MVe, medial vestibular nucleus; scp, brachium conjunctivum; Sp5, spinal tract of the trigeminal nerve; SpVe, spinal vestibular nucleus; SuVe, superior vestibular nucleus; unc, uncinate tract; vma, anterior medullary velum; vsc, ventral spinocerebellar tract. Modified by Voogd (1964).

from the brain stem and the spinal cord that pass lateral to the spinal tract of the trigeminal nerve to enter the cerebellum in between the brachium pontis and the brachium conjunctivum. One group of spinocerebellar fibers does not join the restiform body but enters the cerebellum far rostrally, along the brachium conjunctivum, by passing ventral to the entering root of the trigeminal nerve (Fig. 11.13). At its emergence from the hilus of the cerebellar nuclei the brachium conjunctivum intersects with the juxtarestiform body. Bundles of Purkinje cell axons pass as perforating fibers through the brachium at its emergence from the hilus of the dentate nucleus (Fig. 11.10B, C).

Topography of Efferent Pathways from the Fastigial Nucleus

The efferent pathways of the fastigial nucleus have not been studied in man, fragmentary information is available from the myelogenetic studies of von Bechterew (1888, 1899) and De Sanctis (1898, 1902/03). Von Bechterew traced fibers from the fastigial nucleus to the superior olive. Obviously he mistook the early myelinating fibers of the olivocochlear bundle for the distal part of this pathway. The fibers crossing between the fastigial nuclei, which he saw arching over the brachium conjunctivum (Fig. 11.15, fos), clearly belong to the uncinate tract. In humans the decussating fibers of the uncinate tract occupy the dorsal and rostral periphery of the fastigial nucleus. Dorsally the decussation extends into the anterior medullary velum (Figs. 11.14 and 11.16). Fibers of the afferent component of the cerebellar commissure, which are thinner and are derived from the restiform body and the brachium pontis, occupy a more peripheral position.

In the cat (Fig. 11.14) the fibers of the uncinate tract subsequently arch over the brachium conjunctivum, to take up a position in the lateral part of the juxtarestiform body, traveling lateral to Deiters' nucleus, in the ventrolateral portion of the descending vestibular nucleus. A small bundle detaches from the uncinate tract, to ascend to the mesencephalon, dorsomedial to the brachium conjuctivum. The ascending limb of the uncinate tract was first described in the experimental studies of Probst (1902). In cat (Voogd, 1964) (Fig. 11.14) and monkey (Batton *et al,* 1977), a bundle of coarse fibers from the ipsilateral fastial nucleus passes medial to the brachium and Deiters' nucleus, to become located in the medial part of the juxtarestiform body. These "direct fastigiobulbar fibers" have not been observed in human material. The third, efferent pathway from the fastigial nucleus consists of fibers traveling in the medial third of the brachium conjuctivum. This component has been substantiated in the experimental studies of Voogd (1964) in the cat, and of Batton *et al.* (1974) and Asanuma *et al.* (1983c) in

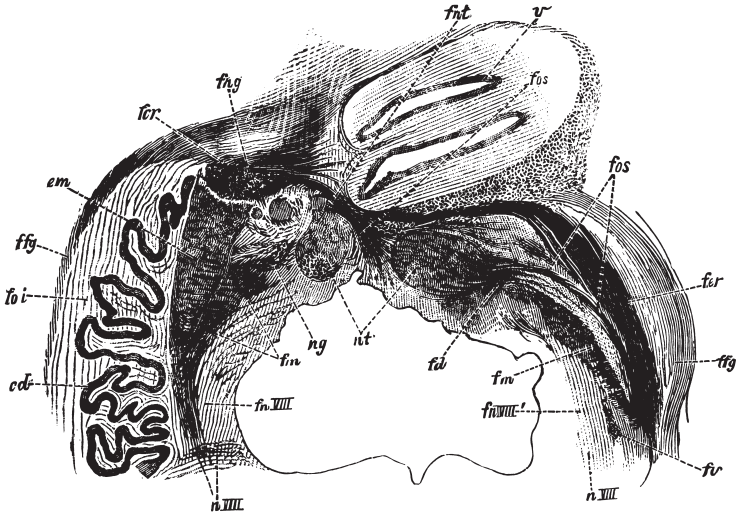

FIGURE 11.15 Myelin-stained section through the cerebellum of a human fetus of 44 cm. Abbreviations: cd, dentate nucleus; emboliform nucleus; fcr, spino-, cuneo-, and lateral reticulocerebellar fibers in restiform body; fd, fm, and fv, dorsal, medial, and ventral components of the brachium conjunctivum; ffg, external arcuate fibers; foi, unmyelinated olivocerebellar fibers; fng and fnt, fibers from central nucleus to the cortex; fos, fibers from fastigial nucleus to superior olive (uncinate tract); fnVIII', vestibulocerebellar fibers; nVIII, Von Bechterew's superior vestibular nucleus; ng, globose nucleus; nt, fastigial nucleus; v, vermis. From Von Bechterew (1899).

Abbreviations: Ce, central lobule; Cu, culmen; De, declive; Fo; Folium vermis; Tu, tuber vermis; Py, pyramis; Sis, superior semilunar lobule; Uv, uvula; Nod, nodulus; Tons, tonsilla; vma, velum medullare anterior; afx, cerebellar comissure: afferent portion; ux, cerebellar commissure, uncinate tract; F, fastigial nucleus; Fast, fastigium.

monkeys. The fate of this fastigial efferent pathway is not known.

Origin, Course and Termination of the Brachium Conjunctivum in the Human Brain

The subdivision of the cerebellar nuclei by Weidenreich and Ogawa receives strong support from the localization of their efferent tracts in the brachium conjuctivum. A small medial and a large lateral portion can be distinguished in the brachium in most mammals at its exit from the cerebellar nuclei (Verhaart, l956b). Experiments in cats (Voogd, 1964) (Fig. 11.17A), rat (Haroian *et al.*, 1981), and monkey (Kievit, 1979; Stanton,1980a; Kalil, 1981) have shown that the medial part of the brachium takes its origin from the nuclei of the caudomedial group, the ipsilateral fastigial and posterior interposed nucleus, and the lateral portion from the ipsilateral anterior interposed and lateral cerebellar nucleus. The excitatory anterior canal—vestibulooculomotor neurons of the superior vestibular nucleus, and possibly from the group Y—occupy the extreme ventrolateral pole of the brachium conjunctivum (Highstein and Reisine, 1979; Lang *et al.*, 1979, Hirai and Uchino, 1984; Steiger and Büttner-Ennever, 1979).

In humans the brachium conjunctivum emerges from the hilus of the dentate and the ventral aspect of the emboliform nucleus. Its dorsomedial part contains a bundle of larger fibers embedded in a small fiber area (Verhaart, 1956b), which is separated from the rest of the brachium by an unmyelinated streak. This portion of the brachium seems to take its origin from the globose nucleus and possibly from the fastigial nucleus (Figs. 11.9 and 11.10A, B, *asterisk*). Such an origin would be in accord with the situation in lower

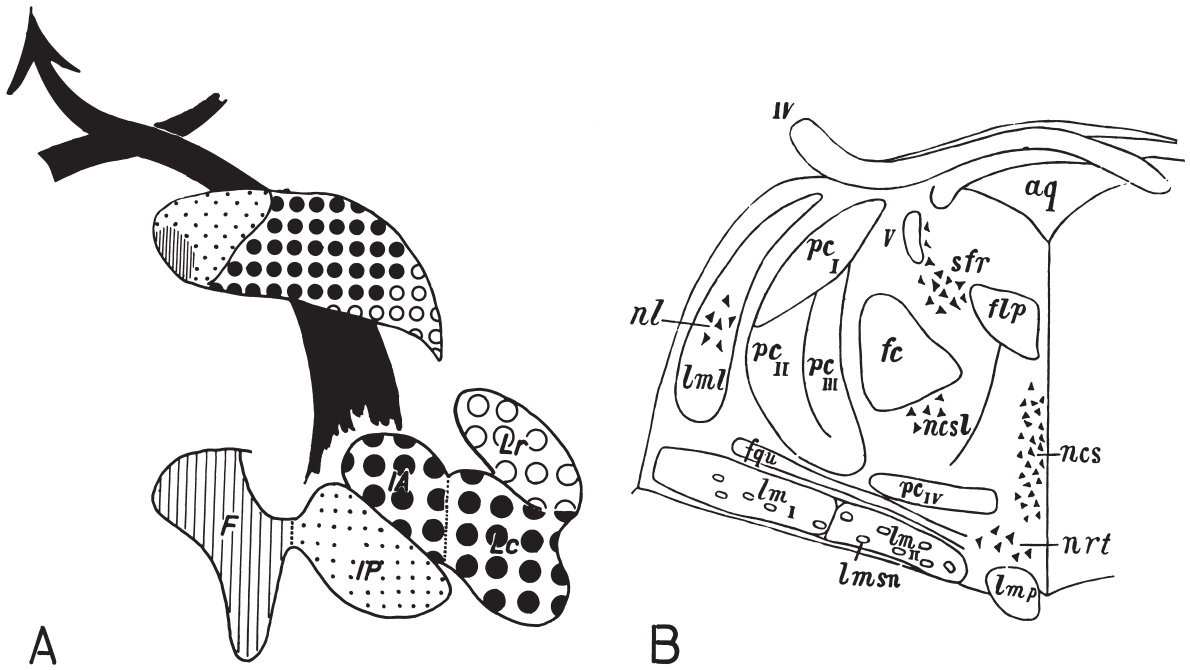

FIGURE 11.17 Components of the brachium conjunctivum. **A.** The brachium conjunctivum in the cat. Fibers from the fastigial and posterior interposed nucleus occupy its medial one-third; fibers from the anterior interposed and the dorsal part of the lateral nucleus (Lc) occupy the middle region of the brachium; fibers from the ventral part of the lateral nucleus (Lc) occupy its lateral pole. From Voogd (1964). **B.** The four components of the human brachium conjunctivum according to Von Bechterew (1888, 1899). pcI: early myelinating dorsal bundle from fastigial and globose nuclei (Fig. 11.15: fd); pcII: later myelinating fibers from emboliform nucleus (Fig. 11.15: fm); pcIII: fibers from dentate nucleus, myelinate postnatally (Fig. 11.15: fi); pcIV: fibers from the vestibular nuclei are the first to acquire their myelin sheaths (Fig. 11.15: fv). Abbreviations: aq, aqueduct; F, fastigial nucleus; Fc, central tegmental tract; Flp, medial longitidinal fascicle; IA, anterior interposed nucleus; IP, posterior interposed nucleus; IV, trochlear nerve; Lc, dorsocaudal part of lateral cerebellar nucleus; lmI, lmII, components of the medial lemniscus; Lr, ventromedial part of lateral cerebellar nucleus; msn, areae nebulosae in the medial lemniscus; Ncs, central superior nucleus; Ncsl, lateral part of the central superior nucleus; nrt, nucleus reticularis tegmenti pontis; sfr, locus coerulaeus; V, mesencephalic root of the trigeminal nerve.

mammals. Von Bechterew (1888, 1899), who studied the myelinization of the brachium conjunctivum in man, distinguished four components (Fig. 11.17B). The dorsal and middle components (PC-I and II) acquire their myelin rather early and are related to the fastigial nucleus, and the globose and emboliform nuclei, respectively. The PC-I component probably corresponds with the dorsomedial-, globose-; and fastigially derived portions of the brachium and the PC-II component includes the efferent pathway from the emboliform nucleus. The ventral component (PC-III) takes its origin from the dentate nucleus and acquires its myelin postnatally. The ventromedial position of the fibers of the dentate closely corresponds to their localization in the cat (Fig. 11.13A). The fourth component (PC-IV), which is the first to acquire its myelin, is related not to the cerebellar but to the vestibular nuclei. According to von Bechterew, it belongs to the vestibular commissure; in the pons these fibers decussate in the ventral part of the tegmentum. The ventral position of these fibers in the brachium and in its decussation are typical for the ascending vestibulooculomor fibers from von Bechterew's superior vestibular nucleus and the group Y, referred to above.

The decussation of the brachium conjunctivum consists of dorsal and ventral portions. In the ventral portion fibers from the ventral pole of the brachium cross dorsal to the interpedunclar nucleus; the dorsal portion contains decussating fibers of the dorsal and ventral brachium. Rostrally the two portions fuse and the decussation tapers out, ventral to the caudal pole of the red nucleus (Voogd, 1964). According to Chan-Palay (1977), the decussation in the monkey is incomplete: uncrossed fibers originate mainly from the caudal part of the dentate nucleus. Chan-Palay (1977) observed a dorsolateral fiber bundle, which detaches from the

brachium conjunctivum prior to its decussation, in all of her experiments with injections of tritiated methionine in the dentate nucleus. The fibers of this dorsolateral bundle decussate rostral to the main brachium and join the descending branch of the brachium conjunctivum. The course of the dorsolateral bundle in the monkey closely resembles the route followed by the nucleoolivary fibers from the interposed and dentate nuclei in cat (Legendre and Courville, 1987) and rat (Cholley *et al.*, 1989).

After their decussation the fibers of the brachium conjunctivum split in ascending and descending branches. The descending branch consists of collaterals from axons of cerebellar relay cells (Ramon y Cajal, 1909) and the nucleoolivary fibers of the dorsolateral bundle.

The fibers of the ascending branch ascend through and along the red nucleus. Apart from the red nucleus, terminations of the ascending branch include the central gray, the oculomotor nuclei, and the superior colliculus. The major ascending pathway leaves the red nucleus as a dorsolaterally directed bundle (the tegmental field H of Forel). In the subthalamus it passes through the external medullary lamina of the thalamus (field H1 of Forel) to terminate in the thalamus. This course was first described in the human brain by Forel (1877), who also coined the names for the tegmental fields (the "Haubenfeld"—tegmental field—which divides in the dorsal and the ventral "Haubenfeld," H1 and H2, with the zona incerta located in between).

The termination of the brachium conjunctivum in the thalamus in man has only been described in two studies using axonal degeneration techniques. The study of Probst (1901) used the Marchi method in a case with an isolated softening of the brachium conjunctivum. According to Probst, the decussation of the brachium is not complete, a few degenerated fibers ascend toward the ipsilateral red nucleus. The degenerated fibers traverse the red nucleus, where they are sparse in its dorsal part and where they constitute a ventromedial and lateral capsule of myelinated fibers. The dorsomedial part of the capsule of the red nucleus is formed by the emerging fibers of the central tegmental tract (Fig. 11.32; see "Afferent Systems of the Inferior Olive: The Nucleoolivary Projection"). In the subthalamus the degenerated fibers are located dorsal to the zona incerta in the external medullary lamina. Probst used von Monakow's (1895) subdivision of the thalamus. He traced some fibers into the internal medullary lamina, some of which pass through the ventral posterior nucleus (nucleus ventralis b of von Monakow) to terminate in the centre médian (nucleus medialis b). Most fibers terminate between the internal and external medullary laminae, rostral to the ventral posterior nucleus, in a region corresponding to the nucleus ventralis lateralis (nucleus ventralis a, nucleus lateralis b).

In the second study, the Nauta method was used in two cases with degeneration of the brachium conjunctivum (Gebbink, 1967). In one of these cases (H5739, Fig. 11.18) a hemorrhage destroyed the hilus of the dentate nucleus and extended into the medial half of the brachium conjunctivum (Fig. 11.19). The mesencephalon and the thalamus were sectioned sagittally. Degenerated fibers enter the thalamus from the red nucleus through the internal medullary lamina and the centre médian, where they terminate mediodorsally, and through the field of Forel, where they intermingle with the pallidal fibers from the fasciculus lenticularis. They pass rostroventral to the centre médian and dorsal to the zona incerta, which receives some degenerated fibers. Terminal degeneration is found rostral to the centre médian and rostral to the ventral posterior nucleus in the ventrolateral nucleus. Laterally and rostroventrally the amount of degeneration decreases. Some fibers enter the thalamus far rostrally from the reticular nucleus. The distribution in a second, horizontally sectioned case (H5753) with a large hemorrhage involving all cerebellar nuclei is essentially similar. In this case, degenerated fibers also were traced from the central gray into the periventricular region of the thalamus.

Gebbink (1967) also described the degeneration resulting from lesions of the globus pallidus. The sagittal sections from one of these cases (H5541, Nauta method) were redrawn together with the cerebellar degeneration in Figure 11.18. Degeneration is found in the fasciculus and ansa lenticularis, passing around the zona incerta, which did not receive a projection, into the fasciculus thalamicus. The terminations in the thalamus are located rostroventral and lateral to the main termination of the brachium conjunctivum, but there is some overlap of both projections. In addition, degeneration is present in the stria medullaris and the habenular nuclei. The centre médian is devoid of degenerated fibers.

Fibers of the descending branch of the brachium conjunctivum could be traced in the two cases with cerebellar lesions, which served as the basis for the description of the ascending branch by Gebbink (1967). One of these cases, H5739, is illustrated in Figure 11.19 (Schoen, unpublished observations). At the level of the entrance of the trigeminal nerve the degenerated descending branch occupies a triangular area in the ventromedial part of the tegmentum pontis; laterally it extends over the dorsal surface of the medial lemniscus and borders the ventromedial surface of the central tegmental tract. More caudally it intermingles with the

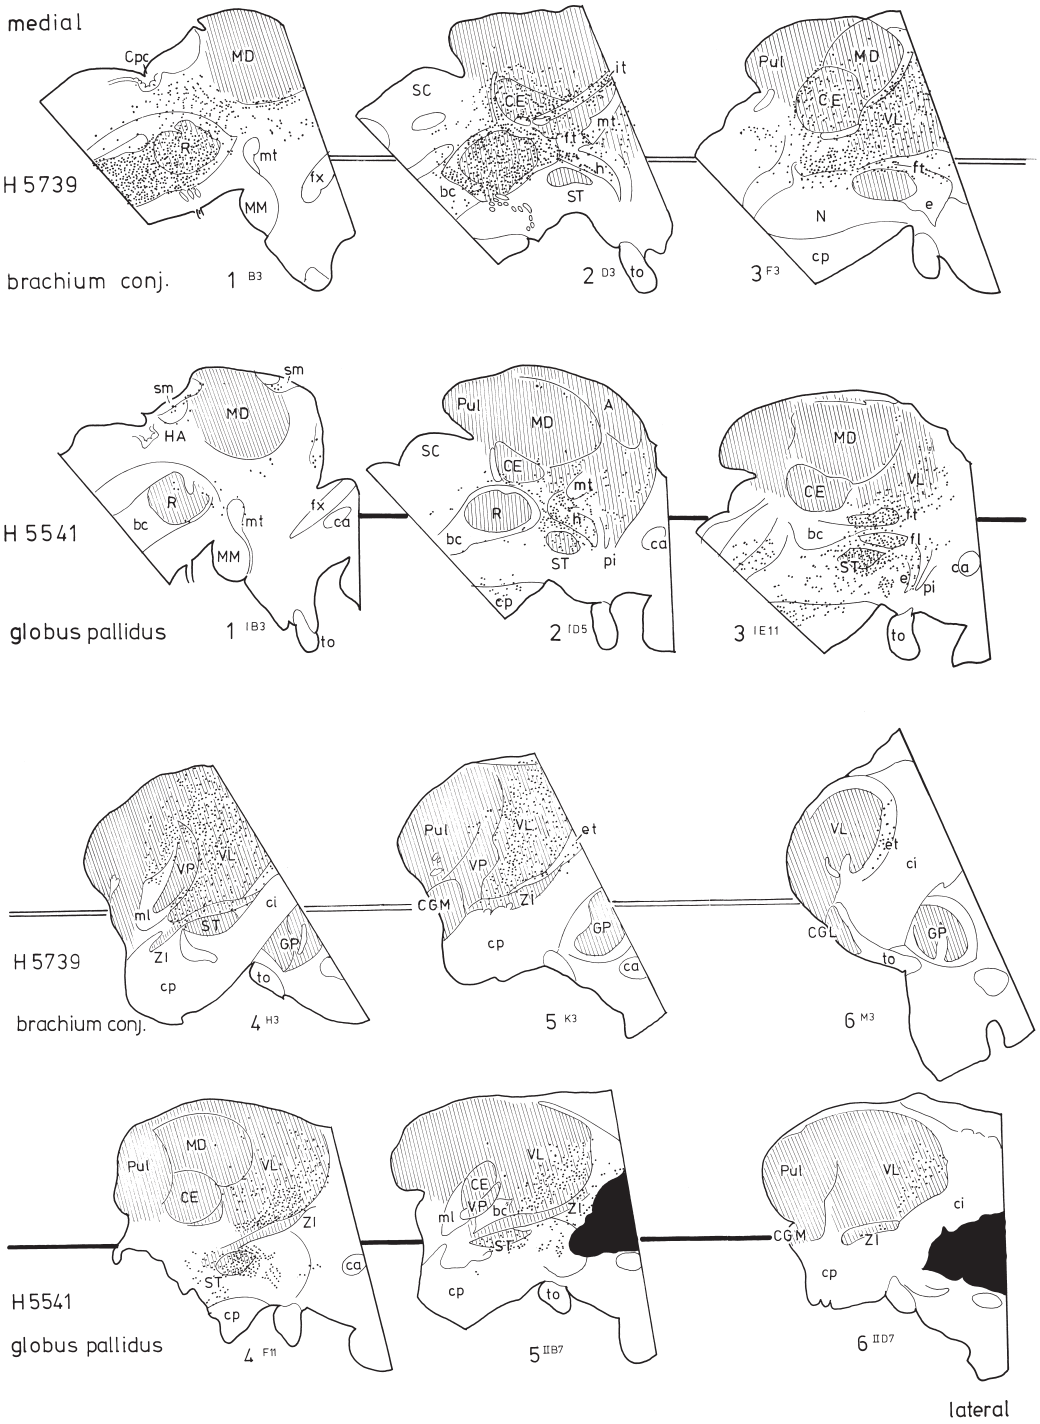

FIGURE 11.18 The termination of the ascending branch of the brachium conjunctivum in case H5739 and the fiber degeneration resulting from a lesion of the globus pallidus in case H5541. Nauta stain on sagittal sections. Lesion of the globus pallidus indicated in black. Abbreviations: Anterior thalamic nucleus; bc, brachium conjunctivum; ca, anterior comissure; CE, nucleus of the centre médian; CGL, lateral geniculate body; CGM, medial geniculate body; ci, internal capsule; cp, cerebral peduncle; Cpc, posterior commissure; e, Edinger's comb system; et, external medullary lamina; fl, fasciculus lenticularis; ft, fasciculus thalamicus; fx, fornix; GP, globus pallidus; h, tegmental field H of Forel; Ha, habenular nuclei; it, internal medullary lamina; MD, mediodorsal nucleus; ml, medial lemniscus; MM, corpus mamillare; mt, mamillothalamic tract; N, substantia nigra; pi, inferior thalamic peduncle; Pul, pulvinar; R, red nucleus; SC, superior colliculus; ST, subthalamic nucleus; to, optic tract; VL, ventral lateral nucleus; VP, ventral posterior nucleus; ZI, zona incerta. Redrawn from Gebbink (1967).

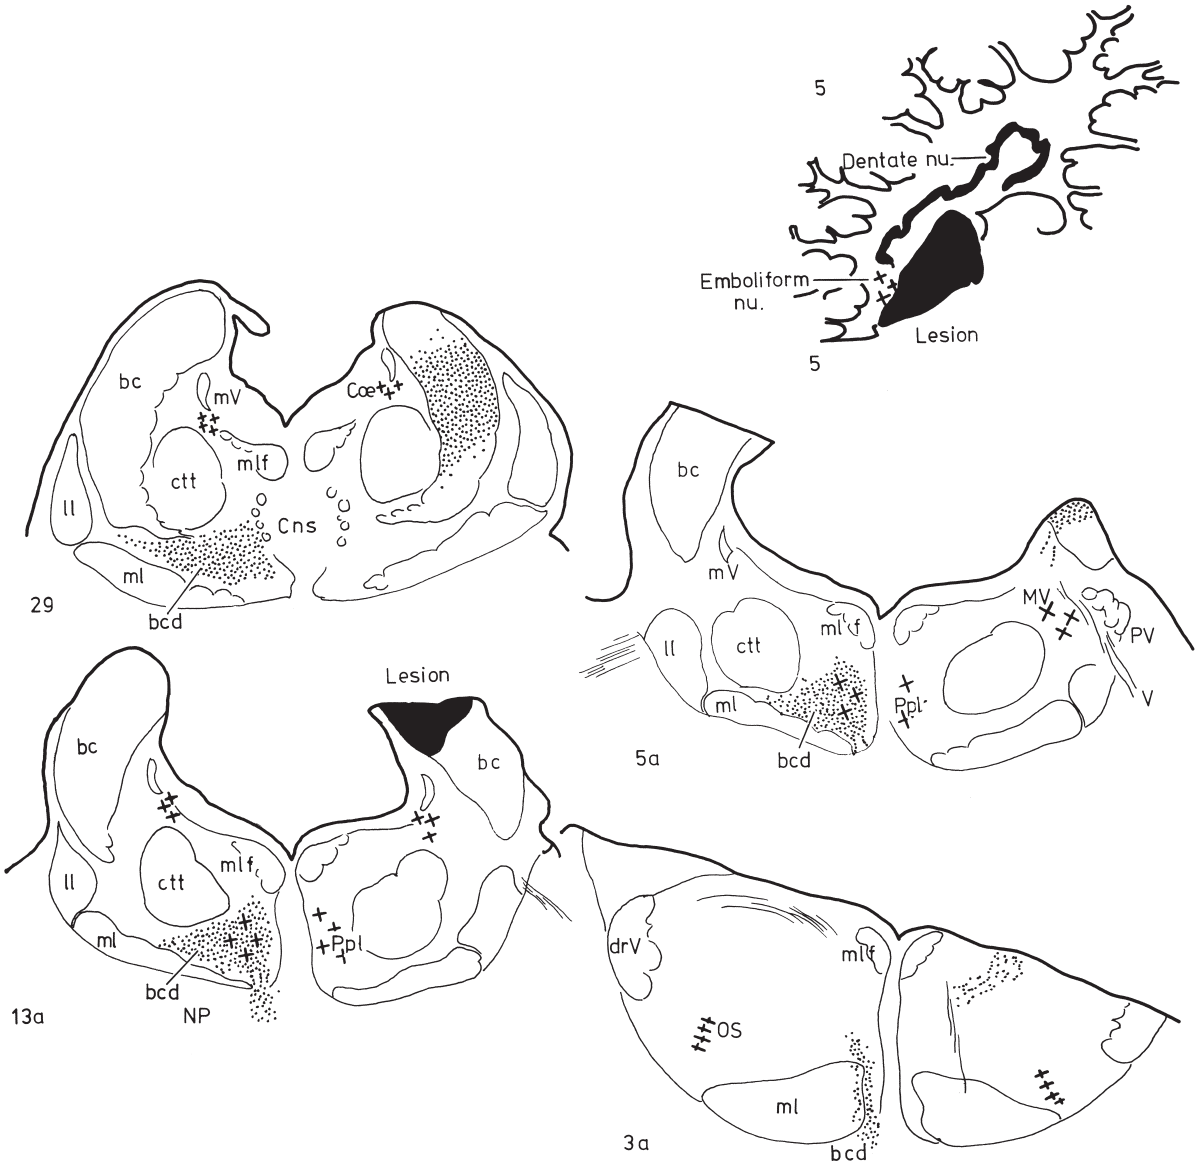

FIGURE 11.19 The termination of the descending branch of the brachium conjunctivum in the tegmentum pontis in case H5739. Nauta stain. Lesion indicated in black in a parasagittal section and in section 13a. (Schoen, unpublished). Abbreviations: bc, brachium conjunctivum; bcd, brachium conjunctivum descendens; Cns, central superior nucleus; Coe, locus coeryulaeus; ctt, central tegmental tract; drV, spinal tract of the trigeminal nerve; ll, lateral lemniscus; ml, medial lemniscus; mlf, medial longitudinal fascicle; mV, mesencephalic root of the trigeminal nerve; MV, medial vestibular nucleus; NP, basal pontine nuclei; nu, nucleus; OS, superior olive; Ppl papillioform nucleus (nucleus reticularis tegmenti pontis); PV, principal sensory nucleus of the trigeminal nerve; V, trigeminal nerve.

fibers of the medial part of the medial lemniscus. All of its fibers terminate around cells of the nucleus reticularis tegmenti pontis (NRTP, the nucleus papillioformis of Olszewski and Baxter, 1954), which lie scattered over the ventromedial pontine tegmentum, as well as in the processus medialis supralemniscalis grisei pontis. Some fibers end in the most dorsomedial pontine nuclei. Caudal to the level of the pons no more degenerated fibers of the brachium conjunctivum can be found.

The descending branch of the brachium conjunctivum was first described in the experimental studies of Thomas (1897) in cat and dog. In primates the descending branch can be traced caudally to the hilus of the inferior olive and beyond in the ventral funiculus

of the cord (Carpenter and Stevens, 1957; Chan-Palay, 1977). The absence of degeneration in the descending limb caudal to the pons in the case illustrated in Figure 11.19 is not so unusual. Some fibers of the descending branch were traced by most authors using the Nauta method in experimental studies, but the full extent of the nucleoolivary projection was not discovered until the application of tritiated amino acids in the tracing of this connection by Graybiel *et al.* (1973).

Cerebellar Projections to the Thalamus in Monkeys

The termination of the brachium conjunctivum in the thalamus in subhuman primates earlier was reviewed by Asanuma *et al.* (1983a–c), Kultas Ilinsky and Ilinsky (1986), Jones (1985), Mehler and Nauta (1974), Percheron *et al.* (1996), and Percheron (Chapter 20 of this volume). At present there is a consensus about the thalamic territory covered by the terminations of the cerebellar nuclei, but the parcellation and the extent of the cortical areas that receive their afferents from the cerebellar thalamus, the somatotopic organization and/or the presence of parallel pathways in the projection of the different cerebellar nuclei to the thalamus, and the question of segregation or overlap of the cerebellar, pallidal, and nigral projections to the thalamus are still being debated.

There is no doubt that the description of these connections has been complicated by the use of different nomenclatures for the nuclei of the thalamus and the areal subdivision of the cerebral cortex. The inconsistencies and the methodological drawbacks in the nomenclatures used to study the primate motor thalamus were pointed out in the critical reviews of Percheron here (Chapter 20) and elsewhere (Percheron *et al.*, 1996). Some papers on the cerebellar and thalamocortical projections stand out as landmarks in the desert. Kievit and Kuypers' 1977 paper offered "an alternate view of the organization of the thalamus" and suggested "that this structure contains a matrix of longitudinal cell columns which in some cases extend across specific nuclear borders" which "may represent the basic thalamic building blocks in respect to the thalamo-cortical connexions" (Kievit and Kuypers, 1977, p. 299). Medial thalamic columns project to rostral sectors in the frontal lobe; more lateral columns project to progressively more caudal regions in the frontal lobe. Kievit's (1979) thesis related the thalamic projections of the individual cerebellar nuclei to this thalamocortical matrix. Figure 11.20 is taken from Kievit's work. Chan-Palay (1977), Kalil (1981), Stanton (1980a), and Asanuma *et al.* (1983b) added new data on the thalamic of the individual cerebellar nuclei. Schell and Strick's paper of 1984 and Strick's subsequent studies on retrograde transneuronal transport from the cerebral cortex specified parallel projections from single cerebellar nuclei to different motor and nonmotor areas of the frontal lobe. Matelli *et al.* (1989, 1991), Matelli and Lupino (1996), Rouiller *et al.* (1994, 1999), Sakai *et al.* (1996, 2000), Yamamoto *et al.* (1992), and others compared corticothalamic projections with their cerebellar, pallidal, and nigral afferents in double- or multiple-labeling experiments. Finally, Nakano (1992), who published one of the few antegrade tracing studies of the projections of the motor thalamus in primates, made it possible to view the many retrograde labeling studies of this pathway in the right perspective.

Percheron (Percheron *et al.*, 1996; see also Chapter 20 of this volume) introduced a new nomenclature for the primate "motor thalamus" based on the existence of three discrete and nonoverlapping territories innervated from caudally to rostrally, by the cerebellar nuclei, the internal segment of the globus, pallidus and the substantia nigra. The three territories were indicated as the nucleus lateralis intermedius, oralis, and rostralis, respectively. On the basis of the data of Schell and Strick (1984), two "source spaces"were distinguished within the cerebellar nucleus lateralis intermedius, indicated as the nucleus lateralis intermedius lateralis and mediodorsalis. In Chapter 20 of this volume, Pecheron changed the prefix "lateralis" for the nuclei of the motor thalamus into "ventralis" and indicated the two nuclei as the ventrolateral (VImL) and dorsomedial subpartss (VImM) of the nucleus ventralis intermedius. His papers specify the invasion by spinothalamic and vestibular thalamic afferents of the cerebellar territory. Overlap of the cerebellar and pallidal projections, as documented in several recent publications (Fig. 11.21), is attributed to "plane, bidimensional, sections of the interdigitation of fringes that, in the absence of three-dimensional reconstruction, may indeed give the impression of a mixture" (Chapter 20). On the presence of overlap of the cerebellar and pallidal territiories in cat and rat, Percheron takes the somewhat unorthodox position that the pallidothalamic projection is a primate innovation. The entopeduncular nucleus in cat and rat does not represent the internal segment of the primate globus pallidus but would correspond to the lateral, intrapeduncular part of the substantia nigra.

Percheron's proposal is attractive in its logic and its simplicity. I have not attempted to use his nomenclature in my review because that would have detracted from the authenticity of the data from different authors, as cited in this section, especially where the possible overlap of cerebellar and pallidal thalamic afferents and the correspondance of cerebellothalamic and

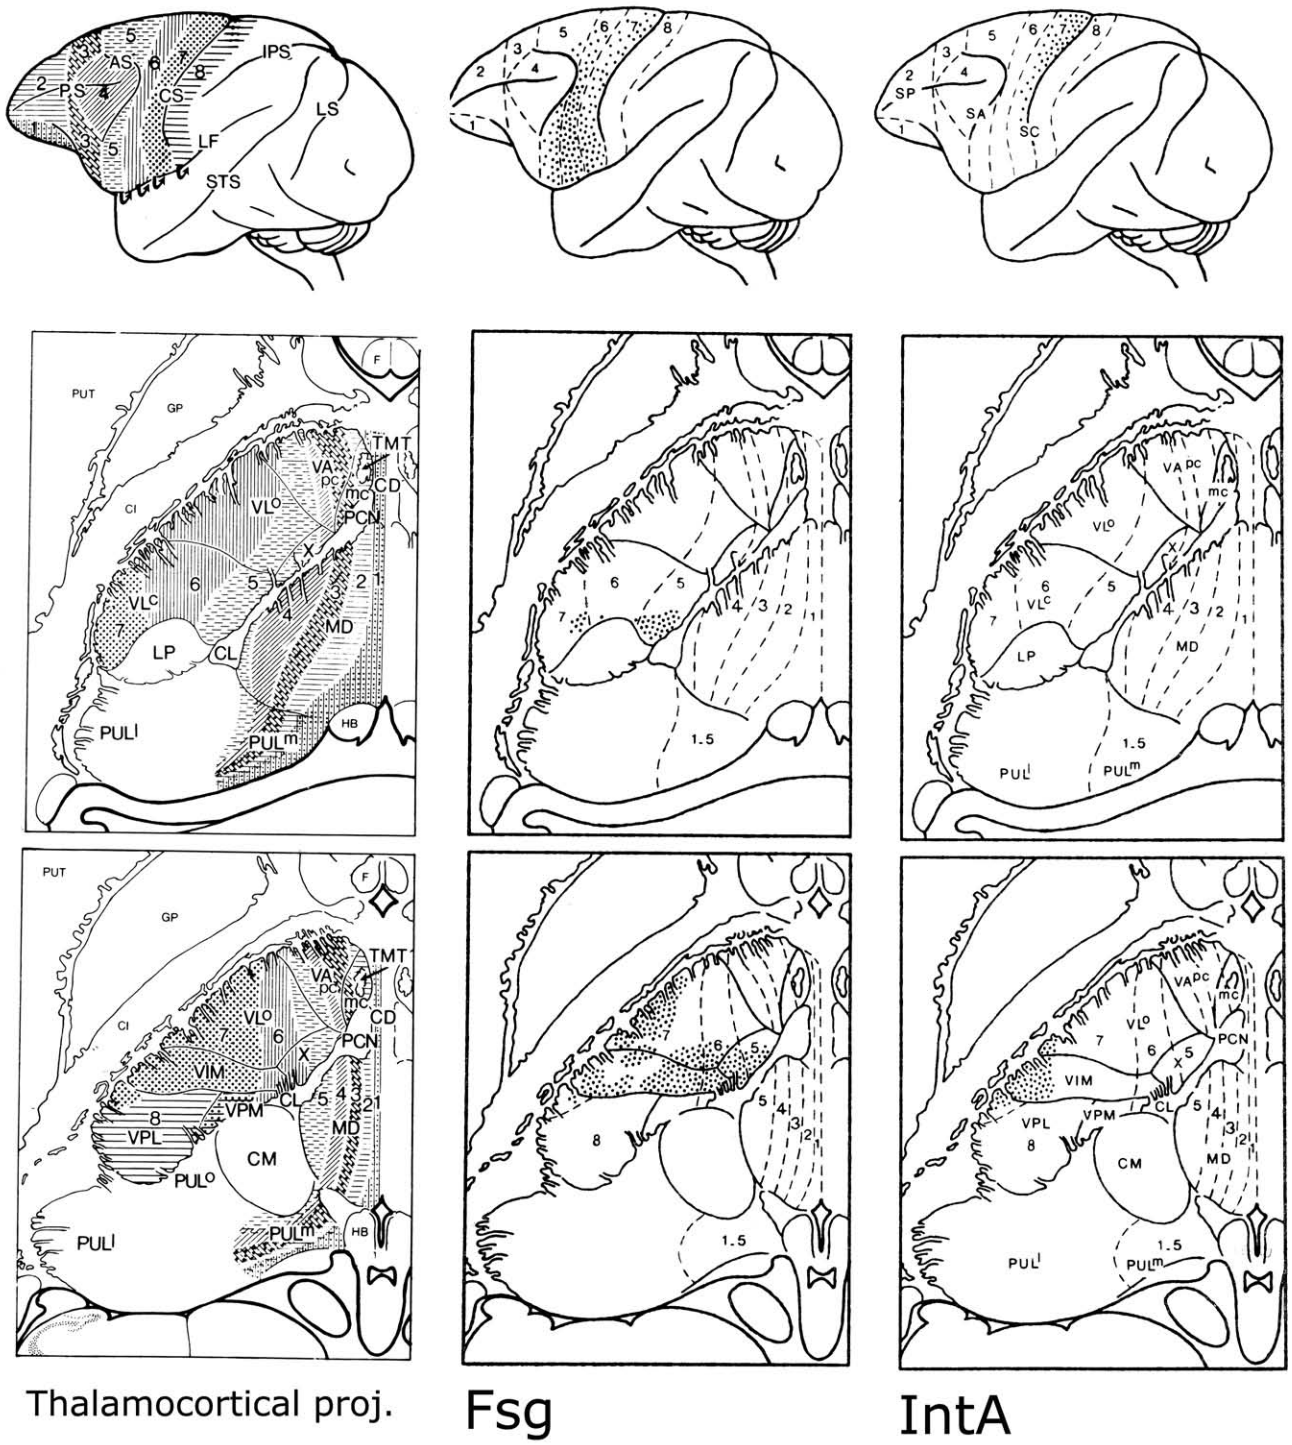

FIGURE 11.20 The cerebellothalamocortical projection in the rhesus monkey. **Upper row:** Diagrams of the left cerebral hemisphere. **Middle and lower rows:** Diagrams of dorsal and ventral horizontal sections through the thalamus. The thalamocortical projection is illustrated in the left-hand column. More caudally located cortical sectors of the frontal lobe receive their thalamic afferents from successively more lateral and ventral thalamic zones. These zones extend across the nuclear borders and the lamina medullaris interna. From Kievit and Kuypers (1977). The cerebello-thalamo-cortical projections of the individual cerebellar nuclei are illustrated in the four right-hand columns. (From Kievit, 1979.) The cortical target areas were reconstructed from the data of Kievit and Kuypers (1977). *Continued*

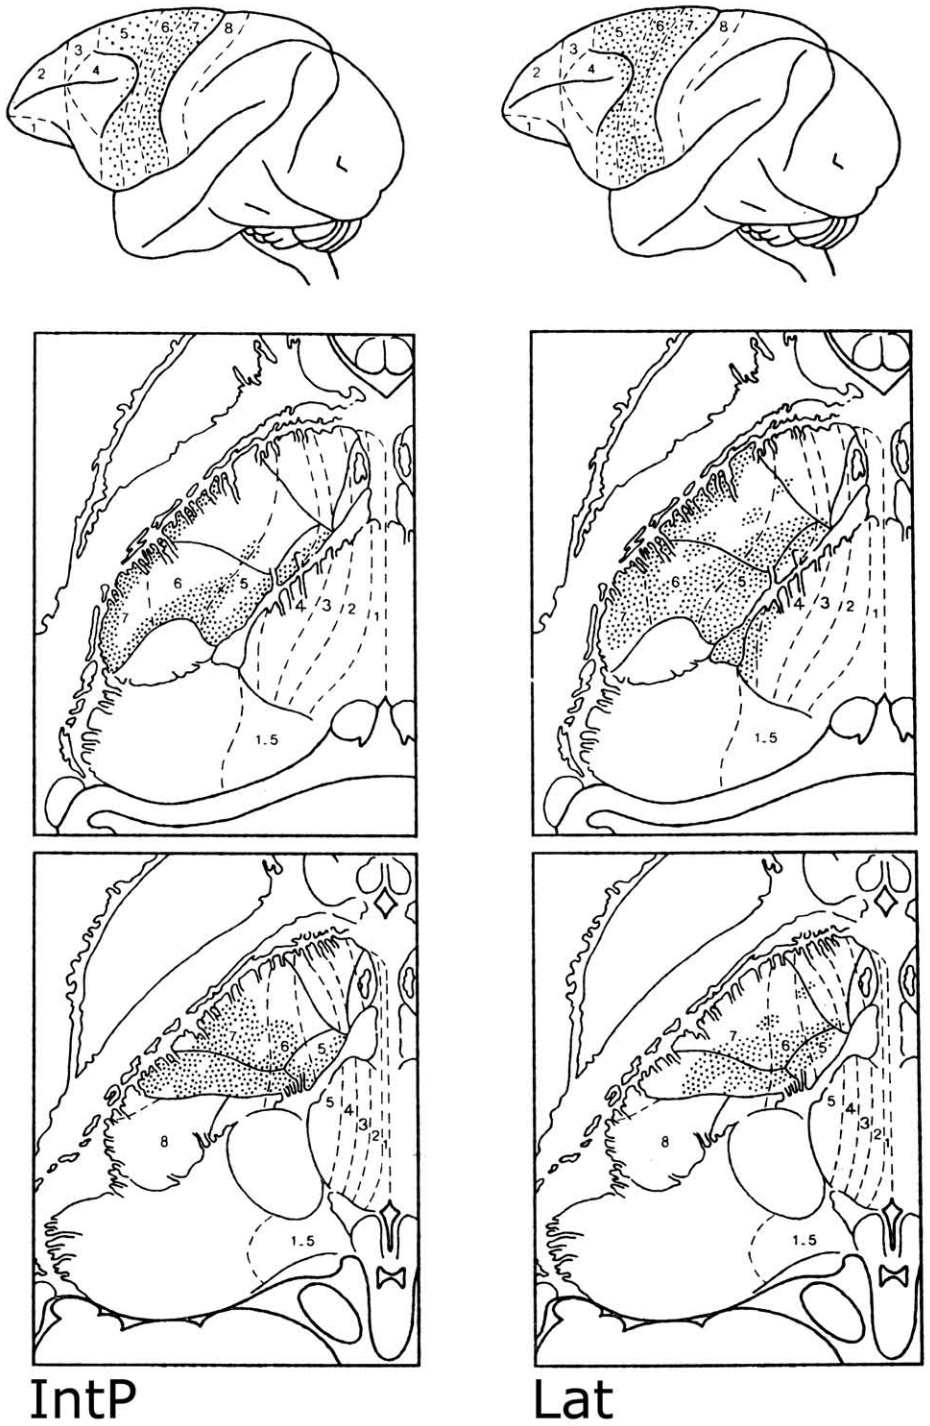

FIGURE 11.20 *Continued* Abbreviations: AS, ansate sulcus; CD, caudate nucleus: CI, internal capsule; CL, central lateral nucleus; CM, centre médian; CS, central sulcus; F, fornix; Fsg, fastigial nucleus; GP, globus pallidus; HB, habenulum; IntA, anterior interposed nucleus; IntP, posterior interposed nucfleus; IPS, intraparietal sulcus; Lat, lateral cerebellar nucleus; LF, lateral fissure; LP, lateral posterior nucleus; LS, lunate sulcus; MD, mediodorsal nucleus; PCN, nucleus paracentralis; PS, principal sulcus; PULl, lateral pulvinar; PULm, medial pulvinar; PUT, putamen; STS, superior temporal sulcus; TMT, mamillothalamic tract.

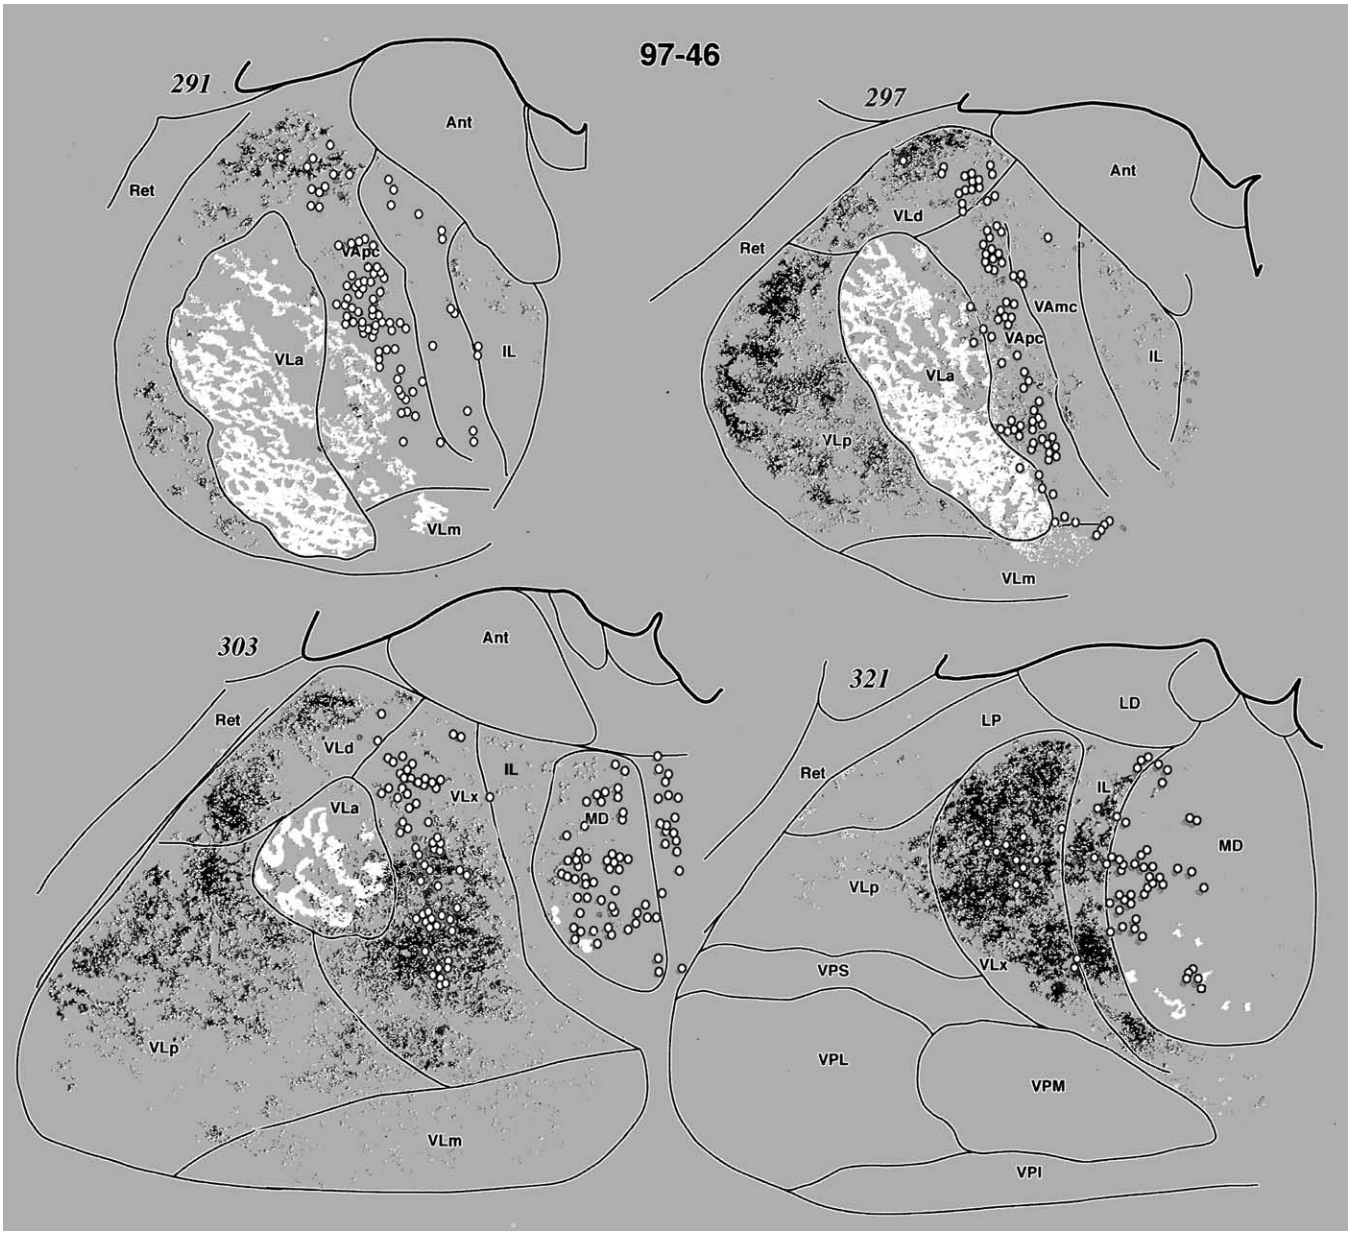

FIGURE 11.21 Drawing of coronal sections through the thalamus showing the distribution of pallidothalamic *(white)* and cerebellothalamic *(black)* anterograde label and the location of presupplementary motor area (SMA) projection neurons *(open circles)* in the owl monkey. Note the overlap of pallidal input with pre-SMA projecting neurons at the Vapc/Vla border (section 297) and cerebellar input with such neurons in VLx, VLd, and IL (sections 297–321). The anterior and posterior divisions of the ventral lateral nucleus (Vla, VLp) in the owl monkey correspond to the ventral lateral nucleus, pars oralis (Vlo) and the ventral posterior nucleus, pars oralis (VPLo) of Olszewski (1952) in the macaque monkey, respectively. Converted in gray scale with Photoshop from a color illustration from Sakai *et al.* (2000). In the conversion some of the detail of the original picture has been lost. Abbreviations: Ant, anterior nucleus; IL, intralaminar nuclei; LD, lateral dorsal nucleus; LP, lateral posterior nucleus; MD, mediodorsal nucleus; Ret, reticular nucleus; VAmc, ventral anterior nucleus, pars magnocellularis; VApc, ventral anterior nucleus, pars centralis; Vla, ventral lateral nucleus, pars anterior; VLd, ventral lateral nucleus, pars dorsalis; VLm, ventral lateral nucleus, pars medialis; VLp, nucleus ventralis lateralis, pars posterior; VLx, ventral lateral nucleus, area x; VPI, ventral posterior nucleus, pars inferior; VPL, ventral posterior nucleus, pars lateralis; VPM, ventral posterior nucleus, pars medialis.

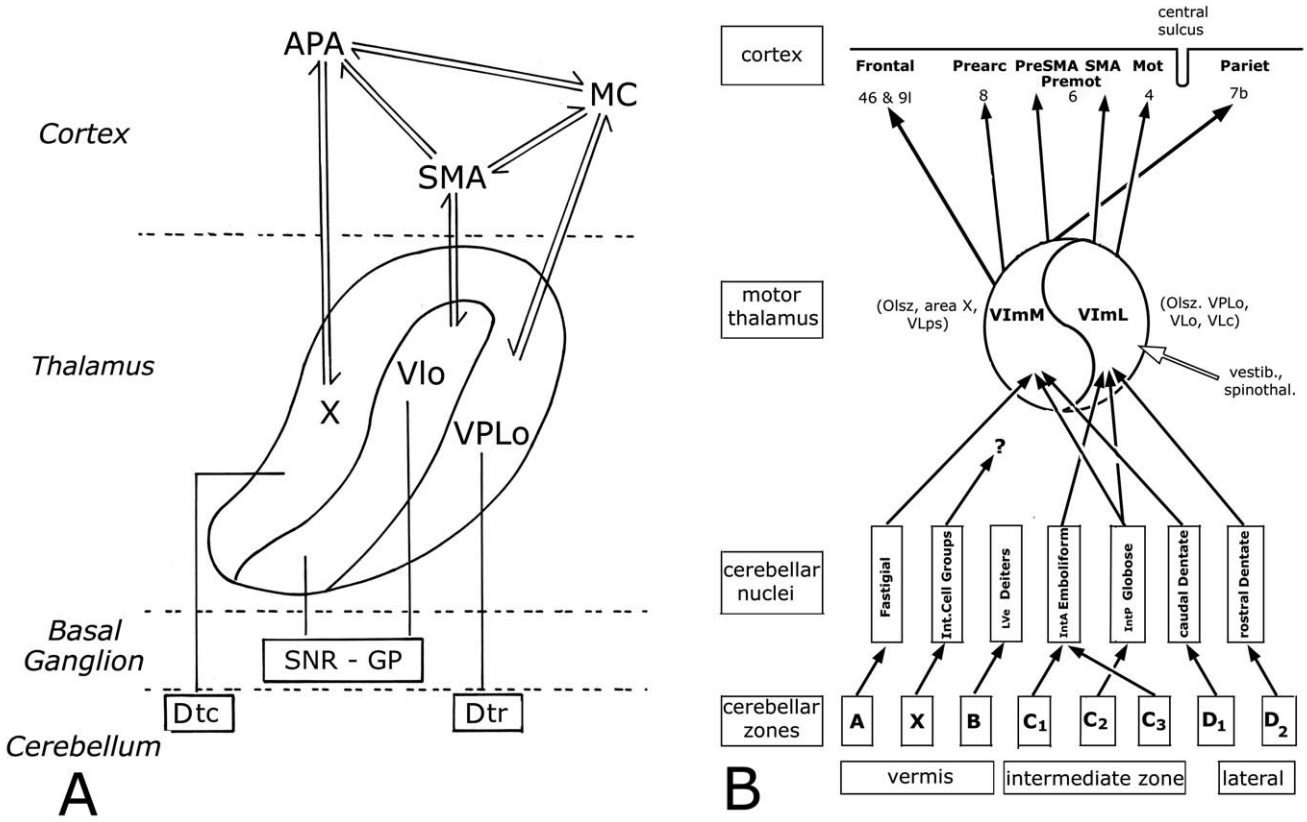

FIGURE 11.22 **A**. Diagram showing the connections of the basal ganglia and the cerebellar nuclei with the motor cortex (MC), the supplementary motor cortex (SMA), and the anterior premotor area (APA) and their relay nuclei in the thalamus. Note projection of rostral dentate nucleus (Dtr), through VPLo to the motor cortex, projection of caudal dentate nucleus (Dtc), through area X, to the premotor area and projections of the substantia nigra, pars reticulata (SNR) and the globus pallidus (GP), through Vlo, to the supplementary motor cortex. From Schell and Strick (1984). **B.** Diagram of parallel chanels in the cerebellothalamocortical projection. This diagram covers the same subject matter as Fig. 11.22A but incorporates Percheron's (Chapter 20) subdivision of the cerebellar territory of the motor thalamus (ventral intermedius nucleus) into ventrolateral (VImL) and dorsomedial subparts (VImM), and data on the connections of the individual cerebellar nuclei with the thalamus and the frontal and parietal cortices. The overlap of the vestibular and spinothalamic projections in the VImL (Chapter 20) is indicated. For details, see text. Abbreviations: IntA, anterior interposed nucleus; IntP, posterior interposed nucleus; Lve, lateral vestibular nucleus; Mot, primary motor area; Pariet., parietal lobe; prearc, prearcuate area; Premot, premotor area; preSMA, rostral part of supplementary motor area; SMS, supplementary motor area proper; VImL, lateral subpart of ventral intermedius nucleus; VImM, medial subpart of ventral intermedius nucleus; VLc, pars caudalis of nucleus ventralis lateralis; VLo, oral portion of nucleus ventralis lateralis; VLps, posterior superior part of nucleus ventralis lateralis; VPLo, oral portion of nucleus ventralis posterior lateralis.

thalamocortical projections are concerned. Percheron's interpretation of some of the same data can be found in his reviews and is summarized in Fig. 11.22B.

Figure 11.21, taken from the paper of Sakai *et al.* (2000), illustrates the distribution of cerebello- and pallidothalamic fibers in the owl monkey. In acordance with previous reports, the cerebellar afferents are directed to separate thalamic subdivisions (Asanuma *et al.*, 1983a–c; Schell and Strick, 1984; Kultas Ilinsky and Ilinsky, 1986; Sakai *et al.*, 1996, 1999; Percheron *et al.*, 1996). The internal segment of the globus pallidus projects to the anterior subdivision of the ventral lateral nucleus (VLa[1]), extending medially in its medial subdivision (VLm) and rostrally into the parvocellular division of the ventral anterior nucleus (Vapc), whereas

[1]The anterior division of the ventral lateral nucleus (VLa) in the owl monkey corresponds to the ventral lateral nucleus pars oralis (VLo) of Olszewski (1952).

the cerebellar projections primarily targeted the posterior motor thalamus, including the posterior division of the ventrolateral nucleus (VLp[2],) area X, and VLd. Both systems terminate in patches. Their terminations overlap or interdigitate in transitional regions between adjacent nuclei, such as the border region between the VLa and the VApc, with area X. The figure is an excellent ihelllustration of Scl and Strick's (1984) description of the cerebellothalamic territory as forming concentrations in lateral and medial areas of the motor thalamus, which are broadly connected by a band of terminals in the region immediately dorsal and rostral to the somatosensory ventral posterior nuclei.

Kievit's (1979) figure of the thalamic projections of the four cerebellar nuclei in *Macaca rhesus* illustrates the particulars in the projection of the four cerebellar nuclei (Fig. 11.20). Medially these projections occupy a position immediately lateral to the internal medullary lamina. Dentatothalamic fibers extend across the medullary lamina to terminate in the caudal, paralamellar portion of the dorsomedial nucleus (MD) and, possibly, in the caudal part of the intralaminar, central lateral nucleus (CL). Rostrally the medial region extends into the area X of Olszewski (1952) and the oral part of the ventral lateral nucleus (Vlo); caudally it includes medial parts of the caudal ventral lateral nucleus (VLc) and the pars posttrema of the VL nucleus. Laterally and caudally the cerebellar terminals occupy the oral portion of the lateral ventral posterior nucleus, the VPLo of Olszewski (1952), which corresponds to the ventral intermedius nucleus (VIM[3]), the term used in Kievit's figure, and the lateral parts of the Vlo, where they may extend into the lateral parvocellular portion of the ventral anterior nucleus (VApc). The projections of the fastigial and anterior interposed nuclei overlap with the dentate in ventral and caudal regions. The projection of the anterior interposed nucleus is restricted to a caudolateral region. The posterior interposed and dentate nuclei project to more extensive but, for the most part, overlapping areas, which include lateral and medial portions of the cerebellar territory. The projections extend into more dorsal, rostrolateral, and rostromedial portions of VLc, Vlo, and area X. The projection of the posterior interposed nucleus typically includes the medial zone of area X; the dentate projection extends into the paralamellar part of the MD nucleus. The cortical projections of the different cerebellar nuclei, as indicated in the diagrams of Fig. 11.20 were reconstructed from the data of Kievit and Kuypers (1977) on the matrix in the thalamocortical projection. These diagrams, though still valid, have been modified in subsequent, more detailed studies of the thalamocortical projection of Schell and Strick (1984) and others.

Schell and Strick (1984) criticized an earlier hypothesis of Asanuma *et al.* (1983b, c) and Jones (1985) that the thalamic regions that receive cerebellar inputs should be considered as a common nucleus (the cell-sparse zone of Asanuma *et al.*, 1983a) which influences only the primary motor cortex. They proposed instead the existence of at least two separate cerebellothalamic systems, which originate from the deep nuclei (Fig. 11.22). "One system, located in the rostral portion of the deep nuclei, projects largely to VPLo [which includes the VIM from Kievit's Figure 11.20] and therefore most directly influences the motor cortex. A second system in the caudal portions of the deep nuclei projects largely to area X and therefore most directly influences the arcuate premotor area," corresponding to the ventral part of area 6, located rostral to the primary motor area.[4] A third, supplementary motor area, located in dorsomedial area 6, receives a projection from the central and rostral Vlo, i.e., from a region located between the rostromedial and rostrolateral extensions of the cerebellar projection area. This part of the thalamus receives its projections from the globus pallidus and the substantia nigra (Figs. 11.21A and 11.22). Since the publication of this paper it has become clear that the medial thalamus, innervated by the caudal dentate and interposed nuclei, projects to more extensive regions of the frontal lobe, including certain premotor areas, and to the inferior parietal lobule (Fig. 11.22B). The medial and lateral territories innervated by the cerebellum were indicated as the lateral (VImL) and medial subparts (VImM) of the nucleus ventralis intermedius by Percheron (Chapter 20) (Fig. 11.22B).

Projections of the contralateral rostrodorsal dentate and the anterior interposed nucleus, through the VPLo, to the primary motor cortex (M1) have been confirmed in the retrograde transneuronal tracing studies of Wiesendanger and Wiesendanger (1985a, b), Oriolo and Strick (1989), Middleton and Strick (1997), and Hoover and Strick (1999). Transneuronally labeled neurons from the leg area of M1 were found in the rostral dentate, from the face area dorsally in its middle third and from the arm area in between (Fig. 11.23). In the anterior

[2]The posterior division of the ventral lateral nucleus (VLp) in the owl monkey corresponds to the ventral posterior nucleus pars oralis (VPLo, Olszewski, 1952) in macaque monkeys.

[3]The ventral intermedius nucleus was distinguished by Cécile Vogt (1903) as the termination of the cerebellar projection in monkeys.

[4]To be supplied.

