awake patients, but potentially impaired during sleep. The dorsoventral extent of the lesions was difficult to determine on the basis of either the clinical signs or the magnetic resonance image. At least some functional recovery (e.g., the ability to swallow) usually occurred between the time of the stroke and the time of respiratory investigation, so that ventilatory sensitivity might have been more severely affected if the investigation was conducted at an earlier stage. The authors also note the difficulties encountered when comparing effects of lesions in humans and experimental animals. The different shape of the human brain stem reflects the massive development of the inferior olives, the pyramidal tracts, and the corticopontocerebellar tracts that constitute the ventral pons.

It is clear, nevertheless, that large portions of the brain stem are quite similar in humans and experimental animals. Moreover, the basic homeostatic functions subserved are also similar in humans and experimental animals. Thus, for each of the functions to be discussed in this chapter, the first step will involve presentation of a summary of our understanding derived from studies on experimental animals. Most of the primary references are cited in "The Lower Brain stem and Bodily Homeostasis" (Blessing, 1997b), a book that summarizes the relevant evidence from animal studies. The task is to transfer this understanding to the human brain stem, principally on the basis of neuroanatomical homologies. Little weight will be placed on the idea that different nervous systems mediate separate aspects of bodily functions. The traditional practice of delineating two relatively independent nervous systems, "autonomic" and "somatic," differentially regulating bodily functions has hindered efforts to understand control of bodily homestasis by the central nervous system (Blessing, 1997a).

Natural selection has molded functionally integrated organisms, so that interactions with the external environment (e.g., catching and eating prey) are coordinated with control of the internal environment (e.g., digesting and absorbing prey). Programs enabling such integrated control are contained at different