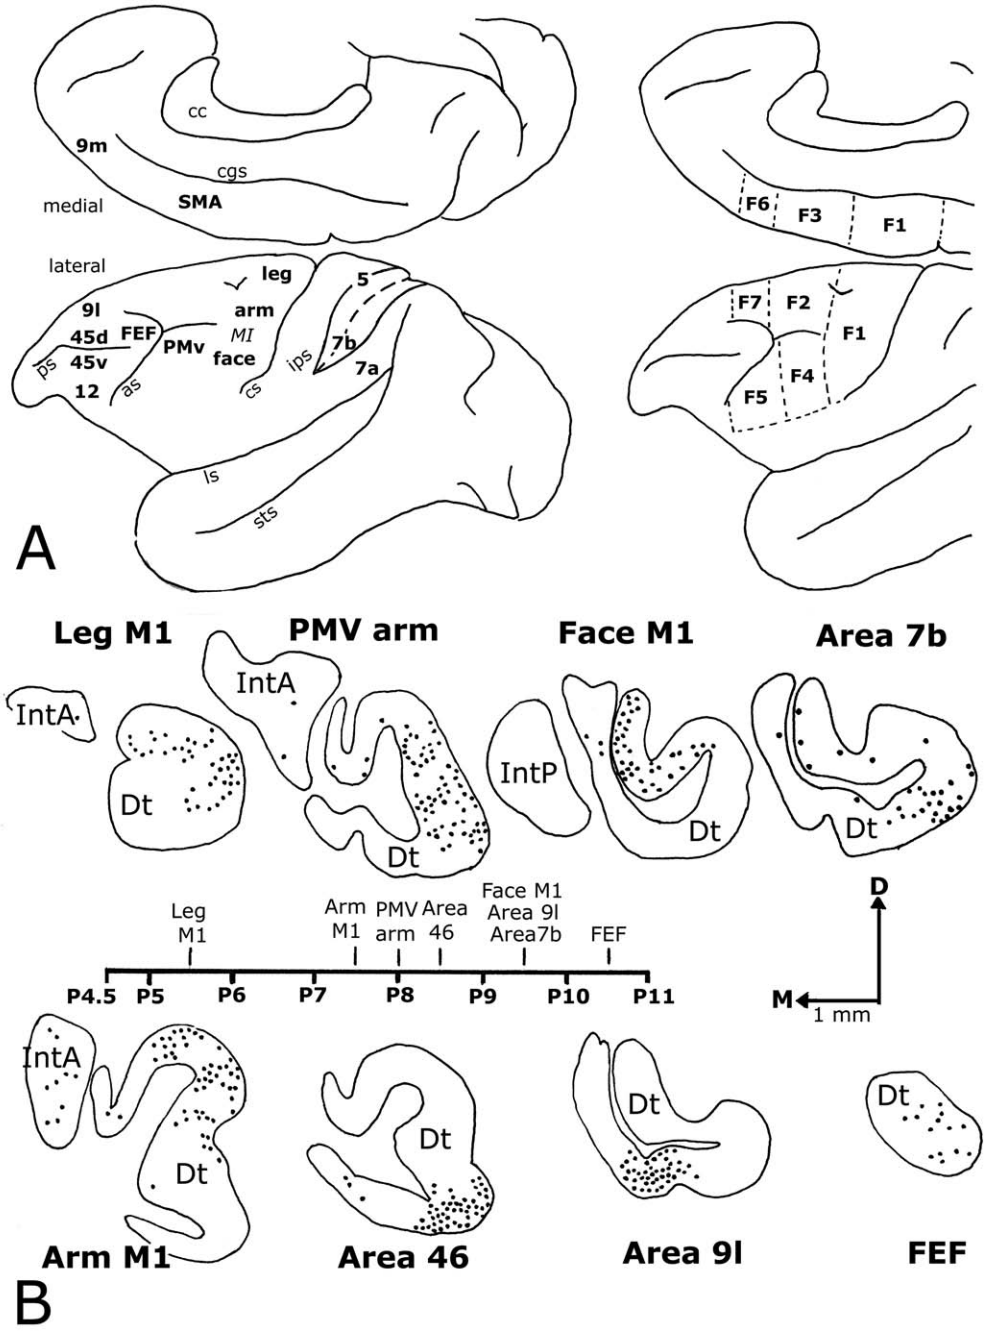

FIGURE 11.23 Transneuronal labeling of neurons in the contralateral cerebellar nuclei of the cebus monkey from injections of herpes simplex virus (HSV-1, McIntyre-B) in the cerebral cortex. **A.** Approximate locations of the injection sites are indicated in the left panel. **B.** The right panel illustrates the nomenclature of the agranular motor cortex introduced by Matelli *et al.* (1989) and Matelli and Lupino (1996). **C.** The location of labeled neurons in the cerebellar nuclei, in sections with the highest numbers of labeled cells. The approximate position of these sections is indicated on the P4.5–P11 bar representing the rostrocaudal extent of the cerebellar nuclei. Redrawn and relabeled from Hoover and Strick (1999), Middleton and Strick (2000, 2001), and Clower *et al.* (2001). Abbreviations: 46d,v, dorsal and ventral area 46; 5, superior parietal area 5; 7a, 7b, inferior parietal areas 7a and b; 9l,m, medial and lateral area 9; as, ansate sulcus; cc, corpus callosum; cgs, cingulate sulcus; cs, central sulcus; Dt, dentate nucleus; F1–F7, areas F1–F7 of Matelli *et al.* (1989) and Matelli and Lupino (1996); FEF, frontal eye field; IntA, anterior interposed nucleus; IntP, posterior interposed nucleus; ips, intraparietal sulcus (opened); ls, sylvian sulcus; M1, primary motor cortex; PMv, ventral premotor area; ps, principal sulcus; SMA, supplementary motor cortex; sts, superior temporal sulcus.

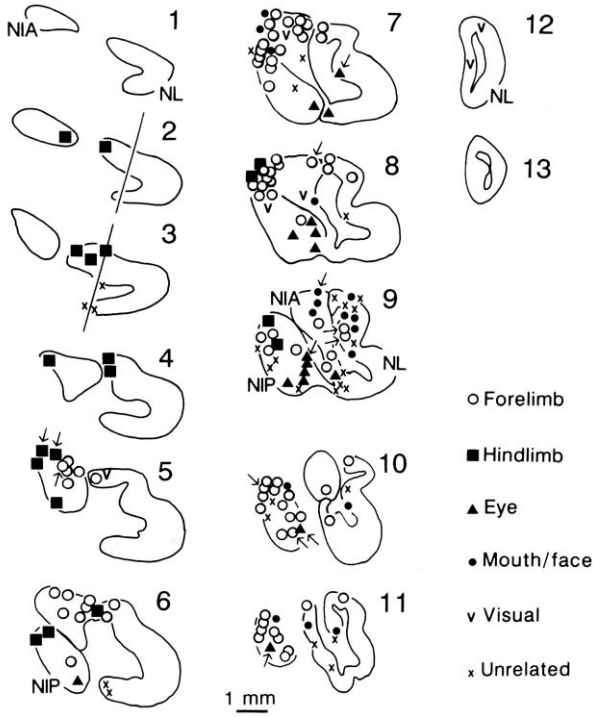

FIGURE 11.24 Somatotopic distribution of 134 movement-related neurons from two monkeys, plotted on equally spaced transverse sections through the cerebellar nuclei. Arrows indicate neurons with mixed movement relations. Lines through sections 2 and 3 indicate angle of the microelectrode penetrations. From Van Kan *et al.* (1993). Abbreviations: NIA, anterior interposed nucleus; NIP, posterior interposed nucleus; NL, dentate nucleus.

interposed nucleus the leg is represented rostromedially and the face caudally and laterally (Fig. 11.24). The posterior interposed nucleus also contained labeled neurons in the cases with M1 injections, but without a clear, somatotopical distribution. Labeled neurons from injections in medial area 6, in the rostral part of the supplementary motor area, were found in the VLc, in the Vapc, and in area X. Transneuronal labeling was observed in cells of the ventral and caudal dentate and the ventral posterior interposed nucleus, but not in the anterior interposed nucleus. The labeling in the cerebellar nuclei resulting from an injection including the caudal part of the supplementary motor area was more widespread (Wiesendanger and Wiesendanger, 1985a, b). Injections in the arcuate premotor area, corresponding to inferior area 6, retrogradely labeled the area X and were located in the rostromedial, ventral, and caudal dentate nucleus and in the caudal pole of the posterior interposed nucleus (Oriolo and Strick, 1989).

In subsequent studies, Strick and his collaborators retrogradely labeled neurons in the dentate, with a small number of cells in the adjacent interposed nuclei, from injections with a strain of the herpes simplex virus, in more rostral parts of the frontal lobe (Fig. 11.24). Injections in the frontal eye field (area 8) label cells in area X, in the ventral anterior and dorsomedial nuclei of the thalamus, and in the caudal dentate (Lynch *et al.*, 1994); injections in the prefrontal area 46 and 9 resulted in labeled neurons in a ventromedial region of the dentate, in the middle and caudal thirds of the ventrocaudal dentate nucleus. A few labeled cells were present in the posterior interposed and fastigial nuclei. Neurons labeled from area 46 tend to be located laterally to the labeled cells from area 9 (Middleton and Strick, 1997, 2001). Injections of inferior parietal area 7b labeled cells located ventrally in the contrlateral caudal third of the dentate (Clower *et al.*, 2001).

Cerebellar projections to the primary motor cortex generally have been confirmed in studies comparing multiple retrograde labeling from the cortex with data on the thalamic distributions of cerebellar and pallidal afferents. According to Rouiller *et al.* (1999), projections to the primary motor cortex mainly stem from the VPLo and remain segregated from the projection of the thalamus to other motor areas. Connections from the globus pallidus to the primary motor cortex are relayed by the Vlo (Rouiller *et al.*, 1994; Stepniewska *et al.*, 1994). According to Matelli *et al.* (1989), pallidal afferents are preferentially relayed to the rostral part of the primary motor cortex. The laminar patterns in the terminations from the VPLo and the Vlo are different. The corticothalamic projections from the Vlo terminate in superficial layer I of the cortex, whereas the projection from the VPLo innervates the deep layers III–V (Nakano *et al.*, 1992). The supplementary motor area (SMA), located on the mesial part of the hemisphere, receives corticothalamic fibers both from cerebellar and pallidal thalamic territories (Rouiller *et al.*, 1994). The thalamocortical projection to its caudal portion (SMA-proper, F3; see Fig. 11.23B for an explanation of the nomenclature of the motor areas) in the frontal lobe of Matelli *et al.* (1989) and Matelli and Lupino (1996) is very similar to the more ventrally located caudal premotor region (F2, F4). It receives projections from the rostrodorsal dentate and interposed nuclei, and the globus pallidus, which are relayed by the Vlo, VPLo, and VLc (Matelli and Lupino, 1996; Rouiller *et al.*, 1999; Sakai *et al.*, 1999). The rostral half of the SMA (F6) and the rostral premotor area (F5, F7) receive pallidal and cerebellar afferents from ventrocaudal parts of the dentate and interposed nuclei, relayed by area X, and the ventral anterior and mediodorsal nuclei (Matelli *et al.*, 1989, Matelli and Lupino, 1996; Rouiller *et al.*, 1999; Sakai *et al.* 2000) (Fig. 11.21). These thalamic nuclei innervate both deep (VA, area X) and superficial cortical layers (VA) of area 6 (Nakano *et al.*, 1992). The

supplementary eye field, located dorsally in F7, receives a preferential projection from lateral area X (Matelli and Lupino, 1996). The thalamic cerebellar territory also includes nuclei which project to prefrontal cortical areas. According to Yamamoto *et al.* (1992) and Rouiller *et al.* (1999), the prefrontal projections are relayed by the ventrolateral, paralamellar part of the mediodorsal nucleus. Middleton and Strick (2001) recently provided evidence that the projections to medial area 9 and 46 originate from the caudal VLc, the VLps, and area X.

Therefore, all motor areas in the monkey receive both cerebellar and pallidal afferents, be it in different proportions, but the cerebellar and pallidal inputs to the cortex are not equivalent. The cerebellothalamic connections are excitatory, whereas the pallidothalamic projections is GABAergic and inhibitory (for reviews, see Voogd *et al.*, 1996b and Gerfen and Wilson, 1996). Moreover, the input from the cerebellum and the globus pallidus to several cortical areas is distributed to different cortical laminae (Nakano *et al.*, 1992). In accordance with Schell and Strick's (1984) original proposal, the primary motor cortex is dominated by cerebellar afferents, derived from rostral dentate and interpositus. The caudal parts of the premotor (F2 and F4) and supplementary motor areas (F3) receive a mixture of cerebellar afferents from the same cerebellar nuclei and the pallidum. These premotor and supplementary motor areas receive substantial inputs from the parietal lobe (for references, see Matelli and Luppino, 1996) and maintain strong connections with the primary motor cortex. They give rise to corticospinal connections, to interneurons in the spinal intermediate zone, and to direct projections to the motoneurons, which are independent from similar projections from the primary motor cortex (Dum and Strick, 1991, 1996; He *et al.*, 1993, 1995). More rostral premotor and supplementary motor areas (F5, 6, and 7) receive afferents from the caudal dentate and interposed nuclei and a projection from the globus pallidus. These areas maintain strong connections with the prefrontal cortex. The most rostral prefrontal areas receiving cerebellar afferents include area 46 and 9 and, according to Lynch *et al.* (1994), the frontal eye field. Cerebellar projections to parietal areas (Sasaki *et al.*, 1976) recently were confirmed by Clower *et al.* (2001).[5]

Schell and Strick (1984) distinguished two parallel cerebellothalamic pathways from the rostral dentate and the anterior interposed nucleus and from the caudal dentate and the posterior interposed nucleus. The fastigial, anterior, and posterior interposed nuclei, however, should also be considered as independent target nuclei of different cerebellar modules, which receive projections by different Purkinje cell zones, and from different subnuclei of the inferior olive. The suggestion by Schell and Strick (1984) that the dentate nucleus consists of rostromedial and caudolateral subnuclei receives support from the observation that these subnuclei may serve as the targets for different Purkinje cell zones in the cerebellar hemisphere (see "Subdivision and Olivocerebellar Projection" and "Longitudinal Zonation of the Cerebellum"). As a consequence, at least five parallel cerebellothalamic pathways can be distinguished with systematically diverging and converging terminal fields in the thalamus and projections to different motor cortical areas (Fig. 11.22B). The terminations of these parallel paths are not limited to the thalamus but also include the brain stem and the upper cord.

Projections of Individual Cerebellar Nuclei to the Brain Stem in Monkeys

There are strong indications that the widely diverging projections of the cerebellar nuclei to the thalamus, the brain stem, and the cord are collaterals of the same highly branched axons of the relay cells of the cerebellar nuclei (Bentivoglio and Kuypers, 1982; Bharos *et al.*, 1981; Shinoda *et al.*, 1988, 1999; Tolbert *et al.*, 1978; Teune, 1999; Teune *et al.*, 1999, 2000). These branching axons are excitatory and should be distinguished from the GABAergic projection of the cerebellar nuclei to the inferior olive (see "Cerebellar Nuclei" and "Afferent Systems of the Inferior Olive: The Nucleoolivary Projection"). Apart from the thalamus, these projections include the vestibular nuclei, the reticular formation, and the tectum, where connections from visually dominated portions of the fastigial, dentate, and posterior interposed nuclei should be differentiated from regions of the cerebellar nuclei that are primarily somatomotor in function. In the mesencephalon, the cerebellar target nuclei include

[5]Connections to parietal areas from the cerebellar relay have also been reported in the cat. In a study, combining antegrade tracing from the cerebellar nuclei with retrograde tracing from areas 5 and 7. Hendry *et al.* (1979) and Sugimoto *et al.* (1981) observed some neurons in the cerebellar zone of termination to project to these parietal areas. Neurons in parietal association areas 5 and 7, located in the caudal bank of the ansate sulcus and the suprasylvian gyrus; responded to stimulation of the dentate and interposed nuclei. These effects were mediated by the VA-VL complex (Wannier *et al.*, 1992; Kakei *et al.*, 1995; Yamamoto and Oka, 1993). Some of these parietal neurons are corticocortical neurons with projections to the motor cortex (Kakei *et al.*, 1995). Another source of widespread projections to postrolandic areas would be the intralaminar, centrolateral nucleus, which is known to receive afferents from the cerebellar nuclei.

the red nucleus and the nucleus of Darkschewitsch and adjacent nuclei at the meso–diencephalic junction. These nuclei give rise to crossed descending rubrobulbar and rubrospinal pathways and uncrossed pathways to the inferior olive, which are part of a recurrent climbing fiber loop (see "Afferent Systems of the Inferior Olive: The Nucleoolivary Projection"). Similar recurrent loops, terminating as mossy fibers, are formed by cerebellar projections to the nucleus reticularis tegmenti pontis and the pontine nuclei, and the lateral reticular nucleus. These climbing fiber and mossy fiber recurrent loops also innervate the cerebellar nuclei. In the subthalamus cerebellar afferents terminate on the zona incerta.

The *fastigial nucleus* projects bilaterally and symmetrically to the vestibular nuclei and to the contralateral medial bulbar reticular formation and the cervical cord (Batton *et al.*, 1977). The magnocellular medial vestibular nucleus, the spinal vestibular nucleus, and the nucleus parasolitarius are among its main target nuclei. Crossed fibers from the uncinate tract and the ipsilateral fastigiobulbar tract pass lateral and medial to the lateral vestibular nucleus of Deiters but do not terminate there. The lateral vestibular nucleus receives a direct projection from Purkinje cells of the lateral B zone of the anterior vermis. The crossed ascending limb of the uncinate fascicle terminates in the mesencephalon in the dorsal reticular formation, in the central gray, deep and bilaterally in the intermediate layers of the superior colliculus, and in the nuclei of the posterior commissure. The bilateral projection to the intermediate layers is restricted to the rostral pole of the superior colliculus, i.e., corresponds to the foveal area of the contralateral hemifield (May *et al.*, 1990).

In the thalamus fastigial fibers terminate caudally in the suprageniculate nucleus, and ventrally, caudally, and bilaterally in the VPLo and the Vlo (Figs. 11.20 and 11.22B) (Kievit, 1979; Kievit and Kuypers, 1972; Asanuma *et al.*, 1983b), as described in previous paragraphs. Terminations in preolivary nuclei at the mesodiencephalic junction have not been found. Of the precerebellar nuclei with recurrent mossy fiber pathways, the dorsal part of the nucleus reticularis tegmenti pontis (NRTP), the dorsolateral basal pontine nuclei, and the magnocellular part of the lateral reticular nucleus receive projections from the fastigial nucleus.

The oculomotor region of the fastigial nucleus, located in the caudal part of the nucleus, receives Purkinje cell axons from visual areas of the vermis (lobules VII and VIc), which are characterized by a low threshold for evoking saccades (Noda *et al.*, 1990). Projections from the oculomotor region of the fastigial nucleus are not so different from the projections described from complete lesions or injections of this nucleus. They include the vestibular nuclei bilaterally. Contralaterally the oculomotor region projects to the paramedian pontine reticular formation (PPRF) and to a region caudoventral to the abducens nucleus. In the mesencephalon they terminate the intermediate layer of the superior colliculus and in the contralateral rostral interstitial nucleus of the medial longitudinal fascicle and the lateral part of the nucleus of Darkschewitsch. Projections to the PPRF and the preoculomotor nuclei in the mesencephalon are collaterals from the same neurons (Sato and Noda, 1991). The contralateral dorsomedial NRTP and the dorsomedial, rather than the dorsolateral basal pontine nuclei receive a projection from the oculomotor region (Noda *et al.*, 1990). Projections of the fastigial nucleus to the PPRF, the superior colliculus, and the paraoculomotor nuclei were also reported in a retrograde labeling study of Gonzalo-Ruiz *et al.* (1988), but the retrogradely labeled cells in this nucleus never were restricted to its oculomotor region.

The efferent connections of the *U-shaped nucleus*, located between the fastigial and interposed nuclei (Fig. 11.12), which supposedly corresponds to the interstitial cell groups in the rat (Buisseret-Delmas *et al.*, 1993; see "Cerebellar Nuclei"), have not been studied in primates. In cat and rat its neurons give rise to strong projections to the spinal cord, which also collateralize to the tectum and the thalamus (Bentivoglio and Kuypers, 1982; Matsushita and Hosoya, 1978).

Topographically the *posterior interposed nucleus* is closely related to the fastigial nucleus. After their decussation its fibers ascend medial to and through the red nucleus, to enter the central gray lateral to the oculomotor nuclei (Kievit, 1979). They terminate in deep layers of the contralateral superior colliculus (May *et al.*, 1990) and the nucleus of Darkschewitsch. Terminations in the magnocellular red nucleus were denied by Stanton (1980a) but found to be restricted to a caudal and medial shell of the caudal magnocellular part of the red nucleus by Kievit (1979). In the thalamus the projections from the posterior interposed nucleus cover a fairly broad region, which largely overlaps with the projection of the dentate nucleus (Fig. 11.20). The posterior interposed nucleus is the target nucleus of the C_2 zone (Fig. 11.46; see "Longitudinal Zonation of the Cerebellum"). A distinct somatotopical organization appears to be absent in the posterior interposed nucleus (Van Kan *et al.*, 1993) (Fig. 11.24). This corresponds to the characteristic lack of a somatotopical organization in the C_2 zone (Oscarsson, 1980). The projections to the red nucleus supposedly originate from the medial part of the nucleus. The lateral pole of the posterior interposed nucleus contains visual cells (Van Kan *et al.*, 1993) (Fig. 11.24). It is this region that gives rise to the projection to the tectum, which includes the entire

rostrocaudal extent of the nucleus and, therefore, corresponds to the entire contralateral hemifield (May *et al.*, 1990).

The thalamic projections of the posterior interposed nucleus cover both lateral and medial portions of the cerebellar territory (Fig. 11.22B, VImL and VImM). The medial region, corresponding to Percheron's (Chapter 20) medial subpart of the nucleus ventralis intermedius dorsomedialis, includes area X, which is a relay nucleus for the the frontal eye field (Lynch *et al.*, 1994) and the supplementary eye field (Matelli and Lupino, 1996). These projections may arise from the lateral, visual area of the posterior interposed.

One of the distinctive features of the posterior interposed nucleus in cat and rat is the absence of a projection to the NRTP (Voogd, 1964; Teune *et al.*, 1999). In primates this connection has not been studied with appropriate lesions or injection sites. Projections to the PPRF and the preoculomotor nuclei in the mesencephalon have not been reported.

The *anterior interposed nucleus* has a distinct somatotopical organization, with the lower extremity located rostrally and medially, the face laterally and caudally, and the upper extremity in between (Van Kan *et al.*, 1993) (Fig. 11.24). The presence of a detailed somatotopical organization is in accordance with the somatotopical, microzonal arrangement in C_1 and C_3 zones, which innervate this nucleus (Fig. 11.46A). The anterior interposed nucleus projects to the corresponding somatotopical subdivisions of the caudal magnocellular part of the red nucleus, with the leg area ventrally and laterally and the arm dorsomedially in the red nucleus (Fig. 11.25) (Stanton, 1980a; Van Kan, unpublished observations; Van Kan *et al.*, 1993). A representation of the face in the magnocellular red nucleus seems to absent. Neurons projecting to the motor nucleus of the facial nerve have been located in the dorsolateral parvocellular red nucleus (Burman *et al.*, 2000). It may correspond to a caudal region of the red nucleus in the cat, which projects to the upper cervical cord and receives afferents from the lateral anterior interposed and the rostromedial dentate nucleus (Pong *et al.*, 2002). Fibers from the anterior interposed nucleus proceed to the thalamus, where they are relayed by the ventrolateral and caudal regions of Percheron's (Chapter 20) lateral subpart of the nucleus ventralis intermedius (VImL), to the primary motor cortex (Figs. 11.20 and 11.22B) (Kievit, 1979; see also Asanuma *et al.*, 1983b, c). The nucleus projects to the NRTP, but connections with the preolivary nuclei at the meso–diencephalic junction have not been reported.

The *dentate nucleus* projects to the red nucleus, the interstitial nucleus of Cajal, the tectum and pretectum, the preolivary nuclei at the meso–diencephalic border, the prerubral filed, the zona incerta, and the thalamus. It contributes to the descending branch of the brachium conjunctivum, which terminates in the NRTP and the reticular formation. The connections of the dentate with the red nucleus generally have been stated to be limited to its rostral parvocellular portion (Miller and Strominger, 1977; Stanton, 1980a; Asanuma *et al.*, 1983d). However, fibers from the rostral dentate have been observed to ascend through and terminate in both the caudal magnocellular and the rostral parvocellular red nucleus (Chan-Palay, 1977; Kalil, 1980). The lateral, parvocellular portion of the red nucleus includes a dorsolateral group of neurons that contains a representation of the face and projects to the cord (Kennedy *et al.*, 1986; Burman *et al.*, 2000). Pong *et al.* (2002) noted in the cat that the dentate nucleus also established indirect connections with the parvocellular dentate nucleus, which were relayed by the zona incerta and the nucleus of the fields of Forel. The dentate nucleus shares this connection to the parvocellular red nucleus with the entopeduncular nucleus (the cat's homologue of the internal segment of the globus pallidus). Convergence of cerebellar and striatal sytems, therefore, also may occur at the level of the brain stem.

There are strong indications that the dentate nucleus consists of rostrodorsal and caudoventral subdivisions (Schell and Strick, 1984). The rostrodorsal subnucleus contains a representation of the hindlimb in the rostral part, of the face dorsally in the middle third of the dentate, and of the arm in between (Figs. 11.23 and 11.24) (Van Kan *et al.*, 1993; Wiesendanger and Wiesendanger, 1985b; Middleton and Strick, 1997). It projects to ventral, central, and dorsolateral parts of the parvocellular red nucleus (Fig. 11.25B) (Stanton, 1980a). Percheron's (Chapter 20) lateral subpart of the nucleus ventralis intermedius (VImL) is the thalamic relay nucleus for the somatotopically arrranged projection of the rostral denate to the primary motor cortex and the caudal premotor area (Figs. 11.22B and 11.23; see "Cerebellar Projections to the Thalamus in Monkeys"). The projection area in the red nucleus may include the dorsolateral part of the parvocellular subdivsion, which contains a representation of the face and preferentially projects to the upper spinal cord (Kennedy *et al.*, 1986).

The ventrocaudal dentate projects to the dorsomedial part of the parvocellular red nucleus (Fig. 11.25B). A projection to Darkschewitsch's nucleus was mentioned by Stanton (1980a) and Van Kan (unpublished), but its origin from the posterior interposed nucleus cannot be excluded. Projections of the ventrocaudal dentate to more rostral premotor and prefrontal areas (Fig. 11.23) (Middleton and Strick, 1997, 2001), which include the frontal eye field (Lynch *et al.*, 1994 and the inferior

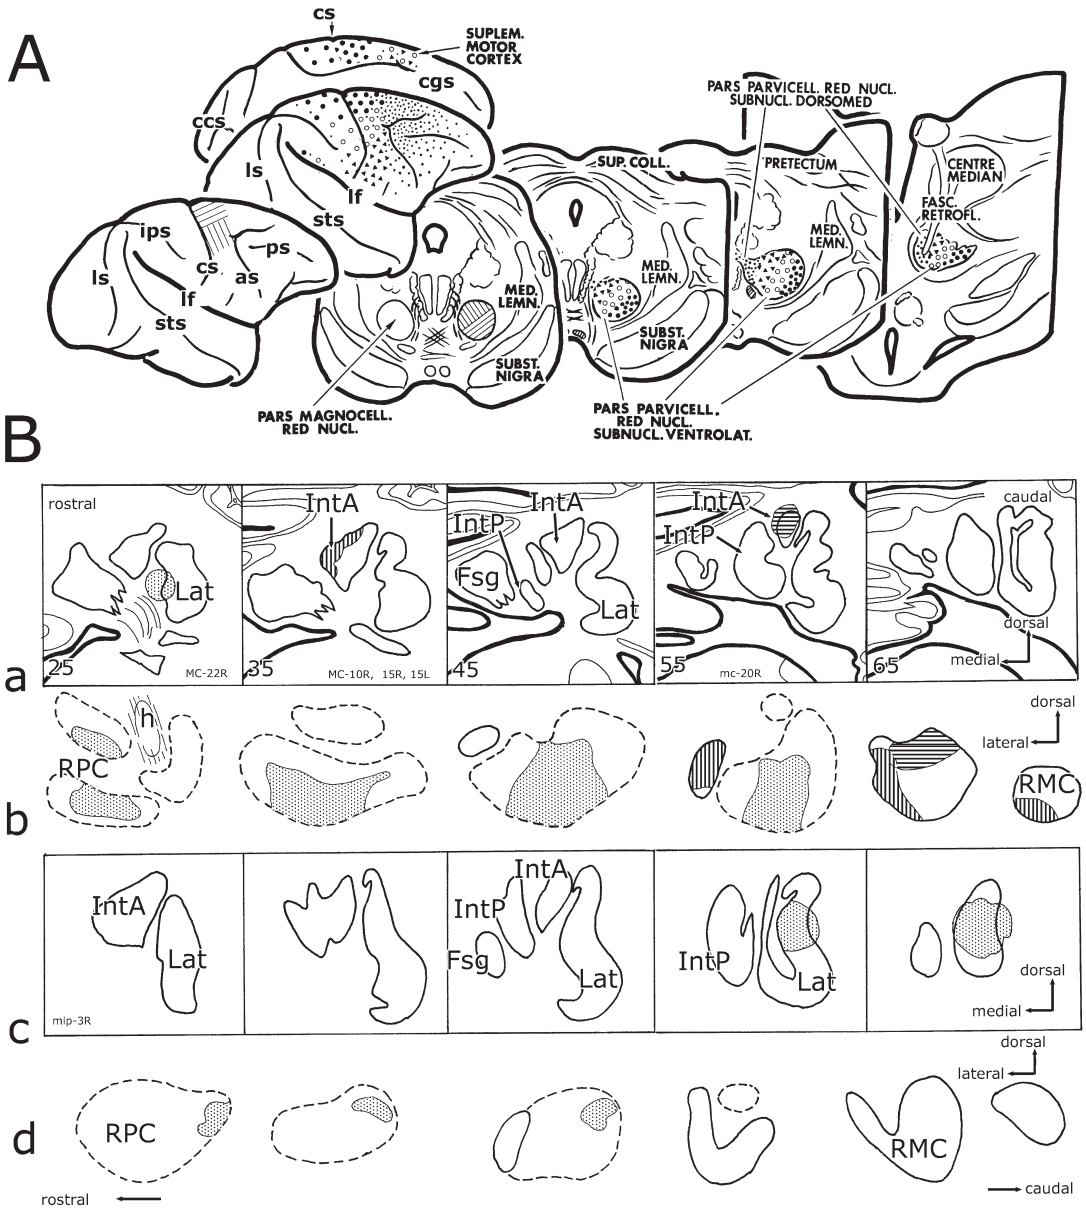

FIGURE 11.25 Afferent connections of the red nucleus in monkeys. **A.** The corticorubral projection. The origin of the corticorubral projections to the caudal, magnocellular portion of the red nucleus is restricted to arm and leg areas of the primary motor cortex. Somatotopically arranged projections from the primary motor cortex and the caudal premotor area terminate in the rostrolateral and caudal parvocellular red nucleus. More rostral frontal areas, including the frontal eye field, project to the rostromedial parvocellular red nucleus. From Kuypers and Lawrence (1967). **B.** Projections from the cerebellar nuclei to the red nucleus. Rows a and b were redrawn from Flumerfelt *et al.* (1973). Rows c and d were reproduced from unpublished materail of Van Kan. **a.** Lesion sites in the rostral dentate nucleus (section 25), three lesions in the rostromedial leg area of anterior interposed nucleus (section 35), and a lesion in the caudolateral, forelimb area of the anterior interposed nucleus (section 55). **b.** Localization of preterminal axonal degeneration from the lesion of the rostral dentate in the rostrolateral and caudal parvocellular red nucleus and of the termination of axons from leg and arm areas of the anterior interposed nucleus in the ventrolateral and dorsal parts of the magnocellular red nucleus. Contours of the parvocellular red nucleus are indicated with broken lines, of the magnocellular red nucleus with continuous lines. **c.** Lectin-coupled horseradish peroxidase injection in the caudal dentate nucleus. **d.** Resultant labeling in rostromedial parvocellular red nucleus. Abbreviations: as., ansate sulcus; ccs, calcarine sulcus; cgs., cingulate sulcus; cs., central sulcus; Fsg, fastigial nucleus; h, fasciculus retroflexus; IntA, anterior interposed nucleus; IntP, posterior interposed nucleus; ips, intraparietal sulcus; Lat, dentate nucleus; ls, lunate sulcus; ps., principal sulcus; RMC, magnocellular red nucleus; RPC, parvocellular red nucleus; sts., superior temporal sulcus.

parietal lobule (Clower *et al.*, 2001), are relayed by Percheron's (Chapter 20) medial subpart of the nucleus ventralis intermedius (VimM, Fig, 11.22B). The two subnuclei of the dentate presumably receive Purkinje cell afferents from different cortical zones in the hemisphere and are connected with different parts of the principal nucleus of the inferior olive (Figs. 11.46, 11.47, and "Longitudinal Zonation of the Cerebellum"). A precise border between the two subdivisions of the dentate cannot be drawn as yet. Their homology with the rostromedial microgyric and ventrolateral macrogyric portions of the human dentate has not been established.

Chan-Palay (1977) traced bilateral projections from the caudal dentate nucleus to the PPRF. These projections may take their origin from the eye movement area in the caudal dentate of Van Kan *et al.* (1993) (Fig. 11.24). The eye movement area in the caudal dentate shares these connections with oculomotor centers in the caudal fastigial nucleus and with the lateral oculomotor region in the posterior interposed nucleus Direct connections of the dentate nucleus with the neurons of the oculomotor nuclei (fibers of Klimoff, 1899 and Wallenberg, 1905) probably do not exist. These connections take their orgin from group Y. Stanton (1980a) traced connections from group Y, in the medial longitudinal fascicle, to the three ipsilateral eye muscle nuclei, and a crossed pathway, through the brachium conjunctivum, to the contralateral oculomotor nucleus.

AFFERENT FIBER SYSTEMS

Organization of Mossy and Climbing Fiber in the Cerebellum

Although most textbooks suggest otherwise, very little is known about the distribution of mossy and climbing fiber system in the cerebellum of humans and subhuman primates. Apart from one antegrade tracing study on the human spinocerebellar tracts, some papers on the pontocerebellar projection, and a few incomplete data on the zonal distribution of olivocerebellar fibers in monkeys, the available information is restricted to data on their origin from retrograde labeling experiments and human cases with damage to the cerebellar cortex. Supposedly the general rules on their distribution, which can be drawn from experimental studies in carnivores and rodents, also apply to the primate cerebellum. These rules are well illustrated by two recent papers of Wu *et al.* (1999) on the course and termination of individual mossy fibers from the lateral reticular nucleus and on the morphology of climbing fibers from single cells in the inferior olive (Sugihara and Shinoda, 1999), both in the rat.

Mossy fibers enter the cerebellum laterally in the restiform body or the brachium pontis, and sweep medially, as semicircular fibers, located rostral and dorsal to the cerebellar nuclei. A proportion of these mossy fibers cross in the rostral and dorsal portion of the cerebellar commissure and distribute bilaterally (Fig. 11.26A). They emit collaterals at certain preferential positions, which enter the white matter of the folia and terminate as ill-defined, longitudinal aggregates of mossy fiber rosettes in the granular layer (Fig. 11.26B). Mossy fibers preferentially influence Purkinje cells located immediately superficial to their terminal sites in the granular layer, by synapses on the ascending branches of the axons of the granule cells (the parallel fibers; Bower and Woolston, 1983). The multiple zonal pattern in the termination of the mossy fibers, therefore, will be reproduced at the level of the Purkinje cells. The transverse branches of the parallel fibers extend over large distances; over the entire width of the lobules of vermis and hemisphere in the rat. As a consequence, mossy fibers will exert a strong influence on certain longitudinal arrays of Purkinje cells and a weaker influence on the Purkinje cells in between. Some mossy fiber systems also provide the cerebellar nuclei with a collateral innervation.

In the case of the rat lateral reticular nucleus (Fig. 11.26B) (Sugihara and Shinoda, 1999), the striped termination pattern is symmetric and occupies the dorsal part of the anterior lobe (lobules IV and V, the lobulus simplex (VI), and the pyramis with the copula pyramidis (VIII). The terminal stripes, therefore, are not necessarily continuous from one lobule to the next; often they are restricted to the base or the apex of a folium. For other mossy fiber systems their distribution is mainly restricted to one side of the cerebellum, with only a few fibers crossing in the commissure. Similar, zonal patterns in their distribution to the cerebellum have been described for different spinocerebellar, cuneocerebellar, and secondary vestibulocerebellar mossy fiber systems in rabbit, rat and cat (Alisky and Tolbert, 1997; Chan-Palay *et al.*, 1977; Gerrits *et al.*, 1985; Gravel and Hawkes, 1999; Jasmin and Courville, 1987a, b; Künzle, 1975; Matsushita and Ikeda, 1987; Matsushita and Wang, 1987; Matsushita and Tanami, 1987; Matsushita and Yaginuma, 1989; Matsushita *et al.*, 1984, 1985, 1991; Oscarsson, 1976; Russchen *et al.*, 1976; Tolbert *et al.*, 1993; Tolbert and Gutting, 1997; Yaginuma and Matsushita, 1986a, b, 1987, 1989; Voogd, 1964, 1967, 1969).

Zonal patterns in the termination of vestibular root fibers and mossy fibers from the basal pons and

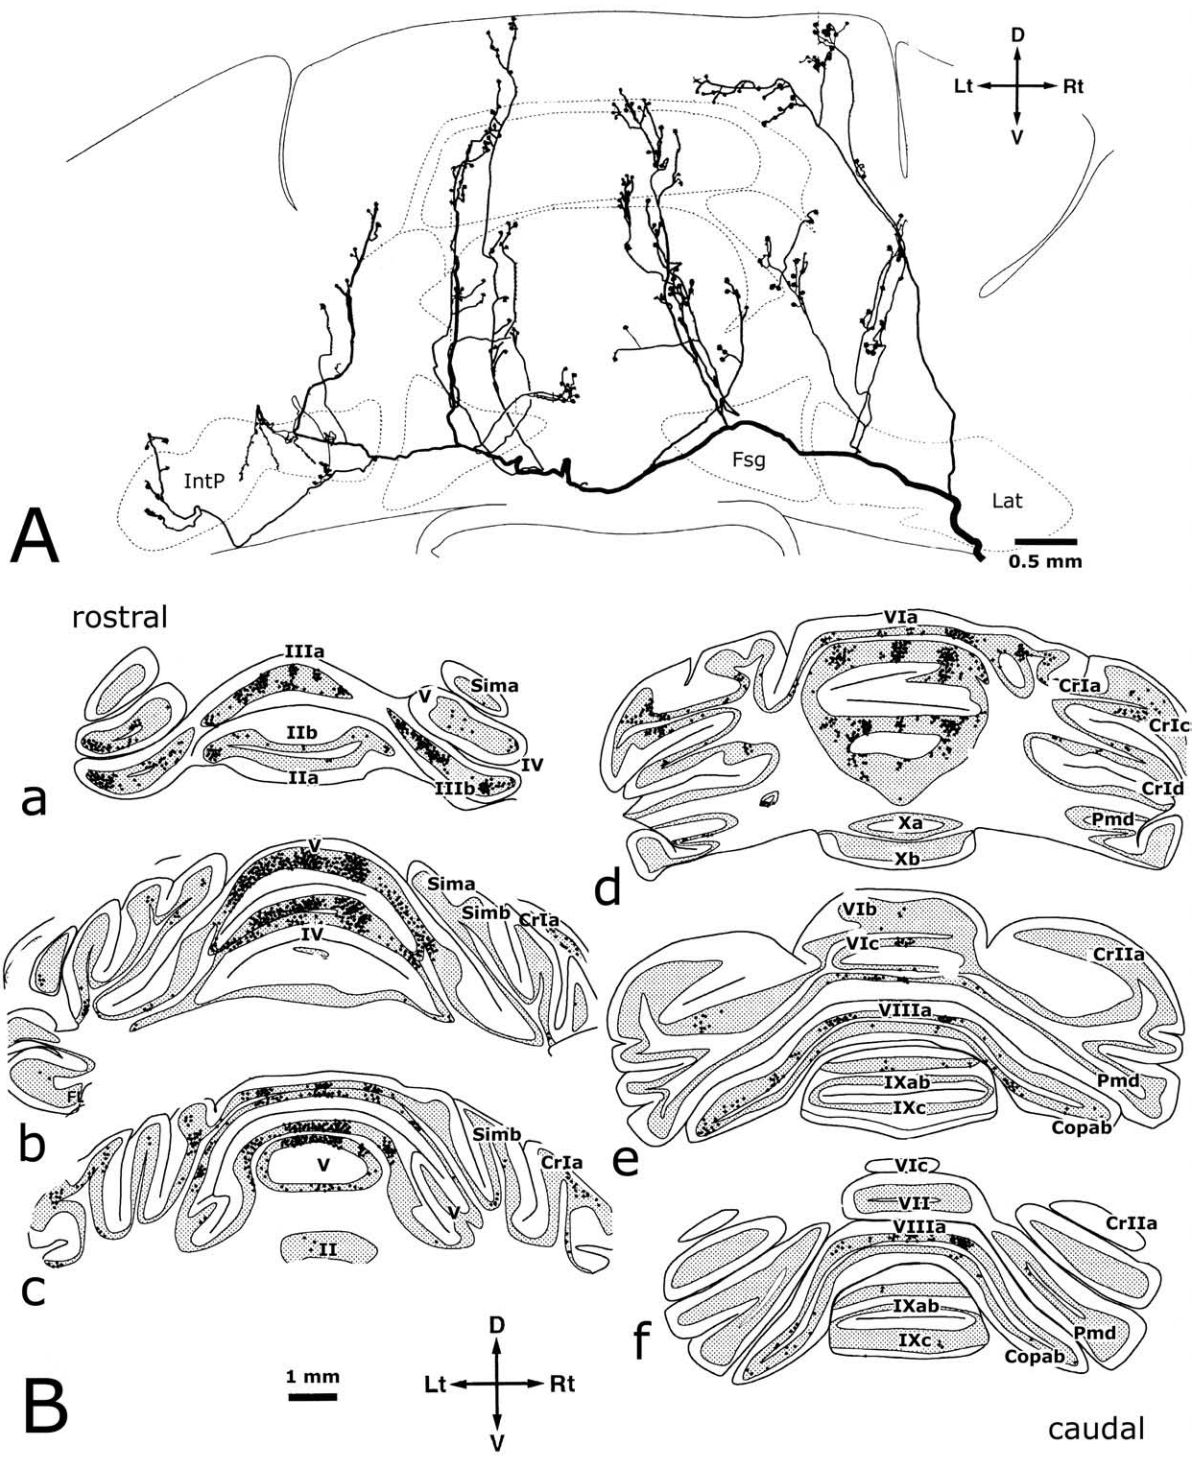

FIGURE 11.26 Course and termination of single mossy fibers in the cerebellum of the rat. **A.** Frontal view of a completely reconstructed, biotinylated dextran amine–labeled, single mossy fiber from the lateral reticular nucleus. The fiber entered the cerebellum through the ipsilateral restiform body, projected bilaterally to the cortex and the cerebellar nuclei and formed a multiple, longitudinal zonal projection pattern by its cortical arboresecnt collaterals. **B.** Mapping of mossy fiber rosettes in the cerebellar cortex after biotinylated dextran amine injection in the left lateral reticular nucleus, showing bilateral projction with ipsilateral predominance and zone-like terminal distribution in the cerebellar cortex. Modified and relabeled from Wu *et al.* (1999). Abbreviations: Copab, copula pyramidis, lobule ab; CrIa-c, Crus I a-c; CrIIa, Crus II a; D, dorsal; Fsg, fastigial nucleus; II-X, lobules II-X; IntP, posterior interposed nucleus; Lat, lateral cerebellar nucleus; Lt, left; Pmd, paramedian lobule; Rt, right; Sima,b, Simb, lobulus simplex, lolule a, b; V, ventral.

the nucleus reticularis tegmenti pontis are generally less conspicuous (however, see Voogd, 1969; Serapide *et al.*, 1994, 2001). Vestibular root fibers terminate in a continuous zone in the nodulus and the adjacent uvula and in patches in the bottom of the deep fissures (see Voogd *et al.*, 1996a for a review). Pontocerebellar fibers terminate diffusely in lateral parts of the cerebellum, in the apex of the medial lobules II–VI and VIII more medially, and massively in lobules VII and IX of the caudal vermis (Voogd, 1967; Gerrits and Voogd, 1986; Kawamura and Hashikawa, 1981).

The terminations of different mossy fiber systems in the cerebellum clearly overlap. Interesting observations on the mediolateral overlap and segregation of spinocerebellar and cuneocerebellar mossy fibers were made by Gravel and Hawkes (1990) and Alisky and Tolbert (1997) in the rat. The basoapical segregation of mossy fiber terminals, with vestibular root fibers located at the base, spinocerebellar terminals in the middle, and pontocerebellar fibers at the top would impart a characteristic mossy fiber profile to each individual lobule.

Collateral projections to the cerebellar nuclei have only been traced from the lateral reticular nucleus, the nucleus reticularis tegmenti pontis, the vestibular nuclei, and the spinal cord. These collaterals usually terminate bilaterally in multiple nuclei. The collateral projections of the two reticular nuclei appear to be complementary (Brodal, P., *et al.*, 1986; Dietrichs and Walberg, 1987; Gerrits and Voogd, 1987; Matsushita and Yaginuma, 1990, 1995; Mihailoff, 1993; Qvist, 1989a, b; Ruigrok *et al.*, 1995; Shinoda *et al.*, 1992; van der Want *et al.*, 1989). Other mossy fiber systems, such as the cuneocerebellar tract and the system from the basal pons seem to lack a collateral projection to the nuclei.

Olivocerebellar fibers only branch very sparingly. In the rat, one neuron of the inferior olive innervates ten Purkinje cells on the average (Schild, 1970; Sugihara *et al.*, 1999). Olivocerebellar fibers from subnuclei of the contralateral inferior olive distribute to discrete longitudinal zones and provide collaterals to the target nucleus of the Purkinje cells of this zone (Fig. 11.46; see also "Subdivision and Olivocerebellar Projection"). The precise topographical interrelations of mossy and climbing fiber zones have not been determined. One of the main conclusions of the ongoing discusssion about the spatial organization of mossy and climbing fibers holds that "mossy fiber and climbing fiber inputs to the cerebellar cortex are spatially coincident at the level of the single Purkinje cell" (Brown and Bower, 2000). Similar observations have been made by Ekerot and Larson (1972), and Garwicz *et al.* (1998). Therefore, the spatial and somatotopical organization of the mossy and climbing fibers should be congruent.

The Composition of the Restiform Body

The components of the restiform body, i.e., the dorsal spinocerebellar tract, the contribution of the dorsal column nuclei and the bulbar reticular nuclei, and the olivocerebellar fibers from the contralateral inferior olive, were already distinguished with the myelogenetic method in human fetal materal in the 19th century (von Bechterew, 1886; Darschewitsch and Freud, 1886). Darkschewitsch and Freud (1886) illustrated the dorsal and central position in the restiform body of the fibers from the dorsal column nuclei (1 and l′ in Fig. 11.27 and the more ventrally located dorsal spinocerebellar tract (indicated by "2" in the figure). The olivocerebellar fibers were just beginning to acquire their myelin sheath and could be followed from the contralateral olive, through and lateral to the spinal tract of the trigeminal nerve, into the periphery of the restiform body ("3" in Fig. 11.27A).

The position of the spinocerebellar tracts in the brain stem is indicated in Figure 11.13. The ventral spinocerebellar tract passes rostral to the entrance of the trigeminal nerve and enters the cerebellum along the superior cerebellar peduncle. The initial course of the olivocerebellar fibers is schematically indicated in Figure 11.28. The olivocerebellar fibers make their appearance as bundles of uniform 2-nm fibers passing through the lateral reticular nucleus and along the lateral margin of the spinal tract of the trigeminal nerve. More rostrally they also pass through this tract and its nucleus. In the restiform body the olivocerebellar fibers move through the central core of spino- and reticulocerebellar fibers to surround these mossy fiber systems at the entrance of the restiform body into the cerebellum. As a consequence, the olivocerebellar fibers become applied to the rostral and dorsal surface of the central cerebellar nuclei and their efferent tracts when they enter the cerebellum.

The early myelinating fibers of the dorsal spinocerebellar tract were traced to the cerebellum through the restiform body by Flechsig (1876) in human fetuses.[6] The separation of the spinocerebellar fibers into dorsal and ventral spinocerebellar tracts was first noted by Loewenthal (1885) in a Marchi study in the rabbit.[7] The course and termination of the spinocerebellar tracts in

[6]In the same paper that contains his famous description of the course of the degenerated pyramidal tract, Earlier Türck (1851) described following fiber degeneration from the dorsolateral funiculus of the spinal cord into the restiform body.

[7]It seems likely that the course of the ventral spinocerebellar tract was first described by Meynert (1872) as the "Hirnklappenschleife" (a lateral conmponent of the medial lemniscus, located ventral to the trigeminal spinal tract, which reaches the cerebellum along the "Hirnklappe," i.e., the anterior medullary velum).

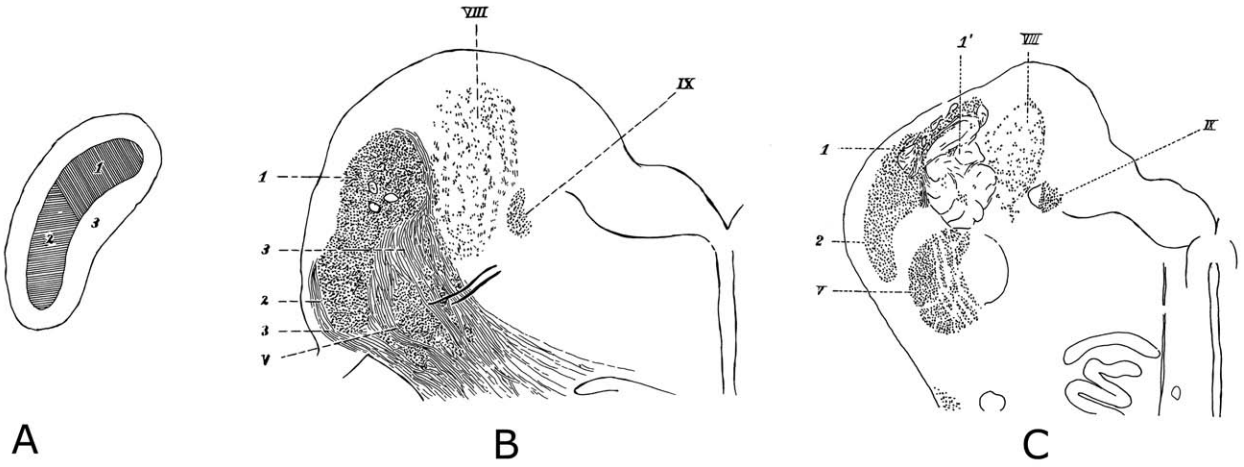

FIGURE 11.27 Myelinization of the restiform body in the human fetus. **A:** Diagram of the restiform body at a stage before myelinization of the olivocerebellar fibers has begun. The restiform body can be subdivided in a peripheral, unmyelinated portion (3) and a core with dorsal (1) and ventral parts (2). **B:** Section through the restiform body at a slightly later stage. Olivocerebellar fibers (3) now enter the restiform body through and ventral to the spinal root of the trigeminal nerve (V). **C.** Slightly more caudal section. The dorsal fibers of the early myelinating core of the restiform body (1) can be traced back to the cuneate nucleus (1′). Fibers from the dorsal spinocerebellar tract occupy its ventral portion (2). Abbreviations: n.XII, hypoglossal nerve; IX, solitary tract; VIII, juxtarestiform body. From Darkschewitsch and Freud (1886).

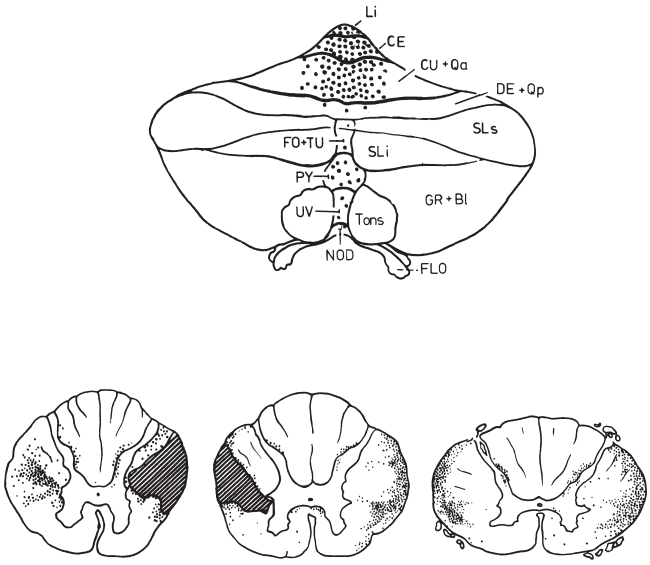

FIGURE 11.29 Termination of spinocerebellar fibers in the human cerebellum. Study using the Marchi method after a hemicordotomy at T.4–5. Lesions of the cord are hatched. Abbreviations: BI, biventral lobule; CE, central lobule; CU, culmen; DE, declive; FLO, flocculus; FO, folium vermis; GR, nucleus gracilis; Li, lingula; NOD, nodule; PY, pyramis; Qa, anterior quadrangular lobule; Qp, posterior quadrangular lobule; Sli, inferior semilunar lobule; SLs, superior semilunar lobule; Tons, tonsilla; UV, uvula. the human cerebellum was described by Bruce (1898), Collier and Buzzard (1903), Hoche (1896), and Thiele and Horsley (1901), all with the Marchi method. In the most recent antegrade tracing study of the spinocerebellar tracts by Jansen and Brodal (1941), using the Marchi method in a case with bilateral thoracic cordotomies and ascending degeneration in both tracts, degenerated fibers were followed to the vermis of the anterior lobe, mainly in the central lobule and the ventral part of the culmen, less in dorsal culmen and lingula, until 1.5 cm out of the midline. In the posterior lobe degenerated fibers were found mostly in the pyramis, less in other lobules of the caudal vermis (Fig. 11.29). This paper is the last study of its kind in primates. The origin of spinocerebellar fibers was studied with retrograde tracing methods by Petras (1977), Petras and Cummings (1977), and Snyder *et al.* (1978). Recent papers on the distribution of spinocerebellar fibers in the cat were published by Tolbert *et al.* (1993) and Grant and Xu (1988).

The external cuneate nucleus has been described in man (Olszewski and Baxter, 1954; see also Chapter 10). Its disappearance has been noted in many pathological cases with cerebellar lesions, but details about the projection of the dorsal column nuclei to the cerebellum in primates are not available. The origin of the cuneocerebellar projection from the external cuneate nucleus was determined in experimental studies by Von Gudden (1882) and from the internal cuneate and

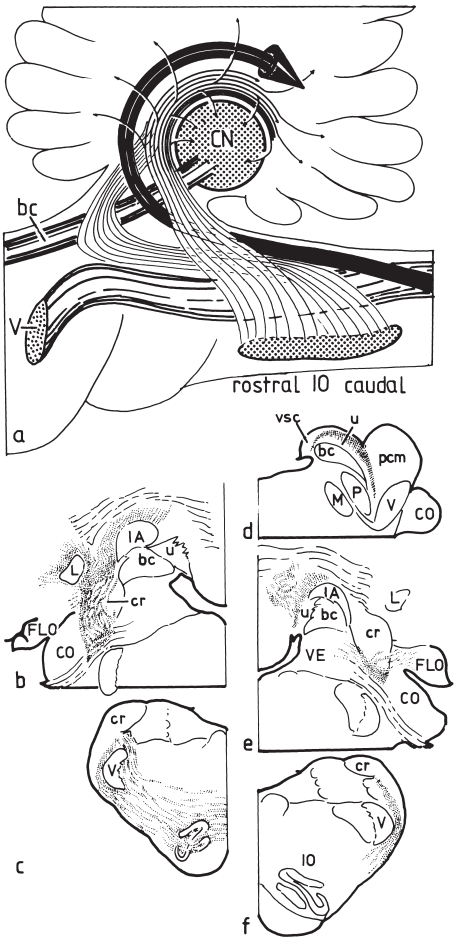

FIGURE 11.28 Lateral view of the localization of olivocerebellar fibers in the brain stem and cerebellum **(a)** Fibers from the caudal half of the inferior olive **(b–d)** pass lateral to the spinal tract (V) and ascend in the restiform body to enter the cerebellum medial to the spino-, cuneo-, and reticulocerebellar components of the restiform body *(thick arrow)*. Fibers from the rostral half of the inferior olive **(e, f)** enter the cerebellum lateral to these systems. In the cerebellum, olivocerebellar fibers become applied to the rostral and dorsal surface of the cerebellar nuclei and their efferent tracts. Abbreviations: bc, brachium conjunctivum; CN, cerebellar nuclei; CO, cochlear nuclei; cr, restiform body; FLO, flocculus; IA, anterior interposed nucleus; IO, inferior olive, L, lateral cerebellar nucleus; M, motor nucleus of the trigeminal nerve; P, principal sensory nucleus of the trigeminal nerve; pcm, brachium pontis; u, uncinate tract; V, trigeminal nerve; VE, vestibular nuclei; vsc, ventral spinocerebellar tract. From Voogd and Bigaré (1980).

gracile nuclei by Gordon and Seed (1961). The exteroceptive and proprioceptive components of the cuneocerebellar tract synapse in the internal and external cuneate nuclei, respectively (Cooke *et al.*, 1971). Data on the distribution of cuneocerebellar mossy fibers in the cat can be found in the papers of Alisky and Tolbert (1997), Gerrits *et al.* (1985), Jasmin and Courville (1987), and Tolbert and Gutting (1997).

The precerebellar reticular nuclei (see Chapter 10) are located in the caudal medulla, the lateral reticular nucleus in the lateral funiculus, and the paramedian reticular nucleus in the anterior funiculus (i.e., in the medial longitudinal fascicle, Fig. 11.32). The lateral reticular nucleus can be subdivided in most mammal into a lateral parvocellular, a medial magnocellular, and a subtrigeminal portion. A subdivision into a ventral main portion and a dorsal subtrigeminal part also is possible in man (Walberg, 1952). Parvocellular and magnocellular portions were difficult to identify. The lateral reticular nucleus is surrounded by the fiber systems of the lateral funiculus. In this position it was first described by Deiters (1865) in man. In human cordotomy cases, fiber degeneration in the lateral reticular nucleus always prevails in the lateral portion of the nucleus. In the cat the dorsal subtrigeminal portion of the lateral reticular nucleus is located in the center of the rubrospinal tract and receives collaterals from this system (Busch, 1961). In man the rubrospinal tract is not as well developed as in lower mammals (Verhaart, 1957). In cases with large lesions of the mesencephalon fibers can be traced to this location and were identified as rubrobulbar fibers terminating on the lateral reticular nucleus. Rubrospinal fibers cannot be traced caudal to the lateral reticular nucleus. The lateral reticular nucleus also receive cortical afferents in man (Kuypers, 1958; Schoen, 1964, 1969) (Fig. 11.40). Fibers from the lateral vestibulospinal tract that terminate in the medial extension of the lateral reticular nucleus in the cat (Ladpli and Brodal, 1968; Walberg *et al.*, 1985) and the projection of the fastigial nucleus to both parts of the nucleus (Walberg and Pompeiano, 1960) have not been identified in human material. The cerebellar projection of the lateral reticular and paramedian reticular nuclei have not been studied in primates. The literature on its distribution in rat and cat was reviewed by Wu *et al.* (1999). The literature on the collateral projection of the reticular nuclei to the cerebellar nuclei is included in the section "Organization of Mossy and Climbing Fiber in the Cerebellum" of this chapter.

Inferior Olive and Its Afferent Systems

Subdivision and Olivocerebellar Projection

The inferior olive in man was described and illustrated in the thesis of Kooy (1916, 1917), a phylogenetic and ontogenetic study on the subdivision of the inferior olive in vertebrates, and is discussed in Chapter 10 of this volume. It consists of dorsal (DAO) and medial (MAO) accessory olives and a principal nucleus (PO). The medial accessory olive is subdivided in rostral and

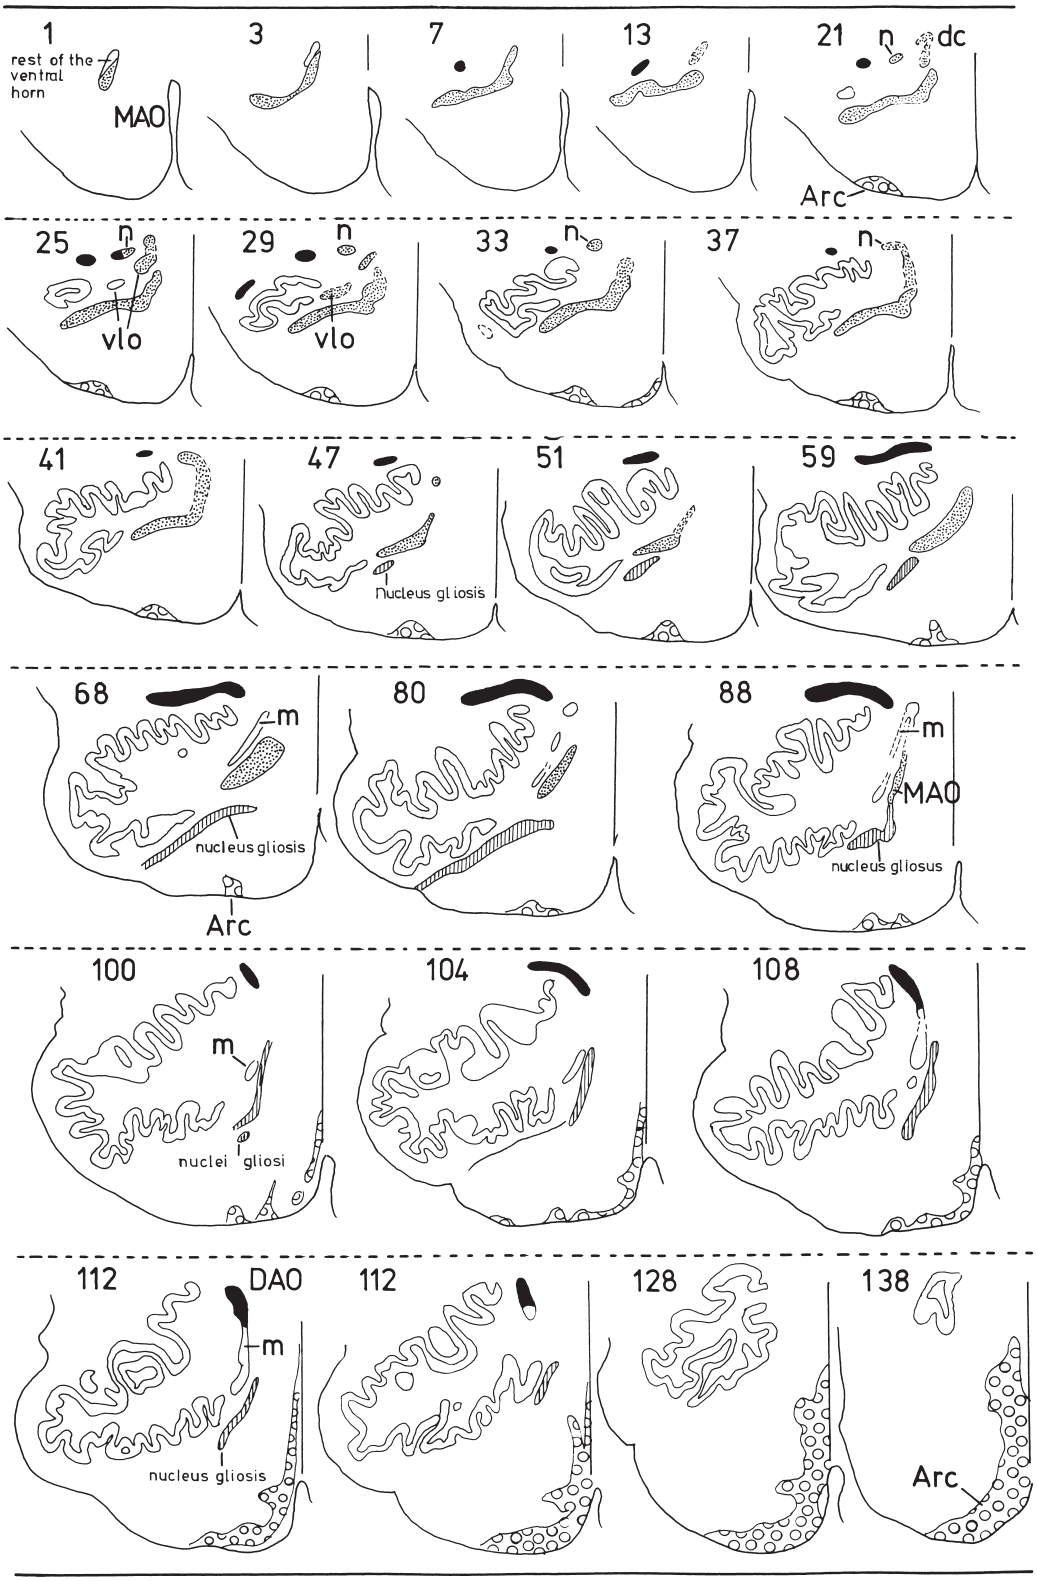

FIGURE 11.30 The human inferior olive. Dorsal accessory olive (DAO), black arreas; medial accessory olive (MAO), stippled areas; principal nucleus of the inferior olive (PO), unmarked areas; glial nuclei are hatched; arcuate nucleus is indicated with open circles. Abbreviations: m, medial leaf of the principal olive; n, connection between dorsal cap and the DAO; vlo, ventrolateral outgrowth. Adapted from Kooy (1916).

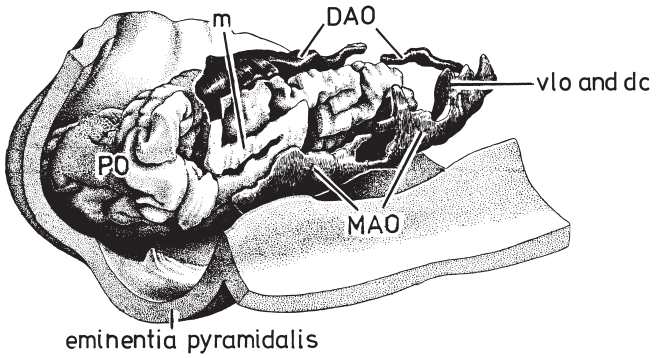

FIGURE 11.31 After a wax model of the human inferior olive. Abbreviations: see Fig. 11.30. From Kooy (1916).

caudal parts, separated by a narrow neck (Fig. 11.30, section 51; Fig. 11.31). The caudal pole of the MAO is located adjacent to the supraspinal nucleus, the rostral continuation of the ventral horn. The dorsal cap and the ventrolateral outgrowth are part of the vertical limb of the MAO (Fig. 11.30, sections 13–29; Figs. 11.31 and 11.32; the so-called Reticularisantheil of the medial accessory olive). The ventral part of the vertical limb was identified as the subnucleus β by Jansen and Brodal (1958). They also indicated a dorsomedial cell column, in the rostralmost parts of the olive. The dorsal accessory olive (DAO) caudally connects with the dorsal cap and rostrally with the medial lamina of the principal olive (PO). The connection of the DAO with either the dorsal or the ventral lamina of the PO is also observed in other mammals; the connections of the DAO with the dorsal cap is unusual. The continuity of the ventrolateral outgrowth with the ventral leaf of the PO, which is present in many other mammals, is also indicated in the human olive. The cell sheet of the principal olive is folded, except for its medial lamina. The PO of subhuman primates has a similar configuration, with strong folding of the dorsal and the lateral laminae, and an unfolded ventral lamina, which is continuous with the medial pole of the DAO (Whitworth and Haines, 1986b).

Knowledge of the olivocerebellar projection has progressed slowly. The decussation of the olivocerebellar fibers and their course and localization were well-known to the 19th century neurologists who described the composition of the restiform body (see "Composition of the Restiform Body"). The myelogenetic method and the Marchi technique, which visualizes degenerated myelin, are not suitable to trace the fine olivocerebellar fibers to their termination. The termination of the olivocerebellar fibers as climbing fibers was suggested in animal experiments by Szentagothai and Raikovits (1959). Desclin (1974) settled the sole origin of climbing fibers in the inferior

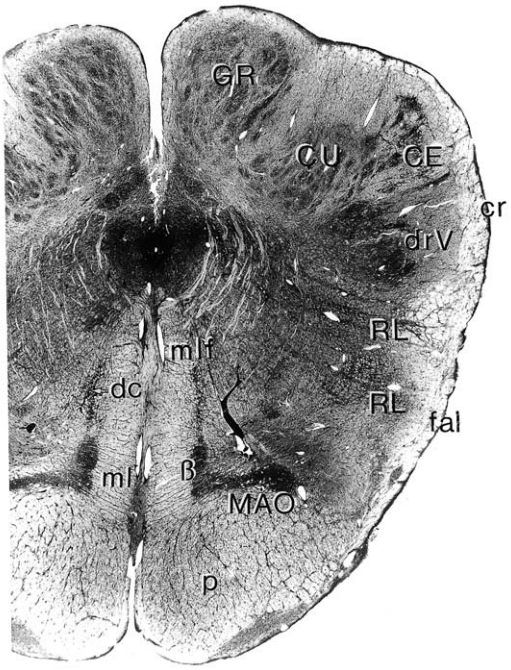

FIGURE 11.32 Häggqvist-stained section through the caudal pole of the medial accessory olive with the dorsal cap and group B. Abbreviations: CE, external cuneate nucleus; cr, restiform body; CU, cuneate nucleus; dc, dorsal cap; drV, spinal tract of the trigeminal nerve; fal, anterolateral fascicle; GR, nucleus gracilis; MAO, medial accessory olive; ml, medial lemniscus; mlf, medial longitudinal fascicle; p, pyramid; RL, retrolemniscal nucleus.

olive with Fink–Heimer modification of the Nauta technique after chemical destruction of the inferior olive of the rat with 3-acetylpyridine. The topography in the olivocerebellar projection had already been studied before the mode of termination of the olivocerebellar became known.

Brodal (1940) used retrograde changes, induced by localized lesions of the cerebellum, in cells of the inferior olive in young kittens and newborn rabbits (modified Von Gudden method) to map the olivocerebellar projection. His lesions were classified according to the lobules they involved, and in the interpretation of his results he made the assumption that a single olivary subnucleus usually projects to a single lobule or group of lobules. The rostral MAO was found to project to the flocculus and the caudal MAO to lobules of the anterior and posterior vermis. The projection of the DAO is restricted to the anterior lobe but extends beyond the vermis in the so-called pars intermedia. The hemisphere, including the hemisphere of the anterior lobe, receives olivocerebellar fibers from the PO. On the basis of these results he postulated the presence of three longitudinal zones in the anterior lobe: the vermis with projections from MAO and DAO, the pars

intermedia with projections from the DAO, and the hemisphere with projections from the PO. In later studies on the corticonuclear projection with Jansen (Jansen and Brodal, 1940, 1942) they described the corticonuclear projection of the three zones to the three cerebellar nuclei of Brunner (1919): the vermis to the fastigial nucleus, the intermediate zone to the interposed nucleus, and the hemisphere to the dentate. Projections to the cerebellar nuclei were found to arise from the dorsal cap and the ventrolateral outgrowth.

Brodal's (1940) lobular pattern in the olivocerebellar projection was challenged when Nauta's anterograde degeneration method was applied to study these connections. According to Voogd (1969), the olivocerebellar projection is organized in a strictly longitudinal zonal fashion: different subnuclei project to narrow longitudinal zones, which extend perpendicular to the long axis of the folia and which are continuous over many successive cerebellar lobules, sometimes including the entire cerebellum. It was postulated in the same paper, and later verified experimentally (Courville and Faraco-Cantin, 1976; Voogd and Bigaré, 1980) (Fig. 11.33), that these climbing fiber zones coexist with the corticonuclear projection zones, which contain Purkinje cells that project to a single cerebellar or vestibular nucleus (Fig. 11.46A). These observations were extended and confirmed using the anterograde tracing with [^{3}-H]leucine (Courville *et al.*, 1974; Gerrits and Voogd, 1982; Groenewegen and Voogd, 1977; Groenewegen *et al.*, 1979; Kawamura and Hashikawa, 1979; Voogd, 1982) and more recent antegrade tracer methods and electrophysiological techniques (Andersson and Oscarsson, 1978a, b; Atkins and App, 1997; Armstrong *et al.*, 1974; Buisseret-Delmas, 1988a, b; Buisseret-Delmas *et al.*, 1989, 1993; Jörntell *et al.*, 2000; Garwicz *et al.*, 1997; Oscarsson, 1969, 1973, 1980; Ruigrok *et al.*, 1992; Tan *et al.*, 1995a, b, c; Trott and Armstrong, 1987a, b; Trott *et al.*, 1998a, b; Voogd *et al.*, 1996). A single lobule therefore may receive its climbing fiber connections from as many as seven different olivary subnuclei, each of which provide one or more longitudinal zones of Purkinje cells with its climbing fibers. Projections to the cerebellar nuclei do not originate from separate subnuclei of the olive but as collaterals from the olivocerebellar fibers. They terminate in those cerebellar nuclei which receive the axons of the Purkinje cells which are innervated by climbing fiber collaterals from the same parent fibers (Ruigrok and Voogd, 2000; Sugihara and Shinoda, 1999; Van der Want and Voogd, 1987; Van der Want *et al.*, 1989). In an extensive series of experiments with retrograde tracers of Brodal and Walberg and their coworkers (reviewed by Brodal and Kawamura, 1980), these authors confirmed the longitudinal organization in the olivocerebellar projection.

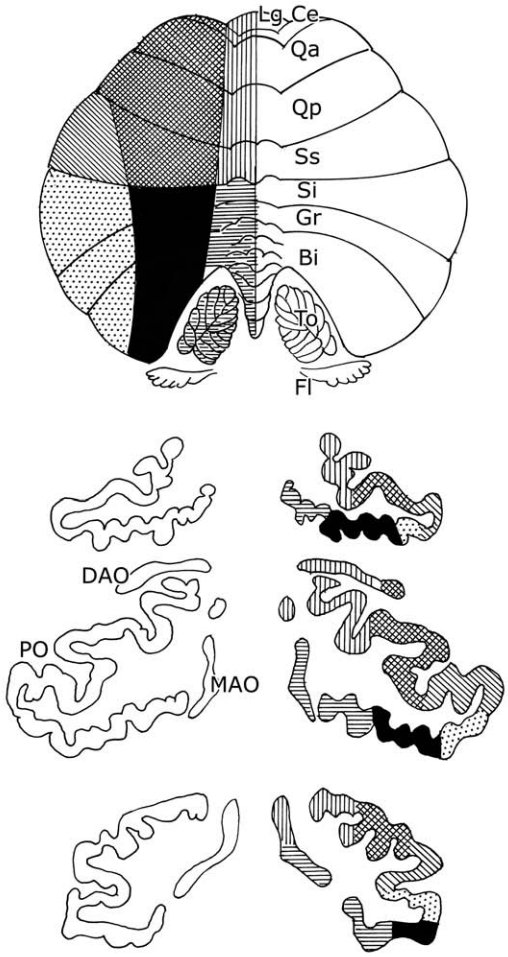

FIGURE 11.33 Diagram illustrating the topographical relations between the inferior olive and the human cerebellum. The dorsal accessory olive and the medial half of the dorsal leaf of the principal olive are connected with the cortex of the superior surface of the cerebellum. Olivocerebellar fibers from the ventral lamina of the principal olive and the ventral part of the medial accessory olive project to the tonsilla and the caudal vermis. Abbreviations: Bi, biventral lobule; Ce, central lobule; DAO, dorsal accessory olive; Fl, flocculus; Gr, lobulus gracilis; Lg, lingula; MAO, medial accesory olive; PO, principal olive; Qa, anterior quadrangular lobule; Qp, posterior quadrangular lobule; Si, inferior semilunar lobule; Ss, superior semilunar lobule; To, tonsilla. From Holmes and Stewart (1908).

The olivocerebellar projection in man was studied in many pathological cases with more or less restricted lesions of the cerebellum. Best known are the studies of Holmes and Stewart (1908)(Fig. 11.33). A topographical arrangement was proposed for the projections of the caudal ventral lamina of the PO and the medial accessory olive to the tonsilla and the caudal vermis, and of the medial part of the dorsal lamina and the dorsal accessory olive to the anterior lobe and the lobulus simplex. The longitudinal pattern in the olivocerebellar projection has not been investigated in man.

The scarce data from nonhuman primates indicated that the same longitudinal pattern that has been documented in carnivores is also present in the olivocerebellar projection in monkeys (Brodal and Brodal, 1981, 1982; Voogd *et al.*, 1987a; Whitworth and Haines, l986a).

One of the most vexing problems in the primate olivocerebellar projection remains the connections of the principal olive to the dentate nucleus and the cortex of the hemisphere. In carnivores Voogd (1969) distinguished two zones in the hemisphere, which are connected through separate white matter compartments, with different subdivisions of the dentate nucleus. Similar observations have been made in subhuman primates (Fig. 11.49; see "Longitudinal Zonation of the Cerebellum"). The medial D_1 zone is connected with the caudal dentate, the lateral D_2 zone with its more rostral portions. This relationship receives support from studies on the reciprocal connections between the dentate and the principal olive in cat and rat, which generally show that the target nucleus of the D_2 zone (the rostromedial dentate) is connected with the dorsal lamina and the lateral bend of the PO, and the target nucleus of D_1 (the ventrocaudal dentate) with its ventral, unfolded portion (Beitz, 1976; Dietrichs and Walberg, 1981; Courville *et al.*, 1983; Gerrits *et al.*, 1984, 1985a; Ruigrok and Voogd, 1990; Ruigrok *et al.*, 2000; Tolbert *et al.*, 1976). Similar observations have been published for monkeys (Chan-Palay, 1977; Kalil, 1979, Figure 36.3). However, the relationship of the ventral and the dorsal lamina of the PO with the D_1 and D_2 zones, as originally proposed by Voogd (1969), Groenewegen and Voogd (1977), and Provini (1982), was reversed in the studies in cat and rat by Brodal (Brodal and Kawamura, 1980; Azizi and Woodward, 1987; Buisseret-Delmas *et al.*, 1989). Therefore, the organization of the projection of the principal olive to the cortex of the the cerebellar hemisphere, which accounts for the major part of the olivocerebellar projections in primates, and the organization of the corticonuclear projection to the dentate nucleus remains undecided.

Afferent Systems of the Inferior Olive

Afferent systems of the inferior olive have been reviewed by Brodal and Kawamura (l980) and Saint-Cyr and Courville (1980) for the cat and by Martin *et al.* (1980) for the opossum. For the rat, the tabulated summery of its afferent connections in the paper of Brown *et al.* (1977) and the reviews by Flumerfelt and Hyrcyshyn (1985) and Ruigrok and Cella (1995) are useful. Afferent systems of the inferior olive can be subdivided into three groups: (1) excitatory projections from the spinal cord, certain brain stem nuclei, and the cerebral cortex; (2) GABA ergic nucleoolivary and vestibuloolivary projections; and (3) monoaminergic afferents. Monoaminergic and peptidergic projections to the inferior olive were reviewed by Voogd *et al.* (1996b).

Afferent Systems of the Inferior Olive: Ascending Connections Somatotopically arranged projections from the spinal cord, the dorsal column nuclei, and the sensory nuclei of the trigeminal nerve terminate in the entire DAO with the adjoining part of the dorsal lamina of the PO and in the caudal MAO, with the exception of the region of the nucleus β (Kalil, 1979; Mehler *et al.*, 1960; Whitworth and Haines, 1983). Spinoolivary fibers were already identified by Von Bechterew (1886). A portion of the caudal MAO, the group β and the dorsomedial cell column, receives afferents from the vestibular nuclei (reviewed by Voogd *et al.*, 1996a).

Afferent Systems of the Inferior Olive: Descending Connections. The Nucleus Ruber and Its Connections A major projection to the olive is derived from the so-called nuclei at the meso–diencephalic junction, which include the zona incerta, the pretectum, optokinetic centers such as the nucleus of the optic tract and the nuclei of the accessory optic tract, the central gray, the Darkschewitsch nucleus, the subparafascicular nucleus, the medial accessory nucleus of Von Bechterew, and the parvocellular red nucleus. The caudal magnocellular division of the red nucleus gives rise to rubrobulbar and rubrospinal tract but does not project to the inferior olive. In the cat, the descending fibers reach the olive through the medial and central tegmental tracts (Busch, l961; Ogawa, 1939; Onodera, 1984) and terminate in the rostral half of the MAO, in restricted parts of the caudal MAO, in the caudal DAO, and in the PO.

The central tegmental tract is especially well developed in man. It takes its origin from the parvocellular part of the red nucleus; the magnocellular portion is poorly developed in man. Its fibers emerge from the dorsomedial part of the red nucleus and traverse the capsule of brachium conjunctivum fibers in small fascicles of uniform 2- to 3-nm fibers in a dorsolateral direction. Together with similar fibers from the medial tegmental tract, which is located in the ventral part of the medial longitudinal fascicle, the central tegmental tract constitutes a single area characterized by its uniform fiber caliber in the mesencephalic tegmentum (Fig. 11.34). The uniform fiber pattern of the central tegmental tract makes it possible to trace it in normal, Häggqvist-stained sections (Verhaart, 1949, 1956a; Verhaart and Sie, 1958). Caudally the two tracts separate. The fibers of the central tegmental tract traverse the fibers of the brachium conjunctivum on

their way to their decussation. They take up their characteristic central position as a comma-shaped tract in the tegmentum at the level of the pons (Fig. 11.35). Still more caudally they can be traced into the amiculum surrounding the inferior olive. The central tegmental tract was discovered by Von Bechterew (1899). The medial tegmental tract descends from its ventral position in the medial longitudinal fascicle, along the raphe to enter the olive dorsomedially (Ogawa, 1939; Busch, 1961; Onodera, 1984).

Termination of the tegmental tracts was reported in the autoradiographic tracing study of Strominger *et al.* (1979) in monkeys. The dorsomedial portion of the parvocellular red nucleus, located medial to the fasciculus retroflexus, projects to the ventral lamina of the PO. More lateral and caudal parts of this nucleus project to the lateral bend and dorsal lamina of the PO (Fig. 11.36, 1–2). The dorsomedial injection sites encroach on the central gray with Darkschewitsch's nucleus and invariably result in labeling in the rostral MAO. The distribution of the label in the cell band of the PO is discontinuous stripes of dense labeling alternating with regions with a lesser concentration (arrows in Fig. 11.36, 2). Similar but less detailed observations were made earlier in an axonal degeneration study of Courville and Otabe (1974). The projection of the nucleus of Darkschewitsch, which is located in the ventrolateral central gray at the level of the posterior commissure, through the medial tegmental tract to the rostral half of the MAO and the dorsomedial cell column is only known from studies in cat and rat (for reviews, see Busch, 1961; Onodera, 1984; Ruigrok and Cella, 1995).

The distribution of the labeling in the human cases depicted in Fig. 11.37 is in general accordance with the experimental data (Schoen, unpublished). Large lesions of the mesencephalon result in a descending degeneration of both tegmental tracts (Fig. 11.37, case 3). Fiber degeneration is found in and around the DAO, the MAO, and the PO over their entire rostrocaudal extent. Caudally degenerated fibers of the central tegmental tract proceed beyond the olive in the ventrolaterally located tract of Helweg. Its fibers are thinner than the fibers of the central tegmental tract at the level of the pons. In cases with medially located lesions of the central gray isolated degeneration of the medial tegmental tract is obtained. The fibers were found to terminate in the medial extremity of the ventral lamina of the PO and in the entire MAO (Fig. 11.37, case 1). A partial degeneration of the central tegmental tract is present in case H6486 (Fig. 11.37, case 2) with a hemorrhagic softening in the ventral part of the central gray matter, extending in the area of the medial and central tegmental tracts and the medial red nucleus. This resulted in degeneration in both medial tegmental tracts and in the medial half of the central tegmental tract. Termination is especially strong around the ventral lamella of the PO and in the entire MAO. The inclusion of the caudal MAO with the dorsal cap in these human cases may be due to the interruption by the large, less well-defined human cases of other descending fibers to the inferior olive, i.e., of fibers from the nucleus of the optic tract and the nuclei of the accessory optic tract to the dorsal cap and the ventral lateral outgrowth (for reviews, see Simpson, 1984 and Simpson *et al.*, 1988) or the interruption fibers from the superior colliculus to the medial part of the caudal MAO adjoining group β, which have been demonstrated in monkeys (Frankfurter *et al.*, 1976; Harting *et al.*, 1977) and other species. A projection of the central tegmental tract to the DAO was not reported in animal studies. Projections to the DAO originate from the pretectal nuclei in monkeys and other species (Sekiya and Kawamura, 1985; Bianchi and Gioia, 1990; for reviews, see Kitao *et al*, 1989 and Bull *et.al*, 1990). These pretectal projections may also exist in humans but in this case would include the entire DAO. It can be concluded that in humans the descending projections from the mesencephalon completely overlap with the ascending somatosensory projections to the accessory olive.

The parvocellular red nucleus and surrounding structures are links in corticoolivocerebellar climbing fiber paths, which are under control of the cerebral cortex. Direct corticoolivary connections exist, but they seem to be rather scanty (Saint-Cyr, 1983; Burman *et al.*, 2000). The corticorubral projection in monkeys seems to be limited to the frontal lobe and therefore is the mirror image of the cerebellothalamocortical projection. The corticorubral pathway to the parvocellular red nucleus in the monkey dominates over the projection to its magnocellular part (Fig. 11.25A). It arises from the entire motor cortex, the premotor cortex, the supplementary motor cortex and the cingulate motor areas, and the frontal eye field (areas 4, 6, 8, 23, and 24 of Brodmann, 1909). Connections from the parietal lobe are few or absent in the monkey. An origin from the prefrontal cortex was never mentioned in the literature but has not been systematically studied. The projection is mainly ipsilateral, with smaller, symmetric projections to the other side. Kuypers and Lawrence (1967), Hartmann-Von Monakow *et al.* (1979), Oriolo and Strick (1989), and Burman *et al.* (2000) established that the projection from the motor cortex occupies the lateral two-thirds of the rostral and the entire caudal portion of the parvocellular red nucleus (Fig. 11.25A). This projection is somatotopically arranged, with the hindlimb ventrolaterally and the face medially. Tokuno *et al.* (1995) observed a similar somatotopical

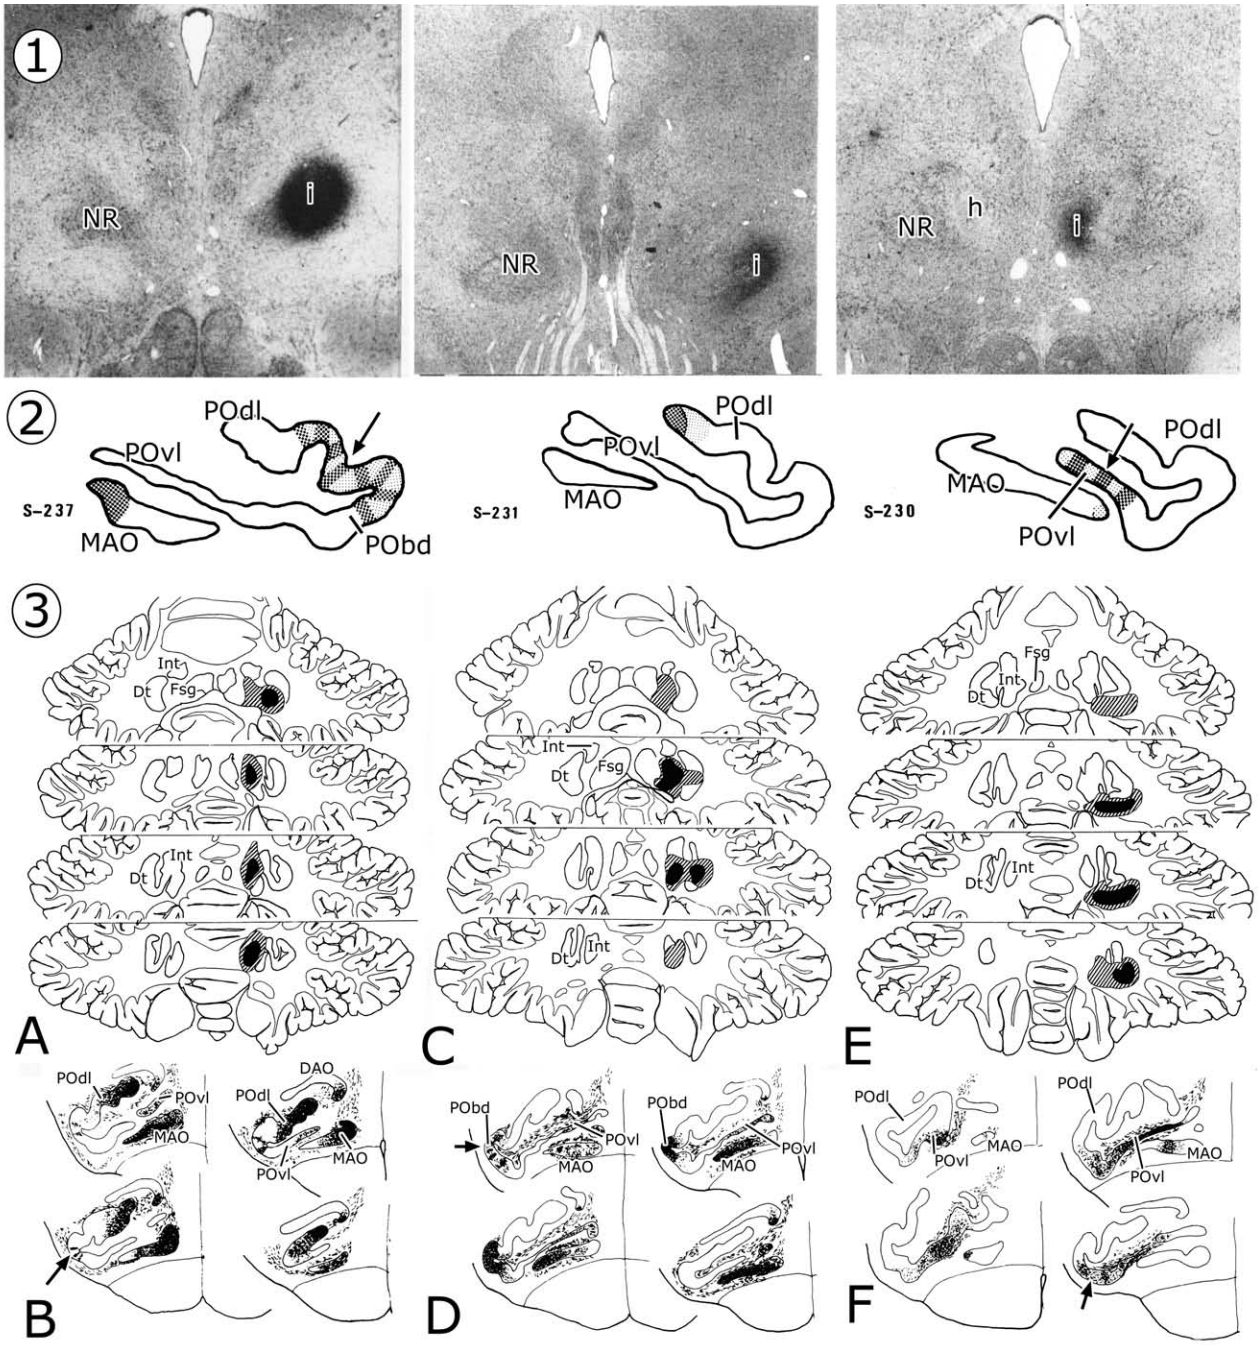

FIGURE 11.36 Afferent connections of the principal nucleus of the inferior olive in the monkey. **1, 2:** Injections of tritiated leucine in rostrolateral part of parvocellular red nucleus (S-237), caudal parvocellular red nucleus (S-231), and rostromedial parvocellular red nucleus (S-230) label a lateral part of the dorsal lamella and the bend of the principal olive, the medial pole of the dorsal lamella, and the ventral lamella of the ipsilateral principal olive, respectively. **3A–F:** Injections of tritiated proline in the rostral **(A),** lateral **(C),** and ventrocaudal **(E)** dentate mainly label the dorsal lamella **(B),** the lateral bend **(D),** and the ventral lamella **(F)** of the contralateral principal nucleus of the olive. Labeling in the rostral part of the medial accessory olive is caused by an extension of the injection into the posterior interposed nucleus. Terminals of both the the rubroolivary and the nucleoolivary projection display a periodicity in the lamella of the principal olive *(arrows).* Abbreviations: DAO, dorsal accesory olive; DAO, dorsal accessory olive; Dt, dentate nucleus; Fsg, fastigial nucleus; h, habenulointerpeduncular tract; i, injection site; Int, interposed nuclei; MAO, medial accessory olive; PObd, lateral bend of the principal nucleus of the inferior olive; POdl, dorsal lamella of the principal nucleus of the inferior olive; Povl, ventral lamella of the principal nucleus of the inferior olive; RN, red nucleus. Rows 1 and 2, from Strominger *et al*. (1979); rows 3A–F from Kalil (1979).

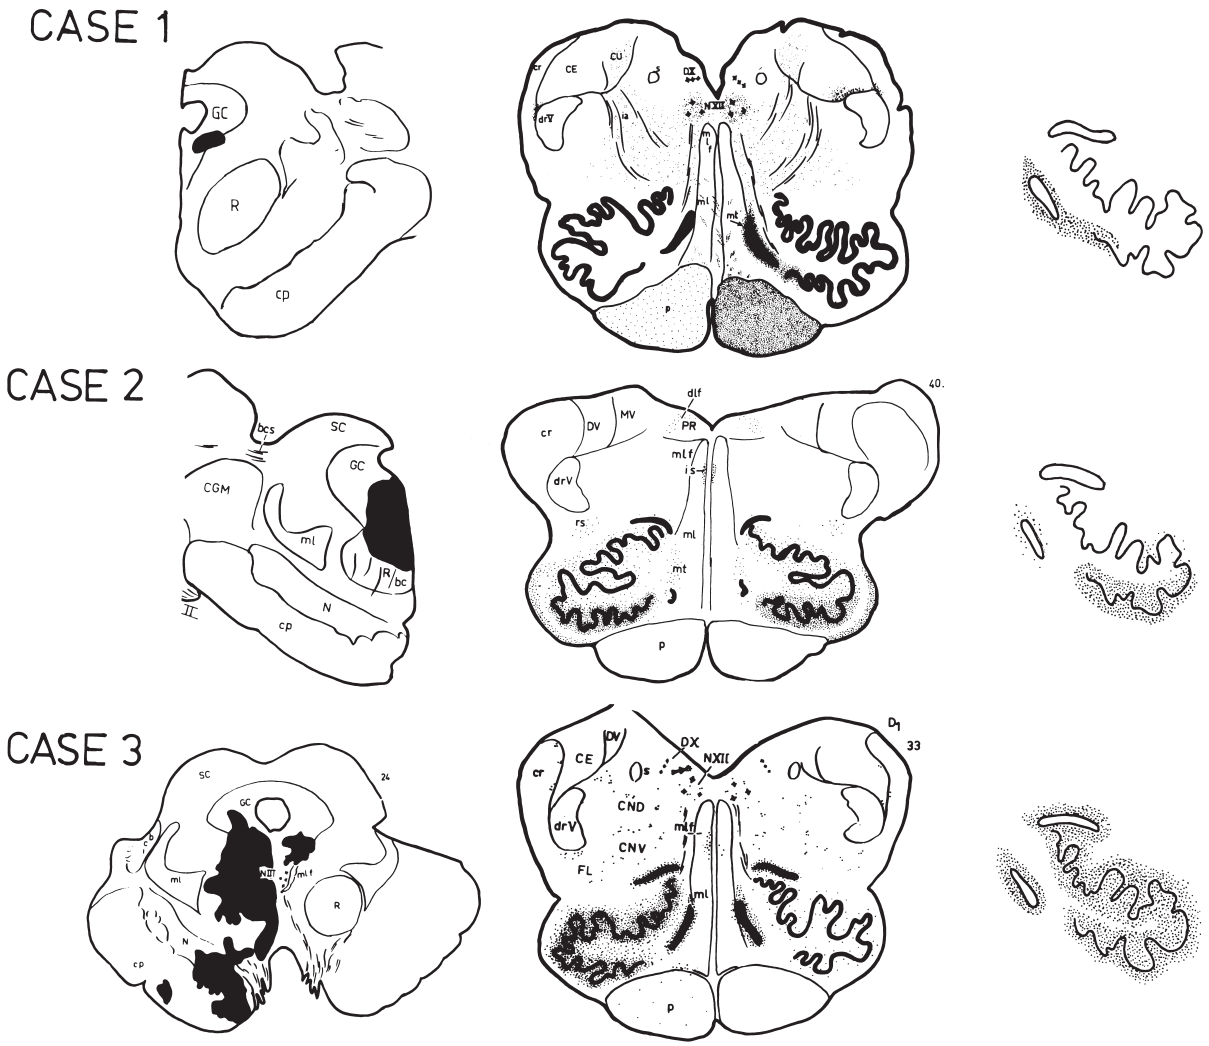

FIGURE 11.37 Lesions and fiber degeneration at the level of the inferior olive in three cases with axonal degeneration of the fibers of different components of the tegmental tracts. Case 1 (H6348) with degeneration of the medial tegmental tract; Case 2 (H6486) with a degeneration of the medial tegmental tract and a partial degeneration of the central tegmental tract, Case 3 (H6386) with a degeneration of the medial and central tegmental tracts. Lesions in the diagrams on the left are indicated in black. Nauta stain. Abbreviations: bc, brachium conjunctivum; bcs, brachium of the superior colliculus; cb, corpus bigeminum; CE, external cuneate nucleus; CGM, medial geniculate body; CND, central nucleus, pars dorsalis; CNV, central nucleus, pars ventralis; Cp, cerebral peduncle; CU, cuneate nucleus; dlf, dorsal fasciculus; drV, spinal tract of the trigeminal nerve; DV, spinal vestibular nucleus; DX, dorsal nucleus of the vagal nerve; FL, fasciculus anterolateralis; GC, central gray; ia, internal arcuate fibers; is, interstitiospinal fibers; m, medial longitudinal fascicle ; ml, medial lemniscus; mt, medial tegmental tract; N, substantia nigra; NIII, ocolomotor nerve; NXII, hypoglossal nerve (nucleus); p, pyramid; PR, nucleus prepositus hypoglossi; R, red nucleus; rs, rubrospinal tract; SC, superior colliculus. Courtesy of Schoen (unpublished).

pattern for the projection of the supplementary motor area. The rostral dorsomedial part of the parvocellular red nucleus, which extends medial to the fasciculus retroflexus, receives afferents from more rostral frontal areas, corresponding to the rostral part of the supplementary motor area (Hartmann-von Monakow *et al.*, 1979), the rostral and dorsal part of the premotor area (Kuypers and Lawrence, 1967; Hartmann-von Monakow *et al.*, 1979), the frontal eye field (Kuypers and Lawrence, 1967; Burman *et al.*, 2000), and the ventral premotor area (Hartmann-Von-Monakow *et al.*, 1979). Darkschewitsch's nucleus receives projections from arm and leg areas of the motor cortex, weakly from the premotor area and more strongly from the

frontal eye field (Kuypers and Lawrence, 1967; Leichnetz *et al.*, 1984a; Huerta *et al.*, 1986; Stanton *et al.*, 1988), and from posterior area 7 (Faugier-Grimaud and Ventre, 1989). The organization of the projections from the frontal lobe to the subdivisions of the inferior olive can be understood from a comparison with the data of Strominger on the rubroolivary projection (Fig. 11.36, 1–2). The corticorubral projections to the magnocellular red nucleus is uncrossed and derived from the primary motor cortex only. The leg area projects to the lateral part of the nucleus, the arm area medially. A projection from the face area is lacking (Fig. 11.25A).

The origin of most corticorubral fibers to the parvocellular red nucleus from superficial lamina Va pleads against their collateral origin from corticospinal fibers. Projections to the magnocellular red nucleus mainly arise from lamina Vb, and are part of a collateralizing system of corticospinal fibers, which also terminates in the medial reticular formation of the lower brain stem (Catsman-Berrevoets *et al.*, 1979; Humphrey *et al.*, 1984; Kuypers, 1987).

The parvocellular red nucleus and Darkschewitsch's nucleus and adjacent structures also receive strong projections from the cerebellar nuclei. Those terminating in the parvocellular red nucleus are derived from the dentate nucleus, with the rostral and dorsal dentate projecting to lateral and caudal parts of the red nucleus, and the caudal and ventral dentate to its rostral and dorsomedial portion. (see "Projections of Individual Cerebellar Nuclei to the Brain Stem in Monkeys" and Fig. 11.25). Projections to Darkschewitsch's nucleus originate preferentially from the posterior interposed nucleus (Voogd, 1964; Kievit, 1979).

The parietorubroolivary pathway, which seems to absent in primates, may be present in cats. Responses in the inferior olive, relayed by the red nucleus, were recorded after stimulation of parietal association areas in the suprasylvian gyrus (Oka *et al.*, 1979, 1988). The latencies of these responses were longer than those from stimulation of the motor cortex. This may be due to slower conducting axons arising from smaller pyramidal neurons in the parietal cortex projecting to the parvocellular red nucleus. Alternatively, they may have been transmitted by an indirect pathway, involving parietal layer III neurons with projections to the motor cortex, observed by Kakei *et al.* (1995). Projections of parietal association areas to the red nucleus have been reported repeatedly in the cat. However, according to Saint-Cyr (1987), these corticorubral fibers terminate in the magnocellular spinal projecting part of the red nucleus. In the cat, the cell groups at the meso–diencephalic junction that project to the inferior olive receive their cortical inputs primarily from precruciate areas 4 and 6, with only sparse contributions from postcruciate areas 3a, 3b, and perhaps 5. Precruciate and suprasylvian cortical afferents of Darkschewitsch's nucleus were confirmed by Rutherford *et al.* (1989) and Miyashita and Tamai (1989). The parietorubroolivary projection in the cat may be reciprocated by cerebello-parietal connections (see footnote 4).

Afferent Systems of the Inferior Olive: The Nucleo-Olivary Projection. The Inhibitory and Excitatory Feedback Loops Involving the Inferior Olive The cells in the central cerebellar nuclei that project to the inferior olive constitute a population of small, GABAergic neurons (see "Cerebellar Nuclei" and "Cerebellar Peducles"). GABAergic projections to certain subdivisions of the inferior olive also take their origin from the vestibular nuclei (Nelson and Mugnaini, 1989); the nucleus prepositus hypoglossi and the group Y project to the dorsal cap (De Zeeuw *et al.*, 1993, 1994) and the nucleus parasolitarius to the group β and the dorsomedial cell column (Barmack *et al.*, 1998).

The GABAergic nucleoolivary projection has a high resolution and displays an almost complete reciprocity, with the system of nuclear collaterals from the crossed olivocerebellar projection, apart from the presence of a minor, uncrossed nucleoolivary component (see Ruigrok *et al.*, 1990 for a review). The main features of the topical projection of the cerebellar nuclei to the olive have been confirmed in monkeys (Chan-Palay, l977; Kalil, 1979). Their main conclusions concern the projection of the ventrocaudal dentate to the ventral lamina of the PO, and of the rostral and dorsal portions of the nucleus to an extensive region in the dorsal lamina and the lateral bend of the nucleus (Fig. 11.36, 3). The reversal of the rostrocaudal axis in the projection of the dentate to the PO, as maintained by Chan-Palay (1977), or of the dorsoventral axis, as maintained by Lapresle and Ben Hamida (1965), has not been confirmed. The presence of a nucleoprojection from the fastigial nucleus to the caudal MAO has been questioned. The reciprocity with the olivocerebellar projection is less obvious for the vestibuloolivary paths because the existence of an olivovestibular projection (Balaban, l984, l988) is still debated. A remarkable but unexplained feature of the afferent connections of the principal olive from the parvocellular red nucleus and the dentate nucleus is the periodicity in their terminal labeling (arrows in Fig. 11.36).

Therefore, two kinds of recurrent cerebelloolivary loops, one inhibitory and the other excitatory, exist. The parvocellular red nucleus and the nucleus of Darkschewitsch are links in closed cerebellomesencephalic-olivary circuits that feed back into the cerebellum and presumably are excitatory.

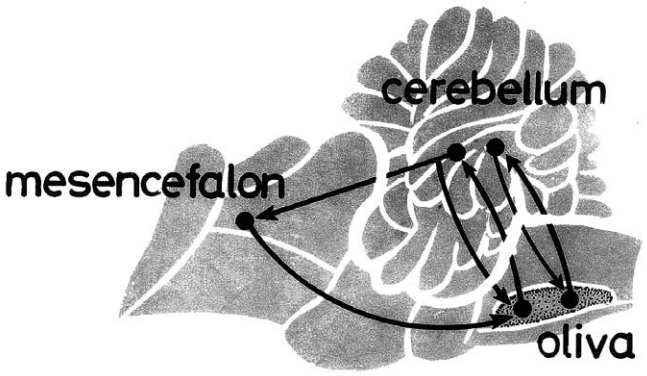

FIGURE 11.38 Diagram of the connections between the cerebellar nuclei and the inferior olive. The reciprocal olivonuclear and nucleoolivary projections and the cerebellomesencephaloolivary circuits are shown.

These multisynaptic loops are superimposed on the direct, inhibitory olivary projections from the same cerebellar cerebellar nuclei (Fig. 11.38). At the level of the inferior olive, these excitatory and inhibitory loops exert an opposite influence on electrotonic coupling of the olivary neurons; the nucleoolivary pathway decreases coupling, whereas the tegmental tracts enhance it (Ruigrok and Voogd, 1995).

When the data from the olivocerebellar projection ("Subdivision and Olivocerebellar Projection"; Figs. 11.36 and 11.46), the cerebellorubral projection ("Projection of Individual Cerebellar Nuclei to Brain Stem in Monkeys"; Fig. 11.25) and the cortico-olivary projection (Figs. 11.25 and 11.36) are combined, three multisynaptic recurrent loops can be distinguished One loop includes the posterior interposed nucleus, Darkschewitsch's nucleus, and the rostral MAO. The second loop includes the rostral and dorsal dentate nucleus, the caudal and lateral portion of the parvocellular red nucleus and the dorsal lamina, and the lateral bend of the principal nucleus of the inferior olive. The third loop consists of the caudal and ventral dentate nucleus, the rostromedial parvocellular red nucleus, and the ventral lamina of the principal olive. The cortical areas controlling each loop generally are the same as the areas that receive a projection from the cerebellar nucleus involved in the loop. It is of interest that the rostromedial part and the rostrolateral and caudal portion of the parvocellular red nucleus have been distinguished as separate subnuclei in the human brain stem (Papez and Stotler, 1940; Paxinos and Huang, 1995; see also Chapter 10).

Hypertrophy of the Inferior Olive Nucleoolivary projections have not been reported in humans, but this connection remains of particular importance because its existence was postulated by Trelles (1935) to explain the occurrence of hypertrophy of the inferior olive after lesions affecting the dentate nucleus. Olivary hypertrophy is a condition characterized by demyelinization of the amiculum of the olive (and apparent widening of the unmyelinated cell band of the olive: pseudohypertrophy) and swelling and vacuolization of its cells (true hypertrophy). In humans true hypertrophy of the inferior olive is associated with palatomyoclonus (Deuschl *et al.*, 1996; Wilms *et al.*, 1999).

Olivary hypertrophy can be induced in cats by ablation of the contralateral cerebellum with the cerebellar nuclei (Verhaart and Voogd, 1962; Boesten and Voogd, 1985; De Zeeuw *et al.*, 1990; Ruigrok *et al.*, 1990). The cellular changes are the same as in humans (Barron *et al.*, 1982). The cells swell, the nucleus is displaced to the periphery, the nucleolus is enlarged, and the rough endoplasmatic reticulum proliferates. The cisternae of the rough endoplasmatic reticulum are enlarged and may developed into vacuoles, filled with floccular material and globular inclusions. The hypertrophy does not subside but remains present for more than a year after the cerebellectomy.

Hypertrophy in the human cases is situated in the principal olive and the medial accessory olive, never in the dorsal accessory olive (Voogd *et al.*, 1990). The localization in the cat differs from that in human cases. In the cat hypertrophic cells are always present in the rostral medial accessory olive; the area that is involved appears to increase with longer survival times when hypertrophy is also present in the dorsal lamina of the PO. In other parts of the olive normal-looking cells or severe cellular atrophy may be present.

Different explanations for the occurrence of olivary hypertrophy have been forwarded. Interruption of the tegmental tracts, i.e., of the main excitatory input of the olive, has been associated with this condition. Trelles (1935) and, more recently, Lapresle and Ben Hamida (1965, 1967, 1968) concluded that hypertrophy is the consequence of lesions of the crossed nucleoolivary pathway, which as we have since, learned is inhibitory. A third explanation suggests that myoclonus, and by inference olivary hypertrophy, is caused by a reduction in the serotonergic innervation of the inferior olive (Welsh *et al.*, 1998).

None of these explanations alone is sufficient to explain the localization of the hypertrophic neurons in human pathological or in experimental cases. Interruption of the tegmental tracts, although often present, is not essential because hypertrophy can develop with an exclusive lesion of the contralateral dentate nucleus (Lapresle and Ben Hamida, 1965, 1967, 1968; Schoen, 1977). Lesions that damage the cerebellar nuclei or their nucleoolivary pathways are a more likely cause but do not fully explain the localization of the hypertrophy

in particular regions of the olive. Similarly, the distribution of serotonin in the inferior olive (Voogd *et al.*, 1996b) differs from the preferred localization of the hypertrophy.

The Pontocerebellar Projection

In 1885 Von Bechterew set the scene for the study of the corticopontocerebellar projection. The localization of the corticopontine fibers in the cerebral peduncle, with frontopontine fibers medially, fibers from the pericentral region, which form the pyramidal tract more caudally, in an intermediate position, and fibers from postrolandic cortex laterally, was already known from the studies of Arnold, Meynert, Charcot, and Flechsig (reviewed by Schmahmann *et al.*, 1992). In this review, Schmahmann uncovered the false attribution of the name of Türck, to the lateral, parietotemporal pontine component of the peduncle, and traced its subsequent history, including the important contributions of Dejerine (1885). In the same paper, von Bechterew (1885) also described the nucleus reticularis tegmenti pontis (NRTP) as a separate nucleus from the basal pontine nuclei. He distinguished two systems, one caudal ("spinal") and the other rostral ("cerebral"), in the pontocerebellar projection. The spinal system connects the NRTP and the pontine nuclei with the cortex of vermis and hemispheres of the superior surface of the cerebellum. It occupies the deep strata of the brachium pontis and acquires its myelin before birth (Fig. 11.39).

Von Bechterew was not always clear about the direction of the fibers; he believed that the spinal system originates from the cerebellum and terminates in the pons. The cerebral system is unmyelinated at birth. It originates from the contralateral pontine nuclei, which receive the lateral, parietotemporal pontine, and medial frontopontine components of the cerebral peduncle. It is distributed to caudal, basal, and lateral regions of the cerebellar hemisphere.

Von Bechterew's observations in the human brain were confirmed in the antegrade axonal degeneration study of Spitzer and Karplus (1907) in the monkey using Marchi's method. A lesion of the rostral one-fourth of the pons caused bilateral fiber degeneration in the dorsolateral periphery of the brachium pontis, which distributes to the caudal vermis and hemisphere of the posterior lobe. Fibers interrupted by a lesion of the caudal half of the pons, including the NRTP, distribute to the anterior vermis and hemisphere, from the dorsal lobulus centralis to the posterior superior fissure, with an especially heavy projection to the lobulus simplex. The flocculus receives a strong projection; the caudal vermis and the rest of the hemisphere remain free from label. The projection of the rostral pontine nuclei to the caudal cerebellum was studied in more detail in the antegrade tracing study of Glickstein *et al.* (1994). They followed labeled axons from injections in the rostrolateral pontine nuclei in monkeys. The fibers cross in the pons and terminate mainly in the contralateral dorsal paraflocculus, with moderate to scarce labeling in the paramedian lobule, and the crus II and I. Few fibers project to the ventral paraflocculus, none to the flocculus. There is a distinct projection to dorsal lobule IX. Afferents to the flocculus and the ventral paraflocculus were retrogradely traced from the NRTP. Some of these observations were later confirmed by Nagao *et al.* (1997).

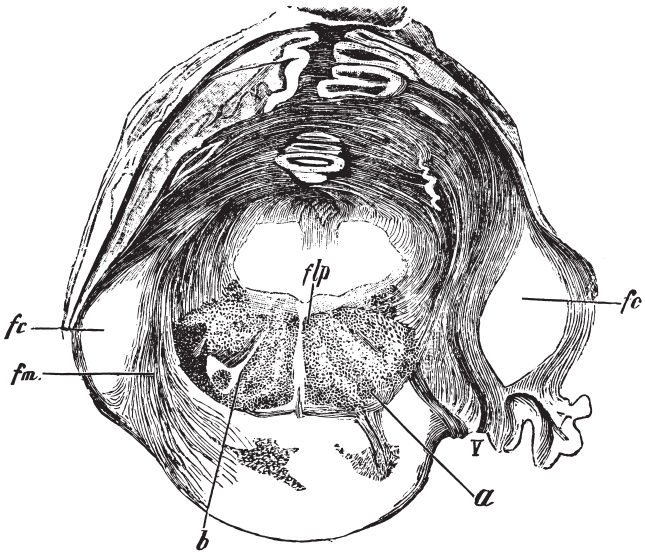

FIGURE 11.39 The "spinal" and "cerebral" pontocerebellar systems of Von Bechterew (1885). Myelin-stained section from the brain of a human infant. The cerebral system (fc) is still unmyelinated. Abbreviations: a, central tegtmental tract; b, fibers from Deiters' nucleus to the central tegmental tract; fc, late myelinating "cerebral system" of the brachium pontis; flp, medial longitudinal fascicle; fm, early myelinating "spinal system" of the brachium pontis; V, trigeminal root.

The corticopontine projection has been studied extensively in primates and other mammalian species. Patterns in the termination of corticopontine fibers have been variously described as patchy, columnar or lamellar, with a specific localization along the rostrocaudal, mediolateral, or dorsoventral axis of the pons. The mediolateral arrangement of frontopontine, pericentral, and parietotemperopontine fibers in the cerebral peduncle is reproduced in the pontine nuclei by their termination in medial, central, and lateral parts of the pontine nuclei (Fig. 11.40) (Schoen, unpublished). For a discussion of the subdivision of the pontine nuclei, the reader is referred to Chapter 10.

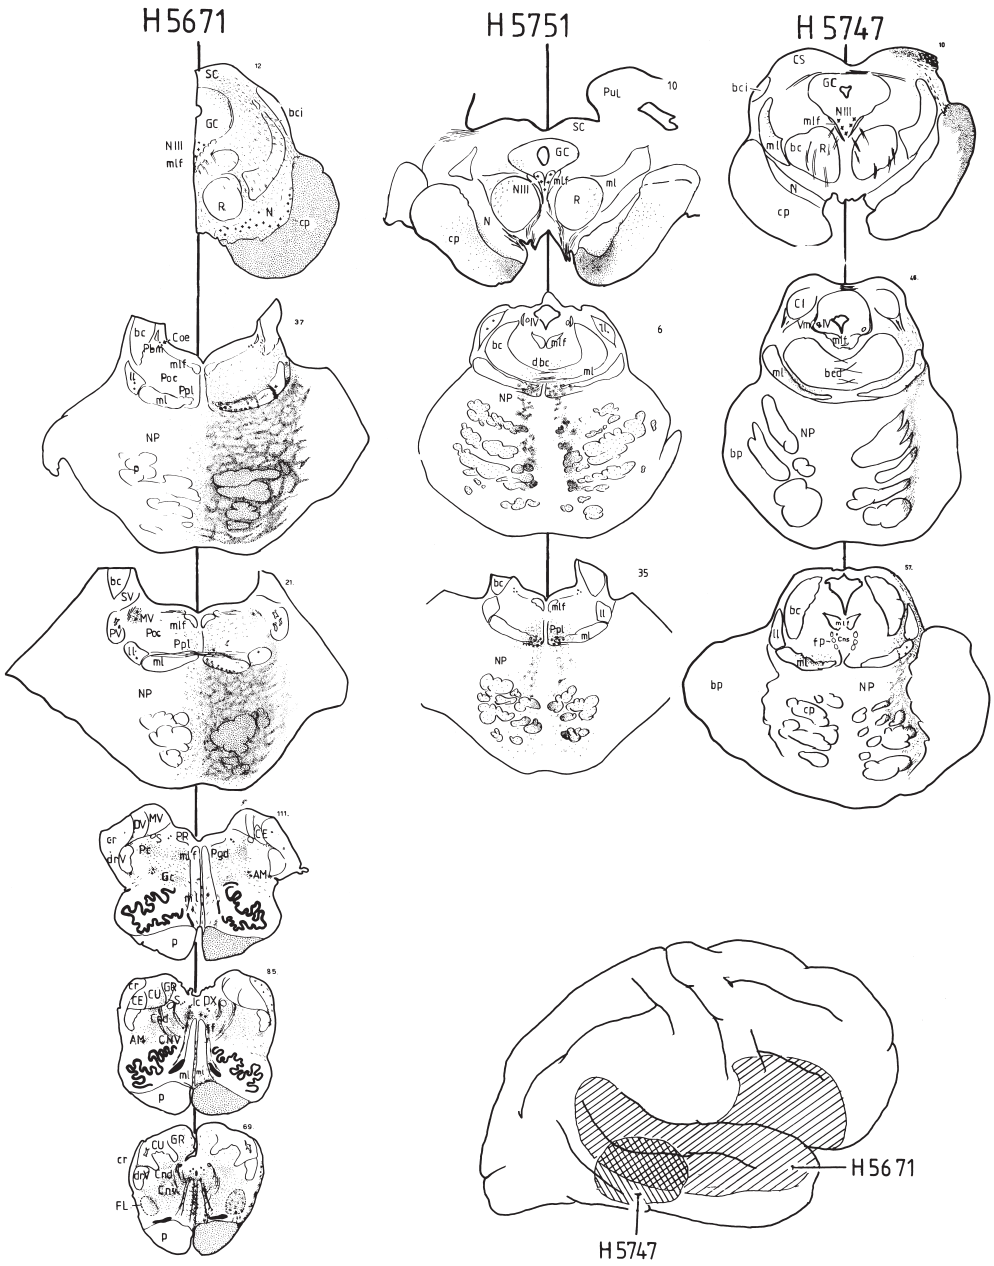

FIGURE 11.40 Corticofugal projections to pons and the lower brain stem. Case H5671: total degeneration of the cerebral peduncle, after an infarct including the basal ganglia and the internal capsule. From Schoen (1969). Case H5751: degeneration of the frontopontine tract. Case H5747: degeneration of the parietotempero-pontine tract. The extent of the lesions in two of the cases is indicated on a diagram of the right cerebral hemisphere. Nauta stain. Schoen, unpublished. Abbreviations: AM, nucleus ambiguus; bc, brachium conjunctivum; bci, brachium of the inferior colliculus; bp, brachium pontis; CE, external cunenate nucleus; CI, inferior colliculus; Cnd, nucleus centralis medullae oblongatae, pars dorsalis; CNV, nucleus centralis medullae oblongatae, pars ventralis; Coe, locus coerulaeus; cp, cerebral peduncle; cr, restiform body,; CU, nucleus cuneatus; dbc, decussation of the brachium conjunctivum; drV, spinal tract of the trigeminal nerve; DV, spinal vestibular nucleus; DX, dorsal nucleus of the vagal nerve; FL, nucleus reticularis lateralis; fP, predorsal fascicle; GC, central gray; Gc, nucleus gigantocellularis; GR, nucleus gracilis; IV, trochlear nerve; ll, lateral lemniscus; ml, medial lemniscus; mlf, medial longitudinal fascicle; MV, medial vestibular nucleus; N III, oculomotor nerve; N, substantia nigra; NP, pontine nuclei; p, pyramid; Pbm, parabrachial nuclei; Pgd, nucleus paragigantocellularis; Poc, nucleus pontis oralis, pars caudalis; Por, nucleus pontis oralis, pars rostralism; Ppl, papillioform nucleus (nucleus reticularis tegmenti pontis); PR, nucleus prepositus hypoglossi; PUL, pulvinard; PV, principal sensory nucleus of the trigeminal nerve; R, red nucleus; S, tractus solitarius; SC, superior colliculus; SV, superior vestibular nucleus.

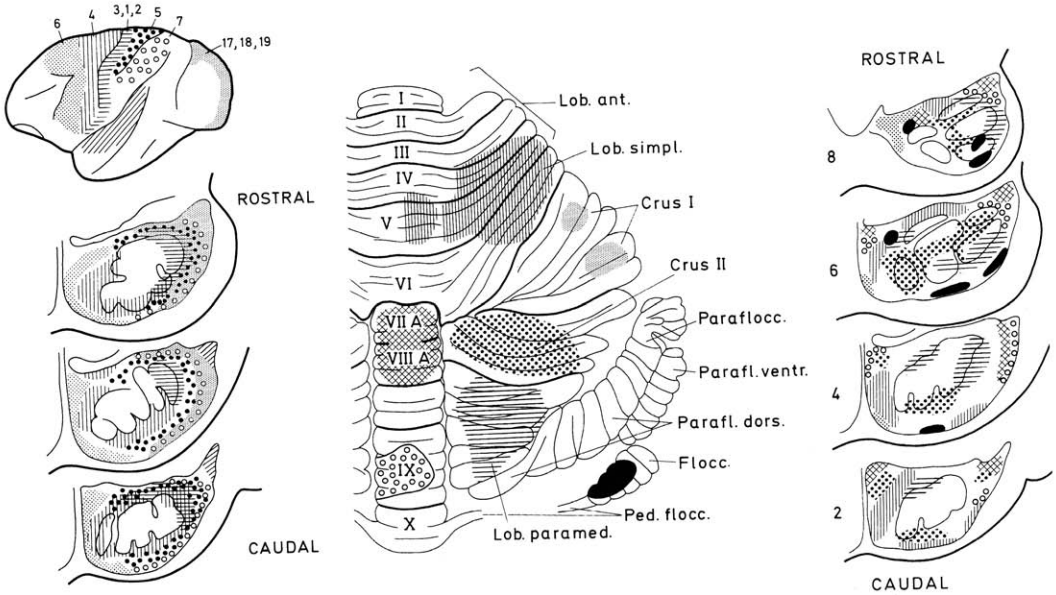

FIGURE 11.41 Diagram of the overall topography of corticopontine and pontocerebellar pathways of the monkey. From Brodal (1982).

Shifts in localization along the rostrocaudal and dorsoventral axis have been related to the mode of corticopontine development by Leergard *et al*. (1995) in the rat. They concluded that corticopontine fibers develop as collaterals of descending sytems and that they innervate a system of concentric shells in the pontine nuclei. These shells resemble the settling of pontocerebellar neurons during their migration, with early arriving neurons in the center and later arriving neurons in more external concentric layers (Altman and Bayer, 1987). Early arriving corticopontine fibers from ventral pericentral regions terminate in the core of the pons; collaterals from fibers from more frontal and occipital regions of the cortex, which arrive later, enter the pontine nuclei at rostral and caudal locations, and terminate in more external shells. Because the more external shells are thicker rostrally, the late-arriving corticopontine projections from more frontal or occipitotemporal regions predominate in the rostral pons. The distal branches of the descending corticofugal systems, which collateralize in the pons, may disappear later (Pittman and Tolbert, 1988; Tolbert, 1989).

The distribution of corticopontine fibers in the adult in more or less continuous lamellae is reminiscent of their development. The pericentral projection is located in and around the cerebral peduncle, and the more frontal and occipital projections ocupy more external lamellar spaces in the medial and lateral parts of the pons, respectively (Fig. 11.41). Similarly, lamellar shifts have been observed for the localization of pontine neurons projecting to different cerebellar lobules or folia (P. Brodal, 1978; Hartmann-Von Monakow *et al*., 1981; Brodal and Bjaalie, 1992; Bjaalie and Brodal, 1997). Still, the corticopontine terminals and the neurons projecting to a particular cerebellar region usually are discontinuous within multiple patches in a lamellar subspace. The corticopontine systems may terminate preferentially in the medial, lateral, rostral, or caudal pons, but smaller patches of terminals usually are present in a complementary region of the pons.

Corticopontine fibers originate from layer V pyramidal cells in large parts of the cerebral cortex (Glickstein *et al*., 1985) (Fig. 11.42). In descending order the densities of cells projecting to the pons were motor cortex (areas 4 and 6), parietal association cortex (areas 5 and 7), cingulate cortex (areas 23–25), somatosensory cortex (areas 3, 1, 2), frontal eye field (area 8 and dorsal frontal area 9, insular areas 13 and 14), and the striate and extrastriate visual cortex. There are large regions of the frontal cortex, the inferotemporal and occipital cortex that contained few or no cells with projections to the pons. The origin of the corticopontine projection was confirmed in the studies of Schmahmann and Pandya (1995, 1997a). The origin of the corticopontine projection in monkeys, therefore, includes postrolandic association areas, which are largely lacking from the origin of the corticorubral projection (Fig. 11.25) and from the region targeted by the cerebellar nuclei (Fig. 11.23).

The origin of pontocerebellar fibers from the prefrontal and premotor cortex in humans includes the lateral, medial, and dorsal aspects of the convexity

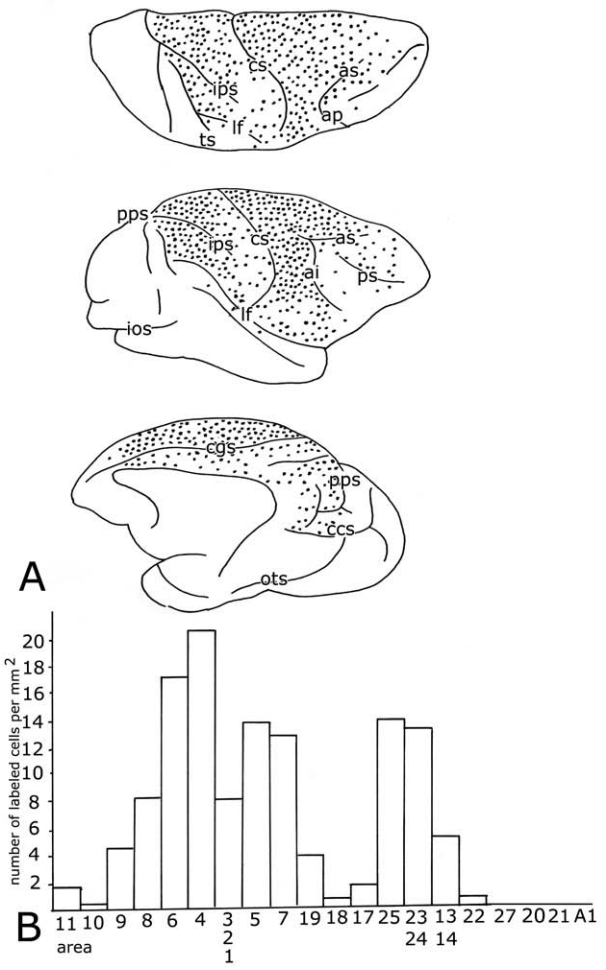

FIGURE 11.42 Distribution of corticopontine meurons in macaque monkeys. **A.** Distribution of retrogradely labeled neurons in the left cerebral hemisphere from a complete wheat germ agglutinin–coupled horseradish peroxidase filling of the pontine nuclei. **B.** Bar graphs illustrating the numbers of retrogradely labeled neurons in different cortical areas. Abbreviations: ai, ansate sulcus, inferior limb; as, ansate sulcus superior ilmb; ccs, calcarine fissure; cs, central sulcus; ios, inferior occipital sulcus; ips, intraparietal sulcus; lf, lateral fissure; ots occipitotemporal sulcus; pps, postparietal sulcus; ps, principal sulcus; ts, superior temporal sulcus. From Glickstein *et al.* (1985).

over its full anteroposterior length (areas 45, 46, 32, 24, and caudal area 9) and areas 8 (frontal eye field) and 6 (premotor cortex). The frontal pole, the ventrolateral convexity, and the orbital surface did not give rise to corticopontine fibers (Beck, 1950). Beck's observations are in accordance with the conclusions from experimental studies of Glickstein *et al.* (1985) and Schmahmann and Pandya (1995, 1997a). These frontopontine finers terminate, mainly rostrally, in medial, dorsomedial, and ventromedial regions of the pontine nuclei (Sunderland, 1940; Nyby and Jansen, 1951; P. Brodal, 1978; Hartmann-Von Monakow *et al.*, 1981; Leichnetz *et al.*, 1984b; Künzle and Akert, 1977; Künzle, 1978; Stanton *et al.*, 1988; Shook *et al.*, 1990; Schmahmann and Pandya, 1995, 1997b).

Pontocerebellar fibers from the pericentral region terminate centrally in the pons, in the pedunculular and peripeduncular region (Fig. 11.41). The motor cortex projects strongly to medial and less to lateral lamella–like areas, surrounding the peduncle in the caudal pons, with the face located rostrally and medially and the leg laterally and caudally. The somatotopically arranged projections of the primary sensory cortex are very similar to the motor cortex but favor more lateral peripeduncular regions (P. Brodal, 1978; Hartmann-Von Monakow *et al.*, 1981).

Postrolandic corticopontine projections, from parietal areas 5 and 7, peristriate, parahippocampal, and superior temporal cortices, mainly occupy the lateral pons. Area 5 projections are located most medially, partially overlapping the SI projection; striatal and peristriatal projections are located more dorso- and ventrolaterally, but also include a medial component; superior temporal projections, including area MT, occupy the extreme dorsolateral part of the pons (Fig. 11.41), (P. Brodal, 1978; Faugier-Grimaud and Ventre, 1989; Nyby and Jansen, 1951; Schmahmann and Pandya, 1989, 1991, 1993, 1997b; Sunderland, 1940).

The projection from the primary visual cortex (area 17) is restricted to a few cells in the caudal part of the calcarine fissure. However, many more corticopontine cells were found in the rostral end representing the visual periphery and the number of corticopontine cells decreased in an ordely way sucessively more caudally. Thus, there appears to be a systematic over-representation of the peripheral visual field in the corticopontine projections from striate cortex of monkeys (Glickstein *et al.*, 1983, 1985). Projections of moderate intensity arise from peristriate visual areas 18 and 19 including MT (Glickstein *et al.*, 1985). Striate and peristriate projections to the dorsolateral pons are located rostral to the termination of the uncrossed tectopontine tract from the superficial visual layers of the superior colliculus (Münzer and Wiener, 1902; Frankfurter, 1976; Harting, 1977; Wells *et al.*, 1989). Receptive fields of pontine visual neurons were large. Most cells responded to moving stimuli and were directionally selective (Baker *et al.*, 1976).

In accordance with their development as branches from long descending fiber tracts, many if not all corticopontine fibers should be considered as collaterals from corticofugal fibers terminating in other regions of the brain stem and the cord. Ugulini and Kuypers (1986) found retrogradely labeled collaterals from fibers of the pyramidal tract in the cat to be distributed in medial and lateral peripeduncular clusters, corresponding

with the region receiving pericentral cortical afferents and projecting to the anterior lobe and the lobulus simplex. Similarly, Baker *et al.* (1983) and Keizer *et al.* (1987) found up to 60% of the corticotectal neurons to project both to the tectum and the pons.

It can be concluded from the origin and distribution of the corticopontine projection that the main projections are derived from motor, premotor, somatosensory, parietal, and peristriate areas. Occipitotemporal and parietal projections are derived from areas included in the so-called dorsal visual stream of Ungerleider and Mishkin (1982) of visual and visually related cortical areas that contain representations of speed and direction of stimuli in the peripheral visual field and are concerned with the visual guidance of movements. Areas belonging to the "ventral visual stream," directed at the temporal lobe, which are concerned with object recognition, do not project to the pons. Prefrontal corticopontine connections are limited to dorsolateral and medial areas, related to kinesthetic, motivational, and spatially related functions, including spatial memory. Inferior and orbital prefrontal areas, related to autonomic and emotional response inhibition, stimulus sugnificance, and object recognition, do not project to the pons (Glickstein *et al.*, 1985; Schmahmann and Pandya, 1995, 1997a).

Much less is known about the pontocerebellar projection in primates. Pontocerebellar mossy fibers share a bilateral distribution with many other mossy fiber systems. Most of the ipsilaterally terminating fibers recross in the cerebellum (Rosina and Provini, 1984). Systematic collateralization of pontocerebellar mossy fibers, with terminations restricted to more or less discrete longitudinal zones, occasionally has been observed (Voogd, 1969; Voogd *et al.*, 1996b), but usually their distribution was reported to be a diffuse one. However, Serapide *et al.* (1994, 2001) recently observed zonally arranged projections to the paraflocculus and most other lobules of the cerebellum, from small injections of antegrade tracers in the pontine nuclei of the rat. With larger injections the zonal pattern gives way to diffuse labeling. The explanation of this phenomenon is not known.

In accordance with the classical observations of von Bechterew (1885) and Spitzer and Karplus (1907), caudal, peduncular, and peripeduncular regions of the pons containing a representation of the motor and somatosensory cortex project to the anterior lobe and the lobulus simplex (Fig. 11.41). More rostral, lateral, and medial regions of the pons mainly project to the hemisphere of the posterior lobe, with the more medial regions receiving frontopontine fibers, projecting rostrally to the ansiform lobule, and lateral regions receiving pontocerebellar fibers from parietal peristriate and superior temporal association cortex, projecting caudally to the dorsal paraflocculus and lobule IX of the caudal vermis. The target area of the tectopontine pathway in the caudal dorsolateral pons projects to the visual vermal area in lobule VII (P. Brodal, 1979, 1982; Glickstein *et al.*, 1994; Nagao *et al.*, 1997).

Collateral projections of the pontine nuclei to the cerebellar nuclei have been observed (Shinoda *et al.*, 1992), but most authors agree on their preferential origin from the NRTP. The NRTP receives a strong projection from the cerebellar nuclei, mainly from the anterior interposed and dentate nuclei ("Projection of Individual Cerebellar Nuclei to the Brain Stem in Monkeys") and afferents from the cerebral cortex, with parietal afferents located laterally, the motor cortex located centrally, and projections from the premotor cortex located laterally (P. Brodal, 1980; Hartmann-Von Monakow, 1981). In addition, it receives a crossed tectopontine projection from deep layers of the superior colliculus (Frankfurter, 1976; Harting, 1977; Wells *et al.*, 1989). In cat and rat the NRTP projects bilaterally to ventrocaudal regions of the dentate lateral regions of the posterior interposed nucleus and to the caudal visual area in the fastigial nucleus (Gerrits and Voogd, 1987; Mihailoff, 1993). This projection is complementary to the collateral projection of the lateral reticular nuclei to the cerebellar nuclei. Collateralization of (reticulopontine) pathways to the cerebellar nuclei has not been studies in primates.

THE VESTIBULOCEREBELLUM

The caudal part of the cerebellum, comprising the flocculus and the nodulus, often is indicated as the vestibulocerebellum. The arguments for this distinction recently were discussed by Voogd *et al.* (1996a). For references on this complicated topic, the reader is referred to this review. Generally, the typical distributions of cell types, primary and secondary vestibulocerebellar mossy fibers, climbing fibers from optokinetic and vestibular subnuclei of the inferior olive, and Purkinje cells with projections to the vestibular nuclei extend beyond the flocculus and the nodulus to include adjoining portions of the ventral paraflocculus and the uvula. In monkeys the entire ventral paraflocculus belongs to the vestibulocerebellum (see "Longitudinal Zonation of the Cerebellum").

One of the typical features of the vestibulocerebellum is the preferential distribution of unipolar brush cells in its cortex (Dino *et al.*, 1999). Primary vestibular root fibers terminate in the nodulus and the adjoining ventral uvula, but not in the flocculus.

Secondary vestibulocerebellar mossy fibers terminate bilaterally, in both divisions of the vestibulocerebellum; a subpopulation of these mossy fibers is cholinergic. The termination of primary and secondary vestibulocerebellar mossy fibers extends beyond the vestibulocerebellum, in the granular layer in the bottom of the deep transverse fissures and lobules I and II of the anterior lobe. The majority of the mossy fibers terminating in the flocculus are derived from the pontine reticular formation (cell groups of the paramedian tracts) (Büttner-Ennever and Horn, 1996) and the nucleus reticularis tegmenti pontis.

Climbing fibers to the flocculus and the adjoining ventral paraflocculus terminate in two pairs of alternating longitudinal zones (Fig. 11.46). In monkeys the most medial of these four zones seems to be lacking (Fig. 11.49). These climbing fibers are derived from the dorsal cap and the ventrolateral outgrowth, i.e., from optokinetic subnuclei of the inferior olive. These subnuclei also innervate the nodulus and adjacent parts of the uvula, but here the dorsal cap and ventrolateral outgrowth-innervated zones, alternate with strips that receive their climbing fibers from vestibular subnuclei of the inferior olive, such as the group β and the dorsomedial cell column.

The efferent projections of the nodulus and the flocculus are also arranged in a modular pattern. Zonal pairs in the flocculus, which receive optokinetic information about retinal slip in either the horizontal or an oblique vertical plane, project via the vestibular nuclei to the eye muscle nuclei, which move the eye in the corresponding plane. A more complicated arrangement in the corticonuclear projection involving both vestibular and cerebellar nuclei is present in the nodulus.

LONGITUDINAL ZONATION OF THE CEREBELLUM

The distinction of longitudinal zones in the cerebellar cortex is based on embryological and histochemical evidence and on anatomical and physiological studies of its afferent and efferent fiber connections (for reviews, see Hatten and Heintz, 1995; Herrup and Kuemerle, 1997; Hawkes and Eisenman, 1997; Hawkes, 1992; Voogd, 1998; Ozol *et al.*, 1999; Voogd *et al.*, 1996b; Voogd and Glickstein, 1998). Although it appears likely that a similar zonation is also present in the human cerebellum, there is no evidence available on this matter. Corticonuclear and afferent mossy and climbing fiber connections have not been studied in sufficient detail, and histochemical studies failed to demonstrate band patterns in the adult human cerebellum.

Direct evidence for zonation in the human cerebellum was obtained in studies of cerebellar development. Several authors noted that developing Purkinje cells are clustered in a number of parasagittal zones during early stages of cerebellar development, prior to the stage when the first fissures make their appearence (for reviews, see Sotelo and Wassef, 1991; Voogd *et al.*, 1996b). Purkinje cells and the cells of the cerebellar nuclei are generated in the ventricular layer (Jakob, 1928; Miale and Sidman, 1961). Purkinje cells migrate to the meningeal surface of the cerebellum where they settle in the cortical plate, deep to the external granular layer. Clustering of Purkinje cells in the cortical plate in human fetuses has been observed by several authors (Hochstetter, 1929; Korneliussen, 1968; Maat, 1978, 1981) (Fig. 11.43).

The significance of the clustering of Purkinje cells during early stages of cerebellar development has been clarified in animal studies. In monkey fetuses an interdigitating pattern of Purkinje cell clusters develops in the cortical plate between days 48 and 54 of gestation (Kappel, 1981; Voogd *et al.*, 1987b) (Figs. 11.44 and 11.45). The subsequent development of the first transverse fissures, and the inward migration of the granule cells, with the consequent increase of rostrocaudal extent of the meningeal surface of the cerebellum, transforms the Purkinje cell clusters in longitudinal zones. Cell strands connect these zones with the borders of the cerebellar nuclei (Fig. 11.44). The resulting zonal pattern is very similar to the patterns based on corticonuclear and olivocerebellar projection in adult mammals. With transformation of the multicellular clusters into a monolayer of Purkinje cells, the borders between the zones become lost around day 70 of gestation. The pattern that evolves from the position of the clusters in the cortical plate and their corticonuclear relations is very similar to the adult longitudinal patterns in the corticonuclear projection (Table 11.1). During similar developmental stages in rodents, Purkinje cell clusters show a transient heterogeneity for several Purkinje cell markers (for reviews, see Sotelo and Wassef, 1991; Voogd *et al.*, 1996b). The localization of these substances and the time course in their expression are modified in mouse mutants and transgenic mice, suggesting that these zonal patterns are under genetic control (Oberdick *et al.*, 1998).

The original observations on the zonal distribution of Purkinje cells of the cerebellar cortex were made on myelin-stained sections, which show a subdivision of the cerebellar white matter in parasagittal compartments, which contain one of the cerebellar nuclei (Voogd, 1964, 1969). These compartments serve as conduits for Purkinje cell axons from a longitudinal zone to their target nucleus and direct the olivocerebellar fibers to

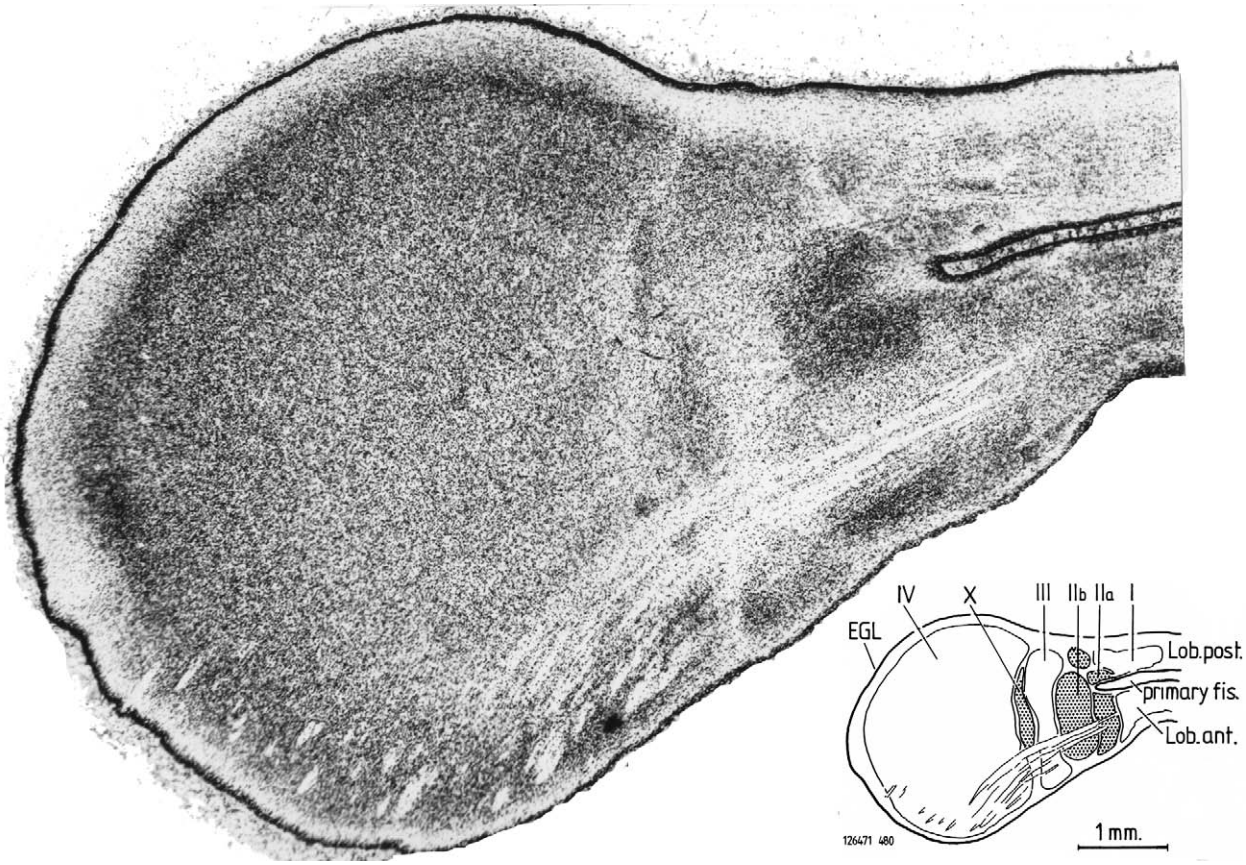

FIGURE 11.43 Coronal section through the cerebellum of a 65-mm human fetus, showing Purkinje cell clusters. The configuration of these clusters is very similar to their distribution in a 55-day-old monkey fetus, illustrated in Fig. 11.44A. Nissl stain. Abbreviations: see Fig. 11.44 and Table 11.1. Schenk collection, Department of Pathology, Erasmus University of Rotterdam.

TABLE 1 Nomenclature for Purkinje Cell Clusters in the Developing Cerebellum and Corresponding Purkinje Cell Zones with Their Target Nuclei in the Adult Cerebellum.

Cluster	Zone	Target Nucleus
I	A zone	Fastigial nucleus
IIa	B zone	Lateral vestibular nucleus
IIc	X zone	Interstitial cell group
IIb	C_1 zone	Anterior interposed nucleus
IIIa,b	C_2 zone	Posterior interposed nucleus
X	C_3 zone	Anterior interposed nucleus
IVa	D_1 zone	Dentate nucleus, caudal pole
IVb	D_2 zone	Dentate nucleus, rostral portion

Source: Kappel (1981).

the Purkinje cells on which they terminate. The organization and the conformity of corticonuclear and climbing fiber zones was established in subsequent experimental studies in carnivores and rodents (for references, see section "Subdivision and Olivocerebellar Projection") (Fig. 11.46). Haines studies on the corticonuclear projection (reviewed by Haines *et al.*, (1982) and the olivocerebellar projection in primates (Whitworth and Haines, 1986b) are especially important in this respect.

AchE histochemistry has proved a useful marker for the study of longitudinal zonation in the cortex and for the deliniation of the corresponding parasagittal compartments in the cerebellum of adult mammals (Fig. 11.47) (Marani and Voogd, 1977; Hess and Voogd, 1986; Boegman *et al.*, 1988; Voogd *et al.*, 1987a, b). The borders between the compartments are selectively stained with AChE and this staining is especially distinct in monkeys (Hess and Voogd, 1986). The image is reversed when the Purkinje cell axons are stained with Purkinje cell–specific markers, such as

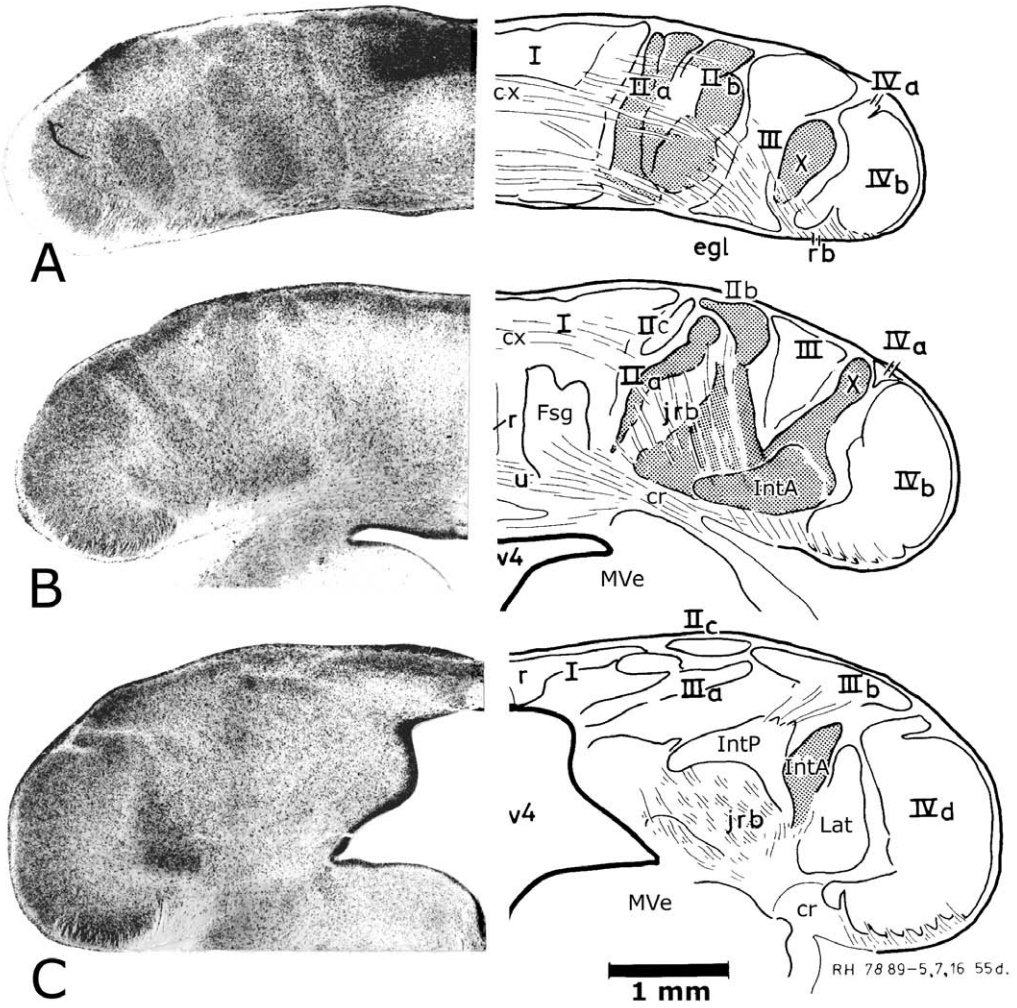

FIGURE 11.44 Three coronal sections through the cerebellum of a 55-day-old rhesus monkey fetus; **A** is the most rostral section. Purkinje cell clusters are indicated with roman numerals (see Table 11.1). Note superficial location of the Purkinje cells of the early arriving clusters I, III, and, IV, which still partially cover the later arriving deep clusters IIa, IIb, and X. Cell strands connect the clusters at this stage with their cerebellar target nuclei. Compare with the human fetus of the same developmental age illustrated in Fig. 11.43 and the reconstruction in Fig. 11.45. Abbreviations: cr, restiform body; cx, cerebellar commissure; egl, external granular layer; Fl, flocculus; I–IV, Purkinje cell clusters I–IV; IntA, anterior interposed nucleus; IntP, posterior interposed nucleus; jrb, juxtarestiform body; Lat, dentate nucleus; MVe, medial vestibular nucleus; prf, primary fissure; r, midline recess; v4, fourth ventricle.; X, Purkinje cell cluster X. From Kappel (1981).

calbindin. In this case the heavily stained interior of a compartment is delimited by a narrow unstained border zone (Voogd and Gerrits, 1997) (Figs. 11.50A, B). AChE histochemistry has not yet been used to study the cerebellum in human.

The antibodies zebrin I and II, developed by Hawkes, specifically stain a subset of Purkinje cells, distributed into multiple longitudinal zones and separated by zebrin-negative areas in rodents and marsupials (Hawkes *et al.*, 1985; Hawkes and Leclerc, 1987; Dore *et al.*, 1990). The zebrins are representative of a number of substances that show more or less the same distribution pattern. The first of these substances to be discovered was 5′-nucleotidase in the cerebellum of the mouse (Scott, 1964). In the squirrel monkey a similar zonal distribution was observed in the vermis (Leclerc *et al.*, 1990). In macaques antibodies against zebrin stain all Purkinje cells, and the resulting image is the same as found for Purkinje cell–specific markers, such as calbindin. Zebrin I has been applied to the human cerebellum, where it is heterogeneously distributed among the Purkinje cells. A clear arrangement in the distribution of these cells was not uncovered (Plioplys *et al.*, 1985).

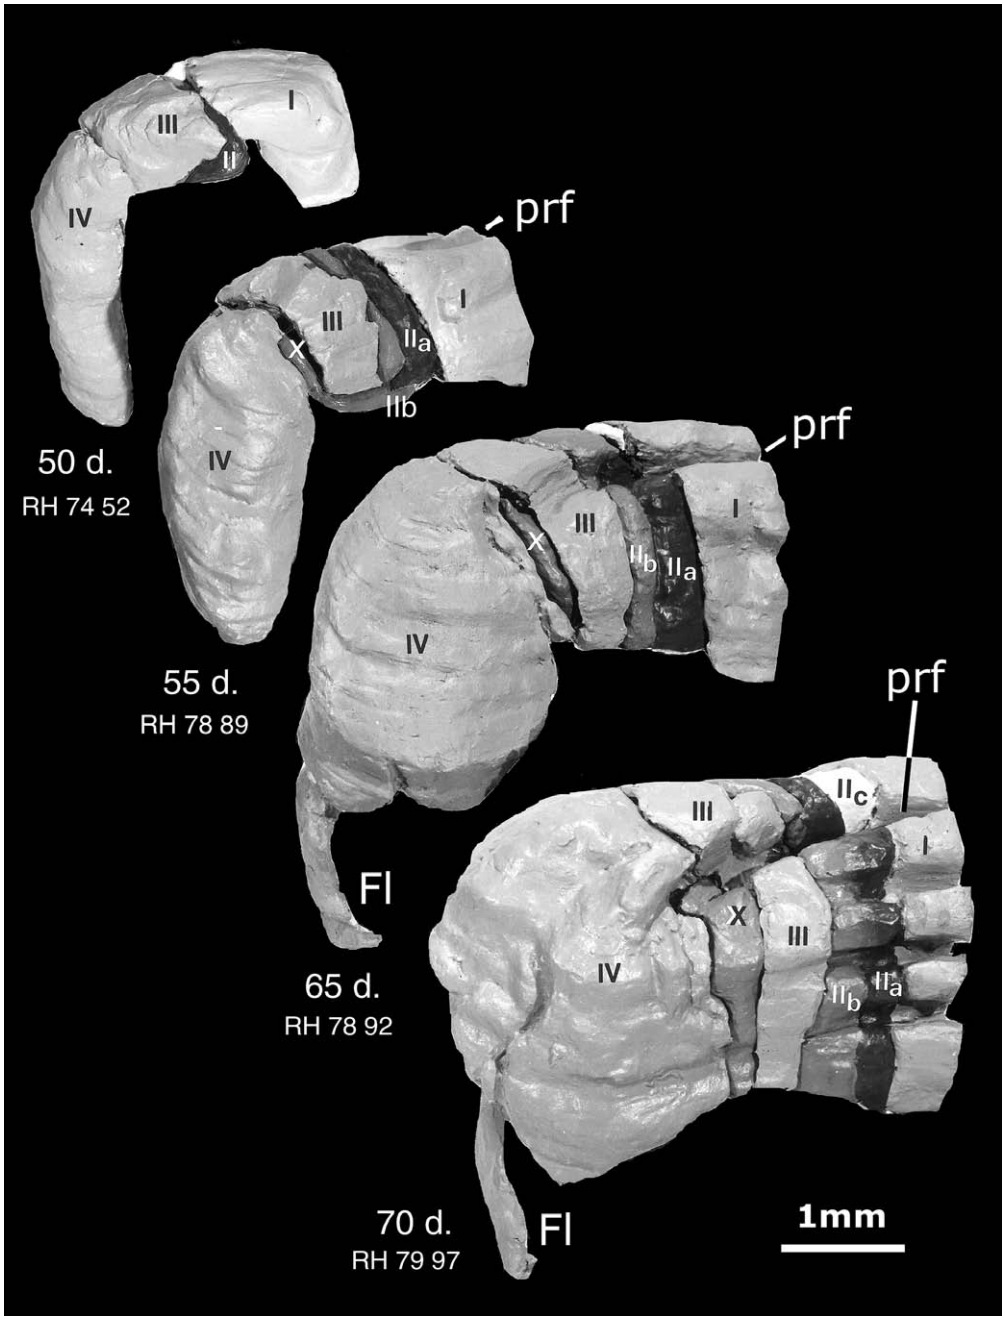

FIGURE 11.45 Photographs of the rostral aspect of reconstructions of the Purkinje cell layer of the cerebellum of four fetuses of the rhesus monkey. Clusters are indicate with different shadings. Note the superficial location of Purkinje cells of the early arriving clusters I, III, and IV in the youngest fetus, and the gradual emergence at the surface of the later arriving clusters IIa, IIb, and X. For explanation of nomenclature, see Table 11.1. Compare with sections of 55-day-old fetus in Fig. 11.44. From Kappel, 1981.

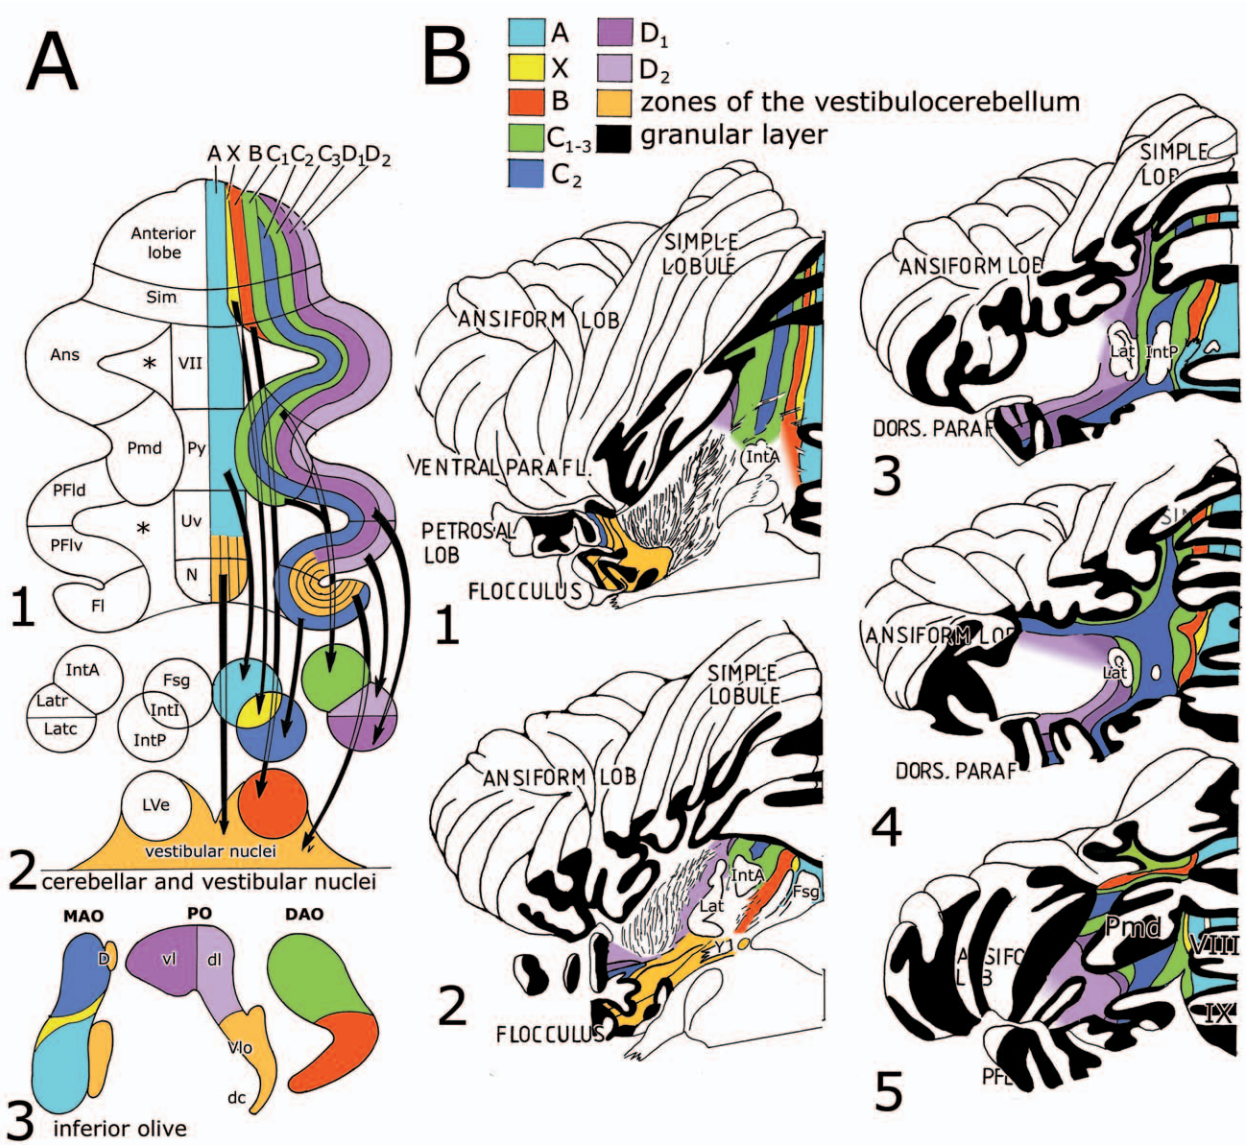

FIGURE 11.46 **A.** Diagram of the zonal organization in the corticonuclear and olivocerebellar projections in the cat. Modified from Groenewegen *et al*. (1979). **(1)** Diagram of the flattened cerebellar cortex. **(2)** Diagram of the cerebellar and vestibular nuclei. **(3)** Diagram of a projection of the inferior olive in the horizontal plane, constructed according to Brodal (1940). The longitudinal corticonuclear and olivocerebellar projection zones are indicated with capitals (A, X, B, $C_{1–3}$, $D_{1,2}$). The zones, their target nuclei, and the subnuclei of the inferior olive that project to these zones are indicated with the same colors. The diagram applies equally to the monkey cerebellum, with the exception of the floccular zones, the most medial one of which is lacking in the monkey. *Asterisks:* areas without cortex. **B.** Diagram of the white matter compartments in acetylcholinesterase-stained sections of the cerebellum of *Macaca fascicularis*. Compare Figs. 11.47, 11.48, and 11.50. Abbreviations: A, A zone; Ans, ansiform lobule; B, B zone; $C_{1–3}$, $C_{1–3}$ zones; D, dorsomedial cell column; $D_{1,2}$, $D_{1,2}$ zones; dc, dorsal cap;dl, dorsal leaf of principal olive; dl, dorsal lamina of the principal olive; Fl, flocculus; Fsg, medial cerebellar nucleus; IntA, anterior interposed nucleus; IntI, intermediate cell group; IntP, posterior interposed nucleus; Lat, lateral cerebellar nucleus; Latc, caudal lateral cerebellar nucleus; Latr, rostral lateral cerebellar nucleus; LVe, lateral vestibular nucleus; MAO, medial accessory olive; N, nodulus; PFld, dorsal paraflocculus; PFlv, ventral paraflocculus; Pmd, paramedian lobule; PO, principal nucleus of the inferior olive; PY, pyramis; Py, pyramis; Sim, lobulus simplex; Uv, uvula; VII–IX lobules VII–IX; vl, ventral leaf of principal olive; Vlo, ventrolateral outgrowth.

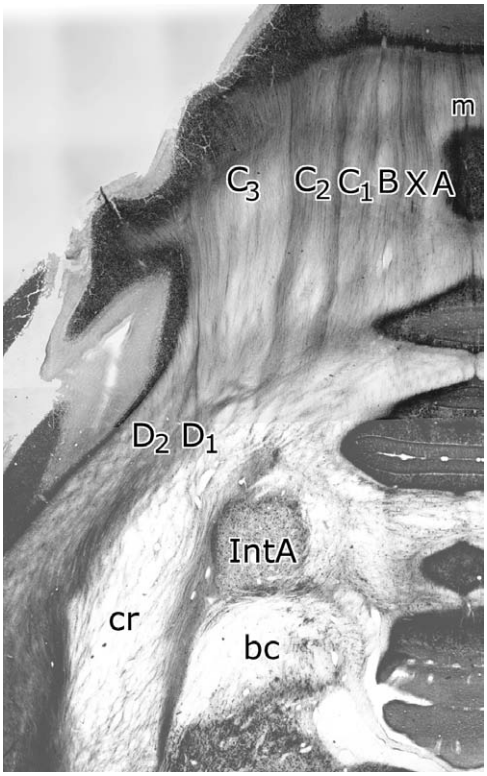

FIGURE 11.47 Coronal acetylcholinesterase-stained section through the anterior lobe of the cerebellum of *Macaca fascicularis*. The borders of the compartments A, X, B, C_{1-3}, D_1, and D_2 are heavily stained. Abbreviations: bc, brachium conjunctivum; cr, restiform body; IntA, anterior interposed nucleus; m, midline.

Compartments that were delineated and reconstructed from AChE-stained sections of Macaca fascicularis display the same configuration as the parasagittal compartments in cat and ferret (Figs. 11.46B–11.50). A, X, and B compartments can be distinguished in the anterior vermis. The A compartment is related to the fastigial nucleus, the X compartment to the U-shaped interstitial cell group located the fastigial and the posterior interposed nucleus (IntI: Fig. 11.12), and the B compartment leads to the lateral vestibular nucleus. In the hemisphere C_1 and C_3 compartments, which converge on the anterior interposed nucleus, are present in the anterior lobe and the lobulus simplex and in the paramedian lobule. C_1 continues into the ventral folia of the paramedian lobule; C_3 terminates more dorsally in this lobule. C_1 and C_3 fuse in the ventral anterior lobe. The C_2 compartment extends from the anterior lobe, throughout the hemisphere, into the flocculus. It converges on the posterior interposed nucleus. A narrow D_1 compartment is present, lateral to C_3, in the rostral parts of the cerebellum (Figs. 11.46A, B, 11.47). From the paramedian lobule, C_2, D_1, and D_2 compartments continue into the dorsal paraflocculus. The D_1 compartments converges on the caudal pole of the dentate nucleus (Fig. 11.48A). The most lateral D_2 compartment is narrow in the paraflocculus and much wider in the rest of the hemisphere. It is related to dorsal and rostral parts of

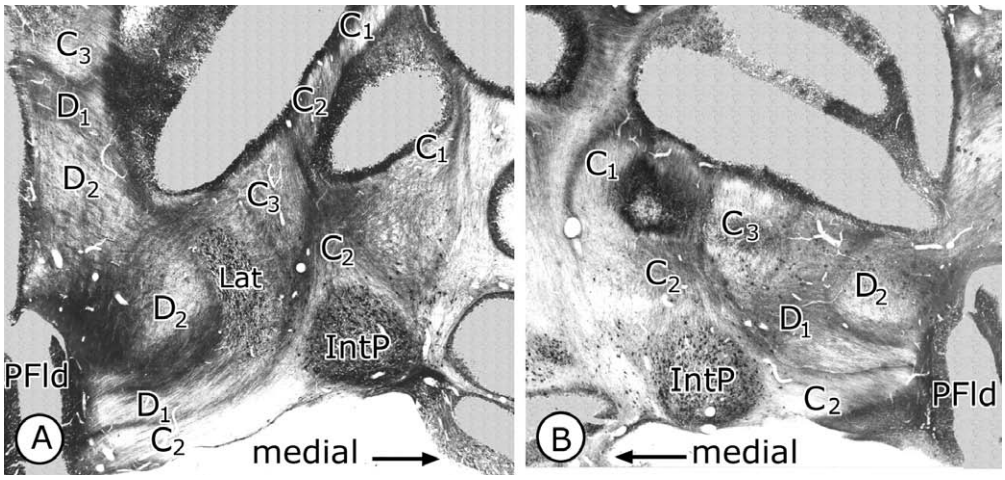

FIGURE 11.48 Left and right halves of a coronal acetylcholinesterase-stained section through the hemisphere of the posterior lobe of the cerebellum of *Saimiri sciureus*, approximately corresponding to level 6 in Fig. 11.46B. The borders of the white matter compartments are heavily stained. On both sides compartments C_2, D_1 and D_2 continue from the posterior white matter of the hemisphere into the dorsal paraflocculus. Compartments C_1, and C_3 terminate in the posterior white matter of the paramedian lobule. On both sides the caudal pole of the posterior interposed nucleus is lodged in the C_2 compartment. The caudal pole of the dentate nucleus appears in compartment D_1 on the left side. Abbreviations: C_{1-3}, compartments C_{1-3}; $D_{1,2}$, compartments $D_{1,2}$; IntP, posterior interposed nucleus; Lat, caudal pole of the dentate nucleus; PFld, dorsal paraflocculus.

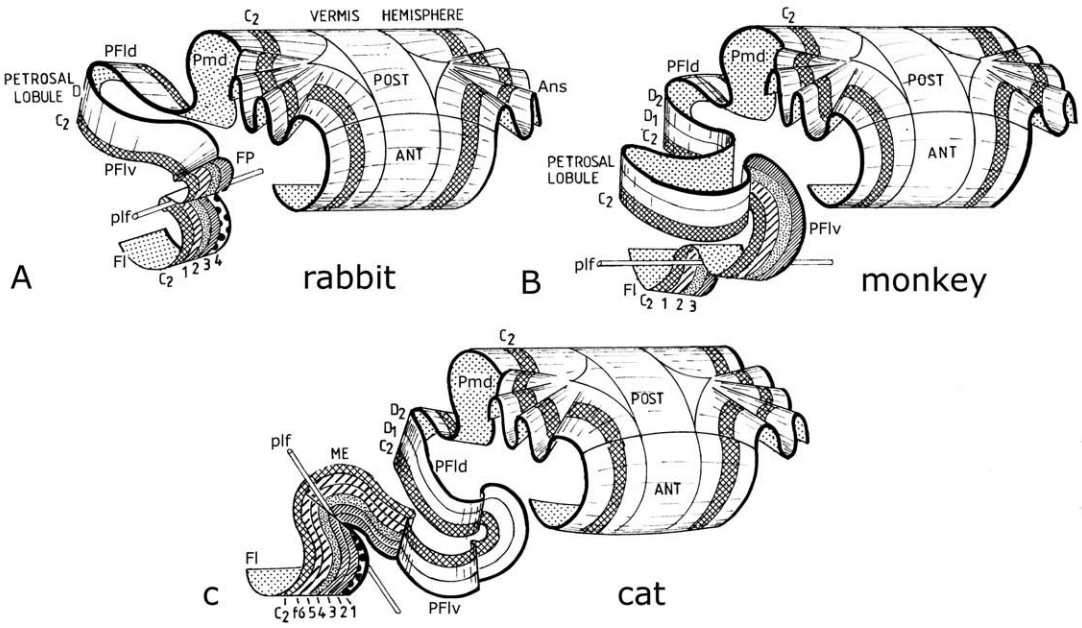

FIGURE 11.49 Diagrams illustrating the continuity of successive segments of the caudal folial chain of the hemisphere in different species. Two principal segments can be distinguished. The proximal segment is characterized by the presence of C_2 and D (D_1 and D_2) zones. It comprises the dorsal paraflocculus and the petrosal lobule in monkey, the dorsal paraflocculus and the proximal part of the ventral paraflocculus in cat, and the petrosal lobule in rat and rabbit. The distal segment consists of a C_2 zone and 3 (monkey), 6 (cat), or 4 (rat, rabbit) floccular zones with vestibular connections. It is represented by the ventral paraflocculus and the flocculus in monkeys, by the distal part (ME, medial extension) of the ventral paraflocculus and the flocculus in the cat, and by folium P and the flocculus in the rabbit. The relationship of the four floccular zones in rat and rabbit to the zonal configuration in cat and monkey is indicated by similar hatchings. Abbreviations: Ans, ansiform lobule; ANT, anterior lobe; C_2, zone C_2; D_1,D_2, zones D_1 and D_2; fl–f6, floccular zones f1–f6; Fl. flocculus; FP, folium P; ME, medial extension of the PFlv; PFld, dorsal paraflocculus; PFlv, ventral paraflocculus; plf, posterolateral fissure; Pmd, paramedian lobule; POST, posterior lobe. Based on data from Gerrits and Voogd (1982), Tan *et al.* (1995a–c), and unpublished observations in the monkey.

the dentate nucleus. The C_2 compartment contains the posterior interposed nucleus (Fig. 11.48A, B).

White matter compartments in the flocculus and he paraflocculus are especially clear in the monkey. Paraflocculus and flocculus are the last two segments of the folial chain of the hemisphere. The first part of the paraflocculus, which diverges from the paramedian lobule, is known as the dorsal paraflocculus (Fig. 11.49). It continues as the laterally directed loop of the petrosal lobule, which is lodged in the subarcuate fossa of the petrosal bone. The petrosal lobule continues as the rostrally directed rosette of the ventral paraflocculus and ends in the caudally directed flocculus. C_2, D_1, and D_2 compartments are present in the dorsal paraflocculus and the petrosal lobule (Fig. 11.46–11.50). The configuration of the ventral paraflocculus and the flocculus is completely different. Here four compartments can be distinguished. Compartments 2 and 4 continue as the floccular peduncle into the superior vestibular nucleus and the group Y. Compartment 3 gives rise to Löwy's angular bundle (Löwy, 1916), which runs in the caudal angle between the cerebellum and the brain stem to the medial vestibular nucleus. A medial compartment "1" is present in th rabbit and cat, but not in monkeys (Fig. 11.49). The fourth, most lateral compartment is connected with the posterior interposed nucleus. and represents the caudal extremity of the C_2 zone. Compartment 3 harbors many of the AChE-positive cells of Langer's (1985) basal interstitial nucleus. Only the C_2 compartment continues uninterruptedly from the dorsal ventral paraflocculus into the ventral paraflocculus and the flocculus (Fig. 11.50).

Therefore, the typical compartmentation of the flocculus is not limited to this lobule but is also present in the adjoining ventral paraflocculus (Fig. 11.49). An extension of the zonally arranged corticonuclear and olivocerebellar connections of the flocculus in the adjacent part of the ventral paraflocculus also was noted in cat (Voogd and Bigaré, 1980; Gerrits and Voogd, 1982), rat (Ruigrok *et al.*, 1992), rabbit (Yamamoto, 1979; Tan *et al.*, 1995a–c), and monkey (Gerrits and Voogd, 1989; Nagao *et al.*, 1997).

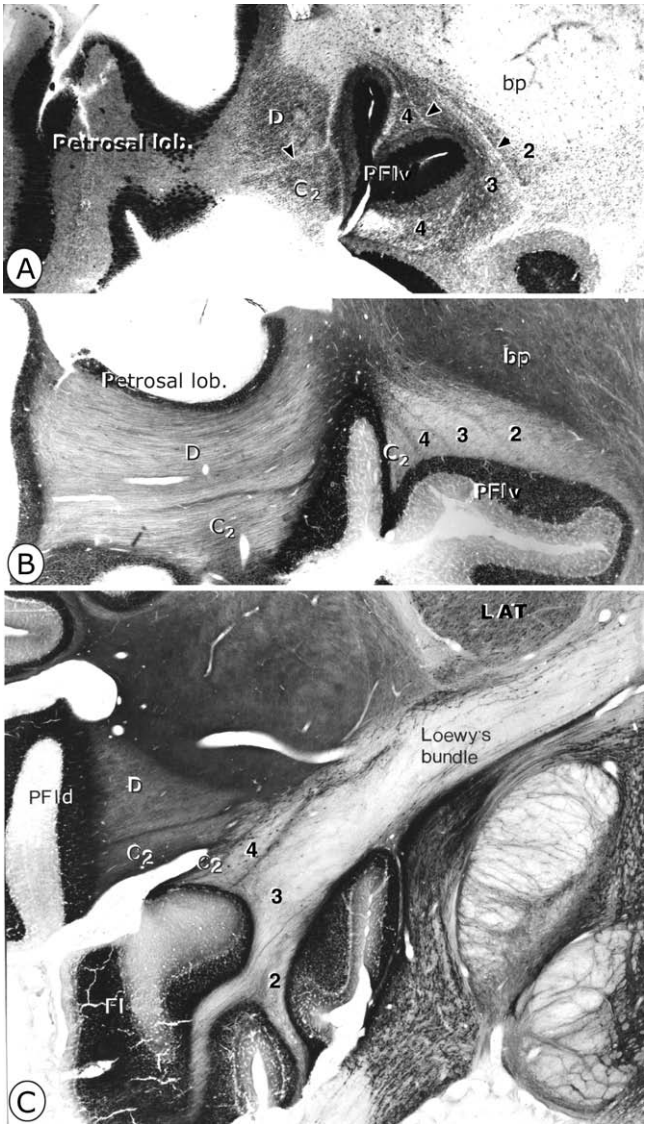

FIGURE 11.50 White matter in the flocculus and paraflocculus of *Macaca fascicularis*. **A.** Section through the petrosal lobule and the base of the ventral paraflocculus, reacted with an antbody against zebrin II. All Purkinjke cells and their axons are stained. Borders between compartments C_2 and D and between floccular compartments 2, 3, and 4 appear as unstained slits *(arrowheads)*. From Voogd and Gerrits (1997). **B.** A similar, acetylcholinesterase (AChE)–stained section, showing the AChE–stained borders between compartments C_2 and D, and between floccular compartments 2, 3, 4, and C_2. **C.** A more caudal AChE–stained section through the dorsal paraflocculus and the flocculus. Floccular compartment 3 continues into Loewy's bundle. Compartment 4 contains the AChE–positive cells of Langer's basal interstital nucleus. Abbreviations: bp, brachium pontis; C_2, C_2 compartment; $D_{1,2}$, $D_{1,2}$ compartment; Fl, flocculus; Lat, dentate nucleus; PFld, dorsal paraflocculus; PFlv, ventral paraflocculus; 2–4, floccular compartments 2–4.

Acknowledgments

I thank Eddy Dalm and Herman Chouffoer for their assistance in the preparation of the figures. Material for Figure 11.4 was on loan from the Neuroregulation Group of the Department of Physiology of the University of Leiden (Prof. Dr. Enrico Marani); acetylcholinesterase-stained monkey material was put at my disposal by Dr. Douglas T. Hess. Dr. Sharleen Sakai, Dr. Jeremy Schmahmann, Dr. Norman Strominger, and Dr. Peter van Kan made the originals of some of their figures available for reproduction in this chapter. Professor Yoshi Shinoda and Professor Mitchell Glickstein corrected the text on corticopontine and corticorubral connections. The responsibility for the statements contained therein remains mine.

The University of New South Wales, Sydney, Australia

MICHAEL M. MORGAN
Department of Psychology, Washington State University
Vancouver, Washington, USA

The periaqueductal gray (PAG) or central gray of the midbrain is the midline structure that encircles the mesencephalic aqueduct. It is a large structure made of poorly differentiated gray matter; it is rich in neuropeptides, and it forms an interface between the forebrain and the lower brain stem. There has been considerable attention focused on the PAG, especially the human PAG, because of its role in putative analgesic mechanisms. The aim of this chapter is to review and discuss the anatomical and functional aspects of the human PAG.

EXTERNAL BOUNDARIES OF THE PERIAQUEDUCTAL GRAY

The PAG is continuous with the periventricular gray of the third ventricle rostrally and with the pontine gray matter in the floor of the fourth ventricle caudally. The PAG starts approximately at the level of the posterior commissure and ends at the level of the locus coeruleus. Laterally it extends into the adjacent mesencephalic tegmentum but is separated from it by the streaming fibers of the tectospinal tract and the longitudinal fibers of the mesencephalic trigeminal tract. These fibers cast out the characteristic shapes of the PAG when viewed on cross-sections: first triangular (anteriorly), then round, and finally trapezoidal (posteriorly). These shapes are recognizable in all mammalian species and are best seen when the plane of section is perpendicular to the axis of the aqueduct. Dorsally, the PAG is bounded by the commissures of the superior and inferior colliculi.

To be exact, the PAG does not completely encircle the aqueduct. The region ventral to the aqueduct is not considered part of the PAG because it is occupied by well-differentiated nuclei with separate anatomical and functional attributes, i.e., the oculomotor-related nuclei (oculomotor, Edinger–Westphal, supraoculomotor and trochlear nuclei, nucleus of Darkschewitsch,

and interstitial nucleus of Cajal) and, more caudally, the dorsal raphe nucleus and laterodorsal tegmental nucleus. In other words, the PAG is more like a horseshoe than an annulus.

INTERNAL BOUNDARIES OF THE PERIAQUEDUCTAL GRAY

The question on how to subdivide the PAG has occupied neuroanatomists for a long time. The problem is that Nissl staining does not reveal any obvious boundaries within the PAG. Indeed, what characterizes the PAG when compared to the adjacent tectal and tegmental regions is the apparent lack of differentiation of its gray matter (see Chapter 10). Conventional myelin stains do not help either because the only fiber tract that traverses it is the loose and poorly myelinated dorsal longitudinal fasciculus (also known as Schütz bundle; see Schiller, 1984 for a historical review). However, behind this deceiving cytoarchitecture is a rich and complex chemoarchitecture that is gradually being revealed by more specific staining methods (i.e., histochemical, immunohistochemical, or receptor binding). The problem now is to extract meaningful subdivisions from this elaborate chemical mosaic. Ideally, as Blessing (1997) reminds us, subdivisions should be based on function rather than morphology (see also Chapter 15). Changes in morphology do not necessarily correspond to changes in function and vice versa.

Tracing and functional mapping studies in nonhuman mammalian species now suggest the existence of distinct identifiable functional units located in separate quadrants of the PAG. Interestingly, some of these functional units have corresponding chemoarchitectural features. Obviously, the only way these units can be transposed to the human PAG is through the use of chemical markers that are specific enough to consistently outline these subdivisions across species. NADPH-diaphorase, a constitutive enzyme, provides such a technique. The following sections describe how the human PAG subdivisions have evolved from early studies of Golgi and Nissl staining to more recent studies of NADPH-diaphorase staining.

Subdivisions Defined on the Basis of Cytoarchitecture

Golgi studies

Three Golgi studies have described the morphology of primate PAG neurons: Laemle (1979) and Gioia *et al.* (1998) in human and Mantyh (1982c) in the monkey. Mantyh described four types of neurons. The first type is the fusiform cell with two primary dendrites emerging from an elongated soma. Similar neurons have been described by Gioia *et al.* (1998). According to Beitz (1990), these fusiform cells correspond to the vertical and horizontal cells first mentioned by Laemle (1979). The second type is the multipolar cell with three to nine primary dendrites and extensive arborization that tend to spread in a coronal plane; these neurons also have been described by Gioia *et al.* (1998), who counted twice as many multipolar than fusiform cells in the human PAG. The third type, also described by Laemle (1979), is the stellate cell with an oval soma and three to six proximal dendrites. The fourth type is the pyramidal cell described only by Mantyh (1982c) and characterized by the most extensive arborization of all cells in the PAG. All four types are found throughout the PAG, although fusiform cells tend to be more prominent in medial regions near the aqueduct whereas pyramidal cells are more prominent in peripheral regions near the tegmentum or superior colliculus (Mantyh, 1982c).

These studies show that there is a great deal of variability in the cell types of the PAG. This variability is greater, for example, than in the adjacent superior colliculus or midbrain tegmentum. Most importantly, there does not seem to be obvious regional variations in the distributions of the different types to warrant a subdivisional scheme. In agreement with Ramon y Cajal (1909) and Kölliker (1896), Mantyh (1982c) concluded that the PAG is not subdivisible on the basis of distinct cell types.

Nissl Studies

The PAG is a cell-rich, myelin-poor structure (Mantyh, 1982c). Its neurons are small to medium with a diameter ranging from 10 to 35 μm (Mantyh, 1982c). In the human, 50% of cells in the lateral region of the PAG have a diameter between 15 and 25 μm and only 5% have a diameter greater than 25 μm (Laemle, 1979). One consistent feature of the mammalian PAG is the gradual increase in neuronal diameter, fiber size, degree of myelination, and packing density from the more medial to the more lateral regions of the PAG (Beitz, 1990; Mantyh, 1982c). Another consistent feature is the change in orientation of the neurons, from circular (parallel to the edge of the aqueduct) in the medial regions to radial (perpendicular to the edge of the aqueduct) in the more lateral regions (Beitz, 1990; Mantyh, 1982c).

The first cytoarchitectonic-based subdivisions of the human PAG were proposed by Olszewski and Baxter (1954) (Fig. 12.1). Three subdivisions were delineated as follows: (1) a narrow subnucleus dorsalis located on the midline above the aqueduct and characterized by a

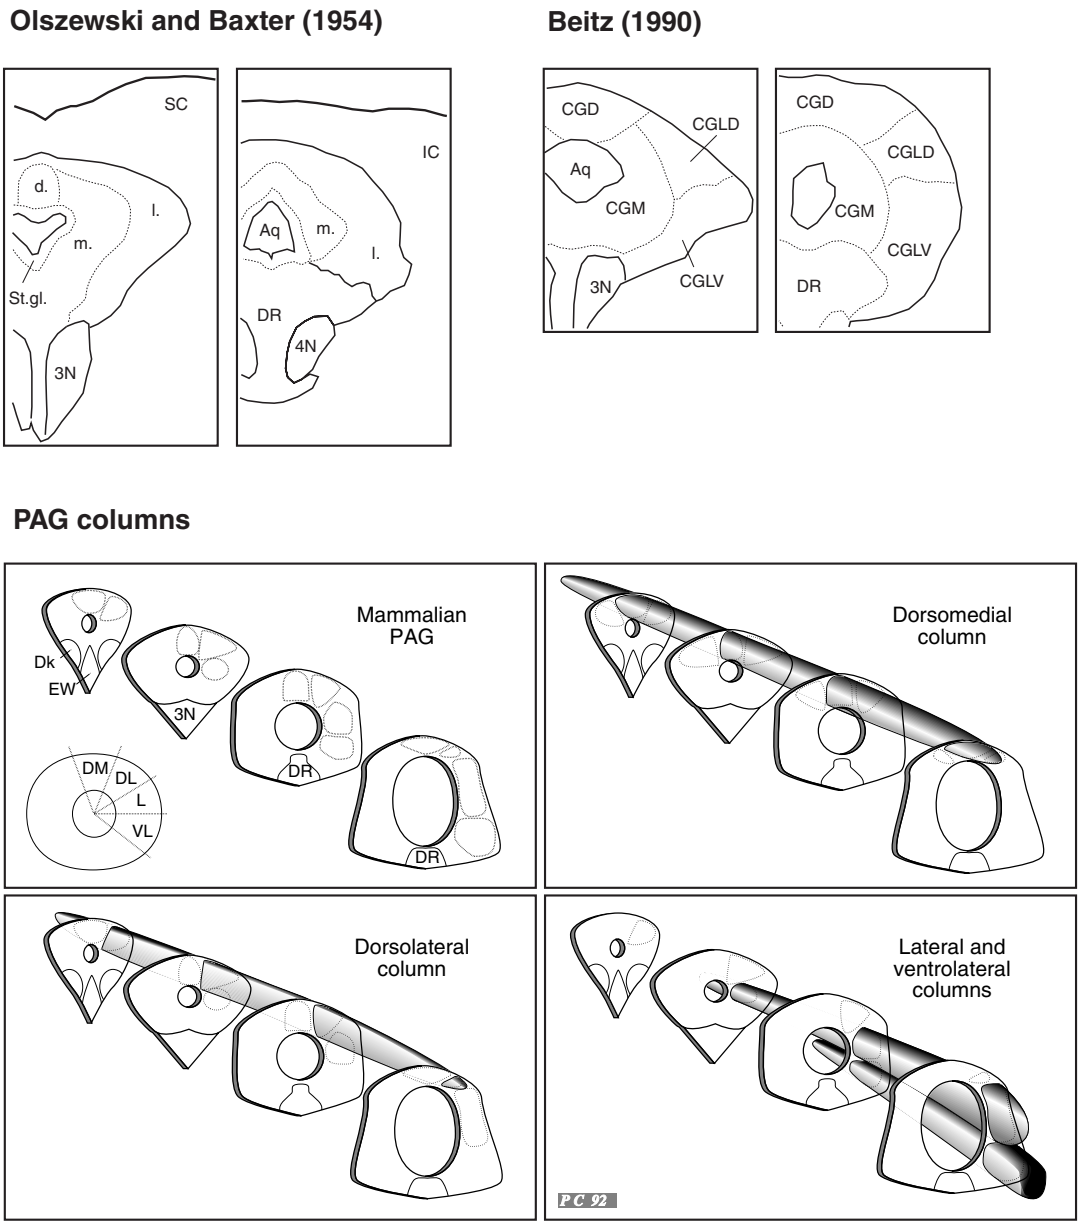

FIGURE 12.1 PAG subdivisions. **Upper left panel:** Subdivisions of the human PAG proposed by Olzewski and Baxter (1954). Abbreviations: Aq, aqueduct; d., subnucleus dorsalis of griseum centrale mesencephali; l., subnucleus lateralis; m., subnucleus medialis; St. gl. stratum gliosum subependymale; DR, dorsal raphe, 3N, oculomotor nucleus; 4N, trochlear nucleus. **Upper right panel:** Subdivisions of the human PAG proposed by Beitz (1990). Abbreviations: CGD, dorsal subdivision of central gray; CGLD, lateral dorsal subdivision; CGLV, lateral ventral subdivision; CGM, medial subdivision. **Lower panel:** PAG columns proposed by Carrive (1993) and Bandler (Bandler *et al.*, 1991b; Bandler and Shipley, 1994). Abbreviations: Dk, nucleus of Darkschewitsch; EW, Edinger–Westphall nucleus. Adapted from Olzewski and Baxter (1954), Beitz (1990), and Carrive (1993).

marked accumulation of glial cells; (2) a subnucleus medialis surrounding the aqueduct along its entire length and characterized by a low packing density; and (3) a subnucleus lateralis covering the lateral regions in the middle third of the PAG and characterized by a higher packing density. These subdivisions were verified and further refined by Beitz (1990) after an extensive quantitative study of neuronal size, shape, and packing density (Fig. 12.1). Beitz's dorsal subdivision, which was more extensive than Olszewski

and Baxter's subnucleus dorsalis, had on average the smallest neurons, the lowest neuronal packing densit, and the highest glia-to-neuron ratio. The medial subdivision was similar to the subnucleus medialis, although less extensive ventrolaterally. Its neurons had a medium neuronal packing density, were of small size, and had a circular orientation preference. The lateral subdivision was more extensive than Olszewski and Baxter's subnucleus lateralis and was characterized by a high neuronal packing density, larger neurons, and a preferential radial orientation of their soma. Beitz further subdivided the lateral division into lateral dorsal and lateral ventral subdivisions on the basis that the lateral dorsal part had a greater packing density, smaller neurons, and lower glia-to-neuron ratio than the lateral ventral part. His subdivisions were basically the same as those he had previously defined in the rat (Beitz, 1985).

Subdivisions Defined on the Basis of Connections and Functions

The current model of functional organization in the mammalian PAG proposes the existence of four basic longitudinal columns located parallel to the aqueduct (Fig 12.1). This columnar organization was originally proposed by Carrive (Carrive, 1989, 1991, 1993; Carrive and Bandler, 1991) on the basis of tracing and functional mapping studies with microinjections of excitatory amino acids in the decerebrate anaesthetized cat. The model has been further developed and documented by Bandler and collaborators (Bandler *et al.*, 1991a, b, 2000; Bandler and Shipley, 1994; Bernard and Bandler, 1998). The four columns are dorsomedial, dorsolateral, lateral, and ventrolateral, and were defined as follows: The dorsomedial, lateral, and ventrolateral columns all project directly to the lower brain stem, whereas the dorsolateral does not. The lateral and ventrolateral columns have similar connections but opposite effects on blood pressure and heart rate in the decerebrate cat (lateral is hypertensive; ventrolateral is hypotensive), and there is growing evidence that they coordinate different forms of defensive responses (lateral coordinates active defense; ventrolateral coordinates passive defense). Interestingly, the lateral and ventrolateral columns appear better separated in larger mammals and in some cases can be revealed as separate columns by neuronal tracers. A striking example is the pattern of termination of spinomesencephalic projections in the monkey (see Fig. 12.10).

These functional columns correspond to some extent to Beitz's cytoarchitectural subdivisions, although columns have better defined boundaries. Similarities include the dorsomedial and dorsolateral columns, which correspond relatively well to Beitz's dorsal and lateral dorsal subdivisions. The ventrolateral and lateral columns together also correspond approximately to Beitz's lateral ventral column. The main difference is that there is no equivalent to Beitz's medial subdivision. A gradient of cellular density may exist, but no obvious difference could be detected between the medial and lateral edges of the columns in terms of connectivity and function.

Subdivisions Defined on the Basis of a Chemical Stain, NADPH-Diaphorase

The enzyme NADPH-diaphorase (NADPH-d), the same enzyme as nitric oxide synthase (Hope *et al.*, 1991), has a remarkable distribution in the PAG. It reveals more subdivisions than any other chemical stain described so far and the boundaries that it reveals are consistent with the functional columns described in the nonhuman mammalian species. It is a simple and robust histochemical stain that reveals axons, terminals, dendritic processes, and neurons with as much resolution as a Golgi stain (Fig. 12.2). Its pattern of staining in the PAG was first described in the rat (Herbert and Saper, 1992; Onstott *et al.*, 1993).

Figure 12.3 is a series of camera lucida drawings showing the distribution of NADPH-d-stained neurons in the human PAG and adjacent tectum and tegmentum. The brain was from a male with no known neurological disease. Figure 12.4 compares this pattern across mammalian species at two rostrocaudal levels: intermediate and caudal. As can be seen, the pattern of staining is basically the same from rat to human. There are three areas within the PAG that contain NADPH-d

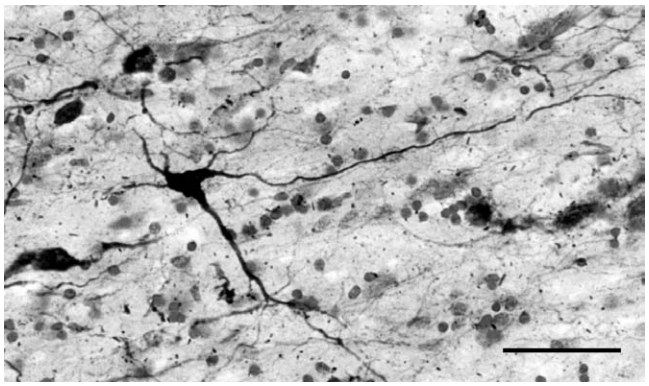

FIGURE 12.2 Microphotograph of an NADPH-diaphorase-stained neuron in the human dorsolateral PAG. The section has been counterstained with Nissl. Note the dense staining in soma and processes. Bar = 50 μm.

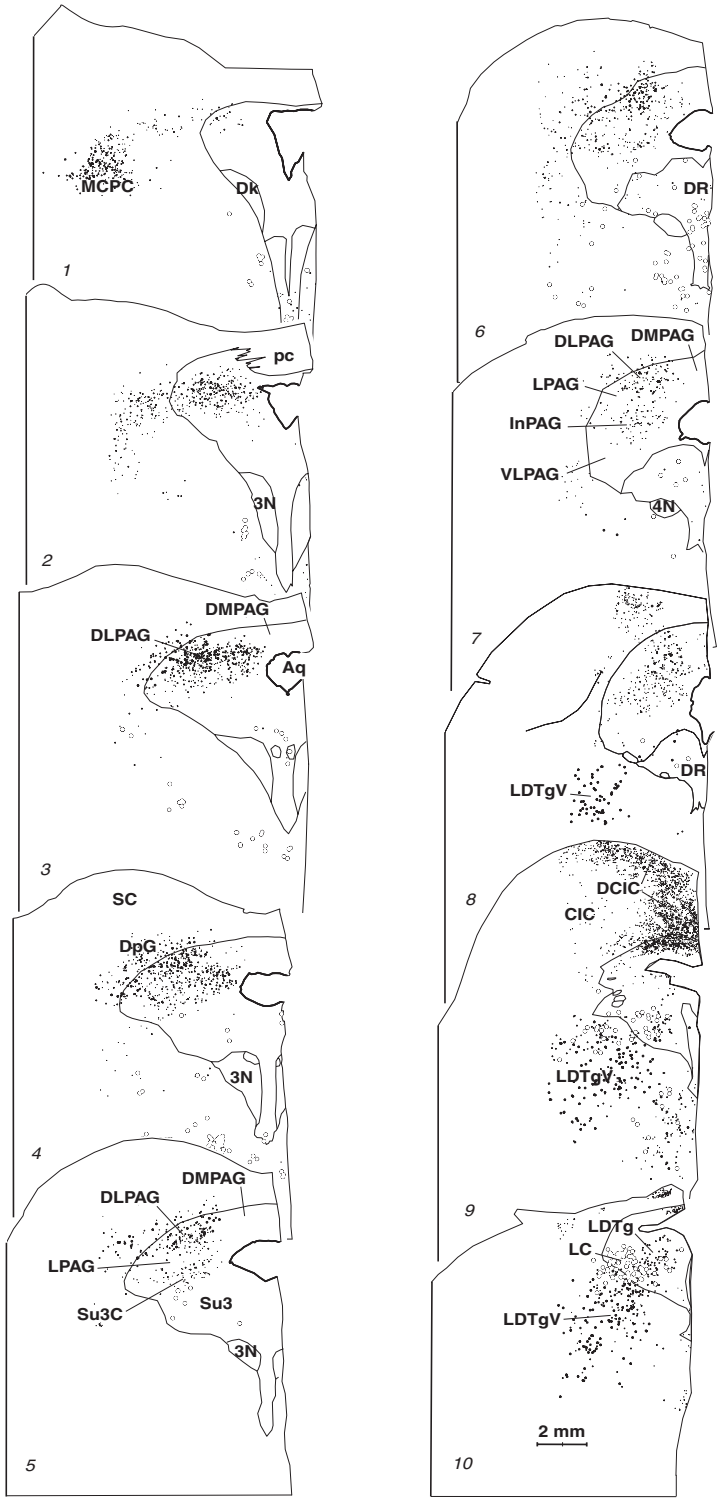

FIGURE 12.3 Camera lucida drawings of equidistant sections of a human midbrain showing the distribution of NADPH-diaphorase-stained neurons in and around the PAG from the level of the posterior commissure (section 1) to the level of the locus coeruleus (section 10). Abbreviations: 3N, oculomotor nucleus; 4N, trochlear nucleus ; Aq, aqueduct; CIC, central nucleus of inferior colliculus; Dk, nucleus of Darkschewitsch; DCIC, dorsal cortex of inferior colliculus; DLPAG, dorsolateral periaqueductal gray; DMPAG, dorsomedial periaqueductal gray; DpG, deep gray layers of superior colliculus; DR, dorsal raphe nucleus; IC, inferior colliculus; InPAG, intercalated PAG; LC, locus coeruleus; LDTg, laterodorsal tegmental nucleus; LTDgV, laterodorsal tegmental nucleus, ventral division; LPAG, lateral periaqueductal gray; MCPC, magnocellular nucleus of the posterior commissure; pc, posterior commissure; PPTg, pedunculopontine tegmental nucleus; SC, superior colliculus; Su3, supraoculomotor nucleus; Su3C, supraoculomotor cap; VLPAG, ventrolateral periaqueductal gray.

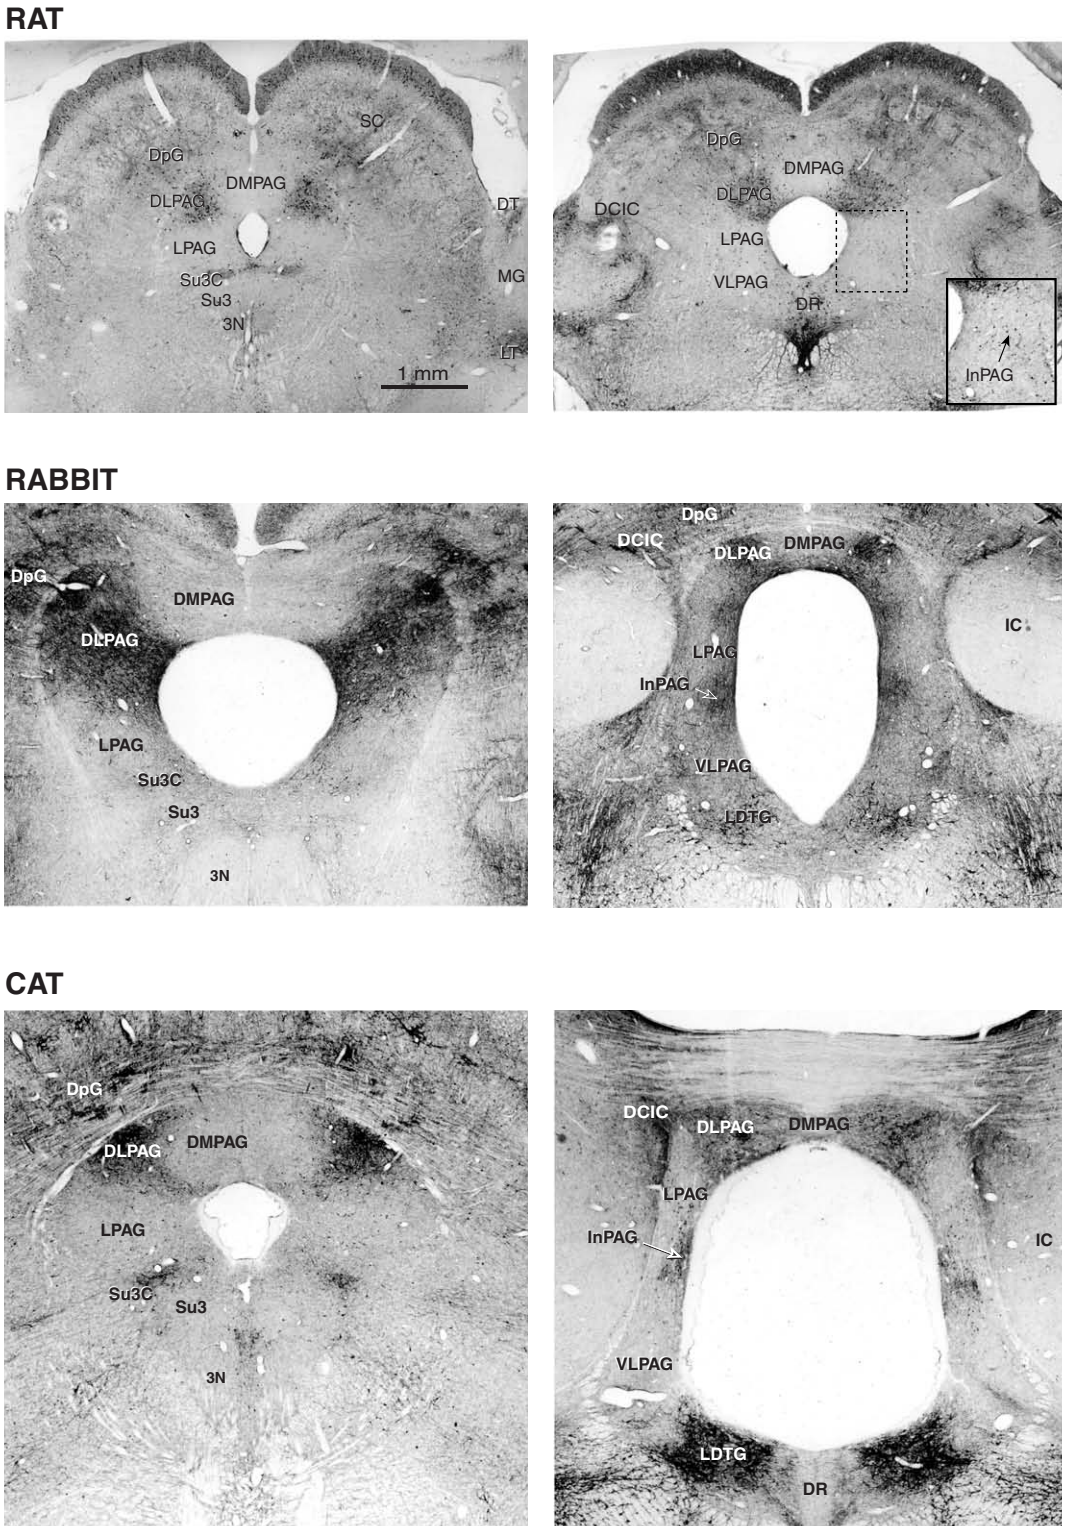

FIGURE 12.4 Comparison of NADPH-diaphorase staining of the PAG across mammalian species (rat, rabbit, cat, monkey, and human). Sections are shown at intermediate **(left)** and caudal **(right)** levels. All sections are shown at the same scale. Abbreviations: DT, dorsal terminal nucleus of the accessory optic tract; LT, lateral terminal nucleus of the accessory optic tract; MG, medial geniculate nucleus. For other abbreviations, see legend of Fig. 12.3.

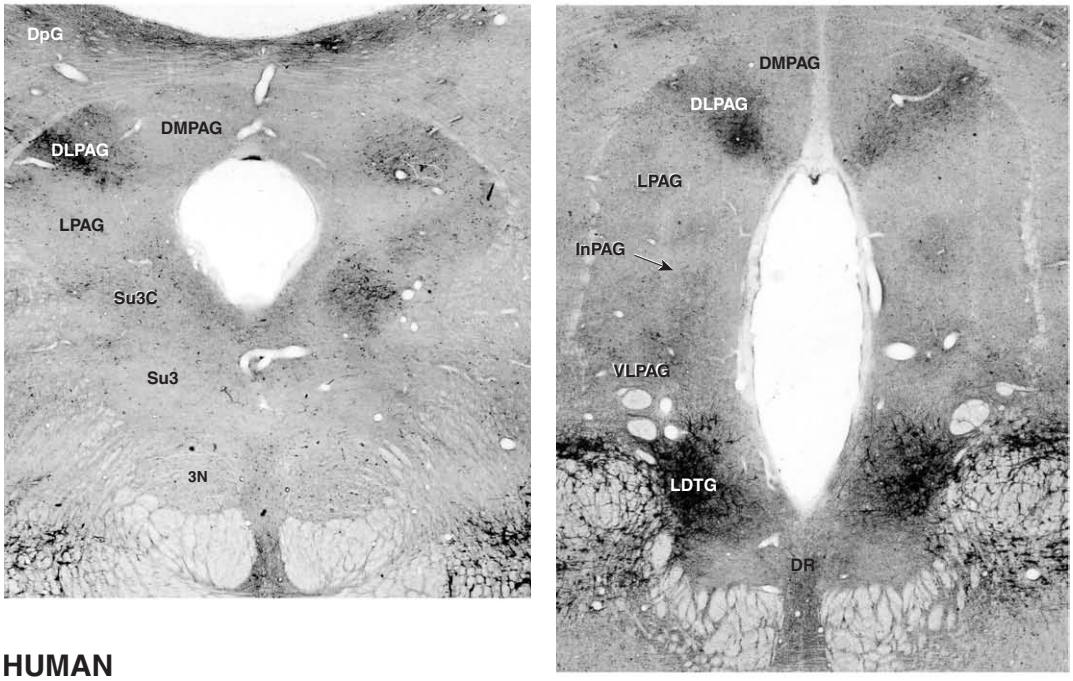
Continued

MONKEY



HUMAN

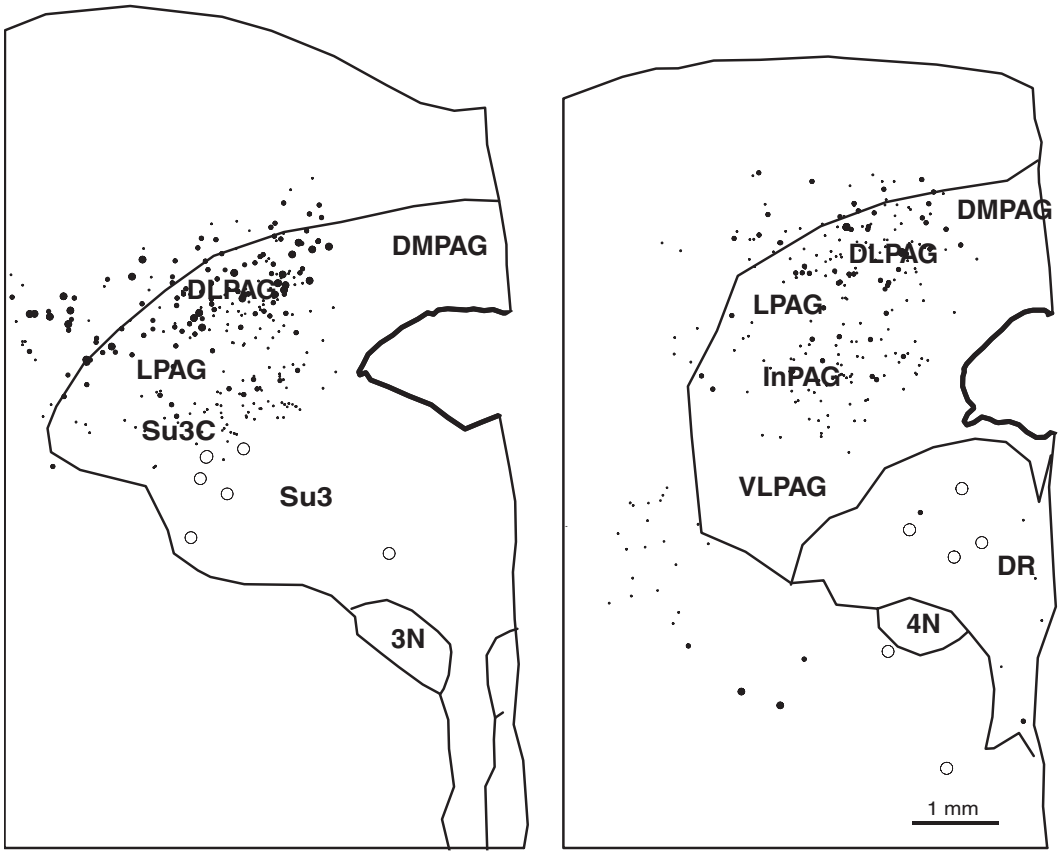


FIGURE 12.4 *Continued*

neurons: the dorsolateral column (DLPAG), the supraoculomotor cap (Su3C), and a small group of intercalated neurons that we will refer to as the "intercalated PAG" (InPAG).

The area of the PAG that stains best for NADPH-d corresponds to the dorsolateral column (Figs. 12.3 and 12.4). Approximately 17% of the neurons in the dorsolateral column are stained, and in some cases the stain is so dense that neurons are revealed in a Golgi-like manner (Fig. 12.2). Note also that the staining extends dorsally into the deep layers of the superior colliculus, suggesting some continuity between the dorsolateral column and the superior colliculus. Indeed, the dorsolateral column is largest at the level of the superior colliculus. Rostrally, the staining also seems to extend towards the magnocellular nucleus of the posterior commissure, which is NADPH-d positive (Fig. 12.3, section 1). Caudally, as the lateral column ends, it appears to merge with the NADPH-d neurons of the dorsal cortex of the inferior colliculus (lamina 1) (Fig. 12.3, section 8). However, this group of neurons is an extension not of the dorsolateral column but of the intercalated PAG (see below).

The second area that contains NADPH-d neurons is the Su3C in the intermediate PAG (Fig. 12.3, section 5). First described by Carrive and Paxinos (1994), the Su3C is located directly above the supraoculomotor nucleus and is also present in other species (Fig. 12.4). Although it is not identifiable on Nissl-stained material, it stains positively for acetylcholinesterase (Paxinos and Huang, 1995; see also Chapter 10). Nothing is known about its connectivity and function. Interestingly, closer examination of midbrain sections also suggests some continuity with clusters of NADPH-d neurons located in and next to the dorsal and lateral terminal nuclei of the accessory optic tract (Fig. 12.4, rat, DT and LT).

The third area is the InPAG, a band of stained neurons located in the caudal PAG, lateral to the aqueduct (Fig. 12.3, section 7 and Fig. 12.4). This band is also present in other species and can even appear as two distinct bands in rabbit and monkey. Interestingly, here again, there seems to be some continuity with more laterally placed NADPH-d groups of neurons, in this case the lamina 1 neurons of the dorsal cortex of the inferior colliculus which is found dorsomedial and ventromedial to the central nucleus of the inferior colliculus (Fig. 12.4, rat, rabbit, cat; see also Paxinos *et al.*, 1999).

In addition to these three PAG groups, NADPH-d staining reveals the large neurons of the laterodorsal tegmental nucleus on the ventral side of the caudal ventrolateral PAG. These darkly stained neurons merge with the neuromelanin neurons of the locus coeruleus.

The three separate groups of NADPH-d neurons described above strongly suggest that the PAG possesses a radial organization. Furthermore, the apparent continuity of these bands with more laterally placed structures also suggests that this radial organization is an architectural feature of the entire mammalian midbrain. Most importantly, it allows us to subdivide the undifferentiated gray of the PAG into quadrants of alternating NADPH-d positivity and negativity. Finally, these quadrants appear to correspond well to the functional columns identified in nonhuman species.

The dorsomedial column is thus defined as the NADPH-d-negative column between the two NADPH-d-positive dorsolateral columns; the lateral column is the NADPH-d-negative column between the NADPH-d-positive dorsolateral column and Su3C; and, finally, the NADPH-d-negative ventrolateral column is between the NADPH-d-positive InPAG and laterodorsal tegmental nucleus/dorsal raphe. This columnar organization is consistent across species and may reflect the basic functional/anatomical organization of the mammalian PAG.

Additional Subdivisions

Additional subdivisions can be added to this basic columnar organization. For example, Paxinos and Huang (1995) have delineated a pleioglial periaqueductal gray subdivision on the midline above the aqueduct in the center of the dorsomedial column (see Chapter 10). It contains a dense accumulation of glial cells and corresponds to Olszewski and Baxter's (1954) subnucleus dorsalis. Onstott *et al.* (1993) and others (Krout *et al.*, 1998) also recognize a juxtaaqueductal column surrounding the aqueduct. This area, characterized by a low neuronal density but a rich neuropil, may correspond to Olszewski and Baxter's (1954) subnucleus medialis but is much narrower. The lateral boundaries of this area are not well defined.

CHEMOARCHITECTURE OF THE PRIMATE PERIAQUEDUCTAL GRAY

Like other periventricular structures, the PAG is rich in neurochemicals. The most interesting and best studied are the neurotransmitters, neuromodulators, and their receptors. Despite the difficulty of detecting these neurochemicals in human tissue (problems with fixation, postmortem delays, size of the sections), information concerning their presence and distribution in the human PAG is nevertheless gradually accumulating. The following is an update on the neuro-

chemicals that have been identified in the human and monkey PAG so far. Parallels are drawn with studies in cat and rat when appropriate.

Monoamines and Acetylcholine

Catecholamines

Neurons. The human PAG contains scattered catecholamine-containing neurons in an area that corresponds to the ventrolateral column. These neurons were first revealed by aldehyde-induced catecholamine fluorescence (Nobin and Bjorklund, 1973) and later confirmed by tyrosine hydroxylase immunoreactivity (Pearson *et al.*, 1983, 1990). It is not clear if these neurons are dopaminergic or noradrenergic. The rostrally located neurons may be an extension of the dopaminergic neurons of the A10 group on the midline and the A8 group in the lateral tegmentum. There is evidence in the monkey of dopaminergic neurons in this area of the PAG (Arsenault *et al.*, 1988). In contrast, the caudally located neurons may be an extension of the noradrenergic neurons in the locus coeruleus.

Fibers and receptors. Epinephrine and norepinehrine are found in relatively high concentrations in the PAG, mainly in the ventrolateral part (Farley and Hornykiewicz, 1977; Mefford *et al.*, 1977). Immunoreactive tyrosine hydroxylase fibers are present in the ventrolateral PAG (Pearson *et al.*, 1983), and phenylethanolamine-*N*-methyltransferase is present there as well (Kopp *et al.*, 1979). The distribution of these fibers in the ventrolateral and lateral PAG has been described in greater detail in the rat (Herbert and Saper, 1992). These projections appear to originate from the adrenergic and noradrenergic groups of the lower brain stem (Herbert and Saper, 1992). *In vitro* autoradiographic studies showing α_2-adrenoceptor binding in the ventrolateral PAG is consistent with the location of these fibers (Pascual *et al.*, 1992).

Indoleamines

Apart from displaced dorsal raphe neurons in the ventrolateral area, the human PAG does not contain serotonergic neurons (Chen *et al.*, 2000; Nobin and Bjorklund, 1973; Takahashi *et al.*, 1986; Tork and Hornung, 1990). However, serotonin fibers and receptors are present in the PAG. In the rat, serotonin containing fibers are found mainly in the lateral PAG, are fewer in the ventrolateral PAG, and are rare in the dorsolateral and dorsomedial PAG (Halliday *et al.*, 1995). Receptors are found in moderate concentration in the human PAG, but no regional variation is apparent (Palacios *et al.*, 1983; Reddy *et al.*, 1996). These receptors are primarily of the 1A and 1B subtype, although not all subtypes have been investigated in the primate brain (Castro *et al.*, 1997; Pazos *et al.*, 1987a, b). In the rat, serotonin innervation of the PAG originates mainly from the pontine and medullary raphe nuclei (Beitz *et al.*, 1986).

Acetylcholine

The laterodorsal tegmental nucleus on the ventromedial border of the caudal ventrolateral PAG is a major cholinergic nucleus (Mesulam *et al.*, 1984). These neurons also stain positively for NADPH (Fig. 12.4). In contrast, an immunohistochemical analysis of choline acetyltransferase in the monkey indicates that the primate PAG does not contain cholinergic neurons (Mesulam *et al.*, 1984). However, the PAG is rich in muscarinic (Cortes, 1984, 1986; Reddy *et al.*, 1996) and nicotinic receptors (Adem *et al.*, 1989), with the muscarinic receptors located primarily in the dorsolateral PAG. The catabolizing enzyme acetylcholinesterase is also found in the PAG, where it appears to label the dorsolateral column and the supraoculomotor cap darker than the rest of the PAG (Graybiel, 1979; Paxinos and Huang, 1995; see also Chapter 10).

Amino Acids

Glutamate and Aspartate

Neurons. The two excitatory amino acids glutamate and aspartate are present in PAG neurons, and their distribution in the human PAG has been revealed by immunohistochemistry. Beitz (1990) reports glutamate-like immunoreactive neurons in the dorsomedial, lateral, and ventrolateral regions (as defined by the columns). There are fewer aspartate-like immunoreactive neurons. They are found in the dorsolateral, lateral, and ventrolateral regions. Thus, the distributions differ in the dorsal regions (Beitz, 1990). This pattern is the same in the rat (Clements *et al.*, 1987).

Receptors. Receptors for the glutamate agonist kainate have been reported in the human PAG (Reddy *et al.*, 1996) with the densest binding in the dorsolateral region. In the cat, the dorsolateral column is clearly more strongly labeled with glutamate receptors than the other columns (Gundlach, 1991).

GABA and Glycine

Neurons. The inhibitory amino acid γ-aminobutyric acid (GABA) has also been identified in PAG neurons by immunohistochemistry (Beitz, 1990). These neurons appear to have a similar distribution to the glutamate-like immunoreactive neurons in the human PAG. Much less is known about the distribution of the inhibitory amino acid glycine in human PAG neurons.

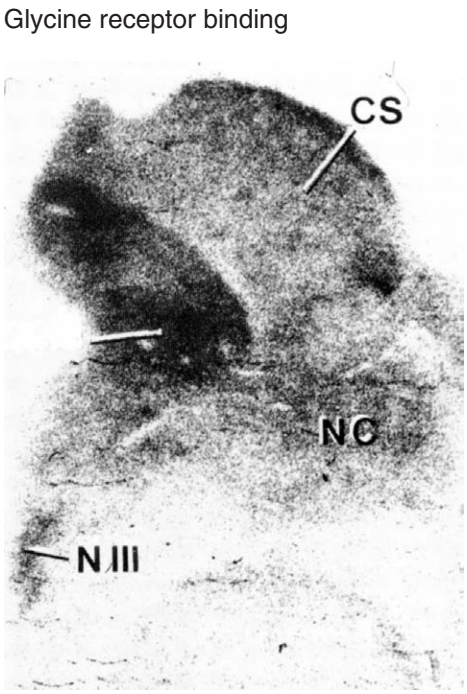

FIGURE 12.5 Bright-field photomicrograph of an autoradiogram of [^{3}H]strychnine binding to a human midbrain section. Dark regions in the dorsomedial and lateral PAG represent areas of high-density binding to glycine receptors. Note the light binding in the dorsolateral PAG. From Probst *et al.* (1986, figure 1, p. 13).

Receptors. The distribution of GABA receptors has not been described in the human PAG, but the closely related benzodiazepine receptor is found in high concentration (Doble *et al.*, 1987). In the cat, benzodiazepine binding is found throughout the PAG, with slightly denser binding in the dorsolateral column (Gundlach, 1991). Finally, glycine receptors display clear regional variations in the PAG. Thus, binding for strychnine is much denser in the dorsomedial, lateral, and ventrolateral columns than in the dorsolateral column (Probst *et al.*, 1986) (Fig. 12.5).

Neuropeptides

Opioids

There are three families of opioid neuropeptides: the enkephalins, the dynorphins, and the endorphins. They are derived from genetically distinct precursor genes: proenkephalin, prodynorphin, and proopiomelanocortin, respectively. The presence of the three opioid peptides—met-enkephalin, dynorphin, and β-endorphin—in the human PAG was first revealed by radioimmunoassay (Gramsch *et al.*, 1979, 1982). Subsequently, other derivatives of the proenkephalin precursor, the octapeptide [met]enkephalin-Arg-Gly-Leu and the heptapeptide [met]enkephalin-Arg-Phe, have been found in the human PAG (Pittius *et al.*, 1984). Of these three opioid families, the enkephalins are the most prevalent (Gramsch *et al.*, 1979, 1982; Pittius *et al.*, 1984).

Neurons. Immunohistochemical staining in colchicine-treated monkeys shows that the opioidergic neurons of the PAG are mainly enkephalinergic (Ibuki *et al.*, 1989). There are a few dynorphinergic neurons and no endorphinergic neurons (Ibuki *et al.*, 1989). *In situ* hybridization for proenkephalin and prodynorphin mRNA in humans confirms the high concentration of enkephalinergic neurons in the PAG but yields no evidence of dynorphinergic neurons (Hurd, 1996). Note that colchicine pretreatment (which blocks axonal transport) is necessary to increase peptide content in the cell sufficiently to be detected immunohistochemically. Because colchicine treatment is not possible in humans, *in situ* hybridization is the only labeling option. Although the columnar distribution of enkephalinergic neurons in the PAG has not been determined in the human, in the rat and cat these neurons are seen mainly in the dorsomedial, lateral, and ventrolateral columns (Conrath-Verrier *et al.*, 1983; Moss *et al.*, 1983; Smith *et al.*, 1994).

Fibers. The distribution of enkephalin- and β-endorphin-containing fibers has been studied by immunohistochemistry (colchicine is not required in this case). Enkephalin-like immunoreactive fibers are found in low density throughout the PAG (Bouras, 1986) but tend to be denser in the dorsolateral region (Pioro *et al.*, 1990). In contrast, β-endorphin-immunoreactive fibers avoid the dorsolateral PAG and target the dorsomedial, lateral, and ventrolateral PAG (Pilcher *et al.*, 1988). The same striking distribution is observed with two other derivatives of the proopiomelanocortin precursor adrenocorticotropic hormone (ACTH) (Buma *et al.*, 1989; Pilcher *et al.*, 1988) and corticotropin-like intermediate lobe peptide (CLIP) (Zaphiropoulos *et al.*, 1991) (Fig. 12.6). Note that this projection originates from a restricted region of the tuberal hypothalamus located in and around the arcuate nucleus (Pilcher *et al.*, 1988).

Receptors. An autoradiographic study shows naloxone binding throughout the adult human PAG with no obvious regional difference (Reddy *et al.*, 1996), and in the infant, naloxone binding is found preferentially in the dorsolateral column (Kinney *et al.*, 1998; Reddy *et al.*, 1996). Finally, competitive radioligand binding shows that the opiate receptors of the human PAG are mainly of the μ and κ types (46% μ, 41% κ and 13% δ type) (Pfeiffer *et al.*, 1982).

Substance P

Substance P neurons and fibers are found in high concentration in the human PAG (Bouras, 1986; Del

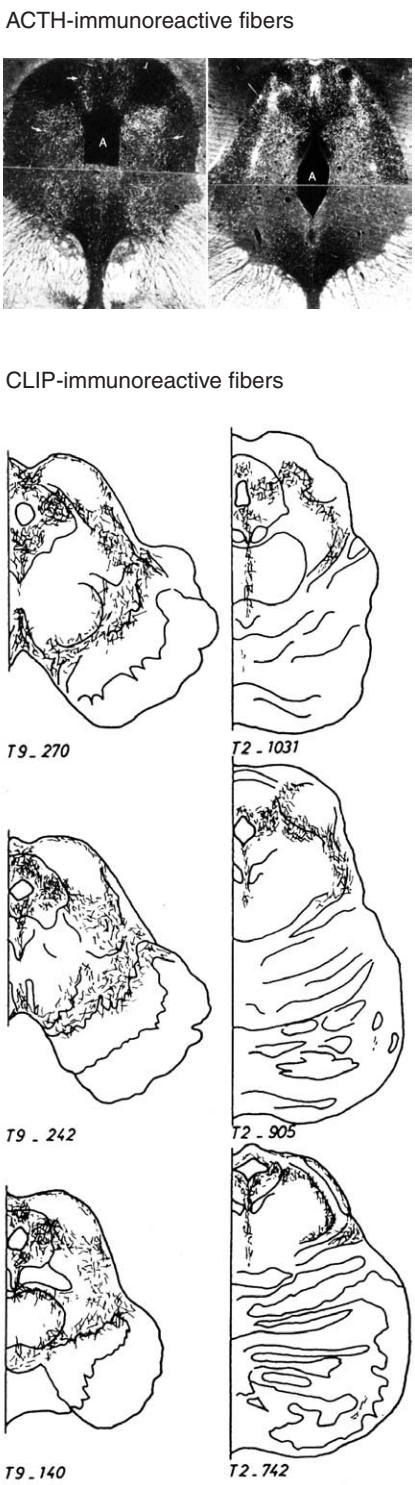

FIGURE 12.6 **Upper panel:** dark-field photomontage showing the distribution of ACTH-immunoreactive fibers and terminals in the human PAG at intermediate and caudal levels (ACTH labeling appears white on a black background). From Pilcher *et al.* (1988, figure 8, p. 627). **Lower panel:** distribution of corticotropin-like intermediate lobe peptide (CLIP)–immunoreactive fibers and terminals in the human midbrain. Adapted from Zaphiropoulos *et al.* (1991, figure 11a, p. 107). Note that in both cases the labeling is in the dorsomedial, lateral, and ventrolateral PAG and avoids the dorsolateral PAG. A, aqueduct.

Fiacco *et al.*, 1984; Halliday *et al.*, 1990; Hurd *et al.*, 1999; Nomura *et al.*, 1987; Pioro *et al.*, 1990). There is no obvious regional variation in the distribution of the neurons in the human or the rat (Smith *et al.*, 1994). However, although fibers are found throughout the PAG, they appear to be denser in the dorsolateral column (Pioro *et al.*, 1990). The same is observed in the rat (Halliday *et al.*, 1995).

Neurotensin

Neurotensin is found in high concentration in the human PAG (Mai *et al.*, 1987). Only a few neurons are revealed by immunostaining (Mai *et al.*, 1987). However, more neurons can be seen in colchicine treated rats, particularly in the dorsomedial, lateral, and ventrolateral regions (Shipley *et al.*, 1987). Most of the immunostaining is found in fibers that appear more densely distributed near the aqueduct (Mai *et al.*, 1987). In the rat, immunostained fibers are also denser near the aqueduct, but within the boundaries of the dorsomedial, lateral, and ventrolateral columns. Finally, the human PAG is rich in neurotensin binding sites; however, the columnar distribution has not been documented (Quirion *et al.*, 1987).

Somatostatin

Immunostaining for somatostatin- and prosomatostatin-derived peptides reveals the presence of both cell bodies and fibers within the human PAG (Bouras, 1986, 1987). In the rat, *in situ* hybridization shows that the cell bodies are found in all four columns of the PAG (Smith *et al.*, 1994).

Neurophysin, Oxytocin, and Vasopressin

Oxytocin, vasopressin, and their associated neurophysins (precursor proteins) are found in fibers in the human PAG (Sofroniew *et al.*, 1981; Unger and Lange, 1991). These peptides originate mainly from the parvicellular part of the paraventricular nucleus and target the dorsomedial, lateral, and ventrolateral regions (Unger and Lange, 1991) (Fig. 12.7).

Vasoactive Intestinal Polypeptide

Vasoactive intestinal polypeptide (VIP)–immunoreactive fibers are found in low density in the human PAG (Bouras, 1986). Moderately dense binding sites are also found in the monkey and appear stronger in the dorsolateral column (Dietl *et al.*, 1990). In the rat, VIP neurons are restricted to a narrow juxtaaqueductal zone (Smith *et al.*, 1994).

Calcitonin Gene–Related Peptide

Only a few fibers containing calcitonin gene–related peptide (CGRP) have been reported in the human PAG (Unger and Lange, 1991). In the monkey, moderate

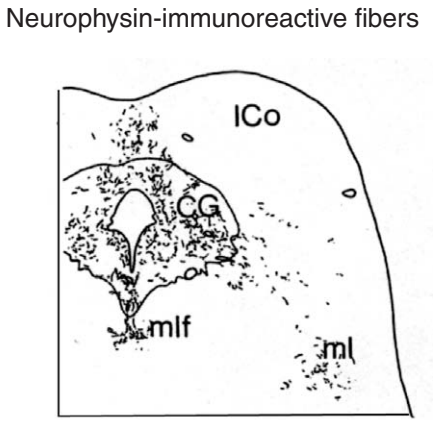

FIGURE 12.7 Distribution of neurophysin-immunoreactive fibers and terminals in the human midbrain. Note that the labeling is in the dorsomedial, lateral, and ventrolateral PAG and avoids the dorsolateral PAG. Adapted from Unger and Lange (1991, figure 1, p. 301). Abbreviations: CG, central gray; ICo, inferior colliculus; ml, medial lemniscus; mlf, medial longitudinal fasciculus.

CGRP binding is found in the dorsomedial, lateral, and ventrolateral columns (Paxinos *et al.*, 1995). Interestingly, calcitonin receptor binding in the monkey is found exclusively in the ventrolateral PAG (Christopoulos *et al.*, 1995; Paxinos *et al.*, 1995). *In situ* hybridization studies in the rat show that the PAG does not contain CGRP neurons (Smith *et al.*, 1994).

Neuropeptide Y

Neuropeptide Y neurons have been reported in the ventrolateral region of the human PAG by *in situ* hybridization (Pau *et al.*, 1998). However, comparison with the rat suggests that these neurons may actually be in the adjacent dorsal raphe nucleus (Smith *et al.*, 1994).

Others

Finally, cholecystokinin fibers and angiotensin-converting enzyme binding are found in low and moderate densities in the human PAG (Bouras *et al.*, 1986; Chai *et al.*, 1990).

Simple Gases

As indicated earlier, the enzyme that synthesizes nitric oxide (nitric oxide synthase) is the same as NADPH-d (Hope *et al.*, 1991). Thus, their identical distribution in the rat PAG is not surprising (Onstott *et al.*, 1993). The high concentration of NADPH-d in neurons of the dorsolateral PAG (Fig. 12.3) (Kowall and Mueller, 1988; Parvizi *et al.*, 2000) suggests that this gas plays an important role in this column. No information is yet available concerning carbon monoxide.

Summary

It will take time and the development of more refined tools before sense can be made of the chemical organization of the PAG. At this stage, the goal is to catalogue the presence or absence of transmitter systems and hope that patterns will emerge. For example, the information gathered so far supports the existence of distinct columns within the PAG. The dorsolateral column in particular is an area that stands out as the region with fewer shared features with the other three columns. This is apparent qualitatively, for example, with the presence of NADPH-d neurons or the absence of proopiomelanocortin (β-endorphin) and neurophysin fibers. It is also apparent quantitatively: for example, it stains darker for muscarinic receptors, substance P fibers, and benzodiazepine receptors. Interestingly, the chemical profile of the dorsolateral PAG is very similar to that of the deep layers of the superior colliculus (e.g., NADPH-d, substance P, and muscarinic receptors), suggesting that it is more closely related to the tectum than to the rest of the PAG. In contrast, the dorsomedial, lateral, and ventrolateral columns have many common features and may be considered more closely related to periventricular structures. For example, all three contain proopiomelanocortin (β-endorphin) and neurophysin fibers that originate from the hypothalamus. It is also difficult to detect quantitative differences between them for a number of markers (e.g., muscarinic and kainate receptors, substance P and neurotensin fibers). Nevertheless, subtle differences can be detected at least in some species. The dorsomedial column differs from the lateral and ventrolateral column in the rat in that it appears to have a lower density of serotonin and catecholaminergic fibers. The adjacent lateral and ventrolateral columns are more difficult to separate although there are differences in calcitonin binding and in the density of catecholaminergic fibers.

Finally, all the studies described so far have used tissue from humans who died of no known neurological diseases. However, cases involving neurological diseases are worth considering because the PAG columns may have different pathologies. This seems to be the case for Alzheimer's disease (Parvizi *et al.*, 2000). Parvizi *et al.* (2000) report that the ventrolateral column was mainly affected with dense core senile plaques, the dorsolateral and dorsomedial columns with diffuse senile plaques, and the lateral column with a mixture of diffuse and dense core senile plaques. No neurofibrillary tangles were found in the PAG but they were plentiful in the dorsal raphe nucleus. The juxtaaqueductal zone was not affected at all. Moreover, the dorsolateral and lateral columns

were the first affected in the progression of the disease and the dorsomedial column was last (Parvizi *et al.*, 2000). These interesting findings further support the existence of the columns and strongly suggest that they have different chemical and functional attributes.

CONNECTIVITY OF THE PRIMATE PERIAQUEDUCTAL GRAY

Although neuronal tract tracing is a powerful method, it is not applicable to humans because of methodological and ethical factors. Thus, the connections of the human PAG can only be inferred by homology with monkeys and other mammalian species. Fortunately, the patterns of afferent and efferent connections of the PAG seem to vary little across species and therefore are probably similar in human. The following describes what is currently known of the PAG connections in the monkey based on retrograde and anterograde tract tracing. These studies give an overall idea of what the PAG does and how it interacts with the rest of the brain. Moreover, these data are consistent with other data demonstrating the existence of PAG columns.

Periaqueductal Gray Afferents

From Forebrain

Forebrain afferents to the PAG arise from limbic structures, mainly from prefrontal cortex (see Chapters 24 and 25), insular cortex, amygdala (see Chapter 22), and hypothalamus (see Chapter 17). It does not receive any significant afferents from the parietal or occipital cortices, hippocampus, basal ganglia or thalamus (Mantyh, 1982b). These projections are mainly ipsilateral.

Cortical areas. The origins of cortical input to the monkey PAG were revealed by Hardy and Leichnetz (1981; see also Leichnetz *et al.*, 1981) and by Mantyh (1982b) using retrogradely transported horseradish peroxidase (HRP). The projection has recently been studied in greater detail by An *et al.* (1998). All three retrograde tracing studies show that cortical projections to the PAG originate principally from the prefrontal cortex. In particular, this input comes from the medial wall of the prefrontal cortex (areas 25, 32, 10m), the dorsomedial convexity of the medial wall (area 9) extending into the anterior cingulate cortex and the posterior orbitofrontal/anterior insular cortex (areas 13a, Iai, 12o, 12l) (An *et al.*, 1998). The lateral wall (areas 8 and 6) makes a minor contribution whereas the medial anterior part of the orbitofrontal cortex (areas 11, 13) does not project to the PAG. Caudal to the prefrontal cortex, other sources of cortical input are the posterior cingulate cortex (24b), the agranular and dysgranular parts of the insular cortex, and the dorsal bank of the superior temporal sulcus. The cortical projections arise from layer V and are predominantly ipsilateral.

The prefrontal projections have been verified by anterograde tracing with [^{3}H]amino acids, HRP, or biotinylated dextran amines (An *et al.*, 1998; Hardy and Leichnetz, 1981; Jürgens and Müller-Preuss, 1977; Müller-Preuss and Jürgens, 1976). Most importantly, anterograde tracing reveals that these afferents are organized along the same PAG columns described above (Fig. 12.8). Thus, the medial wall of the prefrontal cortex targets almost exclusively the dorsolateral column (Fig. 12.8, upper panel), the posterior orbitofrontal/anterior insular cortex targets preferentially the ventrolateral column (Fig. 12.8, lower panel), and the anterior cingulate gyrus targets mainly the lateral as well as the ventrolateral and dorsomedial columns (An *et al.*, 1998; Leichnetz *et al.*, 1981; Müller-Preuss and Jurgens, 1976). The significance of this topographical organization is not well understood, but given the well-known role of the prefrontal cortex in affect and mood, we can speculate that it corresponds to an organized network for processing and mediating the various motivational and emotional aspects of behavior (Bandler *et al.*, 2000). Whether this organization has been conserved with the massive expansion of the prefrontal cortex in humans cannot be known. However, these projections appear to be evolutionarily stable as indicated by the consistent pattern in the primate and rat (Floyd *et al.*, 2000).

Amygdala. The amygdala is another important source of input to the PAG although the projection is not as strong as from the prefrontal cortex (Mantyh, 1982b). Retrograde tracing shows that the projection originates from the central nucleus and the ventrolateral part of the basal nucleus mainly on the ipsilateral side (An *et al.*, 1998; Mantyh, 1982b). Anterograde tracing with [^{3}H]amino acids further shows that the PAG terminals of the central nucleus projection are in the dorsomedial, lateral, and ventrolateral column but not in the dorsolateral column (Price and Amaral, 1981) (Fig. 12.9). The PAG target of the ventrolateral basal nucleus has not been studied directly, but the retrograde studies of An *et al.* (1998) suggest input to the dorsolateral column. This pathway is interesting because the ventrolateral basal nucleus projects to the medial prefrontal cortex, which also targets the dorsolateral column (Bandler *et al.*, 2000; Ongur *et al.*, 1998). Given the well-known role of the amygdala in fear and defensive behavior, we can speculate that this organized projection is involved in the expression

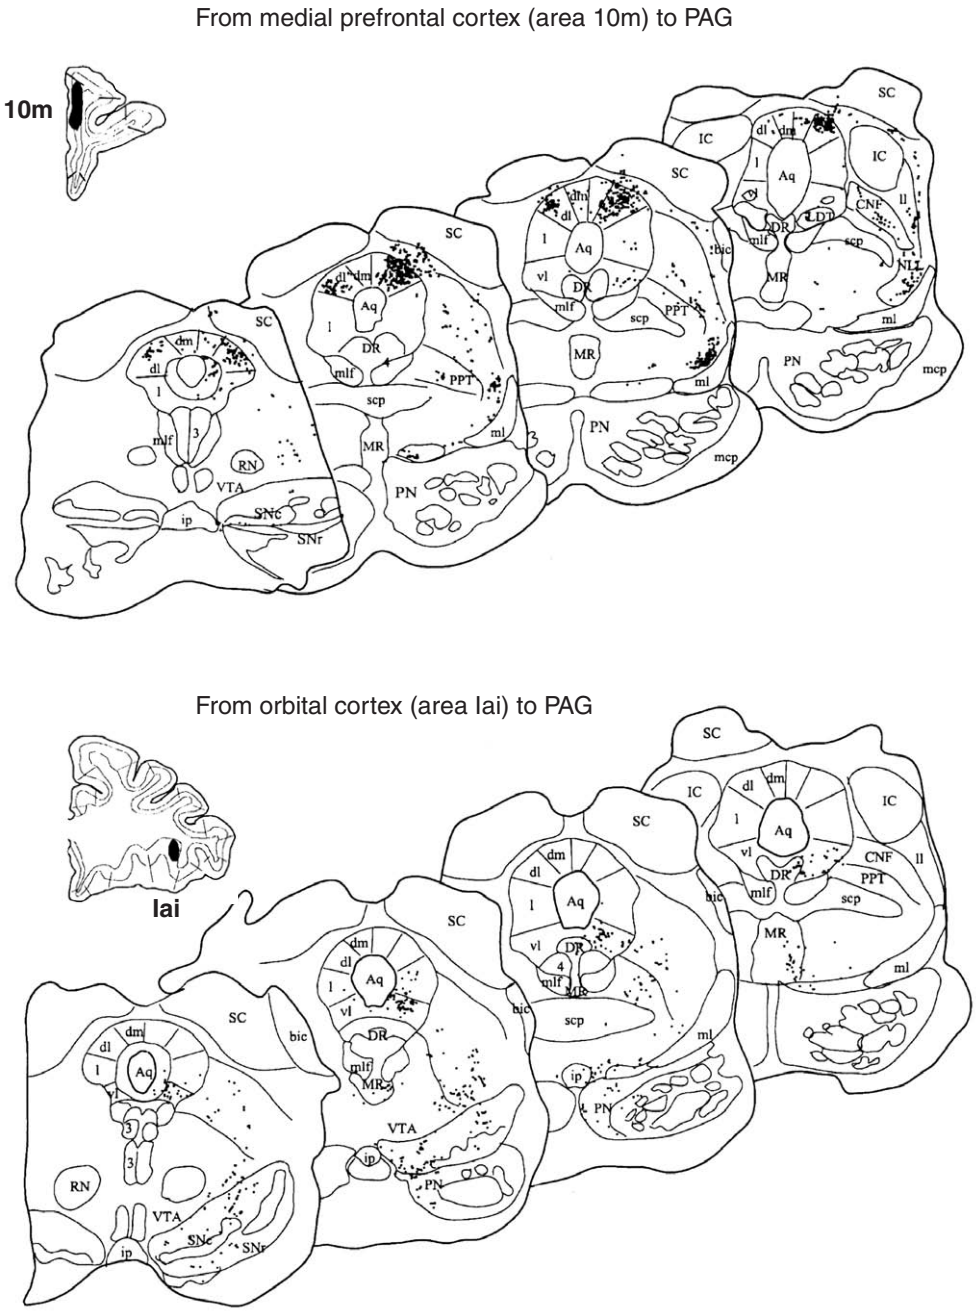

FIGURE 12.8 Distribution of axonal varicosities in the midbrain of the macaque monkey labeled following injections of the anterograde tracer biotinyilated dextran amine in the medial prefrontal cortex area 10m **(upper panel)** and orbital area Iai **(lower panel).** Afferents from medial prefrontal cortex terminate in the dorsolateral PAG column while afferents from the orbital cortex terminate in the ventrolateral PAG column. The frontal cortex diagrams depicting the injection sites are drawn at a lower magnification than the midbrain diagrams. The rostrocaudal axis for the midbrain sections is from left to right. Adapted from An *et al.* (1998, figure 9, p. 468; figure 12, p. 471; and figure 14, p. 473).

of emotional responses; however, the functional significance of the basolateral amygdala–dorsolateral PAG projection vs. amygdala–central dorsomedial/lateral/ventrolateral PAG is not clear at this stage.

Hypothalamus. HRP retrograde tracing shows that the PAG receives a massive input from the hypothalamus predominantly on the ipsilateral side (Mantyh, 1982c). Starting from the rostral hypothalamus, a heavy input originates from the medial preoptic area and the anterior hypothalamic area. In contrast, there is apparently little input coming from the supraoptic, paraventricular (magnocellular), and

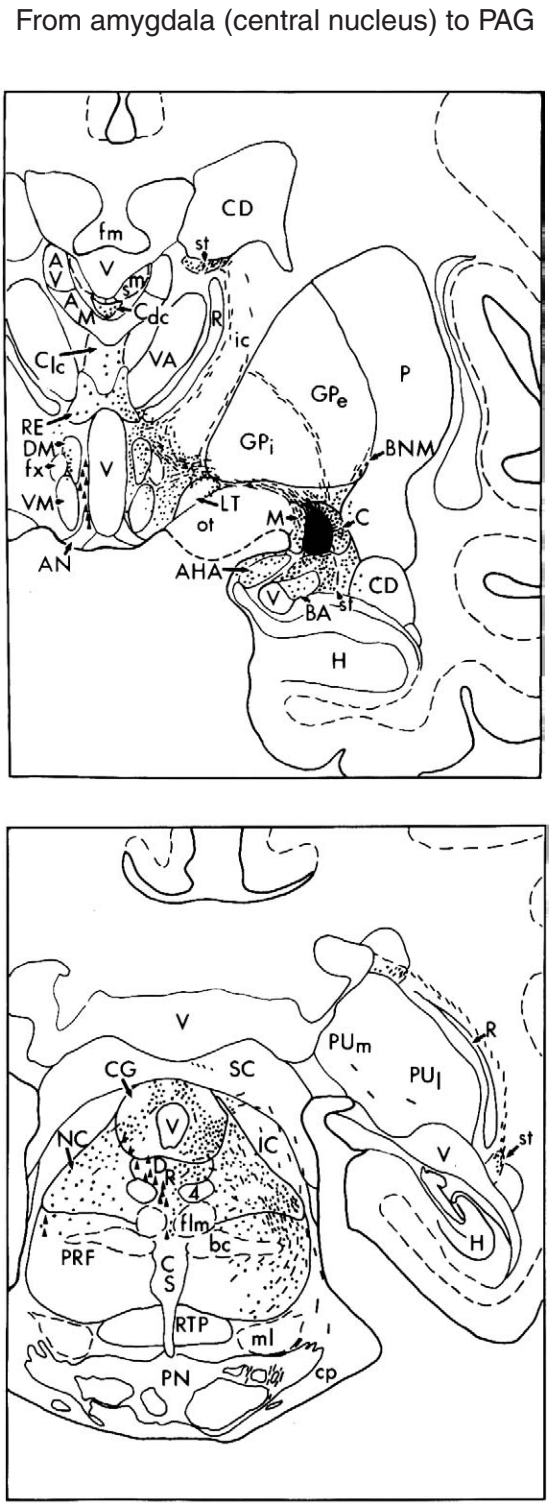

FIGURE 12.9 Distribution of autoradiographic silver grains in the midbrain of a macaque monkey following an injection of [^{3}H]amino acids in the central nucleus of the amygdala. Dots represent terminal fields or transversely cut axons. Note that the labeling is in the dorsomedial, lateral, and ventrolateral PAG and avoids the dorsolateral PAG. Small triangles represented on the left side represent neuromelanin-containing cells. Adapted from Price and Amaral (1981, figure 1, pp. 1244–1245).

suprachiasmatic nuclei. In the middle or tuberal region, the major inputs to PAG are the periventricular dorsal hypothalamus, ventromedial nucleus, and periarcuate region (just dorsal and lateral to the arcuate nucleus) together with the zona incerta laterally. PAG projecting neurons are also found throughout the rostrocaudal extent of the lateral hypothalamus, but few inputs are found from the arcuate nucleus itself. More caudally, the posterior hypothalamus and the supramammillary nucleus also represent major inputs. Most neurons project to the PAG via the periventricular bundle (Schütz bundle), except for those in the zona incerta, which travel more laterally in the medial forebrain bundle.

The specific PAG targets of some of these projections have been identified by anterograde tracing with [^{3}H]amino acids (Saper *et al.*, 1976, 1978; Veazey *et al.*, 1982). The anterior, posterior, and lateral hypothalamus areas project to the dorsomedial, lateral, and ventrolateral columns, but not to the dorsolateral column. The targets of the other areas of the hypothalamus have not been traced in the monkey. However, as mentioned earlier, β-endorphin, ACTH, and neurophysin projections—which arise from the region of the arcuate nucleus and paraventricular nucleus, respectively—terminate exclusively in the dorsomedial, lateral, and ventrolateral columns. Furthermore, studies in the rat indicate that with the exception of the dorsomedial part of the ventromedial nucleus, all areas of the hypothalamus project to the dorsomedial, lateral, and ventrolateral columns (Luiten *et al.*, 1987; Rizvi *et al.*, 1992; Roeling *et al.*, 1993; Veening *et al.*, 1991). The dorsomedial part of the ventromedial nucleus seems to be the only one that projects to the dorsolateral column (Canteras *et al.*, 1995; Veening *et al.*, 1991). These projections are likely to carry visceral, autonomic, and motivational information to the PAG, and to complement the limbic input coming from the prefrontal cortex and amygdala. It is worth noting here that many of these hypothalamic areas receive a reciprocal PAG input. This will be described later.

From Brain Stem

The brain stem afferents to the monkey PAG have been described by Mantyh (1982a) after retrograde transport of HRP. Here again the projections are predominantly ipsilateral. These afferents originate from the superior colliculus (mainly intermediate and deep layers) and the inferior colliculus (external layer) in the tectum, from the mesencephalic reticular formation and the cuneiform nucleus in the midbrain tegmentum, from the locus coeruleus and the parabrachial nucleus (lateral part) in the dorsal pons, and

from the ventromedial and ventrolateral medulla (raphe magnus and pallidus, the adjacent paragigantocellular area, and, more caudally the lateral tegmental field of the medulla). At this stage it is not known whether these afferents target specific columns. However, as mentioned earlier, the catecholaminergic projections that originate from the adrenergic and noradrenergic groups of the lower brain stem target the ventrolateral and, to some extent, the lateral columns. It is interesting to note that, like the hypothalamus, these brain stem areas are also major efferent targets of the PAG. These brain stem afferents could be part of feedback loops for proper integration of PAG outputs. Finally, projections from the solitary nucleus were not described by Mantyh (1982a). However, this could be due to placement of the HRP injection sites. Indeed, a small projection to the caudal ventrolateral PAG adjacent to the lateral parabrachial nucleus has been described after anterograde tracing with HRP and [^{3}H]amino acid injections into the solitary nucleus (Beckstead *et al.*, 1980). It is not known how important this projection is in the monkey, but in the rat there is a definite projection to the ventrolateral column (Herbert and Saper, 1992).

From Spinal Cord/Spinal Trigeminal Nucleus

Spinal projections to the PAG of the monkey were first demonstrated by Mehler (1969) using silver degeneration techniques. Retrograde tracing suggests the projection is sensory because it originates mainly from lamina 1 of the superficial dorsal horn and caudal trigeminal nucleus (Mantyh, 1982a; Wiberg *et al.*, 1987; Zhang *et al.*, 1990, see also Chapter 30). Other regions that contribute to the projection are the deep dorsal horn (lamina V), the lateral spinal nucleus, and, occasionally, the intermediate gray matter (lamina VII and X). These projections are predominantly contralateral, unlike the other afferent and efferent connections of the PAG. The spino-PAG projection has two other remarkable features that were revealed by anterograde tracing with the tracer wheat germ agglutinin–horseradish peroxidase (WGA-HRP) (Wiberg *et al.*, 1987; Yezierski, 1988) (Fig. 12.10). First, it terminates specifically in the lateral and ventrolateral columns and second, it is somatotopically organized (i.e., spinal trigeminal terminates at rostral PAG levels; cervical at intermediate levels, and lumbar at caudal levels) (Fig. 12.10). This latter feature suggests another level of organization within the PAG, this time along the rostrocaudal axis. Interestingly, this somatotopic organization is also present in other species, but it is clearest in the monkey (Blomqvist and Craig, 1991; Yezierski, 1988). There is very good evidence that the spinal neurons at the origin of this projection receive cutaneous, deep somatic, and visceral primary afferents and that they are readily activated by noxious stimulation (Clement *et al.*, 2000; Dougherty *et al.*, 1999; Yezierski, 1991). It also seems to be an important sensory projection given that it is much bigger than the better known spinothalamic projection. For example, a recent study in the cat shows that three times as many lamina I neurons project to the PAG than to the thalamus (Mouton and Holstege, 1998). All of this suggests that the PAG has an important role in processing and mediating responses to somatic and visceral noxious stimuli.

Periaqueductal Gray Efferents

To Forebrain

Anterograde tracing with [^{3}H]amino acids in the monkey shows that the forebrain targets of the PAG are in the diencephalon, mainly the hypothalamus and thalamus (Mantyh, 1983). The PAG does not project to any cortical region or to the hippocampus, amygdala, or basal ganglia. However, consistent labeling is found ventral to the aqueduct after retrograde tracing from these regions (Aggleton *et al.*, 1980; Amaral and Cowan, 1980; Porrino and Goldman-Rakic, 1982). These neurons clearly belong to the dorsal raphe and not to the PAG, but it is often a source of confusion.

Thalamus. The dorsal thalamus receives a substantial projection from the PAG, also predominantly ipsilateral (Mantyh, 1983). The targets are (1) the intralaminar nuclei, (2) the midline nuclei (central medial, central inferior, intramedial dorsal, reuniens, and paraventricular), and (3) the reticular nucleus. There is no input to the other main nuclei of the thalamus, including the ventrobasal complex. No retrograde study is available yet to know exactly how the different columns contribute to these projections in the monkey. However, a recent study in the rat (Krout and Loewy, 2000) showed that all four columns of the PAG contribute. Although no clear-cut demarcation was observed, the lateral and ventrolateral columns appear to provide the largest input. This is interesting because these two columns are the targets of the spino-PAG projection. Thus, the lateral/ventrolateral PAG connection with the intralaminar and midline nuclei may be an important link in the paleospinothalamic pathway (the polysynaptic ascending sensory system thought to mediate diffuse pain and its associated emotional overtones). Most importantly, the projection to the intralaminar and midline nuclei is a gateway to the cortex, especially limbic cortex and prefrontal cortex, and also to the amygdala and basal ganglia (Krout and Loewy, 2000; Mantyh, 1983). This may be the route by which the PAG accesses higher forebrain structures and is able to influence affect (e.g., fear). The reticular nucleus, on the other hand, does not project to any

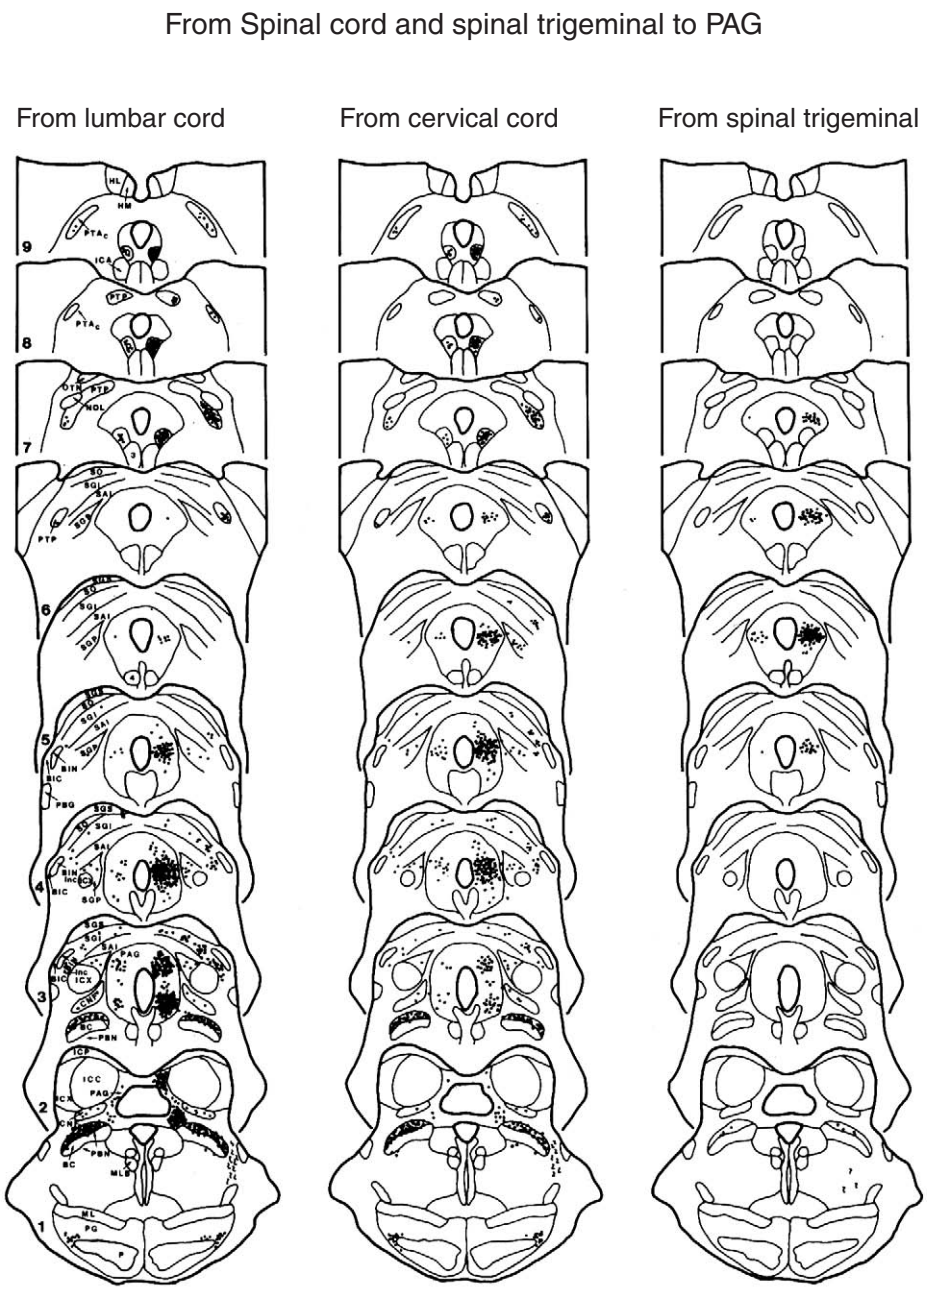

FIGURE 12.10 Distribution of axonal terminal labeling in the midbrain of macaque monkeys after injections of anterograde tracer wheat germ agglutinin–horseradish peroxidase (WGA-HRP) in the lumbar spinal cord, cervical spinal cord and laminar spinal trigeminal nucleus. All injections were on the left. Labeling is found in the contralateral lateral and ventrolateral PAG columns. Note also the somatotopic organization of the projections. Adapted from Wiberg *et al.* (1987, figure 2, p. 97).

cortical area, but regulates thalamic activity and controls thalamic output to the cortex. The input from PAG may represent a connection through which the PAG can modulate overall cortical activity (Mantyh, 1983).

Hypothalamus, substantia innominata, and zona incerta. The hypothalamus receives a heavy projection from the PAG that is predominantly ipsilateral (Mantyh, 1983). More specifically, the main targets in the rostral hypothalamus are the anterior medial areas and the substantia innominata. The supraoptic, paraventricular, and suprachiasmatic nuclei do not receive any afferents. In the intermediate hypothalamus, the projection is particularly dense, especially in the periventricular and dorsal nuclei. The ventromedial nucleus receives a moderate projection whereas the arcuate,

tuberal, and tuberomammillary nuclei do not appear to receive any input from the PAG. The posterior hypothalamus receives a heavy projection and blends with the periventricular bundle (Schütz bundle), which carries most of the connections between PAG and hypothalamus. Finally, the laterally located zona incerta also receives a heavy input from the PAG. Interestingly, many of these hypothalamic areas were already described as projecting to the PAG. There is indeed a high degree of reciprocity in this connection (Mantyh, 1983). However, it is not known whether this reciprocity extends to the level of the PAG columns. Nevertheless, the hypothalamus and the PAG are intricately related and appear to be key structures in the control of autonomic and behavioral responses (see also Chapter 17).

To brain Stem

The PAG projects to many structures in the brain stem, predominantly on the ipsilateral side (see also Chapter 30). Anterograde tracing (Mantyh, 1983) shows that the main PAG targets in the midbrain are the mesencephalic reticular formation laterally adjacent to the PAG, the superior colliculus (deep and intermediate layers but not superficial), and the cuneiform nucleus. In the dorsal pons, the locus coeruleus and the lateral parabrachial nuclei receive heavy projections, whereas the projections to the subcoeruleus nucleus and reticularis pontis oralis and caudalis are comparatively lighter. At this stage the efferent fibers move medially and ventrally to provide a heavy projection to a number of important structures in the caudal ventral pons and rostral ventral medulla, such as the median raphe nuclei (magnus and pallidus) and the paramedian gigantocellular and paragigantocellular nuclei. The more laterally placed parvicellular reticular nucleus receives a lighter projection. More caudally, there is a moderate-to-heavy projection to the retroambiguus nucleus and a lighter one to the surrounding reticular formation. Finally, no projection was found to the solitary nucleus or dorsal motor nucleus of the vagus (Mantyh, 1983).

Some of these projections to the raphe nuclei and paramedian reticular formation and to the retroambiguus nucleus have been verified by retrograde tracing (Chung *et al.*, 1983; Van der Horst *et al.*, 2000; Yezierski *et al.*, 1982). The projections to the raphe and paramedian reticular formation originate from the dorsomedial, lateral, and ventrolateral columns (Chung *et al.*, 1983; Yezierski *et al.*, 1982), and the projection to the retroambiguus nucleus originates from the lateral column, especially its intermediate part (Van der Horst *et al.*, 2000) (Fig. 12.11). This pattern of projection, which is very consistent across species, also indicates that the dorsolateral column does not project to the lower brain stem. The most caudal targets of the dorsolateral PAG, at least in the rat, appear to be the cuneiform nucleus (Redgrave and Dean, 1991; Redgrave *et al.*, 1988) and the adjacent superior lateral division of the parabrachial nucleus (Krout *et al.*, 1998). However, the cuneiform nucleus in turn projects to the lower brain stem (Korte *et al.*, 1992).

As pointed out by Holstege (1998), many of the PAG targets in the brain stem are premotor centers that in turn project to cranial nerve nuclei or to different groups of spinal interneurons (Fig. 12.12; see also Chapter 36). Some of these premotor centers have been well studied, and it is possible to understand their function. That the PAG projects to all these premotor centers suggests that it is an important integrating motor center for the coordinated expression of basic behavioral responses.

To Spinal Cord

Finally, the monkey PAG sends a moderate to light projection to the spinal trigeminal nucleus and into the spinal cord as far down as lumbar levels (Mantyh, 1983). However, these fibers end not in the superficial layers of the dorsal horn but in the deep layers and intermediate gray (V, VII, VIII) predominantly on the ipsilateral side. Thus, there is no reciprocity with the spino-PAG projection that originates from the superficial layers (mainly lamina I) on the contralateral side. The only way the PAG can access the superficial layers is via a relay in the rostral ventromedial medulla (e.g., raphe magnus). The PAG-spinal projection has been verified by retrograde tracing (Mantyh and Peschanski, 1982). It originates from a restricted region on the border between the lateral and ventrolateral columns. This projection is thought to target interneurons controlling motoneurons of the axial musculature (Mouton and Holstege, 1994) and some sympathetic preganglionic neurons (Fig. 12.12).

Summary

In summary, tracing studies reveal that the PAG is an important integrating center of the brain stem (Fig. 12.13). It is strategically located at the crossing of two systems: an ascending pain sensory system and a descending limbic (emotional) motor system (see Chapter 36). The two systems may modulate each other at the level of the PAG. Thus, the ascending sensory system, which relays noxious input from the spinal cord to the thalamus and then to the cortex and basal ganglia, can be modulated by limbic influence from prefrontal cortex and hypothalamus. This could lead, for example, to changes in the perception of pain

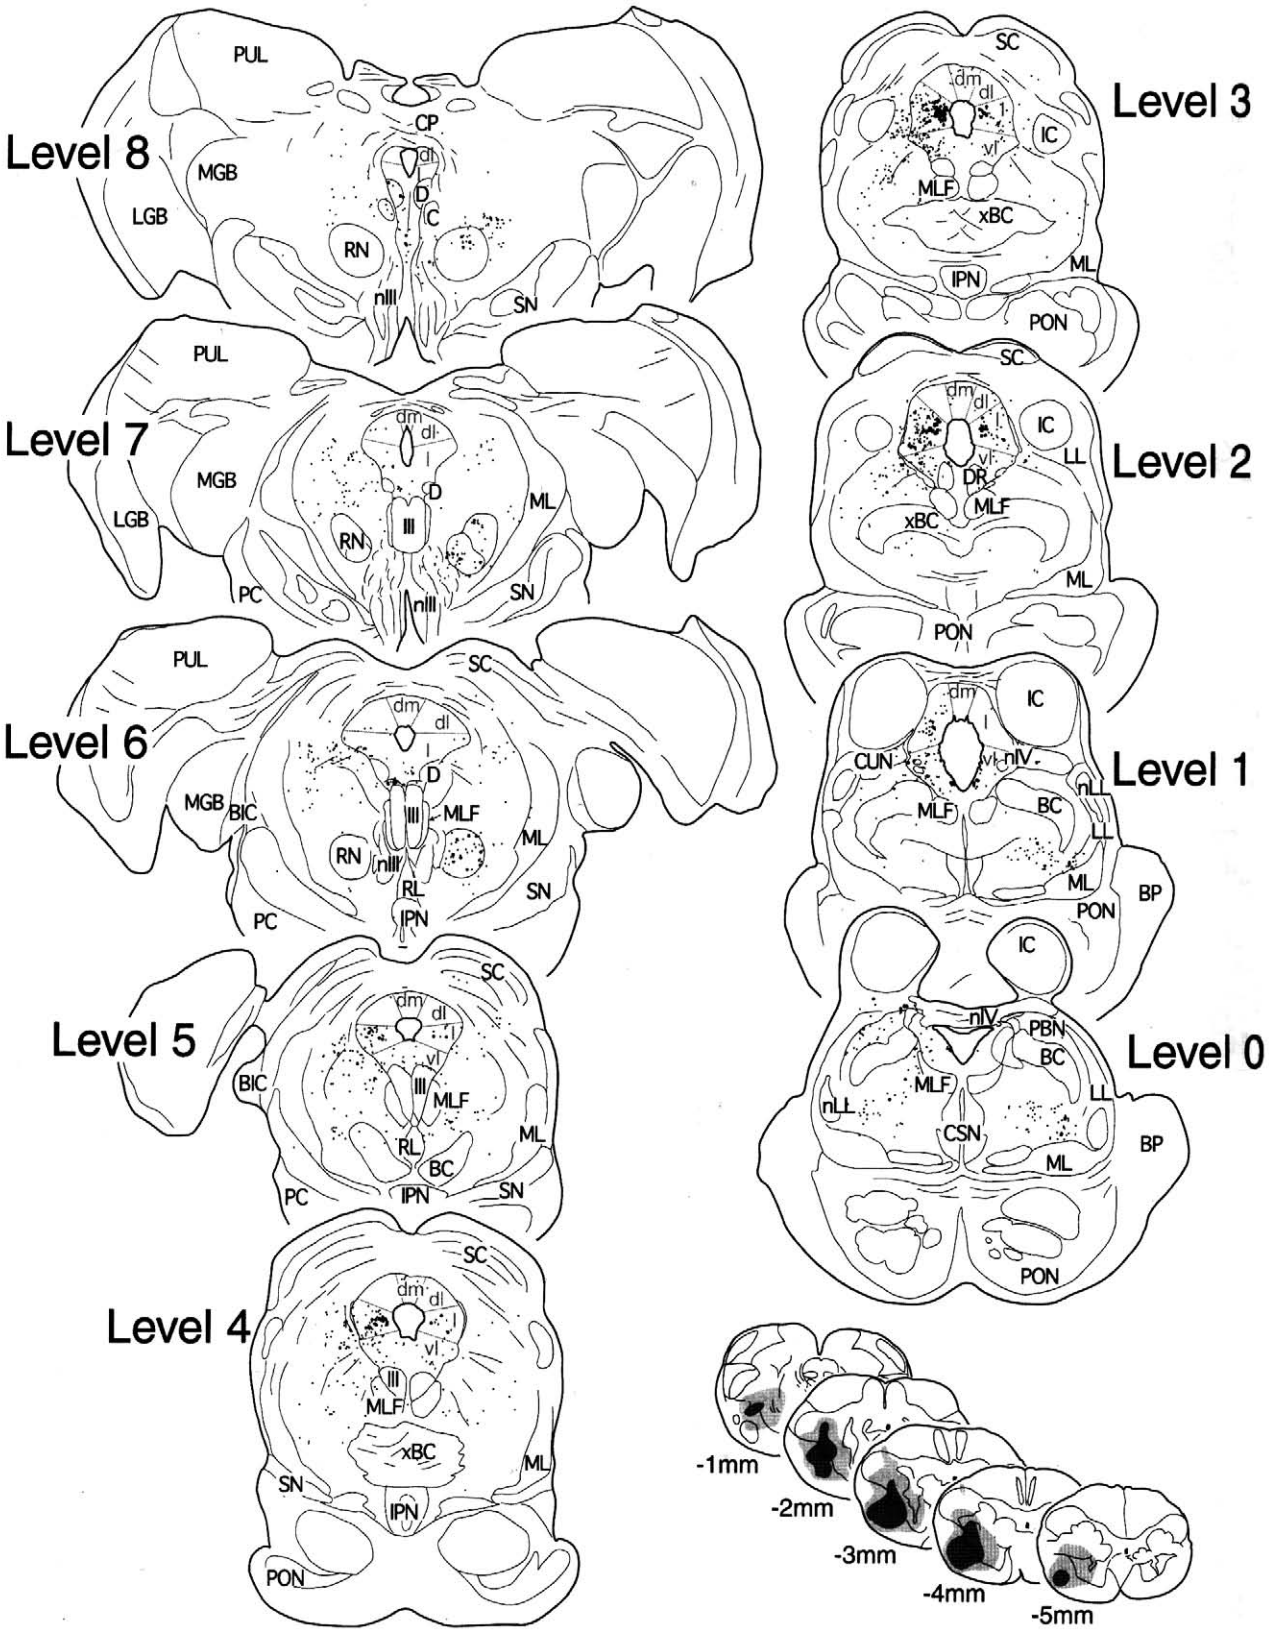

FIGURE 12.11 Distribution of retrogradely labeled neurons in the midbrain of a rhesus monkey after a wheat germ agglutinin–horseradish peroxidase (WGA-HRP) injection in the retroambiguus nucleus. The labeled cells are found mainly in the lateral PAG column. Adapted from Van der Horst *et al*. (2000, figure 3, p. 256).

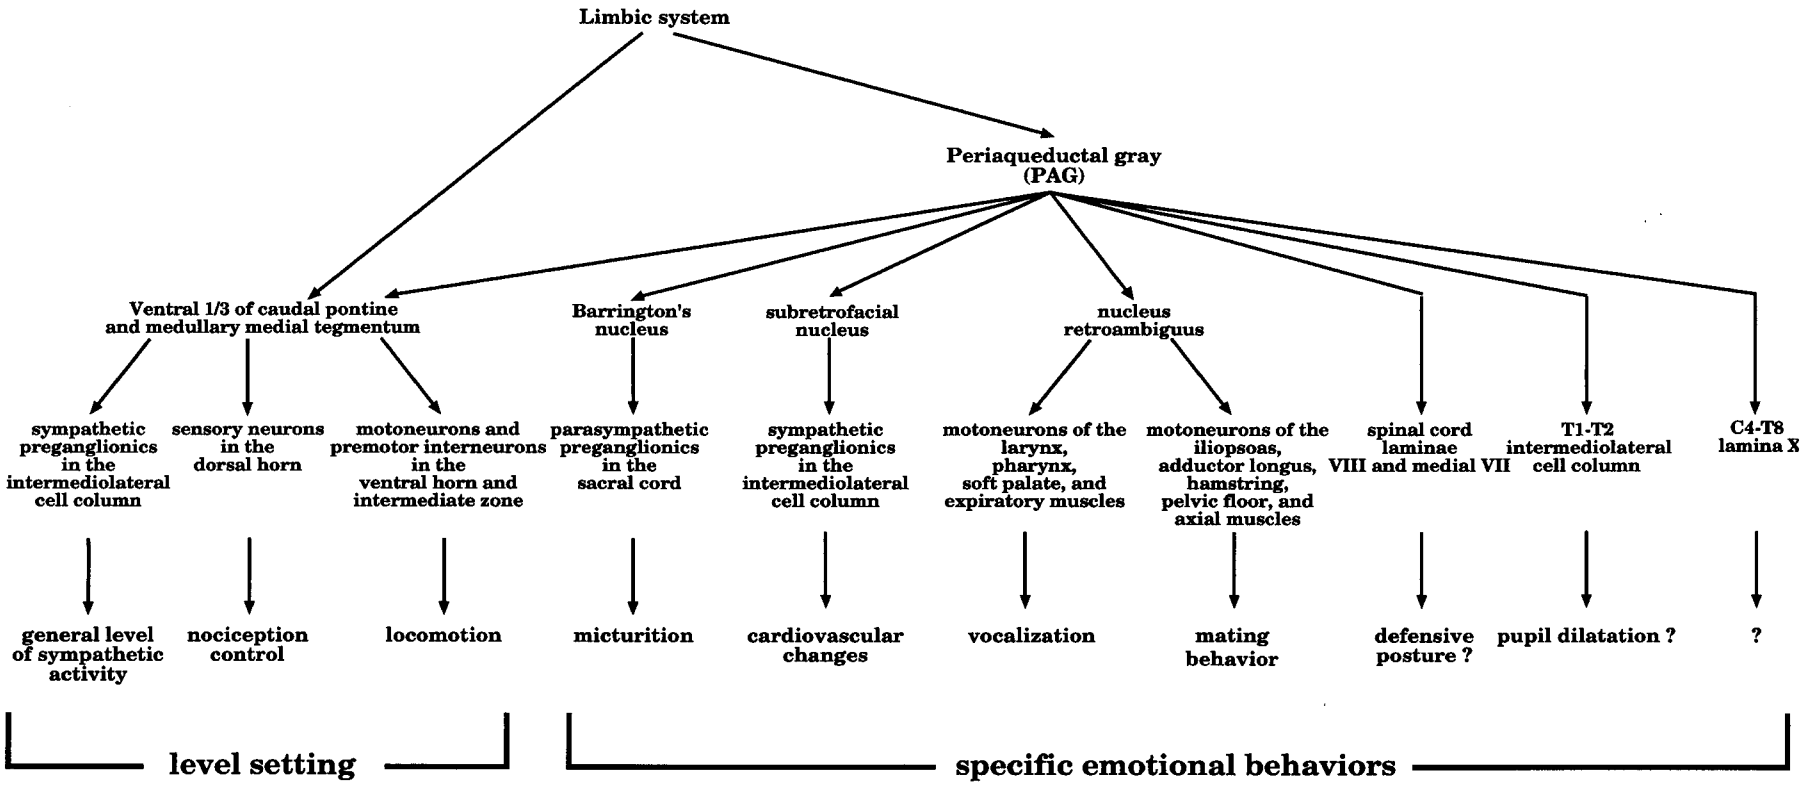

FIGURE 12.12 Schematic overview of the descending projections from the PAG to premotor centers of the caudal brain stem and to the spinal cord. The functions or possible functions of each projection is also indicated. From Holstege (1998, figure 2, p. 105).

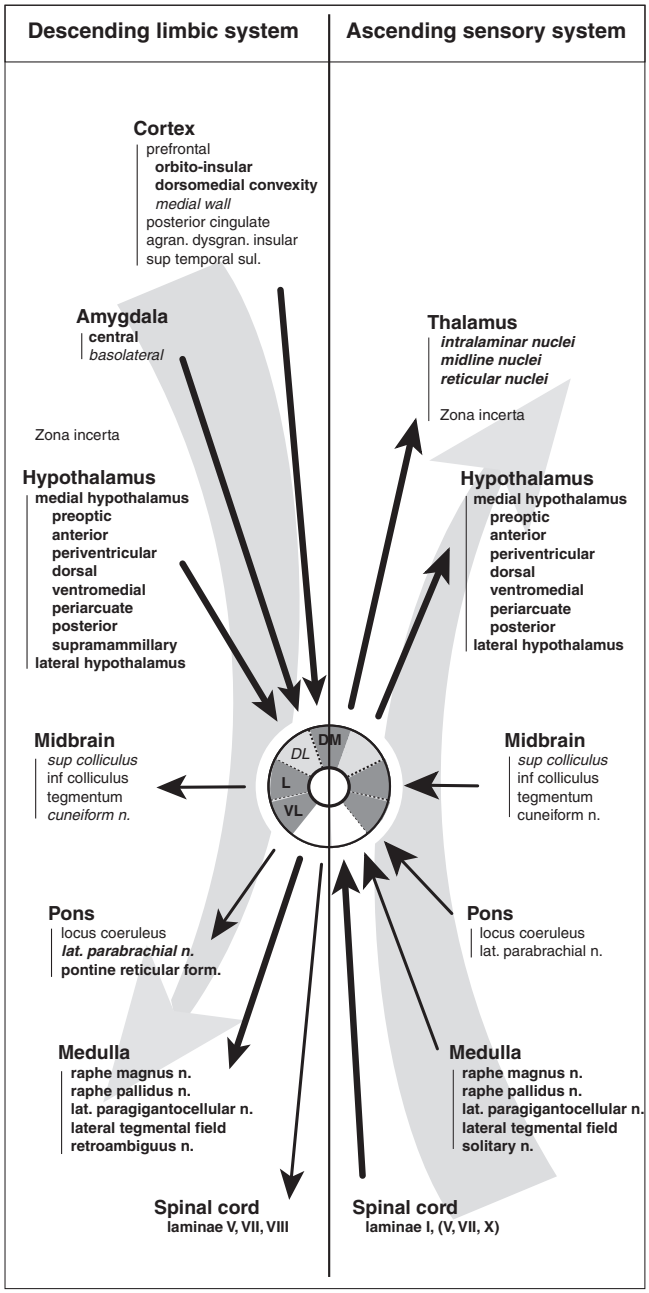

FIGURE 12.13 Schematic overview of the organization of PAG afferent and efferent connections. Represented on the left are the connections forming the descending limbic system and on the right are the connections forming the ascending sensory system. The two systems interact in the PAG. Structures indicated in **bold** are connected to either the dorsomedial, lateral or ventrolateral columns or two of them or all of them. Structures indicated in *italic* are connected to the dorsolateral column. Structures indicated in ***bold and italic*** are connected to all four columns. The specific connections of the structures indicated in regular style have not been established.

and other more subtle somatosensory stimuli. On the other hand, the descending limbic motor system, which controls basic but coordinated emotional responses by acting on premotor centers, can be modulated by sensory input coming from the external or internal (visceral) world. This could contribute to the transformation of mood or emotional state into different patterns of defensive reactions. It is important to bear in mind this basic organization when considering the different functional aspects of the PAG (i.e., pain modulation, fear, defensive behavior, vocalization, and reproductive behavior).

Tracing studies also support the existence of the columns and confirm the chemical disparity between the dorsolateral column and the other three columns established by chemoarchitecture. Thus, the lateral, ventrolateral, and, to some extent, the dorsomedial columns not only have common chemoarchitectural features; they also share common inputs and outputs. They are the integrating centers located at the crossing of the ascending sensory and descending limbic systems mentioned above (Fig. 12.13), and appear to be responsible for the best-known functions of the PAG. In contrast, the dorsolateral column stands out by its different chemical features and by a separate set of connections. It receives an important input from the prefrontal cortex but no direct somatosensory input, and only projects to the thalamus and caudal midbrain. The role of the dorsolateral column and the functional significance of its connections are still unknown.

FUNCTIONAL ASPECTS

Methodology and Limitations

The PAG appears to contribute to a wide range of behavioral reactions in animals. These include pain modulation, defensive reactions, cardiovascular regulation, vocalization, and reproductive behavior (Bandler and Shipley, 1994; Behbehani, 1995). Despite this diverse and extensive research, several problems have made a clear understanding of PAG function difficult to obtain. First, the PAG is an anatomically complex structure (see preceding sections). Second, the different subdivisions of the PAG (i.e., the columns) probably contribute to different behavioral reactions. Third, the widely held view of the PAG as an "analgesia center" has inhibited a broader understanding of its function.

Much of what is known about the function of the human PAG has been revealed by examining the effects of electrical stimulation. In the mid-1970s neurosurgeons began targeting the PAG with stimulating electrodes

as a means of treating chronic pain patients. Although some patients found pain relief, many refused stimulation because of unpleasant side effects. Regardless of the outcome, these stimulation studies revealed two things that have contributed to a better understanding of the function of the PAG. First, the unpleasant side effects revealed that the PAG is more than an "analgesia center." Second, the function of the PAG in humans appears consistent with reports of PAG function in animal studies (see below).

Additional insights into the function of the PAG have been revealed by examining patients with damage to that area (Collins *et al.*, 1995; Esposito *et al.*, 1999). However, these case reports must be viewed with caution because the deficits associated with PAG damage could be caused by damage to or activation of adjacent structures. In particular, damage to the PAG is often associated with ocular deficits because of the close proximity of ocular nuclei (e.g., Edinger–Westphal nucleus) and fibers traversing the PAG to these nuclei.

More recently, imaging technology such as positron emission tomography has been used to address questions about PAG function. For the most part, these studies have examined PAG activity in response to application of noxious stimuli or the anticipation of such stimuli. Although these studies have been interpreted as evidence that the PAG is part of an endogenous analgesia system, the significance of PAG activation in response to noxious stimuli is difficult to deduce from these data alone.

Role of the Periaqueductal Gray in Pain Modulation

The view of the PAG as an analgesia center dates back to a 1969 study in rats showing that PAG stimulation produced analgesia sufficient to perform abdominal surgery (Reynolds, 1969). Subsequent studies confirmed and extended this finding showing that (1) PAG stimulation inhibited the activity of nociceptive neurons in the dorsal horn of the spinal cord (Liebeskind *et al.*, 1973); (2) analgesia occurred in the absence of other behavioral effects (Mayer *et al.*, 1971); and (3) administration of the opiate antagonist naloxone attenuated PAG-mediated antinociception (Akil *et al.*, 1976). Although all three of these findings have been challenged (Cannon *et al.*, 1982; Gebhart and Jones, 1988; Klatt *et al.*, 1988; Morgan *et al.*, 1998; Thorn *et al.*, 1989), these early reports contributed to the view of the PAG as part of an endogenous analgesia system and led to the development of PAG stimulation as a treatment for chronic pain in humans (see also Chapter 30).

The first two papers describing PAG stimulation as a treatment for chronic pain reported positive results (Hosobuchi *et al.*, 1977; Richardson and Akil, 1977a). Not only did this enhance the view of the PAG as an analgesia center, but it encouraged other groups to target the PAG for stimulation as a treatment for chronic pain. Although the efficacy of brain stimulation to treat pain reported in subsequent studies varied greatly (Table 12.1), one point of agreement was that the more rostrally located periventricular gray (PVG) was a much more effective target than the PAG. Although the efficacy of brain stimulation is limited by medical problems caused by the electrode regardless of stimulation site (e.g., infection), the success of PAG stimulation is limited further by unpleasant side effects produced by the stimulation.

Table 12.1 shows that the long-term success rate for PAG stimulation is between 0 and 100%. Given that the goal is to reduce a patient's pain, the neurosurgeons optimize success using two approaches. First, surgery is carried out in awake patients so that the effects of stimulation at different sites can be determined and the electrode can be implanted in the most effective location. Second, multiple electrodes are implanted in each patient to maximize the chance of success. Optimistically high success rates may result when clear criteria for pain relief are not defined and when tests of efficacy are not carried out using blind procedures. Thus, the success of PAG stimulation in pain management is almost surely overstated. On the other hand, brain stimulation is only used to treat pain in the most severe cases, so that any success is noteworthy and of value to the patient. It should be noted that recent advances in intracerebroventricular and intrathecal administration of opioids has reduced the need for brain stimulation as a treatment for chronic pain (Gybels *et al.*, 1993).

Although the PVG and PAG form a seemingly continuous structure surrounding the third ventricle and aqueduct, the PVG has become the preferred site of stimulation because of the unpleasant side effects accompanying PAG stimulation. These effects can be so aversive that chronic pain patients refuse to stimulate the PAG despite a resultant reduction in pain (Boivie and Meyerson, 1982). Aversive reactions and antinociception also have been reported to co-occur with stimulation of the lateral and dorsal regions of the PAG in rats (Di Scala *et al.*, 1987; Fardin *et al.*, 1984; Morgan *et al.*, 1998; Prado and Roberts, 1985; Sandner *et al.*, 1987). However, these aversive reactions do not appear to cause analgesia (e.g., stress-induced antinociception) as has been postulated (Sandner *et al.*, 1987). Administration of the anxiolytic diazepam attenuates PAG evoked aversive reactions without

TABLE 12.1 Short and Long-Term Efficacy of Periaqueductal Gray Stimulation for the Management of Chronic Pain

Citation	Number of Patients	Initial Success[a]	Long Term Success	Notes

[a]Initial success refers to the number of electrodes that were internalized as a result of pain inhibition during surgery.
PAG, periaqueductal gray; PVG, periventricular gray.

blocking stimulation-produced antinociception (Morgan *et al.*, 1987).

An important question is whether some regions of the human PAG will support stimulation-produced analgesia in the absence of unpleasant side effects. The anatomical subdivisions of the PAG described earlier in this chapter suggest functional differences. Because of ethical considerations, systematic mapping of the human PAG has not been carried out. Although the electrodes implanted into humans typically have four active sites, each separated by a millimeter or two, they are typically implanted in such a way that they are oriented along a single PAG column as opposed to across columns (see Gybels *et al.*, 1980; Richardson and Akil, 1977a). In the rat, pronounced differences in antinociception are produced simply by shifting stimulation from the lateral to ventrolateral column (Morgan, 1991). The most obvious difference is that activation of the lateral PAG in rats produces aversive reactions whereas activation of the ventrolateral PAG in the rat produces antinociception in the absence of any obvious aversive reaction (Fardin *et al.*, 1984; Morgan *et al.*, 1998).

In addition, differences in the characteristics of the antinociception mediated by the ventrolateral and more dorsal regions of the rat PAG have been reported (Morgan, 1991). The opioid antagonist naloxone attenuates the antinociception mediated by the ventrolateral but not more dorsal regions of the PAG (Cannon *et al.*, 1982; Thorn *et al.*, 1989). Another provocative difference is that the antinociception mediated by lateral and dorsal regions of the PAG appears resistant to tolerance in comparison with the antinociception mediated by the ventrolateral PAG. This has been demonstrated with both electrical stimulation (Morgan and Liebeskind, 1987) and morphine microinjections (Tortorici *et al.*, 1999). Finally, the ventrolateral PAG appears to modulate nociception via both ascending and descending pathways, whereas the antinociception mediated by the lateral and dorsal regions appear to follow a descending pathway only (Morgan *et al.*, 1989). If a similar functional organization exists in the human PAG, one might predict that stimulation of the ventrolateral PAG would produce more manageable pain relief than stimulation of the lateral PAG. It would be of great interest to carry out studies comparing stimulation of the lateral and ventrolateral PAG in humans.

Role of the Human Periaqueductal Gray in Emotion

The unpleasant sensations produced by PAG stimulation demonstrate that the PAG is much more than an analgesia center. Although the precise description of the sensations evoked by PAG stimulation vary from patient to patient and study to study (Table 12.2), the common element is an unpleasant sensation centered along the core of the

TABLE 12.2 Sensations Evoked from Periaqueductal Gray Stimulation

Nashold, Wilson, and Slaughter, 1969 (9 patients):
- "The patient also experienced an additional feeling described as fear which was so unpleasant that she was not willing to tolerate repeated stimulations."
- "… complain of vague bilateral sensations experienced as a 'choking' feeling referred into the chest."
- "In man, the feelings evoked from the central gray stimulation had a quality which he described as 'fearful,' 'frightful,' or 'terrible,' and he would not allow further stimulations."

Richardson and Akil, 1977 (4 patients):
- "… slight dizziness and shortness of breath …"
- "… numerous undesirable side effects, including nystagmus, nausea, vertigo, and a feeling of a 'rising vapor.'"
- "… increasing the stimulation above a certain level led to reports of poorly described noxious effects, such as discomfort, oppressiveness, or anxiety."

Cosyns and Gybels, 1979 (3 patients)
- "All patients displayed, on stimulation, an aversive emotional response which could outlast the stimulation itself."
- "The patients describe it as unpleasant and giving them feelings of anxiety and panic …"
- "All emotions were also bodily felt in the abdomen, chest, or head …"

Amano *et al.*, 1980 (8 patients):
- "… patients had a strong fear sensation on high frequency electrical stimulation …"
- "… patients complained of dizziness and unpleasant feeling … on low frequency stimulation …"

Amano *et al.*, 1982 (14 patients):
- "… substantial rise in pulse rate and systolic blood pressure (up to 50% increase). Bilaterally dilated pupils and flushing of the face were seen."
- "the patients suddenly expressed very strong fear sensation and a burning, hot feeling of the entire body. All of them appeared to be in a confused and acutely perplexed state."
- "The patients described themselves, 'Something horrible is coming', 'Somebody is now chasing me, I am trying to escape from him.'"
- "… he had an abrupt feeling of uncertainty 'just like entering into a long, dark tunnel.'"

Hosobuchi, 1987 (7 patients):
- "Five patients reported a significantly unpleasant sensation associated with stimulation …"
- "Five of the seven patients reported nausea, and four reported fright or a 'funny feeling' …"

body (from the bladder to inside the head). These sensations are so unpleasant that patients would rather endure chronic pain than receive stimulation of the PAG (Boivie and Meyerson, 1982). In contrast, stimulation of the more rostrally located PVG has been reported to have no effect (Hosobuchi, 1986) or to produce a warm or cold sensation throughout the body (Adams, 1977; Kumar and Wyant, 1985). These sensations are possibly a result of activation of the ascending sensory system, which relays in the lateral and ventrolateral PAG. As shown in Fig. 12.13, this system originates from lamina I of the spinal cord and terminates in the thalamus.

Fear and Defensive Behavior

PAG stimulation also produces sensations of fear, anxiety, and danger (Table 12.2). The stimulation was immediately stopped when these sensations occurred. Had they been prolonged they would certainly have led to strong behavioral responses. The co-occurrence of fear and antinociception suggests the PAG may contribute to defensive reactions. This hypothesis is supported by imaging studies showing that noxious stimulation or anticipation of a noxious stimulus activates the PAG (Hsieh *et al.*, 1996; Iadarola *et al.*, 1998; Kupers *et al.*, 2000). Noxious stimuli are threatening and have been shown to evoke defensive reactions (Fanselow, 1991). However, whether the noxious stimuli used in these studies are sufficient to evoke defensive reactions is debatable, so that these imaging data must be interpreted cautiously.

In contrast, behavioral studies in rats provide convincing evidence that the PAG contributes to defensive reactions. Fight-or-flight defense is evoked by attack from a predator or conspecific. A similar response consisting of explosive running and jumping is evoked upon activation of the lateral or dorsal regions of the caudal PAG (Fardin *et al.*, 1984; Morgan *et al.*, 1998; Sandner *et al.*, 1987). In addition, activation of the lateral PAG column produces cardiovascular changes consistent with defense. These include an increase in heart rate, blood pressure, and respiration, and a shift in blood flow from the viscera to the hindlimb muscles (Carrive and Bandler, 1991; Carrive *et al.*, 1987, 1989). Moreover, these coordinated responses can be evoked from precollicular decerebrate cats, indicating that such responses are integrated at the level of the PAG, not above. These responses are expressed via the lower part of the descending limbic system, i.e., the descending projections to the premotor centers of the lower brain stem, as indicated in Figure 12.12.

Fear can also induce a defensive reaction in rats known as freezing. Defensive freezing is a species-specific response produced by a threatening situation (Fanselow, 1991). A number of findings suggest that the ventrolateral column of the PAG contributes to this response. Activation of the ventrolateral PAG produces immobility (Depaulis *et al.*, 1994; Morgan *et al.*, 1998). Inactivation of the ventral PAG prevents the antinociception and immobility produced by placing

a rat in a frightening environment (Helmstetter and Tershner, 1994; Kim *et al.*, 1993; LeDoux *et al.*, 1988; Liebman *et al.*, 1970). Finally, placing a rat in an environment that induces defensive freezing activates neurons in the ventrolateral PAG as measured by c-fos-like immunoreactivity (Carrive *et al.*, 1997). Although the lateral and ventrolateral columns exist within the human PAG (see sections above), whether these regions correspond to functionally distinct types of defense as in the rat is open to speculation (Bandler *et al.*, 2000).

Vocalization and Reproductive Behavior

Although most of what is known about the PAG in humans focuses on analgesia and emotional reactions, animal studies indicate the PAG contributes to a number of other behaviors such as vocalization and reproduction (Fig. 12.12) (Bandler and Shipley, 1994; Behbehani, 1995; see also Chapter 36). The vocalization data are of particular interest because activation of the PAG evokes naturally occurring vocalizations in a wide range of species such as rat (Waldbillig, 1975), cat (Bandler and Carrive, 1988), and squirrel monkey (Jürgens and Ploog, 1970). Some of these vocalizations can be explained as part of PAG-mediated emotional (Table 12.2) and defensive responses (Bandler and Carrive, 1988), although stimulation of the ventrolateral PAG of the squirrel monkey elicits cooing and growling, vocalizations associated with comfort and dominance calls (Jürgens, 1991). PAG lesions also produce mutism in many species, including monkey (Jürgens, 1994) and human (Esposito *et al.*, 1999). Moreover, PAG lesions disrupt vocalizations evoked from higher brain structures such as the anterior cingulate cortex and amygdala (Jürgens and Pratt, 1979). In contrast, such lesions do not block vocal fold movements evoked from the facial motor cortex (Jürgens and Zwirner, 1996). Thus, two separate vocal pathways have been proposed: (1) a limbic one that relays in the PAG for nonverbal emotional vocal expression, and (2) a neocortical one that does not relay in PAG for the production of learned vocal patterns (Jürgens and Zwirner, 1996). The neocortical pathway is obviously crucial for human speech. However, the production of well-coordinated and intonated speech and in particular singing may require that the limbic pathway (the descending limbic system in Fig. 12.13) and the PAG be active as well (Davis *et al.*, 1996). As suggested by Davis *et al.* (1996), the role of the PAG may be to act as a generator and integrator of specific respiratory and laryngeal motor patterns to permit proper expression of the neocortical output. This would be made possible through the PAG's projections to the lower brain stem and in particular to the retroambiguus nucleus, which controls laryngeal motoneurons (Van der Horst *et al.*, 2000) (see Fig 12.12). This may be orchestrated by the lateral PAG column because it is a main target of the anterior cingulate gyrus and the amygdala and the main source of afferents to the retroambiguus nucleus (Fig. 12.13).

The PAG has been implicated in reproductive behavior in rat and cat, mainly as a coordinating center for mediating lordosis in the female (Pfaff *et al.*, 1994; Van der Horst and Holstege, 1998). This behavior, which may be seen as a form of emotional response, is thought to be mediated by PAG projections to the retroambiguus nucleus and rostral ventral medulla and to be the result of convergent influences in the PAG from limbic structures (especially hypothalamus), sex steroids, and sensory input from the perineum and pelvic viscera (Van der Horst and Holstege, 1998). Indeed, the sacral input to the PAG in the cat originates from dorsal horn regions that receive pelvic and pudendal sensory afferents (Van der Horst *et al.*, 1996). However, there is no evidence of any PAG involvement in reproductive behavior in the monkey and apparently no related comment has been made from human patients receiving PAG stimulation.

Finally it should be mentioned that the PAG has been implicated in micturition (Blok and Holstege, 1998) and that PET studies reveal activation of the PAG during micturition (Blok *et al.*, 1997).

CONCLUSION

In this chapter, we have presented anatomical evidences that the human PAG is not a homogeneous structure. Behind a deceiving cytoarchitecture lies a chemical organization that suggests the existence of four longitudinal columns located dorsomedial, dorsolateral, lateral, and ventrolateral to the aqueduct. The boundaries are revealed by a number of neurochemical markers like NADPH-diaphorase or ACTH-containing fibers. These columns appear to be important features as they are conserved across mammalian species. Furthermore, the afferent and efferent connections of the PAG are organized along these same columns. Although anatomical techniques prevent these connections from being demonstrated in humans, it is very likely that they exist because they are basically the same from rat to monkey. From these connections, it appears that the PAG is located at the crossroads of an ascending sensory system relaying noxious input and a descending limbic system organizing emotional responses. This seems clear at least for the lateral, ventrolateral, and dorsomedial columns, which share many common features. In

contrast, the dorsolateral PAG appears to have more in common with the deep and intermediate layers of the superior colliculus than with the other three columns. From a functional point of view, the PAG is one of the few brain structures that has been implanted with chronic electrodes and stimulated in awake human. The results of these studies indicate that the human PAG is involved in antinociception and aversive emotional responses—findings consistent with the anatomical connections. Although functional and anatomical data suggest the PAG is an important integrating center for coordinated emotional responses, the contribution of the various columns to these responses in human remains largely unknown. Such information requires the development of better functional imaging techniques with sufficient resolution to separate the different columns.

CHAPTER

13

Raphe Nuclei

JEAN-PIERRE HORNUNG
Institut de Biologie Cellulaire et de Morphologie
University of Lausanne, Lausanne, Switzerland

The *raphe nuclei* constitute a collection of cell groups distributed in the midline region of the tegmentum, from the rostral midbrain to the spinal cord transition at the pyramidal tract decussation. The term *raphe* refers to a seam or a ridge along the midsagittal plane of the body where left and right side structures fuse or join. In the brain stem, the union of both sides along the midline region is underlined by the crossing of numerous tracts, the most prominent ones being the decussation of the superior cerebellar tract in the mesencephalon, and, in the medulla oblongata, the medial lemniscal and the corticospinal decussations. As a result, cell density in raphe nuclei varies greatly between regions, with sharp cytoarchitectonic boundaries for the dorsal raphe nucleus and ill-defined limits for the midline caudal nuclei. Collectively, the raphe nuclei are part of the reticular formation bordering the midline, and are referred to as the *median division of the reticular formation* (Brodal, 1981; see also Chapter 10). At variance to the other raphe nuclei, the dorsal raphe nucleus is located dorsal to the medial longitudinal fasciculus, in the ventral periaqueductal gray.

Divisions of the raphe nuclei, first based on cytoarchitectonic features, were described in nonhuman species (Meessen and Olszewski, 1949; Taber *et al.*, 1960), and in humans (Olszewski and Baxter, 1954). With the availability of new histofluorescence techniques to reveal the bioamines in histological preparations, Dahlström and Fuxe (1964) reported that serotonergic neurons were mainly located near the midline in the brain stem. There has been thereafter an extension in the use of the term *raphe nuclei* to define the source of the serotonergic projections in the brain. Since the serotonin-containing cell groups revealed with this histochemical technique did not coincide entirely with known cytoarchitectonic divisions of the brain stem, these cell groups were designated B1–B9, ordered from caudal to rostral. It was demonstrated later by a range of methods and in various mammalian species that most serotonin-containing neurons are located in the raphe nuclei, with a population extending laterally in the medial and lateral reticular formation (Poitras and Parent, 1978; Wiklund, 1981; Steinbusch, 1981; Jacobs *et al.*, 1984; Törk, 1990; *et al.*, 1997). The higher proportion of serotonergic neurons positioned laterally to the median division of the

reticular formation is a characteristic feature of the primate brain, including human (Nobin and Björklund, 1973; Hubbard and diCarlo, 1974; Schoefield and Everitt, 1981; Schoefield and Dixon, 1982; Felten and Sladek, 1983; Azmitia and Gannon, 1986; Takahashi *et al.*, 1986; Hornung and Fritschy, 1988).

The presence in the human brain of serotonin and of its synthetic and degradation enzymatic systems had been well established (Costa and Aprison, 1958; Beskow *et al.*, 1976; Yamaguchi *et al.*, 1981) prior to its cytological localization. Direct visualization of serotonin in the human brain stem by histofluorescence or immunocytochemical techniques could not be applied to postmortem material because serotonin rapidly dissipates from the neurons after death. This applies to all monoamines and amino acids acting as neurotransmitters in the brain, whereas neuropeptides and enzymes specific for neurotransmitter metabolism could still be detected. The problem of postmortem serotonin dissipation could be circumvented by the use of fetal brain tissue, which could be rapidly frozen or fixed for histochemical (Nobin and Björklund, 1973; Olson *et al.*, 1973) or immunocytochemical (Takahashi *et al.*, 1986) studies. For the adult human brain, early studies relied on the aldehyde-fuchsin technique (Braak, 1970). Although not specific for the serotonergic neurons, it clearly delineated the cellular nuclei of the raphe. Alternatively, serotonergic neurons could be specifically stained by immunocytochemical detection of the degradation enzyme monoamine oxidase B (MAO B) (Konradi *et al.*, 1988) or antibodies recognizing the synthetic enzyme tryptophan hydroxylase (Haan *et al.*, 1987).

Since most serotonergic neurons are located in the raphe nuclei, "raphe" refers either to the cytoarchitectonic parcellation of the median division of the brain stem reticular formation, or to the chemoarchitectonic parcellation of the serotonergic neurons, in all mediolateral compartments of the brain stem. The raphe nuclei and the serotonergic system of common laboratory animals have been the subject of several detailed reviews that deal with the topography and aspects of the hodology of the serotonergic neural systems (Jacobowitz and MacLean, 1978; Wiklund *et al.*, 1981; Pecci-Saavedra *et al.*, 1983; Steinbusch and Nieuwenhuis, 1983; Jacobs *et al.*, 1984; Azmitia and Gannon, 1986; Hornung and Fritschy, 1988; Törk, 1995). In the raphe nuclei, the proportion of neurons synthesizing serotonin ranges from about 80% in the dorsal raphe nucleus to 10–20% in medullary raphe nuclei. Numerous neurotransmitters (amino acids, monoamines, peptides) have been localized in raphe neurons, some of them even colocalized in serotonergic neurons. In the present account, the cyto- and chemoarchitecture of the raphe nuclei will be systematically described, following the rostrocaudal axis. In addition, the median and lateral distribution of serotonergic neurons at each level of the brain stem will also be described. The connectivity of the raphe nuclei will be reported in a subsequent section.

The material used for the illustrations on this chapter came from publications describing the cyto- and chemoarchitecture of the human raphe nuclei (Halliday *et al.*, 1988a, 1990; Törk and Hornung, 1990; Baker *et al.*, 1991a, b). Human brain stem material was obtained from formalin-fixed autopsy material of patients without any clinical history of neurological disease. Adjacent sections were immunoreacted to visualize serotonin-synthesizing neurons or catecholamine-synthesizing neurons, stained for Nissl substance or for myelinated fibers. In the case of one brain stem, the immunohistochemically stained cells of every eighth section were plotted and digitized. In the reconstruction, the size and shape of the raphe nuclei could be visualized and the number of their neurons estimated (Hornung and Kraftsik, 1988). The serotonergic innervation of the human cerebral cortex was studied in freshly collected biopsies from patients surgically treated for brain tumors (Hornung and de Tribolet, 1995). Care was taken to collect samples at the margin of the resected pathological tissue, following a procedure in compliance with regulations of the local ethics committee.

DIVISIONS OF THE RAPHE NUCLEI

Caudal Linear Nucleus

The caudal linear nucleus (CLi) is a subnucleus of the ventral mesencephalic tegmentum (Halliday and Törk, 1986). It is located dorsal and caudal to the interpeduncular nucleus, on the midline between the two red nuclei. Posteriorly, the nucleus ends along the anterodorsal surface of the superior cerebellar peduncle decussation, which results in a ventral-to-dorsal shift of its caudal end. At the level of the medial longitudinal fasciculi, CLi merges with the interfascicular part of the dorsal raphe nucleus. The characteristic cytological feature of the CLi is the alignment of the dendrites parallel with the midline, with their major extensions in the rostral and caudal directions.

The CLi contains a large population of serotonergic neurons. This is the most rostral nucleus of the raphe system containing serotonin-synthesizing neurons in humans. The TPH-immunoreactive neurons are found between the levels of the red nuclei and the decussation of the superior cerebellar peduncles, with a gradual increase in cell density from rostral to caudal. These

neurons have small to medium soma and dendrites oriented parallel to the rostrocaudal axis. The most rostral serotonergic neurons in the human (Törk and Hornung, 1990), as in other primates (Azmitia and Gannon, 1986; Hornung and Fritschy, 1988), are located in the rostral part of the interpeduncular nucleus. These neurons have a distinctive multipolar dendritic morphology contrasting with the serotonergic neurons in the CLi.

Among the heterogeneous population of CLi neurons, there are pigmented dopaminergic neurons, immunoreactive for tyrosine hydroxylase (TH), and substance P (SP)–containing neurons. The latter are large-to-medium neurons with round or triangular somata (Halliday *et al.*, 1990).

Dorsal Raphe Nucleus

The dorsal raphe nucleus (DR) lies in the ventral part of the central gray matter of the mesencephalon and rostral pons (Fig. 12.1). It has long been recognized by its accumulation of large, darkly stained neurons in Nissl preparations (Kölliker, 1893). The main body of the DR lies dorsal to the caudal end of the oculomotor nucleus and to the trochlear nucleus (Baker *et al.*, 1992). The nucleus is subdivided in the midline region in a ventral part (DRV), at the bottom of the central gray, and an interfascicular part (DRI) between the trochlear nucleus and medial longitudinal fasciculus. The latter is continuous anteriorly with the CLi and stops caudally at the level of transition from the aqueduct to the rostral opening into the fourth ventricle. There are in addition three large subnuclei central to periaqueductal gray (PAG): the dorsal (DRD), the ventral (DRV), and the ventrolateral (DRVL) parts. Caudal to the isthmus of the brain stem, the portion of the DR in the PAG is reduced to two slits of neurons parallel to the ventricular surface of the anterior rhomboïd fossa, bordered laterally by the lateral tegmental nucleus, and extending caudally up to the level of the trigeminal motor nucleus; this is the caudal division of the DR (DRC). These subdivisions can be seen in Chapter 10.

The DR contains the largest population of serotonergic neurons in the human brain stem, amounting to an estimated 165,000 neurons (Baker *et al.*, 1991). Serotonergic neurons are found in all subdivisions of the DR, in different proportions of the total neuronal population estimated in adjacent Nissl-stained sections. Neurons rostral to the isthmus constitute the B7 group of Dahlström and Fuxe (1964), and those caudal to the isthmus the B6 group. The largest population of serotonergic neurons is in the DRD (28% of the total number of serotonergic neurons of DR, and 61% of all the DRD neurons). The remaining divisions of the DR amount to 16–22% of the total serotonergic population each. In the DRI, 100% of the neurons are serotonergic; in the DRV, 82%; and in the other divisions of the DR, around 60%. The serotonergic neurons in DRI have dendrites oriented parallel with the midline, a morphology similar to that of the serotonergic neurons in the CLi. This similarity is further accentuated by the fact that CLi is continuous with the DRI subdivision. Neurons in the DRVL are multipolar and densely packed. In the DRD, neurons are loosely arranged, medium sized, with radiating smooth dendrites. In the DRC, serotonergic neurons have smaller somatic diameter, with short dendrites often oriented parallel with the floor of the fourth ventricle.

Several neurotransmitters have been identified in the DR. Among the γ-aminobutyric acid (GABA)–containing neurons in the DR, very few colocalize with 5-hydroxytryptamine (Wang and Nakai, 1993; Stamp and Semba, 1995; Charara and Parent, 1998). The distribution of SP and catecholamine is restricted to the rostral DR (B7 group). There is a high proportion of large-to-medium SP-IR neurons with morphologies similar to the serotonergic neurons. The cumulative proportion of SP- and serotonin-containing neurons exceeds the total neuronal population estimated in Nissl-stained preparation of the DR. This is strong indirect evidence for the colocalization of serotonin and SP in the same neurons, this for almost 40% of the serotonergic neurons (Baker *et al.*, 1991b). There are only few catecholaminergic neurons, of variable morphologies, scattered in the rostral DR. There are also a few neurons containing the neuropeptides dynorphin, angiotensin, and enkephalin (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990). In DRC, there is a dense and restricted population of neurotensin-containing neurons (Jennes *et al.*, 1982).

Median Raphe Nucleus and Pontomesencephalic Reticular Formation

Median Raphe Nucleus

The median raphe nucleus (MnR) extends from the decussation of the superior cerebellar peduncles to the middle pons at the level of the trigeminal motor nucleus. Dorsally, the MnR ends below the medial longitudinal fasciculus and ventrally at the bottom of the midline tegmental region (Baker *et al.*, 1991). The MnR is divided in a dorsal, midline, and paramedian cluster. In the caudal two-thirds of the MnR, the midline division is bordered by a paramedian cell cluster that lies at the medial border of the lateral cell cluster.

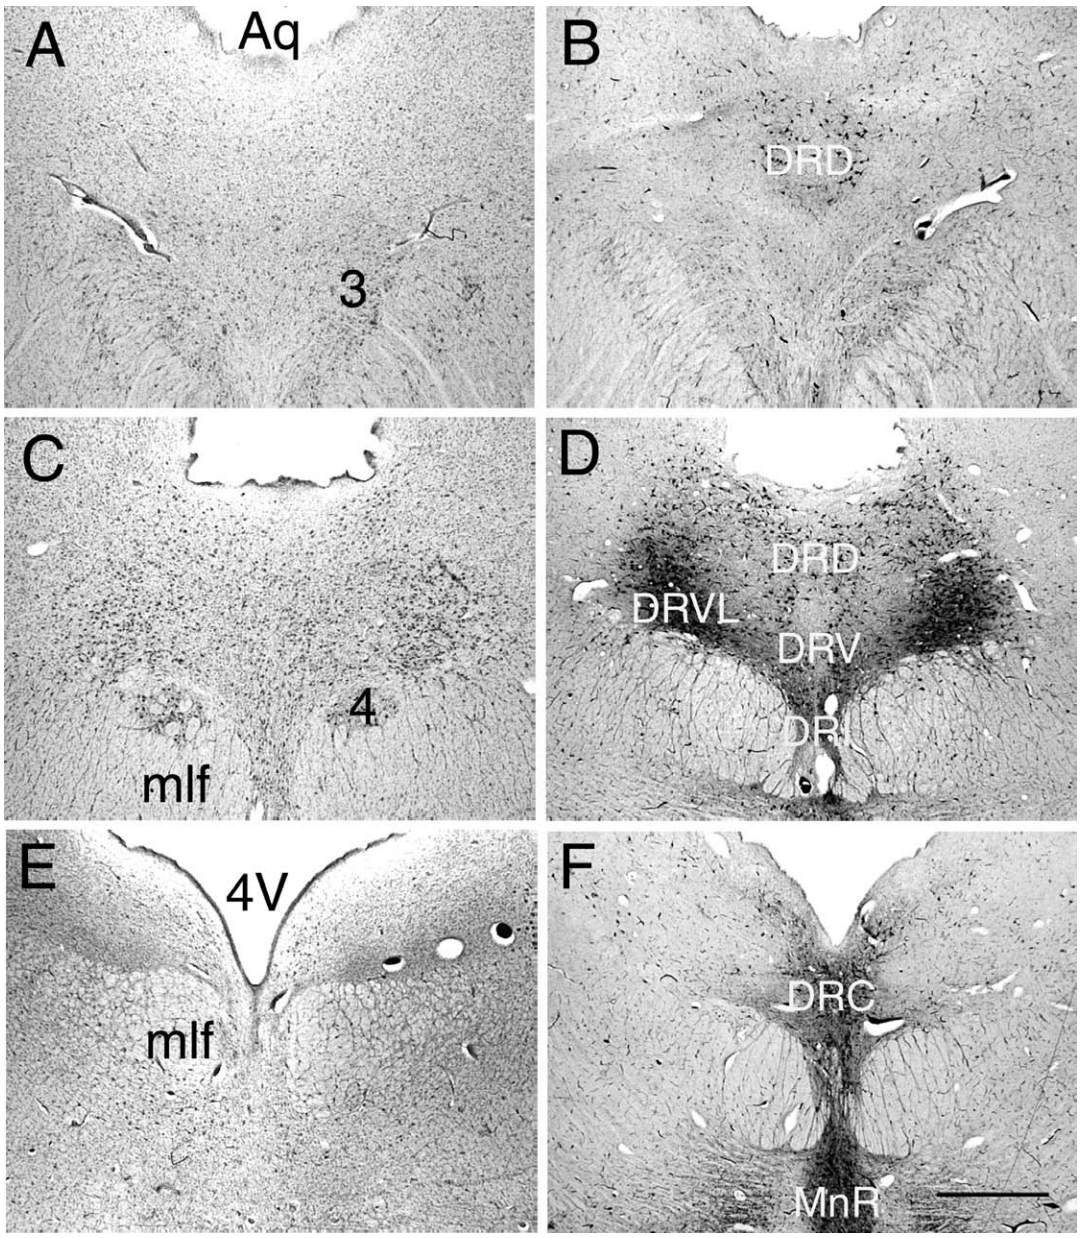

FIGURE 13.1 Transverse sections of the DR stained for Nissl substance **(A, C, E)** and the corresponding levels immunostained for TPH **(B, D, F).** The rostral division of DR (A, B) is at the level of the oculomotor nucleus (3). DR is most developed (C, D) at the level of the trochlear nucleus (4), and ist caudal extension (E, F) overlies the MnR. Scale bar: 1.5 mm.

Since the median and paramedian clusters are poorly myelinated in comparison with the lateral reticular formation, these divisions are also well delineated in myelin-stained sections, at the contrary to the dorsal raphe nucleus which is poorly delineated with such a staining. There is a change in structure from rostral to caudal levels of the MnR. Rostrally, the MnR is restricted to a thin dorsoventral slit of neurons near the midline of the mesencephalon. In the rostral pons, the midline group is segregated in a dorsal division, with densely packed neurons, and a ventral one, with more loosely organized neurons. At the most caudal levels of the MnR, the midline neurons are sparse and the paramedian neurons are more diffusely distributed than at the more rostral levels. In the MnR, most neurons have dendrites oriented in the rostrocaudal direction, reminiscent of the ventral division of the DR. Rostrally, the fact that the vicinity of the DRI neurons

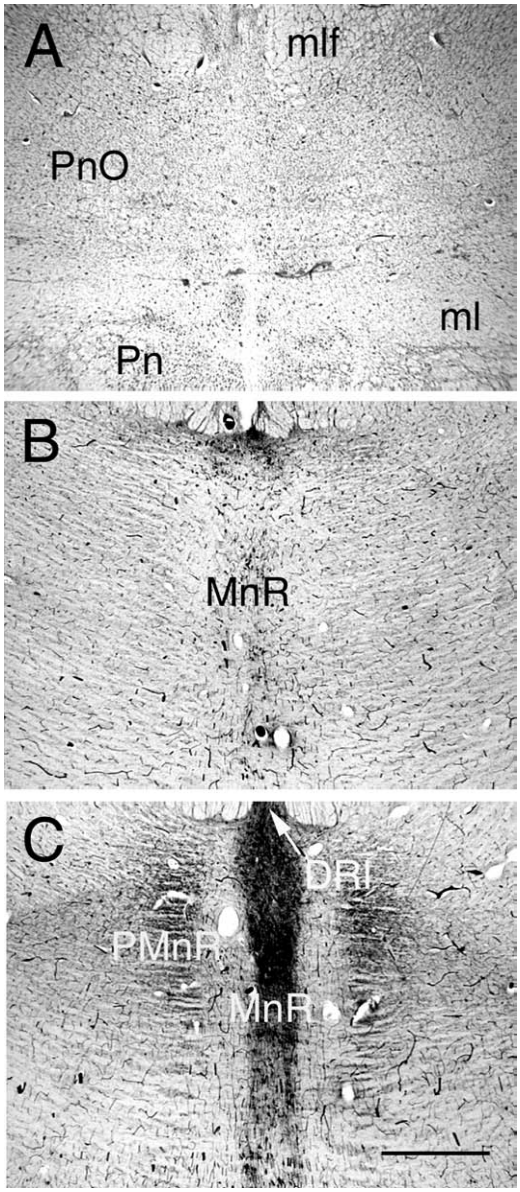

FIGURE 13.2 Transverse sections of the MnR at the level of the caudal mesencephalon **(A, B)** and the rostral pons **(C),** stained for Nissl substance (A) and immunostained for TPH (B, C). A: The MnR is bordered dorsally by the mlf, laterally by the PnO, and ventrally by the ml and the Pn. Rostrally (B), TPH-IR neurons are restricted to a midline stream of cells, whereas caudally (C), there is a major condensation of TPH-IR neurons on each side of the midline raphe (in PMnR) and scattered TPH-IR neurons are distributed even more laterally in the lateral reticular formation. Scale bar: 1.5 mm.

shares similar morphology makes the separation with the MnR somewhat arbitrary, although at most levels it is clearly delineated by small bundles of the medial longitudinal fasciculus. Neurons in the caudal division are characterized by a round somatic morphology and radially oriented dendrites (Fig. 12.2).

Serotonergic Neurons of the Pontomesencephalic Reticular Formation

In the pontomesencephalic region, serotonergic neurons have a wide distribution extending to two subdivisions of the lateral reticular region: the oral pontine nucleus (PnO) and the supralemniscal nucleus (SuL). The proportion of serotonergic neurons in the lateral reticular formation is highest in the primate brain, as compared to rodents and other mammalian species (Azmitia and Gannon, 1986), approaching amounts equal to the total number of serotonergic neurons in the MnR (Baker *et al.*, 1991). Serotonergic neurons in the lateral reticular formation are dispersed, with large radiating dendrites. There is a dorsal lateral extension of the serotonergic neurons surrounding the medial longitudinal fasciculus toward the lateral edge of the DR. This dorsal lateral extension spreads caudally toward the anteromedial limits of the locus coeruleus. The lateral extension of serotonergic neurons is reduced in the middle of the reticular formation traversed by the central tegmental tract. The ventral edge of the PnO is crossed by the fibers of the medial lemniscus. Serotonergic neurons are distributed laterally above the superior cerebellar peduncles in the ventral PnO. Ventrally relative to this peduncle, there is a second group of serotonergic neurons lying at the dorsal edge of the medial lemniscus in the SuL (Baker *et al.*, 1991a). In this latter location, neurons are often bipolar and their dendrites parallel with the dorsal limits of the medial lemniscus.

The division of the MnR and serotonin-synthesizing pontomesencephalic neurons corresponds to the B8 (MnR) and B9 (supralemniscal, SuL) groups. On the other hand, the neurons in PnO are mostly developed in the primates and were not named in Dalström and Fuxe's (1964) study on the rodent. Finally, in rodents a population of serotonergic neurons extends caudal to the MnR along the midline: the B5 group. There is no TPH-IR neurons caudal to the MnR in the caudal half of the pontine raphe. There are an estimated 125,000 serotonergic neurons in the mesopontine tegmentum, half of them in the MnR, a quarter in the PnO, and another quarter in the B9 group (Baker *et al.*, 1991a). In the midline subgroup of MnR, approximately 80% of the neurons are serotonergic, and in the paramedian subgroup, approximately 30%. Since the limits of the other subgroups are hardly distinguishable in Nissl preparations, such estimates are not available.

In the MnR, there are a few SP-IR neurons with small neuronal cell diameter (Baker *et al.*, 1991a). Several neuropeptides have been found in MnR neurons, e.g., cholecystokinin (Schiffmann and Vanderhaeghen, 1991) and, in lower abundance, dynorphin, enkephalin, and

neurotensin (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990). Several observations have only been made in rodent brains.

Raphe Magnus Nucleus

The raphe magnus nucleus (RMg) is located in the caudal pons and the most rostral portion of the medulla (Fig. 12.3). It is restricted to the midline, overlying the medial lemniscus where its fibers are shifting from their ventromedial to a more lateral position as they enter the pons. The RMg is found at the same level as the facial nucleus. The first TPH-IR neurons of the RMg are loosely clustered on the midline in the ventral tegmentum, at the level of the genu of the facial nerve. Rostral to these neurons there is a gap of several millimeters nearly devoid of TPH-IR neurons, which segregates the raphe nuclei of the rostral group (CLi, DR, MnR, and the pontine tegmental nuclei PnO and SuL) from those of the caudal group (RMg, ROb, RPa). Caudally, the nucleus ends just caudal to the anterior tip of the inferior olivary nuclei. The serotonergic neurons have various morphologies ranging from bipolar to multipolar. The former ones predominate near the midline, whereas the latter are more abundant in the ventral and lateral divisions of the nucleus. Laterally in RMg, the major axis of dendritic arborization shifts from dorsoventral to mediolateral. At the level of the pontomedullary junction, TPH-IR neurons have a distribution extending laterally in the neighboring gigantocellular reticular nucleus, pars a (Giα). This population of serotonergic neurons extends laterally and caudally, arching over the dorsal boundary of the inferior olivary nuclei. These neurons bridge the RMg with a population of serotonergic neurons extending across the entire length of the medullary lateral reticular formation (see below). These neurons have elongated cell bodies with three to five dendrites extending within the axon bundles in the medial lemniscus and the reticular formation.

Substance P is found in many RMg neurons of the human brain stem, as well as in the terminals in the neuropil (Halliday *et al.*, 1988b; Rikard-Bell *et al.*, 1990). In rodents, substance P was shown to colocalize in RMg serotonergic neurons, as well as thyrotropin-releasing hormones (Poulat *et al.*, 1992; Wu *et al.*, 1993). Several neuropeptides (enkephalin, somatostatin, cholecystokinin) have also been identified in RMg neurons (Björklund and Hökfelt, 1985; Björklund *et al.*, 1990). A population of NPY-containing neurons has been described in the human RMg (Halliday *et al.*, 1988c).

Raphe Obscurus Nucleus

The rostrocaudal extent of the raphe obscurus nucleus (ROb) amounts to about 20 mm (Braak, 1970), second only in length to the DR. Rostrally, the nucleus appears at the level of the abducens nucleus, just below the medial longitudinal fasciculus. At this level, it overlaps with the RMg, which is located more ventrally. In the medulla, the ROb is restricted to the median division, extending dorsoventrally from the mlf to the dorsal edge of the inferior olivary nuclei. Caudally, the ROb ends in the intermediate division of the first cervical segment, where three to five TPH-IR

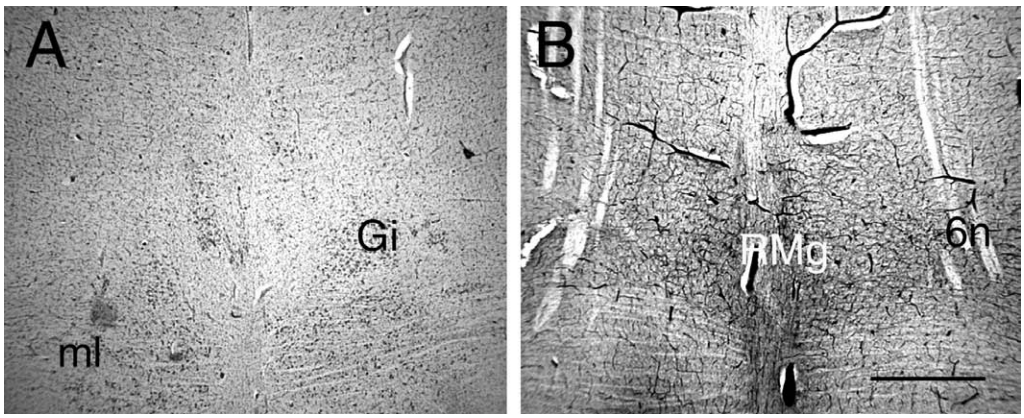

FIGURE 13.3 Transverse sections of the RMg at the level of the caudal pons stained for Nissl substance **(A)** and immunostained for TPH **(B).** The sections are located at the level of the nerve roots of the abducens (6n). The core of RMg is situated at the mediodorsal edge of ml, and is bordered laterally by a division of the reticular formation (Giα) in which TPH-IR neurons are bridging between the RMg and the serotonergic neurons of the lateroventral reticular formation of the medulla. Scale bar: 1.5 mm.

neurons per section flank laterally the pyramidal tract decussation. Neurons of the ROb form two separate paramedian columns of cells on either side of the midline. TPH-IR neurons have dendrites mainly dorsoventrally oriented, with a few of them crossing the midline into the contralateral ROb nucleus, and others oriented laterally, which penetrate in the medial nucleus of the medullary reticular formation.

Numerous SP-IR cell bodies have been reported in ROb of the human brain stem (Del Faccio *et al.*, 1984; Halliday *et al.*, 1988b, Rikard-Bell *et al.*, 1990), together with a dense network of SP-IR fibers surrounding ROb neurons. ROb neurons are very weakly labeled with MAO B antibodies (Westlund *et al.*, 1988). Scattered galanin-containing neurons have been described in the primate ROb (Blessing and Gai, 1997).

Raphe Pallidus Nucleus

The raphe pallidus nucleus (RPa) is the smallest of the human raphe nuclei. Its location in the atlas of Olszewski and Baxter (1954) has been mistaken for that of the RMg (see Braak, 1970). As a result, reference to RPa in some publications may actually refer to RMg or even ROb. The RPa is a narrow collection of cells close to the midline, at the border between the pyramidal tract and the overlying medial lemniscus. Its rostrocaudal extension corresponds roughly to that of the inferior olivary nuclei, starting, rostrally, from the level of the caudal tip of the RMg to the level of the obex, caudally. In our material, there was a clear accumulation of TPH-IR neurons at the pontomedullary junction at the medial side of the pyramids. However, these neurons were restricted to the rostral half of the cytoarchitectonic limits of the nucleus (Braak, 1970; Paxinos and Huang, 1995). TPH-IR neurons are slender, elongated neurons with few dendritic processes oriented predominantly dorsoventrally.

Serotonergic Neurons in the Medullary Reticular Formation

TPH-IR neurons are found in all transverse sections of the human medulla. Rostrally, there is a dense collection of serotonergic neurons in the Giα, at the lateral edge of the RMg. This column of neurons shifts laterally, in the caudal direction, into the lateral paragigantocellular reticular nucleus (LPGi). Further caudally, an additional population of TPH-IR neurons are located in the lateral reticular nucleus; these neurons surround in a U-shapped distribution the catecholaminergic groups (A1–C1) of the ventrolateral end of the intermediate reticular zone (Irt) (see Chapter 15). Serotonergic neurons are situated close to the medullary surface, in a location similar to that observed in other primate and nonprimate species (Chan-Palay, 1977; Steinbusch, 1981; Jacobs *et al.*, 1984; Azmitia and Gannon, 1988). The serotonergic and catecholaminergic neurons are two separate populations, with a limited number of neurons coexpressing serotonin- and catecholamine-synthesizing enzymes (Halliday *et al.*, 1998a) (Figs. 12.4 and 12.5).

In the Giα and the LPGi, TPH-IR neurons have multipolar morphology, and some of them colocalize with substance P, which is abundant in these nuclei (Halliday *et al.*, 1988b; Rikard-Bell *et al.*, 1990). Neurons in the lateral reticular formation have an elongated dendritic arborization, preferentially oriented in the transverse plane. A similar prominent distribution of serotonergic neurons in the lateral reticular nucleus of the medulla has been reported in several primates species (Azmitia and Gannon, 1988; Hornung and Fritschy, 1988). However, these cells fail, to stain with MAO B antibodies (Westlund *et al.*, 1988).

CONNECTIVITY

The tract-tracing methods available to demonstrate the connections in the mammalian brain have not been applied to the human raphe system. The pathways described are extrapolated from animal studies, though the existence of many has been confirmed in nonhuman primate studies. These data have been correlated with direct observations in human brain derived from histochemical or immunocytochemical studies of the serotonergic fibers, and from biochemical measurement of serotonin concentration or TPH activity in postmortem samples or biopsies.

The projections arising from the raphe nuclei are very extensive, as documented by the presence of serotonergic axons in virtually all brain regions. The raphe nuclei can be divided into two subgroups: the *rostral (oral) raphe nuclei* and the *caudal raphe nuclei* (Ohm *et al.*, 1989). The former ones are located in the mesencephalon and rostral pons, and send primarily ascending projections to the forebrain; the latter ones are located in the caudal pons and medulla, and send primarily projections to the lower brain stem and spinal cord (see below). These two regions of the raphe system are distinctly separated developmentally (Lidov and Molliver, 1982; Aitken and Törk, 1988).

The serotonergic axonal varicosities containing numerous synaptic vesicles are the main release sites for serotonin. Only a minority of them form classical chemical synapses with close apposition to the postsynaptic membrane. The incidence of conventional synapses at serotonergic terminals varies between the

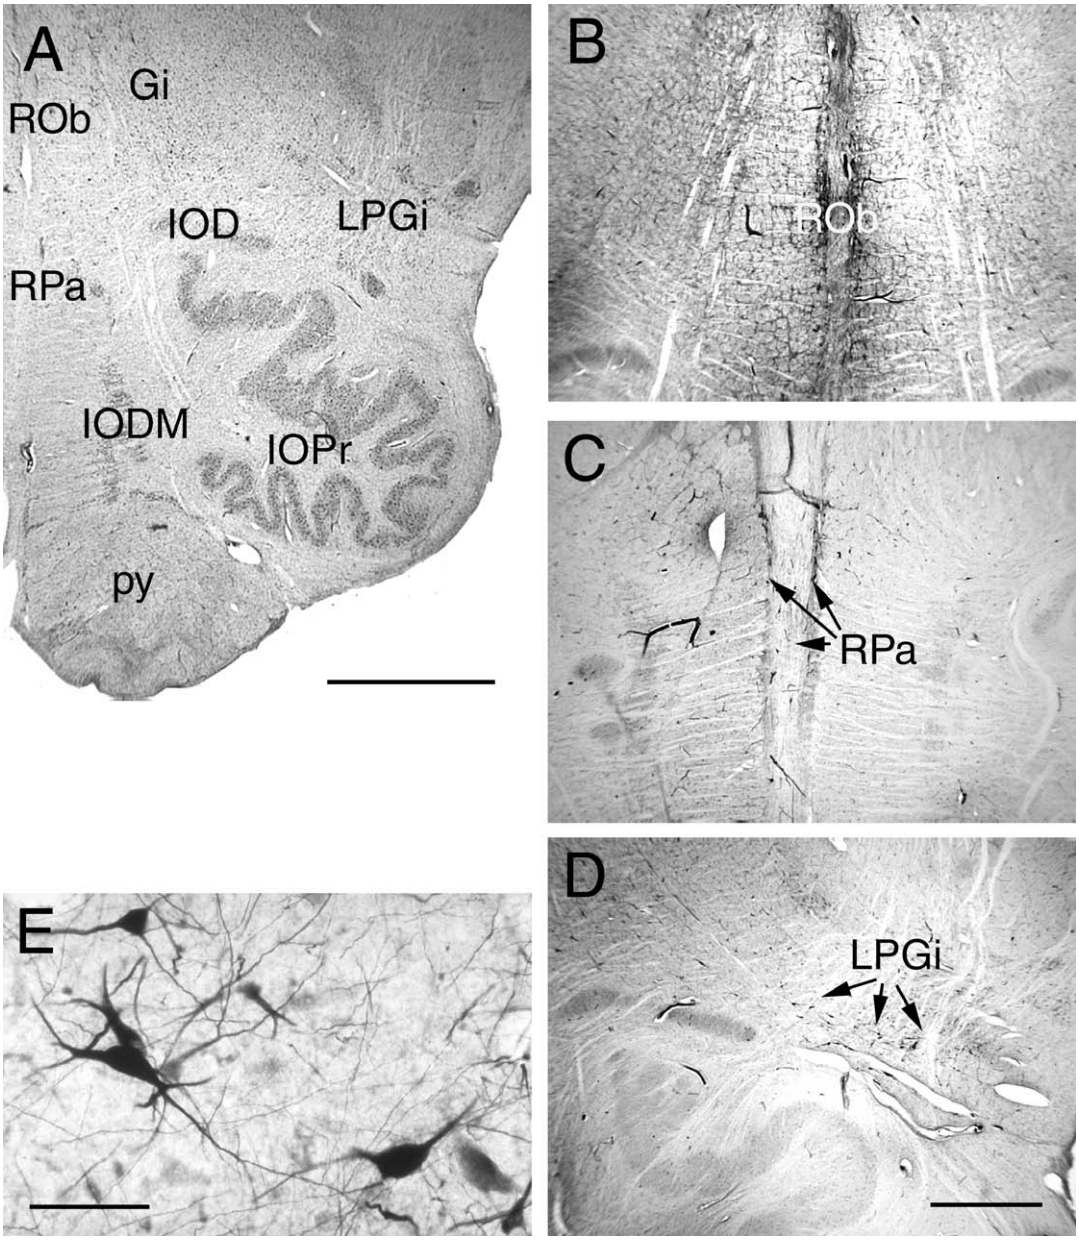

FIGURE 13.4 Transverse sections at the level of the rostral medulla stained for Nissl substance **(A)** and immunostained for TPH **(B–E).** The three serotonergic cell groups of the medulla are present at the rostral level of the inferior olive (A, B). TPH-IR neurons in the lateral reticular formation (LPGi) are bordering the dorsolateral edge of the IOPr. At high magnification (E), TPH-IR neurons in all divisions of the raphe display clearly the morphology of cell bodies, dendrites, and axons. Scale bars: (A) 3 mm, (B–D) 1.5 mm, (E) 40 mm.

sources of serotonergic projections, the brain regions, and the species. Serotonergic axons could be roughly subdivided into two groups: those bearing small or large varicosities (Kosofsky and Molliver, 1987; Ridet *et al.*, 1994). The former ones are associated with non-synaptic terminals whereas the latter ones often form classical chemical synapses (Törk, 1990; Ridet *et al.*, 1994; Smiley and Goldman-Rakic, 1996). For the ascending serotonergic projections, the source of the small varicose fibers is in DR and that of the large varicosities in MnR (Kosofsky and Molliver, 1987).

The Rostral Group

The rostral group is composed of the CLi, the DR, the MnR, and the pontomesencephalic neurons.

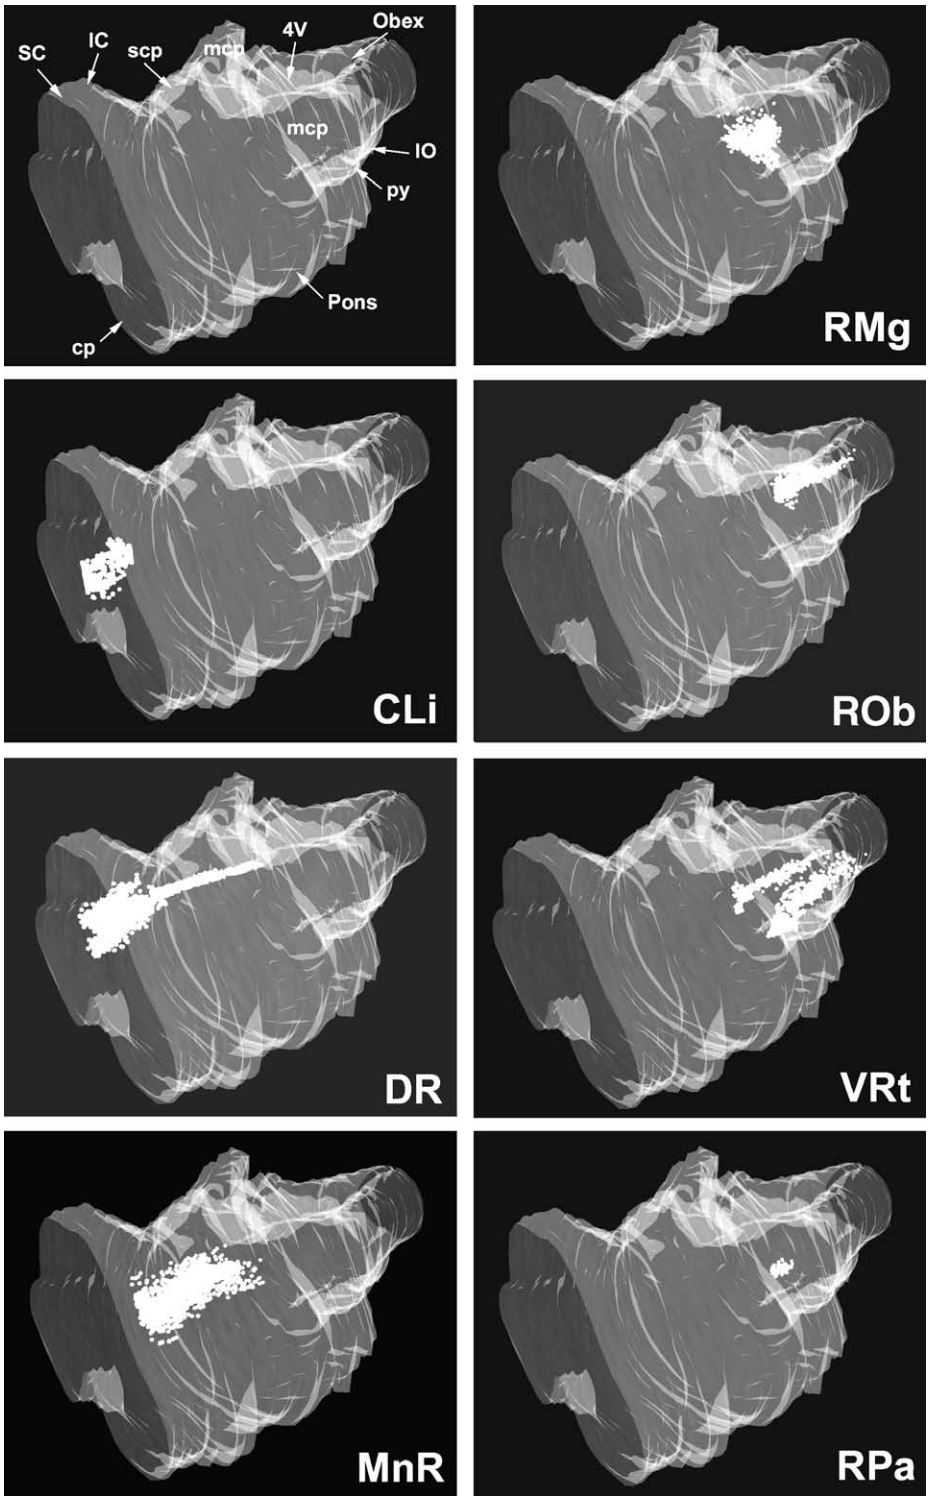

FIGURE 13.5 Three-dimensional representation of the reconstruction of brain stem from a series of transverse sections using the Solid View module of Neuroexplorer (Microbrightfield). The surface of the brain stem is represented in transparency, viewed from its anterior laterodorsal aspect. Top left panel points to the main structures of reference for orientation. The localization of TPH-IR neurons in every eighth section of the series has been plotted in reference to the outline of the brain stem. The distribution of the TPH-IR neurons in each raphe nucleus is illustrated separately in individual panels. Notice that the rostral group of the raphe neurons *(left panels)* are spatially segregated from the caudal group mostly restricted to the medulla *(right panels)*. The rostrocaudal length of the recontructed brain stem is 62 mm.

Collectively, the efferent projections of these nuclei are principally directed to the forebrain. Brodal *et al.* (1960) were the first to propose, using anterograde degeneration methods, that DR has a massive ascending projection to the forebrain, later confirmed by histofluorescence and immunocytochemical studies (Ungerstedt, 1971). More precise descriptions of the pathways of these ascending projections were obtained using anterograde transport of tritiated amino acids (Conrad *et al.*, 1974; Bobilier *et al.*, 1976; Taber-Pierce *et al.*, 1976; Azmitia and Segal, 1978; Moore *et al.*, 1978) or Phaseolus vulgaris (Halasy *et al.*, 1992; Acsády *et al.*, 1993; Datiche *et al.*, 1995), and retrograde transport of cholera toxin (Datiche *et al.*, 1995; Peyron *et al.*, 1998), fluorescent tracers (Kasakov *et al.*, 1993; Li *et al.*, 1993), or horseradish peroxidase (Kievit and Kuypers, 1975; Gonzalo-Ruiz *et al.*, 1995). Although the majority of the efferent targets are located in the upper brain stem and forebrain, there is evidence, for instance, of descending projections to the spinal cord from DR neurons with ascending axon collaterals (Kasakov *et al.*, 1993; Li *et al.*, 1993).

Efferent Projections

Efferent projections from the rostral serotonergic group ascend in two parallel pathways. A dorsal pathway running at the ventral side of the medial longitudinal fasciculus collects projections from DR and the dorsolateral cluster of MnR (Azmitia and Gannon, 1983, 1986). A ventral pathway starting at the level of the trochlear nucleus runs lateral of the MnR and reaches the mesencephalic ventral tegmental area near the dorsal limits of the interpeduncular nucleus. More rostrally, the ventral pathway extends into the medial forebrain bundle reaching the basal forebrain and the medial cortex. The dorsal pathway enters the internal capsule, heading for the lateral cerebral cortex. Fibers of the dorsal and ventral pathways intermingle at the midbrain–forebrain junction. In the monkey, the relative size of the dorsal bundle compared to the ventral one is increased, a feature possibly related to the increased size of the dorsal raphe nucleus and the cerebral cortex (Azmitia and Gannon, 1986). A minority of the serotonergic axons in the axon bundles are myelinated, in a proportion ranging from 0.7% in rodents to 25% in primates (Azmitia, 1987). The dorsal and the median raphe nuclei have distinct and partially overlapping projections, which will be considered separately. The ascending serotonergic projections to the cerebral cortex are described separately.

The projections of the dorsal raphe could be subdivided according to the rostral (B7; DRD, DRV, DRVL, and DRI) and caudal (B6; DRC) divisions of this nucleus on either part of the rhombencephalic isthmus (Azmitia and Segal, 1978; Jacobs *et al.*, 1978; De Olmos and Heimer, 1980; Fallon and Loughlin, 1982). The rostral division of the dorsal raphe nucleus projects principally to the cerebral cortex, neostriatum, amygdala, and substantia nigra (Steinbusch *et al.*, 1980; van der Kooy and Hattori, 1980; Waterhouse *et al.*, 1986; Corvaja *et al.*, 1993), whereas the caudal division projects to the hippocampus, entorhinal cortex, and locus coeruleus (Köhler and Steinbusch, 1982; Imai *et al.*, 1986; Datiche *et al.*, 1995). The dorsal raphe projects also to the thalamus (Westlund *et al.*, 1990; Gonzalo-Ruiz *et al.*, 1995), the ependyma and the subcommissural organ (Mikkelsen *et al.*, 1997), several brain stem nuclei (Li *et al.*, 1993; Thompson *et al.*, 1995; Steininger *et al.*, 1997), and the spinal cord (Kazakov *et al.*, 1993; Li e*t al.*, 1993). A projection from DR and CLi to the bed nucleus of the stria terminalis is made by neurons containing the vasoactive intestinal neuropeptide (Petit *et al.*, 1995). Multiple-tracing studies in rodents demonstrated that some serotonergic neurons could send axon collaterals in distinct divisions such as the cerebral cortex and the nucleus accumbens (Van Bockstaele e*t al.*, 1993), the lateral geniculate nucleus and the superior colliculus (Villar *et al.*, 1988), the trigeminal nucleus and the spinal cord (Li *et al.*, 1993), or even the cerebral cortex and the spinal cord (Kazakov *et al.*, 1993).

The main projections from the midline division of MnR are directed to the basal forebrain, the septal region, and the hippocampus (Azmitia and Segal, 1978; Vertes and Martin, 1988), with a majority of these projection neurons containing serotonin (up to 80%; Köhler *et al.*, 1982). The MnR also innervates also the cerebral cortex (Kievit and Kuypers, 1975; van der Kooy and Kuypers, 1979; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1982). The dorsal region of MnR projects predominantly to the amygdala (Imai *et al.*, 1986). The lateral division of MnR in the PnO projects to more caudal structures (in the diencephalon and brain stem) than the midline division of MnR. There are serotonergic connections with the dopaminergic neurons of the substantia nigra, the intralaminar nucleus of the thalamus, and the mammillary nuclei (Vertes and Martin, 1988). Thus, MnR projections could modulate both the striatal system via its projections to the substantia nigra and the intralaminar nucleus of the thalamus, and the hippocampus via direct projections and indirect projections via the septal and mammillary nuclei (Baker *et al.*, 1991). The neurons in SuL project to the cerebellum (Brodal, 1982), functioning as an additional relay for cortical information forwarded to the cerebellum (Torigoe *et al.*, 1986). In addition to MnR, serotonergic projections to the cerebellum originate in the caudal raphe nuclei (Shinnar *et al.*, 1973; Bishop

and Ho, 1985). Neurons in SuL innervate the septal region (Köhler *et al.*, 1982) and the cerebral cortex, with 30% containing serotonin in rodents (O'Hearn and Molliver, 1984). This cortical projection is sparse in nonhuman primates (Kievit and Kuypers, 1975; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1982).

The cerebral cortex receives dense parallel serotonergic projections from DR and MnR, which could be distinguished on the basis of several criteria: the morphology of the fibers, their areal and laminar distribution pattern, and their vulnerability to specific neurotoxins (O'Hearn *et al.*, 1988; Kosofsky and Molliver, 1987; Mamounas *et al.*, 1991). To summarize, axons originating in DR bear small varicosities (less than 1 μm in diameter), are widely distributed in the neocortex and hippocampus, and are highly sensitive to the application of amphetamine-derived neurotoxins, e.g., p-chloroamphetamine (PCA) and 3,4-methylenedioxymethamphetamine (MDMA, "ecstasy"). In contrast, axons originating in MnR bear large varicosities distributed predominantly in the hippocampus and in certain neocortical areas, and have little vulnerability to PCA and MDMA. The serotonergic innervation of the hippocampus originating in the dorsal raphe is diffuse across laminae and its activitation is likely to be mediated mainly by the activation of the serotonergic 5-HT_{1A} receptors (Mokler *et al.*, 1998), which are abundant in the hippocampus of all mammalian species studied, including nonhuman primates (Azmitia *et al.*, 1996) and humans (Burnet *et al.*, 1995; Pasqualetti *et al.*, 1996). The MnR projection to the hippocampus has been extensively studied with tract-tracing and immunocytochemical techniques in rodents and nonhuman primates. In rodents, this projection selectively innervates populations of GABAergic interneurons expressing calretinin or calbindin (two calcium-binding proteins), with numerous large axonal varicosities forming conventional synapses (Halasy *et al.*, 1992; Miettinen and Freund, 1992; Acsády *et al.*, 1993). Similar connections have been observed in the primate hippocampus (Hornung and Celio, 1992). Through this pathway, raphe neurons indirectly inhibit the activity of the pyramidal neurons of the hippocampus via a synaptic excitation of hippocampal GABAergic interneurons mediated by serotonergic 5-HT_3 receptors (Ropert and Guy, 1991; Maeda *et al.*, 1994; McMahon and Kauer, 1997) (Fig. 12.6).

A dense innervation by DR and MnR nuclei of the neocortex has been documented using both retrograde (Kievit and Kuypers, 1975; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1982; O'Hearn and Molliver, 1984; Waterhouse *et al.*, 1986) and anterograde (Kosofsky and Molliver, 1987) tract-tracing techniques. The combination of these methods with serotonin immunodetection indicated that about 33–80% (100% for DRI) of the raphe projection neurons were serotonergic, depending on the nucleus of origin (O'Hearn and Molliver, 1984). The areal and laminar distribution of serotonergic axons in the neocortex is well differentiated in primates (Morisson *et al.*, 1982; Takeuchi and Sano, 1983; Campbell *et al.*, 1987; Berger *et al.*, 1988; DeFelipe and Jones, 1988; Hornung and Fritschy, 1990; Wilson and Molliver, 1991). There is a dense plexus of serotonergic axons in layer I in all areas, as well as in layer IV of the primary sensory areas (highest in the primary visual cortex). Layer IV innervation is also increased in density as compared to the neighboring supra- and infragranular layers in the associative cortices. In contrast in the agranular cortices (primary motor cortex, anterior cingulate cortex), the serotonergic axonal plexus is evenly distributed from layers II to VI. The laminar pattern of serotonergic innervation is complementary to that of the other aminergic afferent systems (Morisson *et al.*, 1982; Campbell *et al.*, 1987). Large varicose serotonergic axons are most

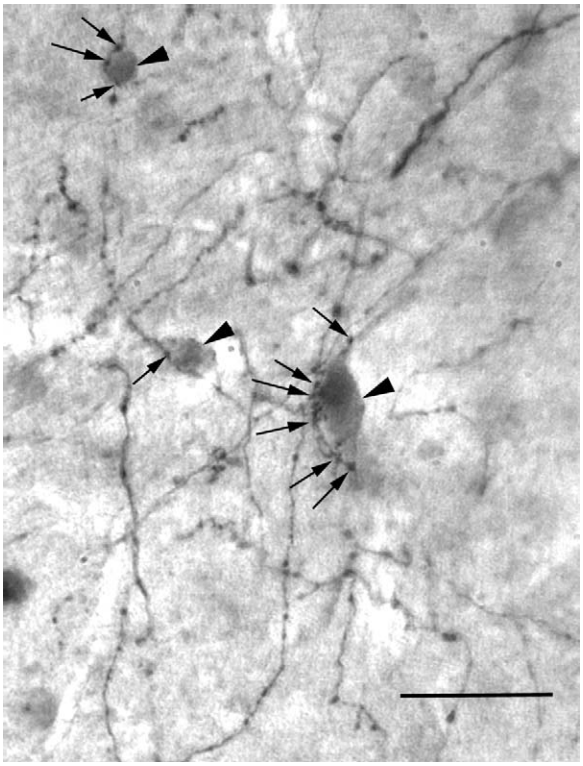

FIGURE 13.6 High-power micrograph of a transverse section of human cerebral cortex stained for 5-HT (black fibers) and for calbindin (gray cell bodies and dendrites, *arrowheads*). Note that serotonin-containing fibers form conspicuous large varicosities, several being in close apposition with the surface of calbindin-containing neurons *(arrows)*. Scale bar: 30 mm.

abundant in all divisions of the medial cortex and in the lateral cortex of the frontal lobe (Hornung *et al.*, 1990; Wilson and Molliver, 1991). These terminals have been shown to terminate preferentially on cortical interneurons (Smiley and Goldman-Rakic, 1996) and to form conspicuous pericellular baskets surrounding the soma and proximal dendrites of a subclass of inhibitory interneurons expressing the calcium-binding protein calretinin (Hornung and Celio, 1992). Immunocytochemical studies of the serotonergic innervation of the human cerebral cortex have been reported by a few groups (Kosofsky and Kowall, 1989; Hornung and de Tribolet, 1995; Trottier *et al.*, 1996). These studies confirmed that the cortical serotonergic innervation in the human brain is similar to that described in nonhuman primates with regard to the laminar distribution of the serotonergic fibers and their morphology (large and small varicose fibers) (Fig. 13.6). In addition, there is also evidence that large varicose fibers preferentially innervate calretinin-containing neurons in the frontal associative cortex (Fig. 13.6) (Hornung and de Tribolet, 1995). Ultrastructural analysis revealed that a minority of serotonergic terminals are engaged in conventional synapses, mostly those with varicosities of larger diameter (Beaudet and Descarries, 1978; Takeuchi and Sano, 1984; DeFelipe and Jones, 1988; De Lima *et al.*, 1988; Törk, 1990; Dori *et al.*, 1996; Smiley and Goldman-Rakic, 1996; Lambe *et al.*, 2000). Although several serotonin receptors have been identified in the cerebral cortex using mainly radioligand and *in situ* hybridization techniques, their cellular localization and function in cortical circuitry are only partially elucidated. Best characterized are the 5-HT_{1A}, 5-HT_{2A}, and 5-HT_3 receptors with a well-documented distribution in nonhuman primates (Lidow *et al.*, 1989; Azmitia *et al.*, 1996; Jakab and Goldman-Rakic, 1998, 2000) and in humans (Burnet *et al.*, 1995; Pasqualetti *et al.*, 1996). 5-HT_{1A} and 5-HT_{2A} receptors are expressed in all divisions of the cerebral cortex, with a predominant expression in pyramidal neurons of layers II, III, and V. There is also evidence for the expression of 5-HT_{2A} receptors in interneurons (Pasqualetti *et al.*, 1996; Jakab and Goldman-Rakic, 1998). In rodent piriform cortex, activation of 5-HT_2 receptors depolarizes layer II interneurons (Sheldon and Aghajanian, 1990; Gellman and Aghajanian, 1994) and hyperpolarizes pyramidal neurons (Sheldon and Aghajanian, 1990). Activation of 5-HT_{2A} receptors in the frontal cortex depolarizes pyramidal neurons (Aghajanian and Marek, 1997).

Afferents Projections

Our knowledge on the afferents to the raphe nuclei is based primarily on tract-tracing studies done on nonprimate mammalian species. The basic architecture of the connectivity of the raphe nuclei is likely to be common to all mammalian species. However, one could speculate that the organization of these pathways in primate and particularly human brains is more complex, since there is well-documented increasing complexity in the organization of the raphe nuclei themselves (see above). A large number of afferents are common to the DR and MnR. The major source of afferents to DR and MnR is the lateral habenula (Peyron *et al.*, 1998; Behzadi *et al.*, 1990), a pathway using excitatory amino acids (Behzadi *et al.*, 1990). There is a projection to both raphe nuclei from noncholinergic neurons of the medial septum and of the diagonal band nuclei (Kalén and Wiklund, 1989) and the ventral pallidum (Behzadi *et al.*, 1990; Peyron *et al.*, 1998). Several hypothalamic projections to the DR and MnR originate from nuclei in the medial and lateral preoptic areas, and the lateral, dorsal, and posterior divisions of the hypothalamus (Behzadi *et al.*, 1990; Peyron *et al.*, 1998). There is an abundant GABAergic innervation of DR neurons (Wang *et al.*, 1992), some of which are of hypothalamic origin (Peyron and Luppi, 1994). The projections from the lateral habenula, the interpeduncular nucleus, several hypothalamic nuclei, the ventral tegmental areas, the laterodorsal tegmentum nuclei, and the cingulate cortex are glutamatergic (Behzadi *et al.*, 1990). Medial prefrontal cortex innervates the DR and MnR nuclei, and stimulation of this pathway generates inhibition of the serotonergic (bursting) neurons in the midbrain (Hajòs *et al.*, 1998). The central nucleus of the amygdala projects to the DRV and DRD (Peyron *et al.*, 1998). Ascending projections to MnR originated from the RMg and RPa nuclei and from the nucleus prepositus hypoglossi (Behzadi *et al.*, 1990). Glycinergic projections to DR originate from the ventral and ventrolateral periaqueductal gray neurons and from neurons in the medullary rostral paragigantocellularis and rostral ventromedial reticular nuclei (Rampon *et al.*, 1999). Afferents from the medial nucleus of the solitary tract forward autonomic inputs to DR (Herbert, 1992).

The Caudal Group

The caudal group is composed of the RMg, the ROb, and the RPa. The group of serotonergic neurons in the medulla extends laterally from RMg in the Gia, the lateral paragigantocellular reticular nucleus (LPGi), and the lateral reticular nucleus.

Efferent Projections

Collectively, the efferent projections of these nuclei are principally directed to the caudal brain stem and spinal cord (Brodal *et al.*, 1960; Carlsson *et al.*, 1964; Skagerberg and Björklund, 1985). Combination of

retrograde labeling and immunocytochemistry reveals that about half of the spinally projecting midline raphe neurons contain serotonin, whereas this proportion falls to 28% in lateral medullary neurons (Jones and Light, 1992). Serotonergic axons to the spinal cord bear small varicosities in the dorsal horn and larger varicosities in the intermediate and ventral horns, the latter one forming conventional synaptic contacts with the spinal neurons (Ridet *et al.*, 1993). The serotonergic input to the somatic motor nuclei originates primarily from the ROb and the RPa, as demonstrated for the motor trigeminal nucleus (Li *et al.*, 1993, Ribeiro-do-Valle, 1997), the facial nucleus (Li *et al.*, 1993), the retrofacial and the ambiguus nuclei (Arita *et al.*, 1993, 1995), and the phrenic nucleus (Holtman *et al.*, 1990, Hosogai *et al.*, 1998). There is also a projection to the autonomic motor neurons of the parasympathetic (dorsal vagal nucleus) and sympathetic (thoracic intermediolateral column, IML) systems (Loewy and McKellar, 1981; Poulat *et al.*, 1992; Yang *et al.*, 1994; Manaker and Fogarty, 1995). Serotonergic projections to the autonomic motor neurons colocalize the neuropeptides thyrotropin-releasing hormone and SP (Poulat *et al.*, 1992; Wu *et al.*, 1993), whereas those to the somatic motoneurons lack SP (Wu *et al.*, 1993). The raphe projections to the dorsal horn and dorsal column nuclei originated primarily from the RMg, and its serotonergic axons are devoid of thyrotropin-releasing hormone and SP (Wu and Wessendorf, 1992). In the sensory relays, there is a dense serotonergic innervation of laminae I and II of the spinal trigeminal nucleus (Costa *et al.*, 1994) and the dorsal horn of the spinal cord (Ridet *et al.*, 1993). Following *p*-chloroamphetamine treatment, the fine varicose serotonergic innervation of the dorsal horn disappears while the large varicose serotonergic innervation is spared in all divisions of the spinal cord (Ridet *et al.*, 1994). Based on the distribution of the serotonergic fibers in the spinal cord, the fine varicose fibers originate primarily in RMg and the large varicose ones in ROb and RPa. The descending projections in the spinal cord follow two pathways: one lateral (and dorsal depending the authors) originates in the RMg and terminates in the dorsal horn, and one medial (and ventral) originates in the ROb and the RPa and terminates in the ventral horn and IML (Felten and Sladek, 1983; Azmitia and Gannon, 1986). There is a mixture of unmyelinated and partially myelinated descending serotonergic axons in the dorsolateral tract (Westlund *et al.*, 1992). Although most raphe projections are directed to caudal divisions of the brain, serotonergic and nonserotonergic neurons of the caudal raphe nuclei send axon collaterals to both the lumbar intermediate and ventral gray matter and the medial preoptic area of the hypothalamus (Leanza *et al.*, 1995).

Afferent Projections

Afferents to the anterior part of the caudal group (RMg, rostral Rpa, and Giα) originate in several hypothalamic nuclei, the dorsolateral periaqueductal gray, the central nucleus of the amygdala, the bed nucleus of the stria terminalis, and the medullary reticular formation (Zagon, 1993; Hermann *et al.*, 1997). Spinally projecting RMg and rostral RPa neurons receive direct catecholaminergic synaptic inputs (Tanaka *et al.*, 1994). The pneumotaxic area in the medial parabrachial area and the retrofacial nuclei have convergent inputs to the RMn (Gang *et al.*, 1993). There are also converging inputs onto RMg, Rob, and RPa midline raphe neurons from visceral sensory afferents and ventrolateral periaqueductal gray neurons (Snowball *et al.*, 1997).

FUNCTIONAL CONSIDERATIONS

The activity of raphe neurons, and of serotonergic neurons in particular, have been shown to be involved in a wide range of physiological and pathological functions. The following account summarizes some of the evidence for the involvement of serotonin in major brain functions, with some reference to nonserotonergic projections for which, however, little information on its contribution is available. This raises several issues that will require further investigation, such as the following: (1) Are the efferent and afferent projections of the non-serotonergic raphe neurons different from their serotonergic neighbors? (2) What is the organization of the intrinsic connections of the raphe and what is the degree of integration generated by this circuit? (3) Do the raphe nuclei constitute a system of their own or are some of their constituents integrative parts of the sensory, motor, or limbic systems? The functional mechanisms described below have been selected for their relevance to human neurobiology and pathology.

Sleep–Wake and Circadian Cycles

It has been known for several decades that the regulation of the sleep–wake cycles is in part modulated by serotonin (Jouvet, 1969) released by DR neurons projecting on the cholinergic laterodorsal tegmental nucleus (Steininger *et al.*, 1997). The activity of DR neurons is highest during waking, low during slow-wave sleep, and nearly abolished during paradoxical sleep (REM sleep) (McGinty and Harper, 1976), thus reducing the inhibition of serotonin on the cholinergic mesopontine neurons implicated in REM sleep generation (Luebke *et al.*, 1992; Thakkar *et al.*, 1998). During the sleep periods, there is a simultaneous increase in

dendritic release of serotonin in DR (Cespuglio *et al.*, 1990), which further inhibits serotonergic neurons activity by activation of 5-HT_{1A} autoreceptors (Sprouse and Aghajanian, 1987; Portas *et al.*, 1996). Inhibition of the DR during REM sleep is also dependent on GABAergic input, possibly originating from the periaqueductal gray and impinging on both the DR and the locus coeruleus, two structures with silent neurons during this phase of sleep (Nitz and Siegel, 1997a, b). The 5-HT_{2A} receptors participate in the control of slow-wave sleep (Dugovic *et al.*, 1989). The 5-HT_{1B} receptors are mainly located at terminals of axons and, for instance, at GABA and cholinergic terminals that are critical in sleep control. Pharmacological and electrophysiological study of the 5-HT_{1B}-deficient mouse demonstrated that this receptor participates in the regulation of paradoxical sleep (Boutrel *et al.*, 1999).

In mammals, the suprachiasmatic nucleus of the hypothalamus (SCh) is the primary circadian pacemaker of locomotor activity and various physiological functions (Hastings, 1997). It is richly innervated by serotonergic fibers (Leander *et al.*, 1998). Neurons in this nucleus have a rhythmic expression of several genes that regulate their cyclic activity (Dunlap, 1999). This intrinsic activity is modulated by photic and nonphotic manipulations. Among the nonphotic manipulations, injection of the serotonergic agonist 8-hydroxy-2(di-*n*-propylamino)tetralin (8-OH DPAT) shifts the rhythm of locomotor activity in the Syrian hamster (Tominaga *et al.*, 1992; Mintz, 1997). Electrical stimulations of DR and MnR induce phase shifts in SCh (Meyer-Bernstein and Morin, 1999). Serotonin application also shifts the activity of suprachiasmatic neurons maintained *in vitro* (Prosser *et al.*, 1993). These behavioral and physiological modifications correlate with the observation that 8-OH DPAT also modifies the rhythm of expression of two of the clock genes: *mPer1* and *mPer2* (Horikawa *et al.*, 2000).

Pain Control

The central modulation of noxious stimuli (opioid receptor–mediated analgesia) involves two structures lying in the raphe and its lateral extension: the ventro–lateral periaqueductal gray and the raphe magnus with the adjacent nucleus reticularis magnocellularis (Fields *et al.*, 1991). The periaqueductal region involves the contribution of DR (Wang and Nakai, 1994). Pain control occurs first at the synaptic relay of pain afferents in the dorsal horn and spinal trigeminal nucleus. It involves serotonergic and nonserotonergic populations of neurons in the rostromedial medulla (Skagerberg and Björklund, 1985). The contribution of serotonin in this descending pathway has recently been reevaluated years (Mason, 1999). This pathway suppresses pain transmission at the level of primary afferent synapses, with medullary serotonergic neurons responding by a tonic activity to noxious stimuli under stressful conditions (Milne and Gamble, 1990; Mitchell *et al.*, 1998). In unstressed conditions, the modulation of pain is regulated by nonserotonergic descending projections with inhibitory (off cells) and facilitatory (on cells) functions (Mason, 1997). The on cells are active during the awake and off cells during the sleep periods (Leung and Mason, 1999). In chronic pain situation, both on and off cells are active together (Montagne-Clavel and Oliveras, 1994). The bulbospinal projection for pain modulation originating from a raphe nuclei contains a mixture of serotonergic and nonserotonergic neurons. This projection illustrates a case where the two raphe neuron populations contribute to complementary and distinct functions.

Mood Disorders and Drug Addiction

Evidence for the involvement of serotonin in mood disorders and drug addiction stems from two main sources: (1) experimental studies on animals with pharmacologically or genetically modified neurotransmission, or (2) biochemical measurement of serotonergic metabolism, functional imaging, or therapeutic drug treatments on psychiatric or addicted patients. Of the abundant and controversial literature on the topic, the following account only reviews some of the issues relevant in the context of this chapter.

Hallucinogenic drugs, such as LSD or psilocibin, activate central neurons via 5-HT_{2A} receptors (Marek and Aghajanian, 1996; Vollenweider *et al.*, 1998). Mood disorders are managed with different drugs modulating serotonin metabolism (monoamine oxidase or serotonin transporter inhibitors, receptor agonists) (Meltzer, 1999). However, the biological substrate regulating the affective responses mediated by the action of 5-HT is still poorly understood The role of the receptor 5-HT_{2A} for the action of hallucinogens and antipsychotic drugs has been recently reported (Scruggs *et al.*, 2000), and the involvement of additional nonserotonergic receptors has been discussed in several reviews (Meltzer, 1999; Aghajanian and Marek, 2000; Harrison, 1999; Lewis and Lieberman, 2000). The activation of 5-HT_2 receptor in the frontal cortex has been studied by electrophysiological techniques in rat brain (Bergqvist *et al.*, 1999), and its expression was shown to be reduced in the brain of patients with major depression (Biver *et al.*, 1997). The genetic determinants of most psychiatric conditions are likely to be multiple genes contributing a fraction of the total genetic variance. The variance analysis of the promoter of the serotonin

transporter reveals evidence for polymorphism of the transporter associated with axiety and affective disorders (Lesch *et al.*, 1996; Greenberg *et al.*, 1998).

Serotonin, acting through a variety of receptors with distinct distributions, modulates differentially affective and cognitive responses. The 5-HT_{1A} agonists are used in the management of axiety disorders (Tunnicliff, 1991). Mice deficient for one of the serotonin receptors have been studied with the aim of identifing the mechanisms involved in the effect of the psychoactive drugs (Brunner and Hen, 1997). The knockout mice for the 5-HT_{1A} receptor have been reported to have anxiety or related disorders (Ramboz *et al.*, 1998). The knockout mice for the 5-HT_{5A} receptor have been reported to have increased locomotor activity and altered response to LSD (Grailhe *et al.*, 1999).

Elevated whole-blood serotonin levels have been reported in patients with autism (Cook *et al.*, 1996). Most individuals with autism who are treated with potent serotonin transporter inhibitors have a reduction of ritualistic behaviors and aggression (McDougle *et al.*, 1996). Genetic variants in this transporter have been linked with autism (Klauck *et al.*, 1997). On the other hand, reduction of serotonin function causes a worsening of stereotyped behaviors (McDougle *et al.*, 1996). A developmental abnormality associated with autism, such as decreased neurite branching in hippocampus (Raymond *et al.*, 1996), is similar to the reduced dendritic branching observed *in vitro* following stimulation of the 5-HT_{1A} receptor with the agonist 8-OH-DPAT (Sikich *et al.*, 1990).

The 5-HT_{1B} knockout mice are characterized by an elevated aggressivity in the resident-intruder paradigm (Saudou *et al.*, 1994). Mice deficient for the MAO A have an enhanced aggressive behavior in males (Cases *et al.*, 1995). In humans, similar behavior has been reported in male members of a family carrying a point mutation of MAO A (Brunner *et al.*, 1993). In rodents, agonists for several serotonin receptors decrease aggressive behavior (Olivier *et al.*, 1995). In genetic lines of mice selected for high or low offensive aggression, the density of 5-HT_{1A} receptors in low-aggressive mice was significantly higher in the hippocampus, lateral septum, and frontal cortex, but not in the DR (Korte, 1996). In small primate colonies deprived of a dominant male, a subordinate male with pharmacologically increased serotonergic function will acquire a dominant position and have lower levels of initiating aggressive behavior, whereas the opposite applies when the subordinate male has a pharmacologically lowered serotonergic function (Raleigh *et al.*, 1991). In humans, low brain serotonin correlates with aggressive behavior (Constantino *et al.*, 1997), and 5-HT receptor agonists reduce aggression (Bell and Hobson, 1994). There are, on the other hand, contradictory reports of elevated blood serotonin in humans with aggressive behavior (Cook *et al.*, 1995) and reduced aggressivity following 5-HT antagonist treatment (Shih *et al.*, 1999). Currently available evidence confirms that serotonin is involved in the regulation of aggressive behavior; however, its mechanism of action remains elusive. In knockout animal models, as in natural genetic deficiencies, the absence of a molecule during development could potentially indirectly affect other neurotransmitter systems or neuronal circuits, which in turn will be responsible for the modified phenotypes (Gingrich and Hen, 2000).

Among other neurotransmitters, serotonin was shown to participate in the circuitry of the reward pathways (Koob, 1992). Self-administration of cocaine by knockout mice with a deletion for the 5-HT_{1B} receptor demonstrated preexisting sensitization in these transgenic mice, resulting from a reduced inhibition by serotonin of the dopaminergic transmission at the level of both the ventral tegmental area and the accumbens nucleus (Rocha *et al.*, 1998).

Another study reported also an elevated self-administration of ethanol in these knock-out mice (Crabbe *et al.*, 1996). Thus, the 5-HT_{1B} receptor modulates the level of vulnerability to the reinforcing effects of certain addictive drugs and could possibly be involved in the individual variations of vulnerability to drugs of abuse.

Neurotoxicity of Amphetamine Derivatives

The recreational illicit drug 3,4-methylenedioxymethamphetamine (MDMA, or "ecstasy") is widely used for its hallucinogenic properties altering serotonergic functions and thus affecting mood states in which the serotonin system is involved (Green *et al.*, 1995). Early experimental studies in lower mammals (O'Hearn *et al.*, 1988) and primates (Wilson *et al.*, 1989) reported that MDMA had a neurotoxic effect on serotonin-containing axons. The effects are mediated by the action of MDMA on the membrane and vesicular serotonin transporters (Rudnick and Wall, 1992), and its neurotoxic action is prevented by prior serotonin depletion in terminals (Berger *et al.*, 1989). MDMA applied to mice lacking the serotonin transporter has no effect on the locomotor activation observed in wild-type animals receiving the same treatment (Bengel *et al.*, 1998). Serotonin neurotoxicity of MDMA has also been substantiated in humans (McCann *et al.*, 1994). The effect of MDMA is comparable to that of other amphetamine derivatives, such as *p*-chloroamphetamine (PCA) (Molliver *et al.*, 1990). The long-term reinnervation by

serotonergic axons in MDMA-treated rodents or primates demonstrated persistent abnormal projections such as a poor or missing reinnervation in the dorsal lateral neocortex and, on the opposite, hyperinnervation of more proximal targets such as the amygdala and hypothalamus (Fischer *et al.*, 1995). The reinnervation of the cerebral cortex by injured serotonergic axons following application of amphetamine neurotoxic drugs is strongly stimulated by the application of the neurotrophin brain-derived neurotrophic factor (Mamounas *et al.*, 2000). This effect is due to enhanced sprounting of spared axons but not an enhanced survival from a protective effect of the neurotrophin.

Motor Activity

Systemic application of serotonin precursors, agonists, or releasing agents induces a motor syndrome with characteristic head movements, tremors, and rigidity patterns (Jacobs, 1983). Alpha motor neurons in the brain stem and the spinal cord are surrounded by dense serotonergic plexuses, with the exception of those controlling finer motor activities such as for oculomotor and distal limb muscles (Steinbusch, 1981). Application of serotonin produces little or no effects on the motor neuron activity, but in combination with electrical stimulation or glutamate release, it produces a strong facilitation of neuronal activities, an effect mediated by the 5-HT_{2A} and 5-HT_{2C} receptors (Jacobs and Fornal, 1997). The activity of serotonergic neurons in all divisions of the raphe system is related to the state of the animal in the sleep–wake cycle (highest during waking and null during REM sleep) (Jacobs and Fornal, 1991). During waking, raphe neurons have a regular baseline activity, which increases dramatically in the rostral raphe in phase with repetitive complex motor activities such as orobuccal movements (chewing, licking, or grooming) (Fornal *et al.*, 1996), or in the caudal raphe in phase with treadmill-induced locomotion or hyperpnia induced by exposure to carbon dioxide (Veasey *et al.*, 1995). A recent case report describes a syndrome "fou rire prodromique" in which motor patterns for the laughing are generated in the absence of relevant behavioral or environmental association. This occured shortly after a vascular infarct restricted to a small area of the ventromedial pontomedullary region encroaching the RMg and anterior ROb nuclei (Assal *et al.*, 2000). Caudal raphe nuclei have also a modulatory role on the autonomic centers, as illustrated by the function of TRH-containing neurons in the raphe pallidus projecting onto the dorsal motor nucleus of the vagus in a loop regulating the physiology of the gastric mucosa (Kaneko *et al.*, 1998).

Modulatory Role of Serotonin During Brain Development

The early expression of serotonin and axonal growth in developing raphe neurons, prior to the cellular and synaptic differentiation of most of their target regions, led to the speculation that serotonin has a modulatory function in brain development (Lauder, 1993; Turlejsky, 1996). Application of synthetic enzyme inhibitors *in vivo* (Lauder and Krebs, 1978) or serotonin on cultured cells (Lavdas *et al.*, 1997) provides experimental evidence for a role of serotonin in cell proliferation and/or cell differentiation. During the early phase of embryonic development, the involvement of serotonin in cell migration has been well documented in neural crest cells (Moiseiwitsch and Lauder, 1995), by the activation of the 5-HT_{2B} receptor (Choi *et al.*, 1997). The dendritic growth of serotonergic neurons themselves is enhanced by the calcium-binding protein S-100β (Azmitia *et al.*, 1990), stored primarily in astroglia and released under stimulation of the 5-HT_{1A} receptor (Whitaker-Azmitia *et al.*, 1990). S-100β acts as a stabilizer of the cytoskeleton by inhibiting phosphorylation of brain cytoskeletal proteins such as MAP2, tau and GAP-43 (Sheu *et al.*, 1994; Nishi *et al.*, 2000). These mechanisms are involved in the serotonergic modulation of synaptic maturation in the dentate gyrus, where early serotonin depletion reduces the number dendritic spines (Yan *et al.*, 1997a, b; Wilson *et al.*, 1998). The anxiety-like behavior characteristic of the 5-HT_{1A} receptor knockout mouse (Ramboz *et al.*, 1998) has been shown to have a developmental origin since a conditional knockout mouse for this receptor showed anxiety-like behavior if the receptor was suppressed during the duration of development and restored in the adults whereas if the receptor was suppressed only in the adult, the animal had a phenotype similar to that of the wild type (Gross *et al.*, 2002).

In a transgenic mouse line with an inactivated gene for MAO A, there is a transient sevenfold increase in extracellular serotonin concentration during late embryonic and early postnatal life (Cases *et al.*, 1995). The morphological phenotype of this transgenic mouse is characterized by a lack of cytoarchitectonic differentiation in the barrel-field region of the somatosensory cortex (Cases *et al.*, 1995) and of ipsi-contralateral segregation of the retinal afferents in the thalamic lateral geniculate nucleus (Upton *et al.*, 1999). These glutamatergic pathways, among others, express transiently during the perinatal period the serotonin transporter, the vesicular monoamine transporter 2, and the 5-HT_{1B} receptor (Lebrand *et al.*, 1996, 1998). This results in a transient accumulation of serotonin in the thalamocortical and retinogeniculate pathways

(Cases *et al.*, 1996, 1998; Upton *et al.*, 1999). Serotonin acts at the thalamic and retinal terminals via the 5-HT_{1B} on the axon terminal, which reduces the amount of glutamate released, thus reducing the efficacy of the afferent terminals in processes of activity-dependent competition for synaptic targets. This hypothesis is supported by the recent study of the rescued morphological phenotype in the barrel-field cortex in double knockout mice for MAO A and the 5-HT_{1B} receptor, where the excess of serotonin is ineffective in absence of this receptor (Salichon *et al.*, 2001).

In the same transgenic mouse line, the maturation of the medullary respiratory rhythm generator is also altered (Bou-Flores *et al.*, 2000). This study demonstrates that cervical phrenic motor neurons develop abnormal dendritic morphologies, which correlates with a delayed maturation of a stable respiratory pattern. These data are relevant for the study of the sudden infant death syndrome, since victims of this syndrome have shown abnormally high cerebrospinal fluid levels of tryptophan and serotonin metabolites (Cann-Moisan *et al.*, 1999). The studies on the transgenic mouse strains illustrate the potential deleterious effects on brain development and functions of altered 5-HT metabolism, from genetic, metabolic, or pharmacological origin.

Neurodegenerative Disorders

In patients with Alzheimer's disease, there is a 70–80% reduction of the population of serotonergic neurons in the rostral group of the raphe, a reduction quantitatively similar in the DR and MnR nuclei (Halliday *et al.*, 1992). This neuronal reduction is corroborated with the reported reduction in serotonergic biochemical markers in brains of patients with Alzheimer's disease (D'Amato *et al.*, 1987). The reduction in serotonergic innervation is thought to be secondary to the cortical pathology of Alzheimen's patients (Mann and Yates, 1986). In brains of Parkinson's disease patients, there are several populations of serotonergic neurons severely affected, among which the MnR and ROb are characterized by the highest reduction in cell number (Halliday *et al.*, 1990). In primates with Parkinson-like symptoms induced by neurotoxic lesions, the loss in number of serotonergic cells parallels a reduction of 5-HT_{1A} receptor density in the hippocampus and other forebrain regions, except in the caudal striatum where an increase in receptor expression is observed (Frechilla *et al.*, 2001). In brains of Huntington's disease patients, the neurochemical alterations have been primarily investigated in the striatum. Parallel to a decrease in GABA, there is an increase in concentration of serotonin and its metabolites (Bird, 1980), which may be accounted for by the shrinkage following degeneration of striatal projection neurons (Kish *et al.*, 1987). Serotonin concentration is also increased in the cerebral cortex and the globus pallidus but not in the hippocampus (Reynolds and Pearson, 1987). In brains of chronic alcoholic patients, with or without Korsakoff's syndrome, the number of TPH-IR neurons in the raphe nuclei were substantially reduced in comparison to nonalcoholic controls (Halliday *et al.*, 1993). This difference was most pronounced in the caudal group of the raphe nuclei.

Acknowledgments

This chapter is dedicated to the memory of late Prof. Istvan Törk. This work was supported by grants of the National Health and Medical Research Council of Australia (to I. Törk) and by grants of the Swiss National Foundation (to J.-P. Hornung). Dr. R. G. H. Cotton and I. Jennings have generously provided the monoclonal antibody to label serotonergic neurons. The valuable assistance of R. Kraftsik and C. Lebrand for the preparation of this manuscript is gratefully acknowledged.

CHAPTER

14

Substantia Nigra and Locus Coeruleus

GLENDA HALLIDAY

Prince of Wales Medical Research Institute, The University of New South Wales
Sydney, Australia

There are two large nuclei containing neuromelanin-pigmented neurons in the human brain stem, the substantia nigra, and the locus coeruleus (Fig. 14.1). Although both nuclei contain neuromelanin-pigmented neurons (Fig.14.1), they have very little else in common; the locus coeruleus consists almost entirely of pigmented noradrenergic neurons (German *et al.*, 1988; Baker *et al.*, 1989), whereas the substantia nigra is a population of mixed neuron types that can be compartmentalized into at least three regions, one of which contains the largest group of dopaminergic neurons in the brain (Gibb and Lees, 1991; van Domburg and ten Donkelaar, 1991; Gibb, 1992; McRitchie *et al.*, 1996).

In humans mature dopaminergic and noradrenergic neurons contain considerable amounts of neuromelanin pigment distinguishing them from their surrounds. Surprisingly, the substantia nigra and locus coeruleus do not contain pigmented neuromelanin-containing cells at birth, but the pigment aggregates in the neurons of both regions during maturation and is clearly visible by eye at age 15–18 years (Mann and Yates, 1974). The brain stem of a 5-year-old child contains pigmented locus coeruleus neurons, with those in the substantia nigra remaining unpigmented (Olszewski and Baxter, 1954). The degree of pigmentation increases with age to reach a steady state within individual cells, and by age 30 a substantial proportion of the neurons in both regions contain neuromelanin pigment (Mann and Yates, 1974; Graham, 1984; Manaye *et al.*, 1995). Neuromelanin pigment is found in abundance only in the human brain stem. It was this characteristic that first drew attention to such neurons vulnerability to neurodegenerative diseases. Because of such vulnerability, both regions have been extensively studied in humans, with the bulk of attention on the changes found in the neuromelanin-containing neurons. Degeneration of the dopaminergic substantia nigra characterizes all parkinsonian conditions, with nondopaminergic nigral neurons also degenerating in selective movement disorders. Overactivity of noradrenergic locus coeruleus neurons is linked with neuropsychiatric conditions, whereas degeneration of this region occurs in diverse dementing and movement disorders. Dysfunction of these regions is common in the elderly.

The substantia nigra encompasses the most ventral part of the entire midbrain tegmentum, just dorsal to the cerebral peduncles (Fig. 14.1A; see also Chapter 10), whereas the locus coeruleus crowds the most lateral part of the pontine central gray matter, spilling over into the nearby tegmentum (Fig. 14.1B; see also Chapter 10). Consistent with other brain stem structures, these two nuclei are larger in their rostrocaudal extent than in cross-section. Research has established the locus coeruleus as a relatively homogeneous group of neurons, whereas the substantia nigra has a complex

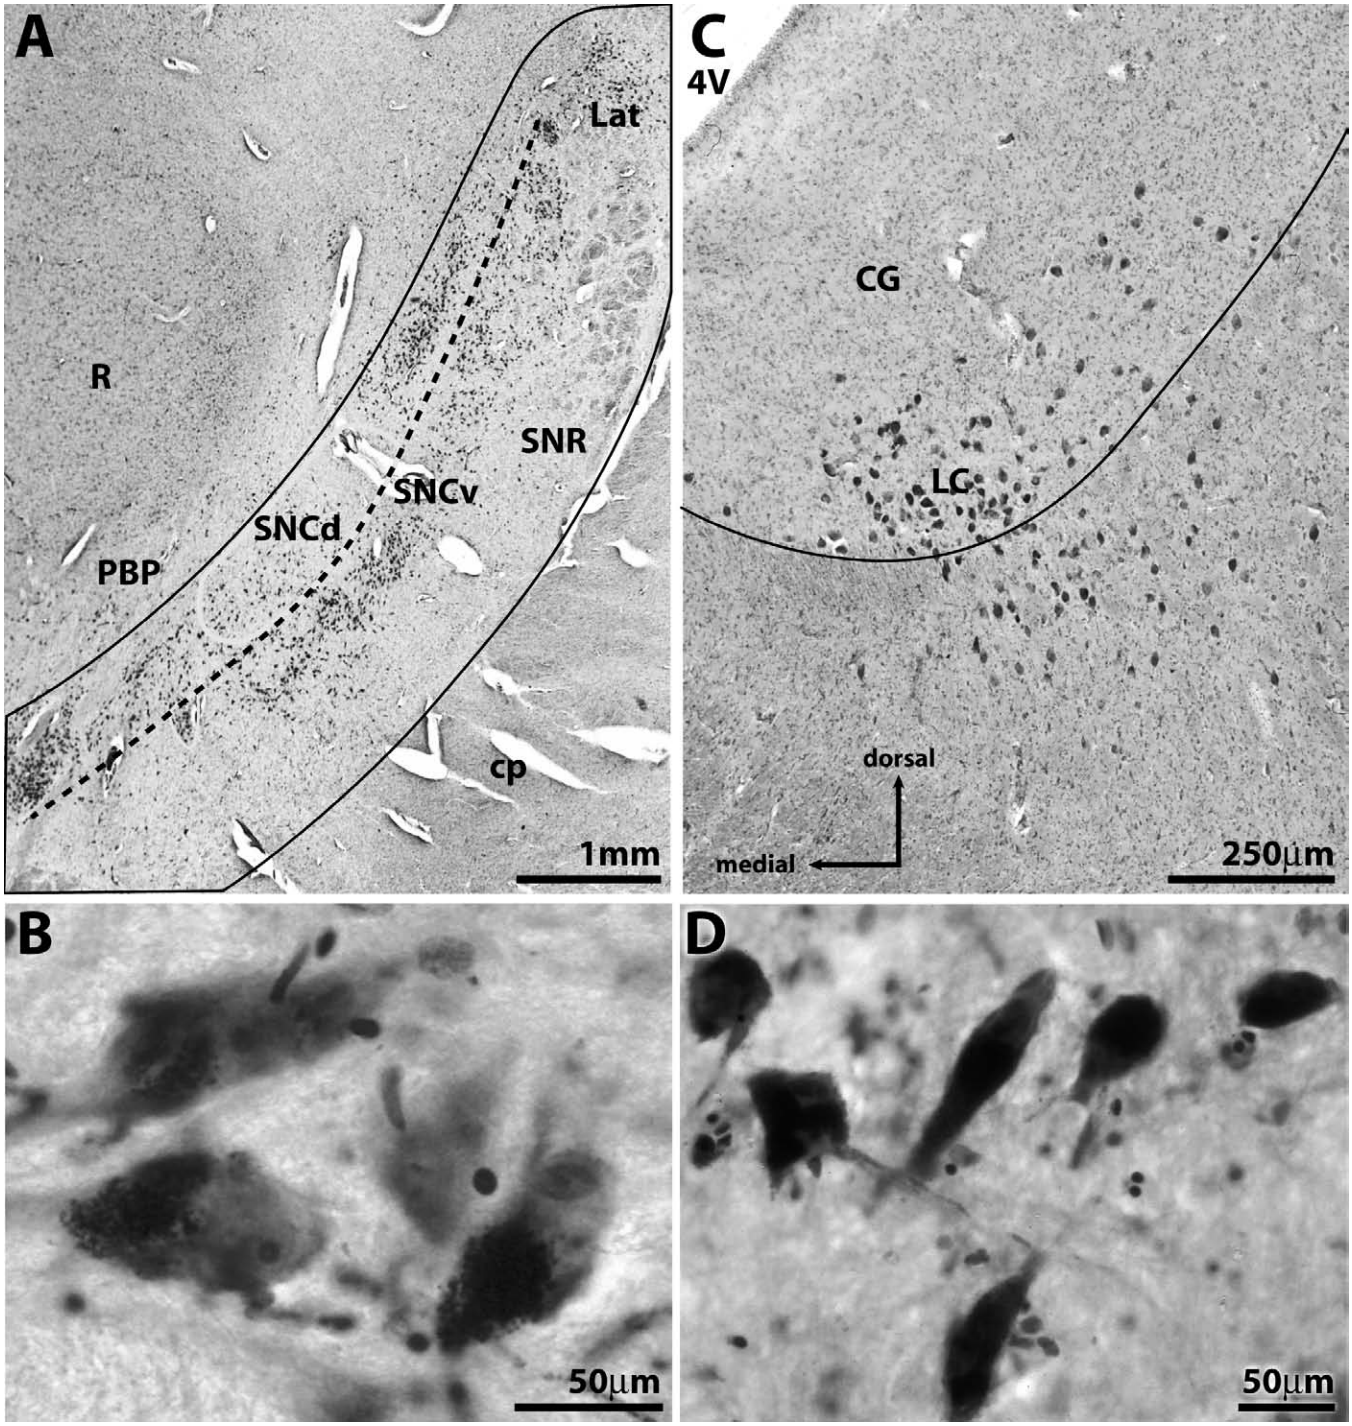

FIGURE 14.1 Photomicrographs of hematoxylin and eosin–stained transverse sections of the substantia nigra and locus coeruleus. These regions contain the highest densities of neuromelanin-pigmented neurons in the adult human brain. **A:** The substantia nigra is located in the ventral midbrain forming the bulk of tissue between the red nucleus (R) and the cerebral peduncle (cp). The nucleus has a three-tiered arrangement of neurons, a dorsal (SNCd) and ventral (SNCv) tier of the pars compacta neurons containing neuromelanin pigment, and the nonpigmented neurons of the pars reticulata (SNR) located more ventrally. It is separated from the red nucleus by the A10 cell cluster, the parabrachial pigmented nucleus (PBP). **B:** High magnification of neuromelanin-pigmented neurons of the substantia nigra. **C:** The locus coeruleus (LC) is located in the ventrolateral region of the central gray (CG) of the upper pons, and spills over into the nearby tegmentum. **D:** High magnification of neuromelanin-pigmented neurons of the locus coeruleus.

organization of multiple cell types. Neurons in the substantia nigra are arranged in a series of sheets or tiers, and within each tier are a series of columnar cell clusters. There is a complex topographical arrangement of carefully targeted projections to thalamic and brain stem sites as well as feedback circuits to the basal ganglia. This complex arrangement within the substantia nigra contrasts with the single-cell column structure of the locus coeruleus. The simplicity of the cellular arrangement of the locus coeruleus belies an extremely complex innervation pattern covering nearly the entire central nervous system.

SUBSTANTIA NIGRA
(see also Chapter 10 and 21)

The substantia nigra is considered an integral part of the basal ganglia, containing the dopaminergic neurons that provide a feedback loop to the striatum as well as the GABAergic neurons that relay basal ganglia output to the thalamus, colliculi, and tegmentum (Fig. 14.2; see also Chapter 21). It therefore plays a major role in the control of actions and thought.

Delineation

The boundaries of the human substantia nigra are not without contention, particularly its dorsal boundaries which interface with other cell clusters containing pigmented dopaminergic neurons. In particular, many works suggest that the substantia nigra extends dorsally to the red nucleus (Olszewski and Baxter, 1954; Hirsch *et al.*, 1988; German *et al.*, 1989; Damier *et al.*, 1999a). It was not until the technique of immunohistochemistry became a standard tool that the delineation of the borders of the human substantia nigra could be consistently identified by the dense neuropil immunostaining for substance P (Mai *et al.*, 1983; Gibb, 1992; McRitchie and Halliday, 1995; McRitchie *et al.*, 1995, 1996). The striatal axons innnervating the substantia nigra contain the tachykinin substance P (Ljungdahl *et al.*, 1978; Gerfen *et al.*, 1985; Pioro *et al.*, 1990), and this pathway identifies the midbrain relay neurons important for direct basal ganglia feedback (Fig. 14.2). Hence, the dense tachykinin staining of the substantia nigra can be used to define its boundaries, and covers a larger cross-sectional area of the ventral midbrain than similar dense immunostaining for either enkephalin or calbindin (Fig. 14.3), despite recent contrary assertions (Damier *et al.*, 1999a).

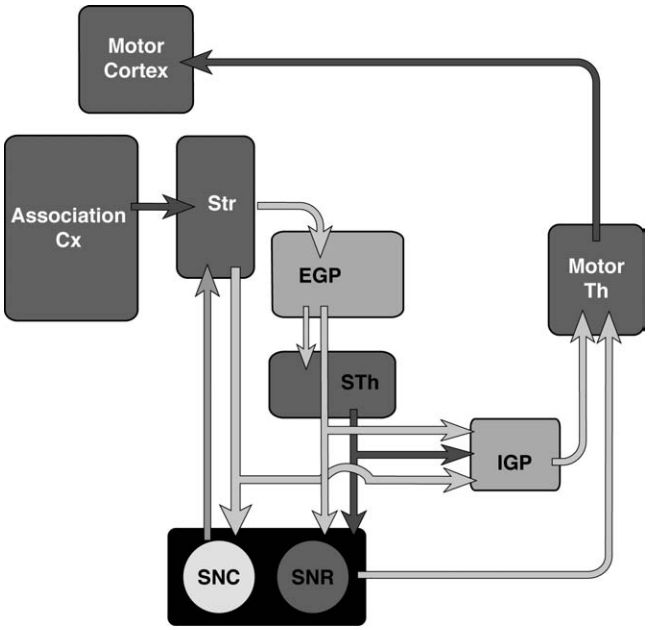

FIGURE 14.2 Schematic diagram of the main circuits of the basal ganglia (see Chapter xx for greater details). Information related to voluntary movement is channeled from the association cortices (Association Cx) to the caudate nucleus and putamen (together termed the striatum; Str). This information is then relayed directly or indirectly to the output nuclei of the basal ganglia (i.e., the internal globus pallidus, IGP; and the substantia nigra pars reticulata, SNR). The external globus pallidus (EGP) and subthalamic nucleus (STh) relay information from the striatum to the output nuclei, while the dopaminergic substantia nigra pars compacta (SNC) modulates striatal activity. The output nuclei project to the motor thalamus (MoTh), which in turn projects to the motor cortices (MoCx).

Neuronal Types

Tyrosine hydroxylase (TH)–positive pigmented neurons are typically medium sized to large, triangular, and multipolar, with a smaller proportion of spindle, bitufted neurons (Fig. 14.4). They contain variable amounts of neuromelanin pigment in the soma (Gibb, 1992) and substantial amounts of the high molecular weight nonphosphorylated neurofilament (Gai *et al.*, 1994) and microtubule-associated protein-2 (MAP 2) (D'Andrea *et al.*, 2001). They tend to have one large and two smaller primary dendrites, which become obscured by the local plethora of similar processes. Although there has been some contention in the literature (Parent *et al.*, 1996), few TH-positive pigmented neurons in the well-defined substantia nigra contain calbindin immunoreactivity (Gibb, 1992; McRitchie and Halliday, 1995; McRitchie *et al.*, 1996). These neurons carry the dopamine transporter (Ma *et al.*, 1999a) with some indication that the amount of this transporter

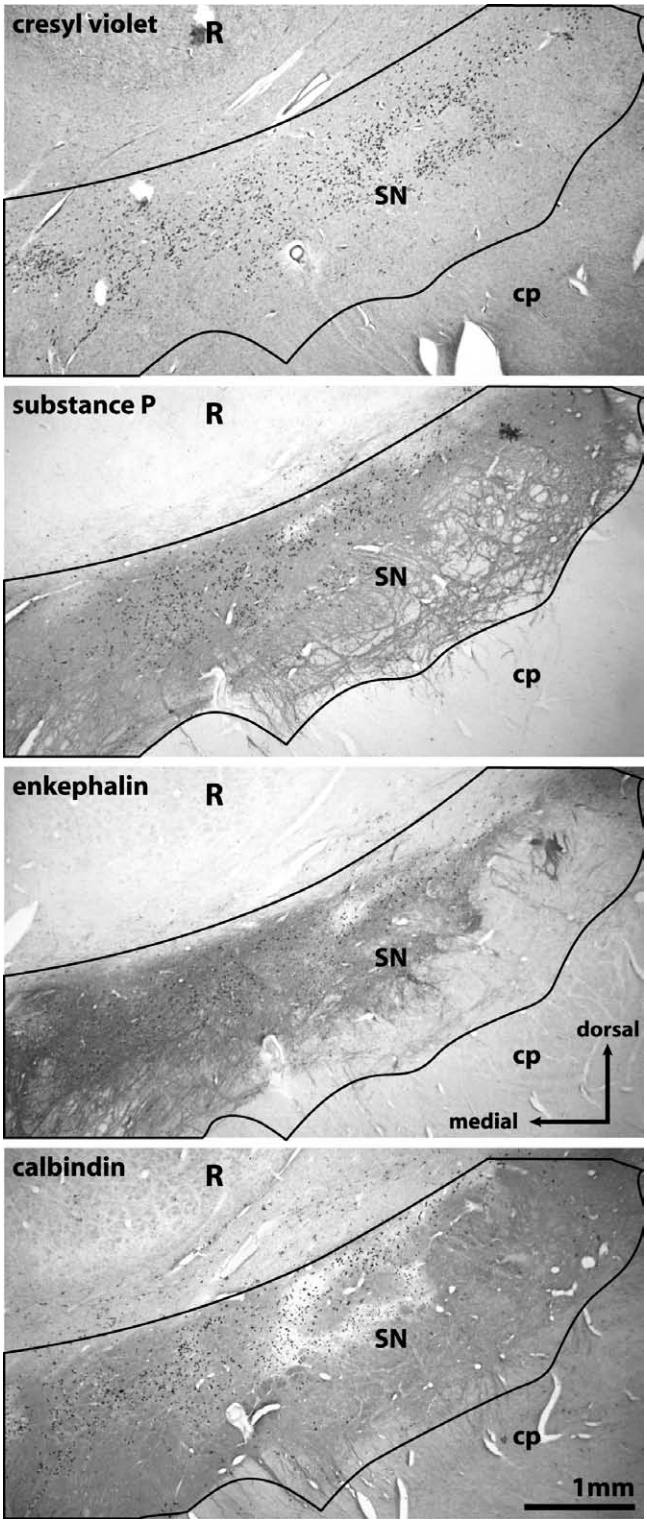

FIGURE 14.3 The substantia nigra can be defined as the midbrain region receiving striatal innervation. This innervation is clearly seen in immunohistochemical preparations identifying the peptide substance P. The dense substance P immunostaining consistently covers a larger cross-sectional area of the ventral midbrain than similar dense immunostaining for either enkephalin or calbindin.

within the soma region declines with age (Ma *et al.*, 1999a). In contrast to rats, human substantia nigra dopaminergic neurons express neurokinin-1 receptors rather than neurokinin-3 receptors (Whitty *et al.*, 1997). The effects of the striatal substance P and neurokinin A are thought to be mediated through this receptor (Whitty *et al.*, 1997). The neurons are also rich in α-synuclein and parkin (Solano *et al.*, 2000; Gavin *et al.*, 2001), as well as different growth factors (Walker *et al.*, 1998; Parain *et al.*, 1999; Howells *et al.*, 2000), synaptic and cellular proteins shown to be important for the survival and normal function of these neurons. The neurons also possess the appropriate trkB (Benisty *et al.*, 1998) and fibroblast growth factor (Walker *et al.*, 1998) receptors in high quantities.

The nonpigmented neurons in the human substantia nigra have not been analyzed with the same intensity. However, these neurons are known to be nondopaminergic as they do not display TH immunoreactivity (Hirsch *et al.*, 1988; Kubis *et al.*, 2000). The calcium-binding proteins calretinin and parvalbumin are found within the nonpigmented neurons of the human substantia nigra (McRitchie *et al.*, 1996). Neurons containing these calcium-binding proteins have been shown to be nondopaminergic in colocalization studies in other species (Parent *et al.*, 1995). Nonpigmented calretinin-containing neurons are typically bipolar, although some multipolar neurons also contain this calcium-binding protein (Fig. 14.4). The processes of these neurons have small varicosities at irregular intervals. Nonpigmented parvalbumin-containing neurons are small and typically multipolar, with round or triangular somas (Fig. 14.4). These neurons are similar in morphology to neurons in the globus pallidus (Yelnik *et al.*, 1987), with sparsely branching dendrites. These three major cell types are similar to those described using Golgi impregnation techniques (Braak and Braak, 1986; Yelnik *et al.*, 1987).

Cytoarchitecture

The substantia nigra contains three broad sheets or tiers of neuronal columns abutting the cerebral peduncle oriented ventromedial to dorsolateral in cross-section. In humans there is quite a complex arrangement of cell clusters in these regions, epitomized by the 21 subdivisions identified by Hassler (1937, 1938). The following descriptions are based on the broad agreement of the majority of studies in this area (Braak and Braak, 1986; Fearnley and Lees, 1991; Gibb and Lees, 1991; van Domburg and ten Donkelaar, 1991; Gibb, 1992; McRitchie and Halliday, 1995; McRitchie *et al.*, 1995, 1996) and incorporate the recent concepts using calbindin immmunostaining to define the

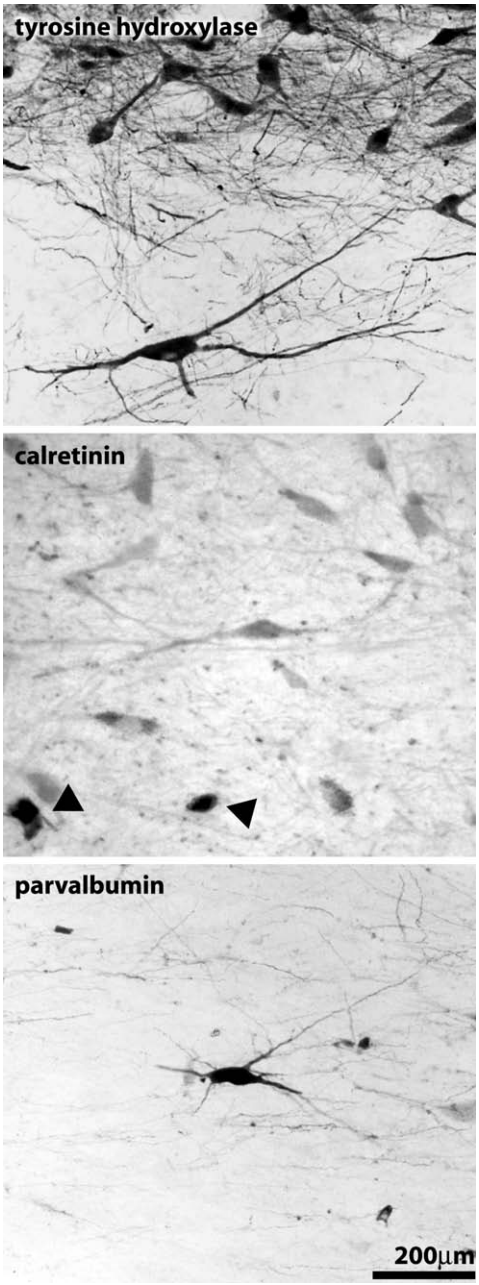

FIGURE 14.4 There are three basic types of neurons in the substantia nigra that can be identified immunohistochemically with tyrosine hydroxylase (TH), calretinin, or parvalbumin. The distinct morphology and distribution of these neurons suggests nonoverlapping populations. TH+ neurons are typically medium sized to large, triangular, and multipolar. They contain neuromelanin pigment and tend to have one large and two smaller primary dendrites, which usually become obscured within the local plethora of similar processes *(top of figure)*. Two types of nonpigmented, nondopaminergic neurons are found within the substantia nigra containing distinct calcium binding proteins. Nonpigmented calretinin-containing neurons are typically bipolar, whereas nonpigmented parvalbumin-containing neurons are typically multipolar, with round or triangular somas. Parvalbumin-containing neurons concentrate in the pars reticulata, while the calretinin-containing neurons are only found between the cell clusters of the pars compacta (pigmented neurons, *arrowheads*).

dopaminergic cell clusters in the substantia nigra (Damier *et al.*, 1999a).

Dorsally the closely related parabrachial pigmented nucleus is found between the substantia nigra and the red nucleus. This region has been recently called the substantia nigra pars dorsalis (Damier *et al.*, 1999a) and is easily distinguished cytoarchitecturally by the lower density of pigmented neurons and the ventromedial to dorsolateral orientation of their dendritic tree. Within the substantia nigra, the most ventral sheet of neurons largely comprises the GABAergic pars reticulata (288,000 ± 32,000 neurons in humans; Hardman *et al.*, 2002) while more dorsally there are two sheets of pigmented dopaminergic pars compacta neurons (totaling 382,000 ± 20,000 neurons in humans, Hardman *et al.*, 2002). These three sheets of neurons are squashed together at both the ventromedial and dorsolateral extremes (Fig. 14.5). These regions are called the pars medialis and pars lateralis. In these regions there is considerable mixing of neuron types.

Pars Compacta

The pars medialis, pars lateralis, and dorsal tier appear aligned along the dorsal border of the substantia nigra. The dorsal and ventral tiers of pigmented dopaminergic neurons are more conspicuous at different rostrocaudal levels (Fig. 14.5). The dorsal tier is significantly larger than the ventral tier and predominates both caudally and rostrally. The ventral tier is most noticeable at intermediate levels of the midbrain. Equal numbers of dopaminergic neurons are found in these tiers (Hardman *et al.*, 2002). In humans these tiers are arranged in longitudinal cell clusters with small bridges of pigmented neurons interspersed between the clusters (Fig. 14.6). These bridges comprise dorsomedial-to-ventrolateral aligned neurons, whereas there is a more random orientation of neurons and processes in the cell clusters. Both the dorsal and ventral tiers can be subdivided into medial, intermediate, and lateral longitudinal cell cluster regions based on the density and aggregations of pigmented neurons (Fig. 14.6). The densest cell clusters in the dorsal tier correspond to a dorsomedial column (McRitchie *et al.*, 1995), called nigrosome 2 (Damier *et al.*, 1999a), and a dorsolateral column (McRitchie *et al.*, 1995), called nigrosomes 4 and 5 (Damier *et al.*, 1999a). Nigrosome cell clusters are defined as having a significant decrease in fibers containing calbindin immunoreactivity around them (Damier *et al.*, 1999a). The dorsomedial column or nigrosome 2 is the most consistent and densely packed cell column, with the dorsolateral column (particularly nigrosome 5) always found at rostral levels (Fig. 14.6). Within the ventral tier, the intermediate and lateral cell columns (McRitchie

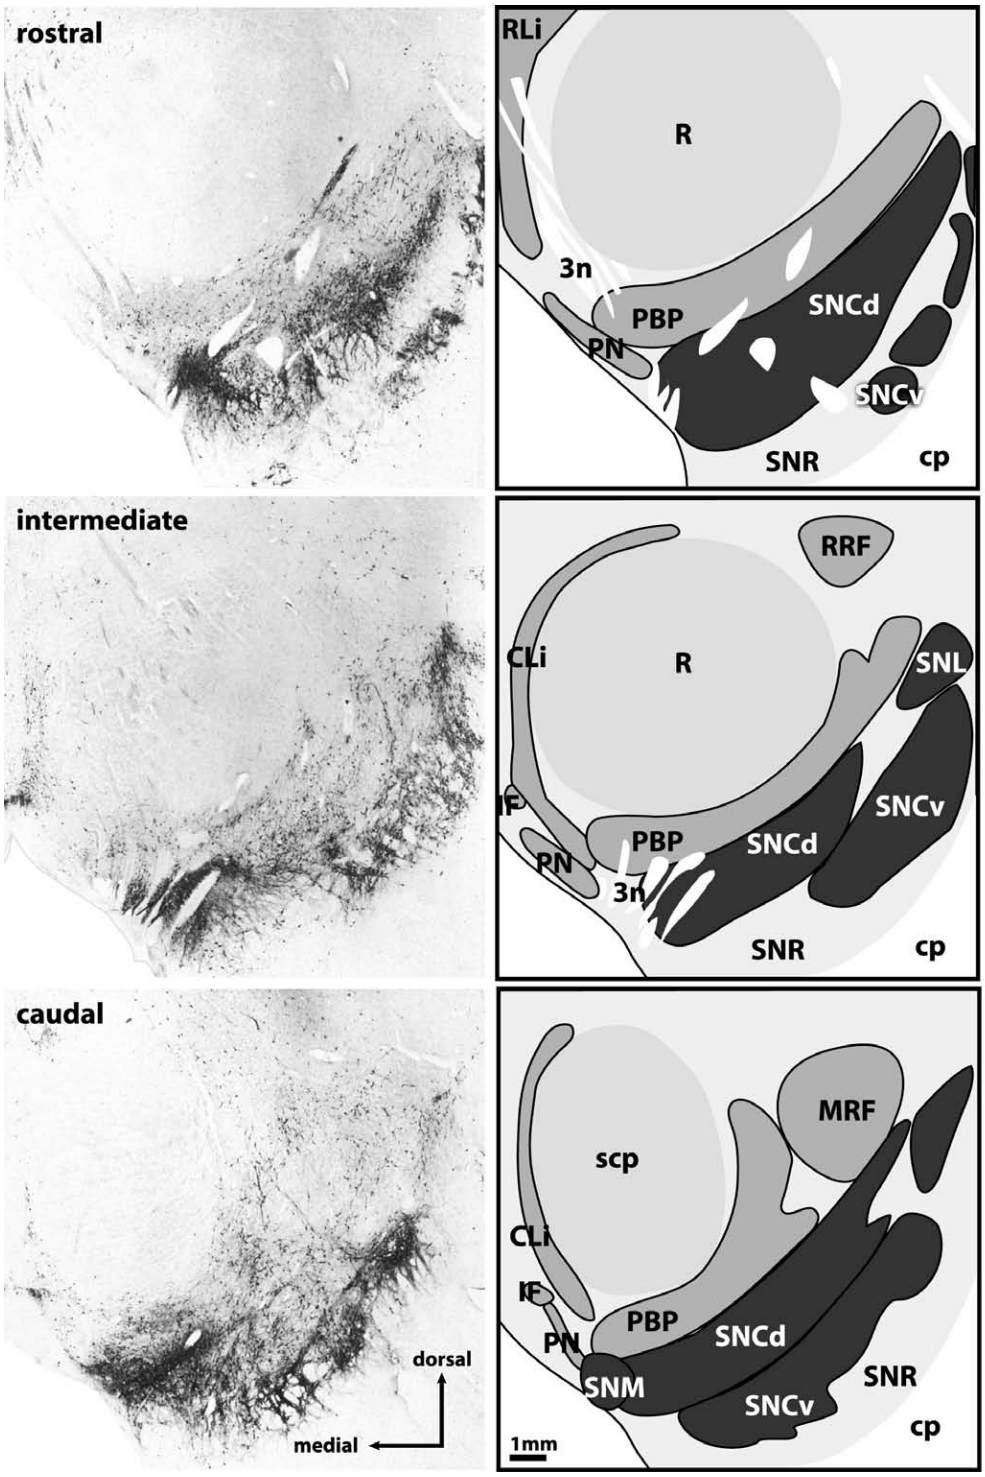

FIGURE 14.5 Three rostrocaudal transverse levels of the midbrain immunohistochemically stained for tyrosine hydroxylase (TH) showing the two dopaminergic tiers of the substantia nigra pars compacta (dorsal, SNCd, and ventral, SNCv) with the position of the more ventral pars reticulata (SNR) indicated. The pars lateralis (SNL) is located dorsolaterally within the substantia nigra, while the pars medialis (SNM) is located caudally on the dorsomedial border. The less cell-dense paranigral nucleus (PN, part of the A10 cell group) medially abuts directly onto this region of the substantia nigra. The very diffuse parabrachial pigmented nucleus (PBP) containing dopaminergic A10 cells can be seen dorsally between the red nucleus (R) and cerebral peduncle (cp). Other midbrain dopaminergic nuclei are indicated—rostral linear nucleus (A10 RLi), caudal linear nucleus (A10 CLi), interfasicular nucleus (A10 IF), and retrorubral fields (A8 RRF). 3n, third nerve; scp, superior cerebellar peduncle.

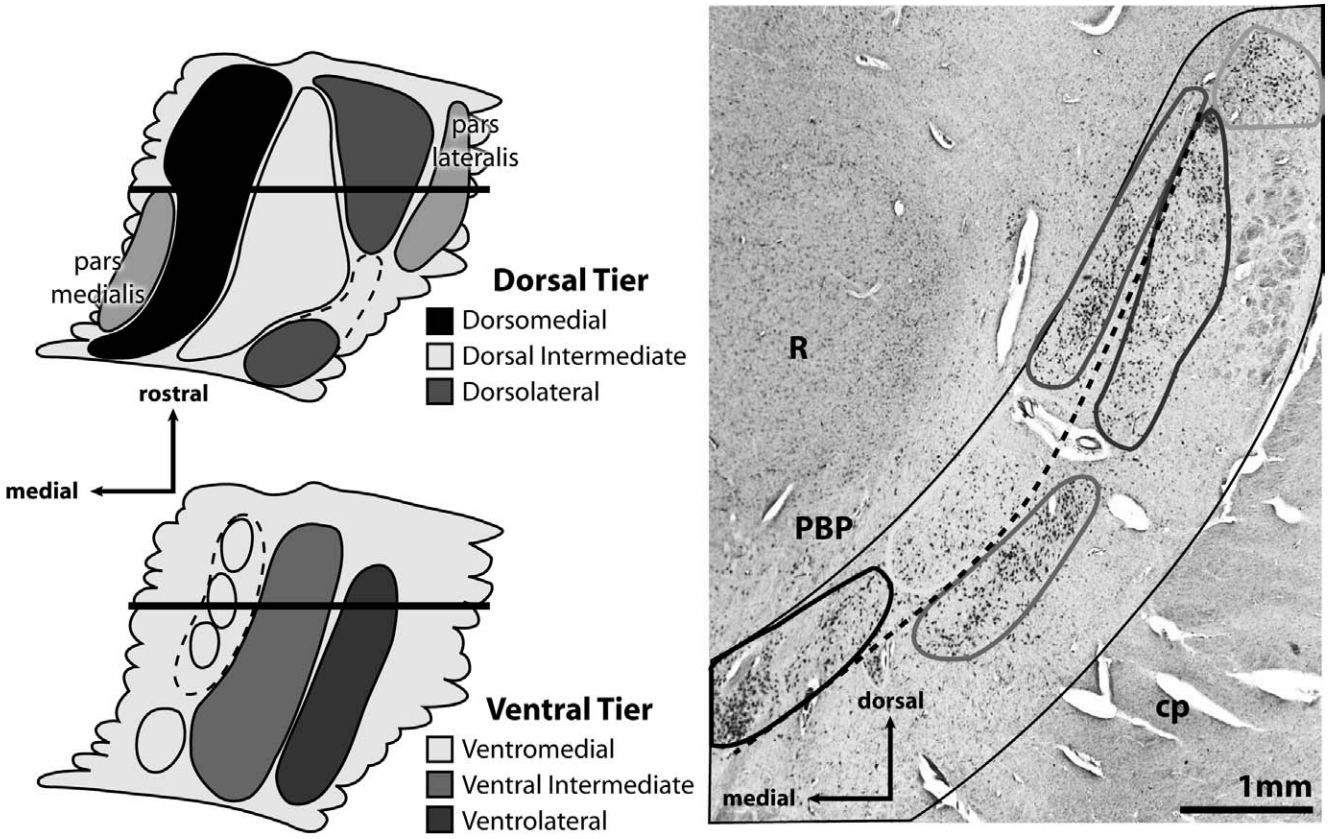

FIGURE 14.6 This diagram represents the consistently found cell clusters of the substantia nigra pars compacta as two-dimensional cell columns oriented obliquely as indicated by the dotted line on the cresyl violet–stained transverse section through this region. The diagrams were drawn from three-dimensional reconstructions of the cross-sections of the cell clusters, which clearly show that these clusters form longitudinal aggregations of neurons (McRitchie *et al.,* 1995). The level of the transverse section shown is indicated by the line. Shading gives some indication of the cell density with variable regions of cell clusters indicated by dotted lines. The dorsomedial column is equivalent to nigrosome 2, the dorsolateral column is equivalent to nigrosomes 4 caudally and 5 rostrally, the pars lateralis is equivalent to nigrosome 3, and the ventral intermediate and ventrolateral columns are equivalent to nigrosome 1 (Damier *et al.,* 1999).

et al., 1995), together called nigrosome 1 (Damier *et al.*, 1999a), have high cell densities, with the lateral cell column concentrating caudally (Fig. 14.6). The other cell columns (dorsointermediate and ventromedial) contain significantly fewer neurons (Fig. 14.6) and are found embedded within the calbindin-immunoreactive matrix (Damier *et al.*, 1999a).

The pars medialis is present only in the caudal midbrain within the dense substance P- and calbindin-immunoreactive striatonigral fiber matrix (Figure 14.6). This matrix separates the nigra from the medial A10 or ventral tegmental area cell clusters. The pars medialis is characterized by densely packed neurons that are smaller than the dorsal tier. Caudally the medial terminal nucleus of the accessory optic tract and the exiting third-nerve fibers separate the pars medialis from the dorsal tier. A proportion of pigmented neurons in the pars medialis contain calbindin or calretinin immunoreactivity. The pars lateralis (McRitchie *et al.*, 1995), called nigrosome 3 (Damier *et al.*, 1999a), is found at the dorsolateral extreme of the substantia nigra (Fig.14.6), lateral to the corticonigral and pallidonigral fiber tracts, and has a significantly decreased cell packing density compared to the dorsal tier. In addition to pigmented dopaminergic neurons, the pars lateralis contains nonpigmented parvalbumin-containing TH-positive neurons.

Pars Reticulata

In humans, neurons of the pars reticulata aggregate rostrally and ventrally (Fig. 14.7), although nonpigmented neurons are also found between the dense cell clusters of the nigra. The nonpigmented neurons between the clusters of pigmented cells contain either

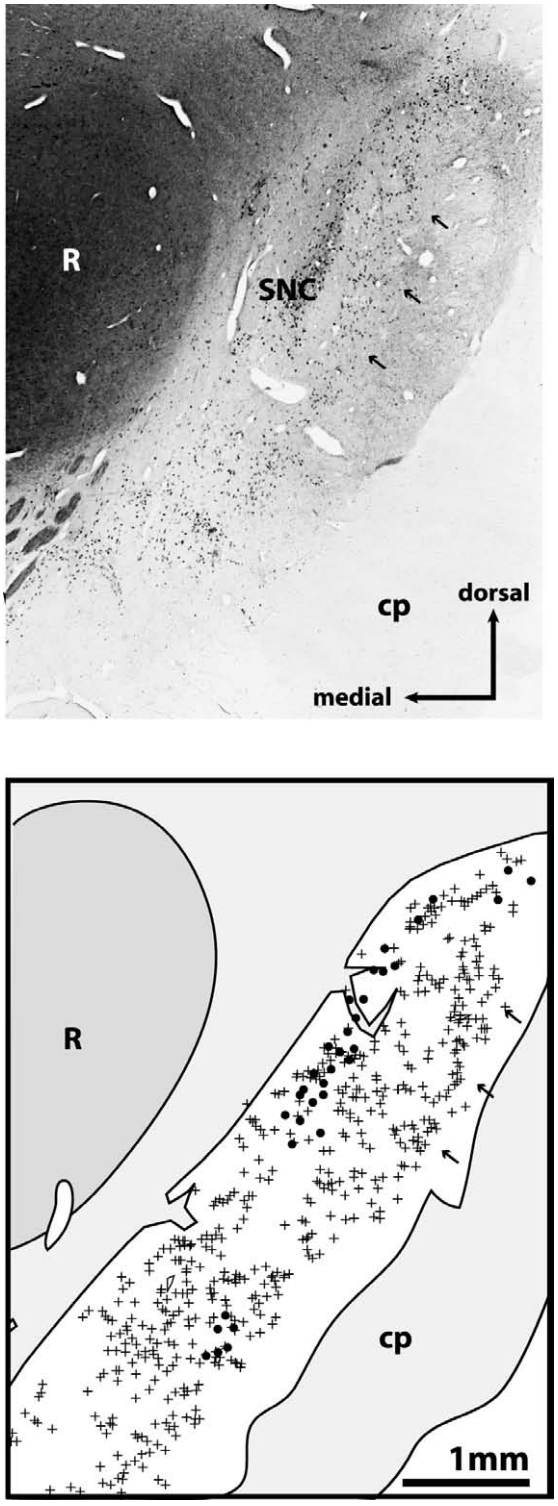

FIGURE 14.7 Parvalbumin-immunoreactive transverse section of the rostral midbrain and distributional plot of the immunoreactive neurons *(crosses)* within the substantia nigra. While many immunoreactive neurons are found in the pars reticulata *(arrows)*, these neurons are widely dispersed within the substantia nigra (pigmented cells indicated by *black circles*). Note the high neuropil immunostaining for parvalbumin in the red nucleus (R). cp, cerebral peduncle.

calretinin or parvalbumin immunoreactivity, whereas the neurons comprising the ventral sheet of reticulata neurons contain only parvalbumin immunoreactivity (Fig. 14.7).

Functional Connections

As stated above, the substantia nigra is an integral part of the basal ganglia, which regulates the pyramidal system (Fig. 14.2; see also Chapter 21). The basal ganglia system may be viewed as a system collecting and processing information from almost the whole extent of the cortex in order to finally furnish adequate information to the only cortex involved in movement preparation and execution. The dopaminergic substantia nigra pars compacta regulates the incoming cortical information at the level of the striatum (see Chapter 21). The GABAergic pars reticulata is one of the two major output nuclei of the basal ganglia, channeling information to thalamocortical relays and brain stem targets (see also Chapters 20 and 21).

Pars Compacta (see also Chapter 21)

While the dopaminergic pars compacta neurons form an integral feedback system to the striatum, the striatonigrostriatal loop is set up to disseminate such feedback (about 100 striatal neurons for each TH-positive nigral neuron) (Percheron *et al.*, 1994). Pars medialis dopaminergic neurons receive projections from the medial limbic striatum (nucleus accumbens) and project to multiple limbic sites, including the accumbens nucleus and limbic cortices (Porrino and Goldman-Rakic, 1982; Swanson, 1982; Loughlin and Fallon, 1984; Takada and Hattori, 1986; Haber *et al.*, 2000). Dorsal tier neurons receive projections from the striatal regions innervated by association cortices (caudate and anterior putamen). These neurons project back to the striatal association regions innervating them (Haber *et al.*, 2000). Ventral tier neurons receive innervation from both associative and sensorimotor regions of the striatum. These ventral neurons, particularly the lateral cell group, nearly selectively innervate sensorimotor innervated regions of the striatum (intermediate and posterior putamen) (Haber *et al.*, 2000). Pars lateralis dopaminergic neurons receive innervation from the caudate region innervated by visual and oculomotor cortical regions. This lateral region projects directly to the inferior and superior colliculi (Francois *et al.*, 1984; Tokuno *et al.*, 1993; Harting *et al.*, 2001).

Pars Reticulata (see also Chapters 20 and 21)

The nondopaminergic neurons in the pars reticulata project to the thalamus, with two smaller proportions projecting to the colliculi (located rostrally and

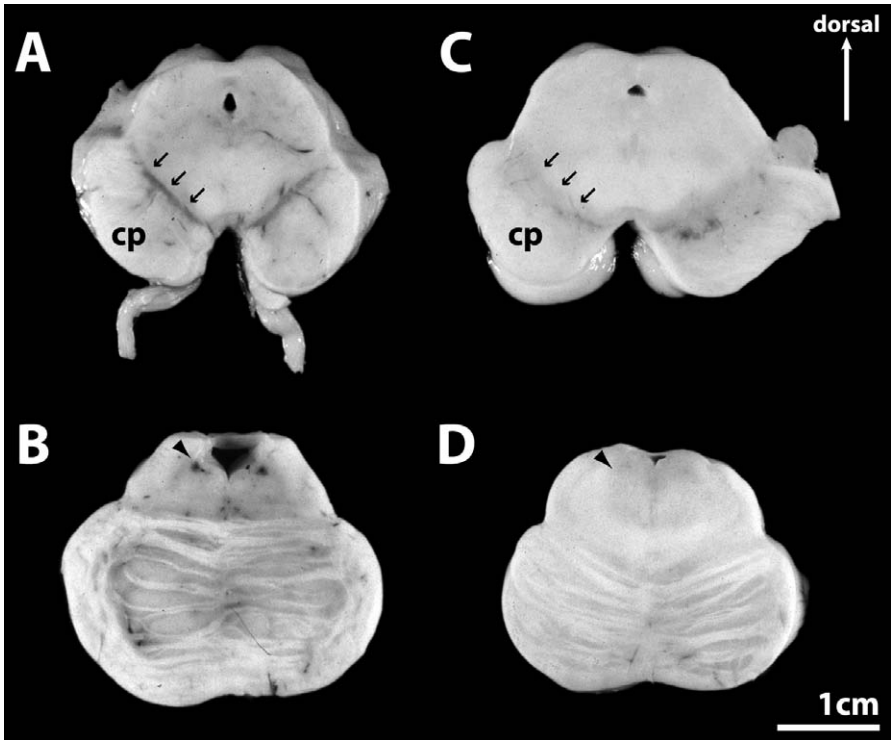

FIGURE 14.8 Macroscopically, the pigmented nuclei of the midbrain and pons are obvious in transverse sections of the normal human brain. **(A)** The pigmented substantia nigra is found in the midbrain just dorsal to the cerebral peduncle (cp). **(B)** The pigmented locus coeruleus is found in the dorsolateral pontine central gray. In Parkinson's disease, both the substantia nigra and locus coeruleus are severely depigmented **(C, D).**

laterally) or the reticular formation (located caudally) (Beckstead, 1983; Francois *et al.*, 1984; Percheron *et al.*, 1994). These projections are largely nonoverlapping in primates.

Change with Age and Human Disease

There is no consistent finding of cell loss with age in the substantia nigra pars compacta (pars reticulata not analyzed). Cross-sectional studies that include people ranging from 40 to 110 years of age consistently find no neuronal loss with age (Halliday *et al.*, 1996; Muthane *et al.*, 1998; Kubis *et al.*, 2000), whereas studies that include people younger than 25 years find age-related neuronal loss (Fearnley and Lees, 1991; Ma *et al.*, 1999b). The differences between studies may suggest that younger people may have an expanded substantia nigra pars compacta. Further studies and larger cohorts are required.

Despite some contention over the presence of age-related cell loss in the dopaminergic substantia nigra, the catastrophic loss of dopaminergic nigral neurons in patients with parkinsonism is without dispute. Thus, the degree of any age-related change is miniscule compared to diseases that impact on this region (Fig. 14.8). The most widely recognized disease affecting this region of the substantia nigra is Parkinson's disease. The definitive analysis of the involvement of the pars compacta in Parkinson's disease was performed by Hassler in 10 cases (Hassler, 1938). He found a constant cell loss with fibrous glial reaction in the central cell groups of the pars compacta and confirmed the presence of Lewy bodies as a defining lesion. Since then a large number of studies have confirmed this finding, which underlies current treatment strategies for this disease (Lozano *et al.*, 1998). Several studies have shown the highly selective nature of the cell loss as impacting most on the ventral intermediate and lateral cell groups of the pars compacta (Fearnley and Lees, 1991; Halliday *et al.*, 1996; Damier *et al.*, 1999b). The reason for this selective vulnerability of only a fraction of the dopaminergic neurons in the substantia nigra remains unknown. No apparent difference in a range of critical measures has been found, e.g., dopamine synthesis capacity (Kingsbury *et al.*, 1999), dopamine transporter gene expression (Counihan and Penney, 1998), and growth factor receptors (Benisty *et al.*, 1998; Walker *et al.*, 1998), although a loss of brain

derived growth factor (Parain *et al.*, 1999; Howells *et al.*, 2000) and nonphosphorylated neurofilament (Gai *et al.*, 1994) occurs in surviving dopaminergic neurons in patients with Parkinson's disease.

The dopaminergic substantia nigra is affected in all parkinsonian conditions, and not just in Parkinson's disease (Jellinger, 1998). Other conditions include dementia with Lewy bodies, multiple-system atrophy, Pick's disease, parkinsonism–dementia complex of Guam, progressive supranuclear palsy, corticobasal degeneration, and postencephalitic parkinsonism. These last three disorders impact severely on both the dopaminergic and nondopaminergic regions of the substantia nigra, depositing tau-positive neurofibrillary tangles in the few surviving compacta and reticulata neurons (Hardman *et al.*, 1997; Jellinger, 1998; Oyanagi *et al.*, 2001). All of these disorders affect multiple brain regions, with the substantia nigra only one of many regions involved in the disease processes.

LOCUS COERULEUS AND SUBCOERULEUS
(see also Chapter 10)

By far the largest group of noradrenergic neurons in the human brain are those located in the locus coeruleus and adjacent subcoeruleus (German *et al.*, 1988; Baker *et al.*, 1989). This relatively homogeneous compact nucleus contains 45,000–50,000 neurons bilaterally in the lateral central gray and another 5000–10,000 neurons in the lateral aspects of the central pontine tegmentum (Baker *et al.*, 1989). These neuronal clusters form a continuous column extending some 15 mm rostrocaudally in the upper lateral pontine central gray of adult humans (Fig. 14.9).

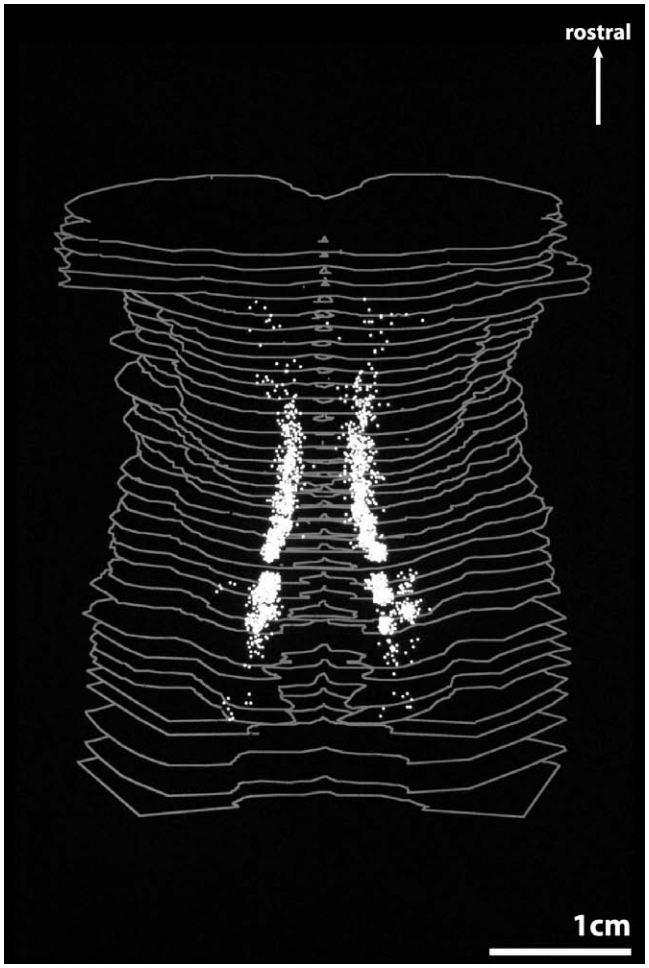

FIGURE 14.9 Three-dimensional reconstruction of transverse cell plots of pigmented locus ceoruleus and subcoeruleus neurons. One in 15 cells is shown with transverse sections spaced 750 μm apart. The locus coeruleus and subcoeruleus form a continuous cell column in the upper pons and caudal midbrain.

Delineation

The definition of the locus coeruleus is without dispute. Its characteristic neuromelanin-pigmented neurons (Fig. 14.1) have been successfully identified in a myriad of studies for nearly a century (Maeda, 2000).

Neuronal Types

Neurons in the locus coeruleus are nearly all pigmented and considered noradrenergic on the basis of their neurochemistry (German *et al.*, 1988; Baker *et al.*, 1989). They possess α_2-adrenoceptors (Klimek and Ordway, 1996), with some indication that the amount of this receptor declines with age (Klimek and Ordway, 1996). Medium (35–45 μm in diameter) and small (15–25 μm in diameter) pigmented neurons are found in this nucleus. The medium-sized locus coeruleus neurons are multipolar and tend to have round or oval somata (Fig. 14.10). Each cell usually has three or four long, thin, cylindrical dendrites that branch once or twice a short distance from the cell. The dendrites are up to 1 mm in length and often extend beyond the nucleus into surrounding structures. The small pigmented neurons are more spindle shaped with two tufts of dendrites (Fig. 14.10). These neurons concentrate in the subcoeruleus, although many medium-sized neurons are also found here, particularly in the rostral subcoeruleus. An unusal feature of the pigmented neurons in the human locus coeruleus is the deeply embedded axosomatic synapses possessed by these neurons (Iwanaga *et al.*, 1995). The anatomical arrangement of these synapses allows neurochemical interactions at previously unsuspected cellular sites.

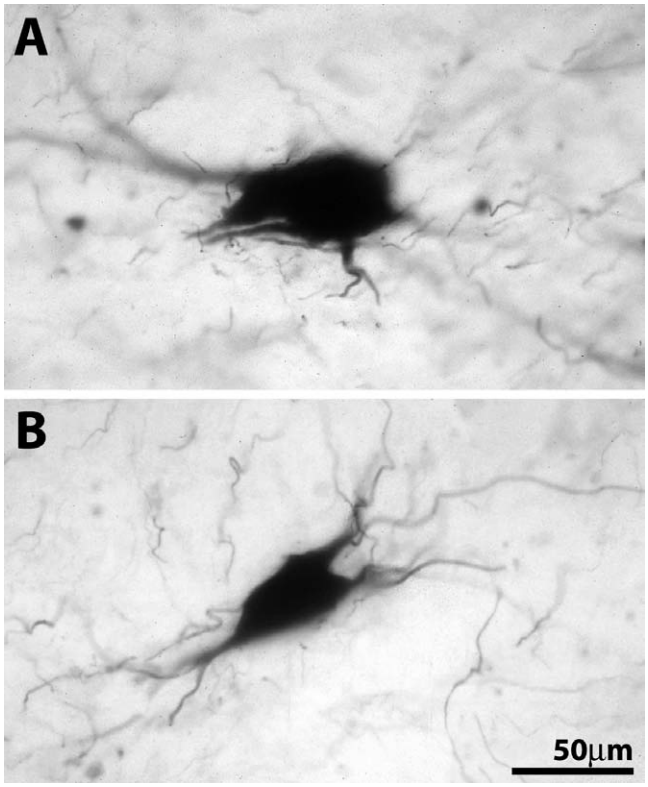

FIGURE 14.10 There are two main types of noradrenergic locus coeruleus neurons. The photomicrographs show TH-immunoreactive neurons of the locus coeruleus **(A)** and subcoeruleus **(B).** Medium-sized neurons are multipolar and tend to have round or oval somata with long cylindrical dendrites (A). Smaller neurons are more spindle shaped, with two tufts of dendrites (B).

A small number of pigmented neurons contain neuropeptide Y and/or galanin (Fodor *et al.*, 1992; Miller *et al.*, 1999).

Cytoarchitecture

Rostrally, locus coeruleus neurons are dispersed in the ventrolateral region of the gray matter, medial to the mesencephalic tract of the trigeminal nerve (Fig. 14.11). At its greatest density at the level of the superior medullary velum, the nucleus is divided into two distinct regions—dorsomedially the neurons are packed closely together whereas ventrolaterally the cells are more dispersed (Fig. 14.11). By midpontine levels the ventrolateral region has extended to form the subcoeruleus proper within the central tegmental regions (Fig. 14.11). The nucleus persists in a caudal direction until few neurons are found in the central gray region and only the subcoeruleus remains (Fig. 14.11). Caudally, scattered neurons extend to the level of the facial nerve whereas rostrally the nucleus tapers at the level of the decussation of the trochlear nerve continuing as scattered neurons in the midbrain periaqueductal gray (Fig. 14.9).

Functional Connections

The locus coeruleus is unique in the brain, being unsurpassed in the divergence and ubiquity of its projections through the central nervous system (Jones, 1991). In this regard it shares certain characteristics with peripheral sympathetic noradrenergic neurons. Nearly all levels of the central nervous system are innervated by this relatively small set of neurons, with the locus coeruleus providing the sole noradrenergic innervation of the cerebral, limbic, and cerebellar cortices. In contrast to this remarkable divergence, there are limited major inputs to the soma of locus coeruleus neurons from the ventral and dorsal medullary relays of sympathetic control and behavioral orienting responses found in the paragigantocellular nucleus and the prepositus hypoglossal nucleus (Aston-Jones *et al.*, 1991). Other afferents (cortical and subcortical) concentrate on the distal dendrites of these neurons, only affecting neuronal output with significant impulse trains (Aston-Jones *et al.*, 1991, 1994, 1999). This unique anatomical arrangement of restricted dominant and diverse weaker afferents along with divergent efferent projections is not found in any other brain stem region. Although it has been difficult to find consensus on the role of this nucleus in the brain, several studies now support the concept that this region is important for vigilance, particularly focused or selective attention and behavioral flexibility or scanning attentiveness (Aston-Jones *et al.*, 1994, 1999).

Change with Age and Human Disease

Similar to research on the substantia nigra, there is no consistent finding of cell loss with age in the locus coeruleus. Cross-sectional studies using modern three-dimensional counting techniques consistently find no neuronal loss with age (Mouton *et al.*, 1994; Ohm *et al.*, 1997), whereas studies using density counts find age-related neuronal loss (Vijayashanker and Brody, 1979; German *et al.*, 1988; Marcyniuk *et al.*, 1989; Manaye *et al.*, 1995). These latter studies emphasize the topographic location of the age-related cell loss (rostral rather than caudal), a finding that is not possible to dissect out using the modern sampling techniques. This location of cell loss is thought to correspond to regions featuring more cortically projecting neurons.

As with the substantia nigra, the degree of cell loss in disease states is an order of magnitude different from that observed with age. The number of conditions affecting the locus coeruleus appears to be more

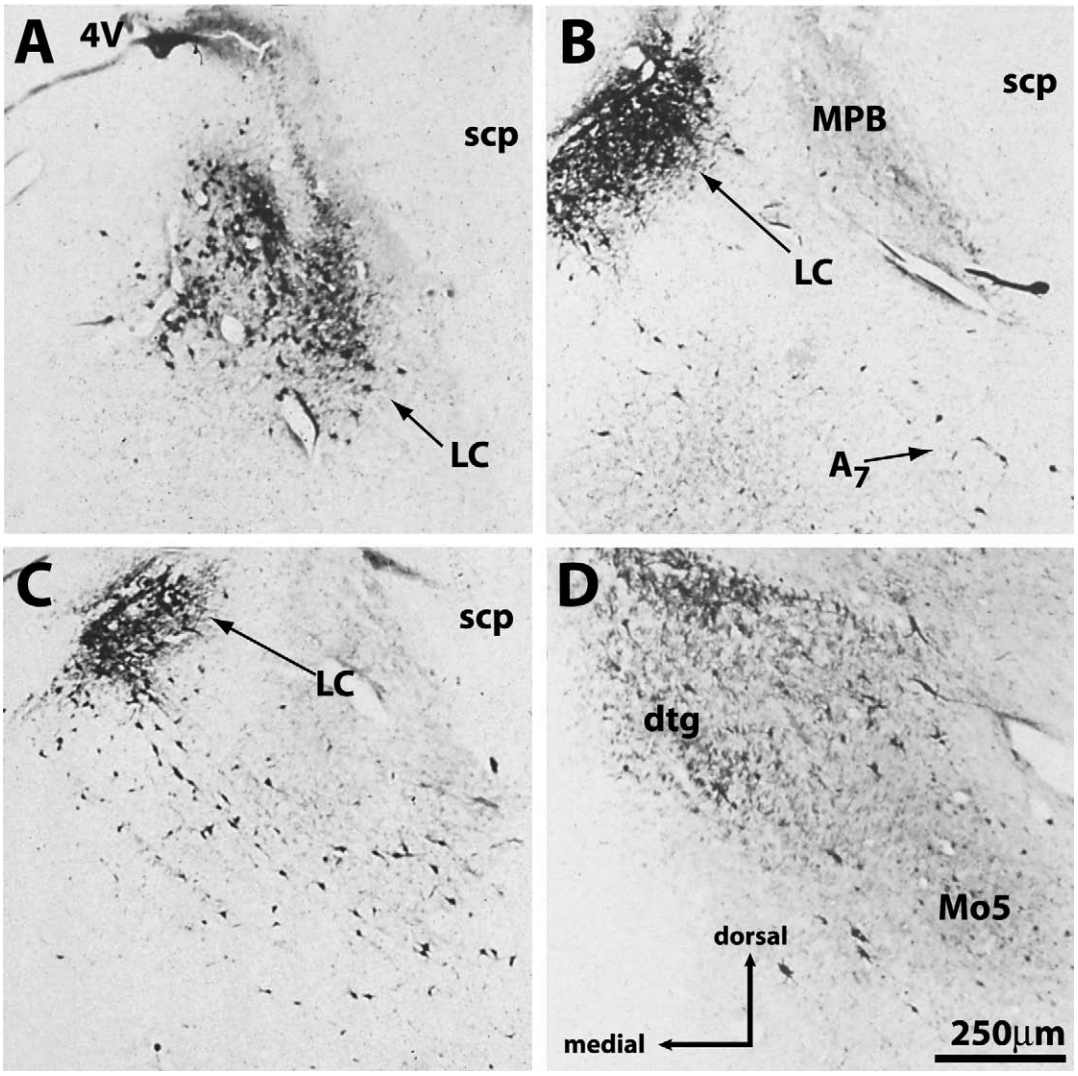

FIGURE 14.11 Photomicrographs of transverse sections through the locus coeruleus at different rostrocaudal levels. 4V, fourth ventricle; dtg, dorsal tegmental tract; MPB, medial parabrachial nucles; Mo5, motor trigeminal nucleus; scp, superior cerebellar peduncle. **A:** Rostrally, locus coeruleus neurons are dispersed in the ventrolateral region of the central gray, around the mesencephalic tract of the trigeminal nerve. **B:** At the level of the superior medullary velum, dorsomedially neurons are packed closely together, whereas ventrolaterally the cells are more dispersed. **C:** At mid-pontine levels, the ventrolateral region has extended to form the subcoeruleus proper within the central tegmental region. **D:** The nucleus persists in a caudal direction until few neurons are found within the central gray region and only the subcoeruleus remains.

diverse, covering both neurodegenerative dementing conditions and movement disorders (German *et al.*, 1992; Hoogendijk *et al.*, 1995). Considering the diverse projections of these neurons, it is not difficult to understand that many neurodegenerative conditions would impact on this region, if only in a retrograde fashion. In addition, a number of nondegenerative psychiatric conditions are suggested to impact on the locus coeruleus. In particular, the levels of TH and binding to α_2-adrenoceptors are increased in neurons of the locus coeruleus in depressed patients (Ordway *et al.*, 1994; Ordway, 1997; Zhu *et al.*, 1999), and a major treatment for depression is the use of tricyclic antidepressants, which reduces locus coeruleus activity. These medications are also effective for panic attacks (Mountjoy *et al.*, 1977).

The majority of research on this region has occurred in patients with Alzheimer's disease or Parkinson's disease. A substantial reduction in noradrenergic locus coeruleus neurons occurs in Alzheimer's disease (German *et al.*, 1992; Hoogendijk *et al.*, 1995), with the small number of remaining neurons containing

galanin (Miller *et al.*, 1999). These remaining neurons up-regulate both their activity (Hoogendijk *et al.*, 1999) and noradrenaline production (Szot *et al.*, 2000) to compensate for the loss of neurons. The cell loss in this region in Alzheimer's disease occurs over decades secondarily to the formation of neurofibrillary tangles (Busch *et al.*, 1997). The significant cell loss of the locus coeruleus in Parkinson's disease (Fig. 14.8) has now been incorporated, along with the substantia nigra, into current diagnostic criteria for this disorder (Gelb *et al.*, 1999). There is even some suggestion that the premature loss or dysfunction of locus coeruleus neurons could exacerbate the selective vulnerability of the dopaminergic nigral neurons (Gesi *et al.*, 2000), although the topographic nature of any neuronal loss has not been factored into this hypothesis. Patients with Parkinson's disease have slow thought reflexes (Gelb *et al.*, 1999), which could suggest a disruption to pathways involved in vigilance. Whether the levodopa medication commonly perscribed for Parkinson's disease can also be utilized in noradrenergic neurons is unresolved.

CHAPTER

15

Lower Brain Stem Regulation of Visceral, Cardiovascular, and Respiratory Function

WILLIAM W. BLESSING
Departments of Physiology and Medicine
Centre for Neuroscience
Flinders University
Adelaide, SA, Australia

The overall structural organization of the human lower brain stem is described in chapter 10 of this book. In this chapter I outline the functional organization of lower brain stem neurons regulating various aspects of homestatic function in humans. This is a somewhat speculative task since we have almost no functional information and little neuroanatomical information concerning the actual connectivity and function of brain stem circuitry in humans. The scant information we do have concerning the nonhuman primate brain is summarized in Blessing and Gai (1997). Studies correlating clinical dysfunction in humans with the site of brain stem lesions (demonstrated by imaging procedures or by postmortem examination) have not been especially helpful in identifying brain stem nuclei controlling basic homeostatic functions. Unilateral lower brain stem lesions may not cause clinically obvious dysfunction, and bilateral lesions are usually fatal. Damage to fibers of passage may confound the clinicopathological interpretation of any particular lesion.

This difficulty of interpreting even the most carefully conducted studies of the human brain stem is illustrated in a recent investigation of breathing after unilateral infarction of the medulla oblongata in the territory of the posterior inferior cerebellar artery (Morrell *et al.*, 1999). Ventilatory sensitivity to CO_2 was reduced in these patients. Ventilation was normal in
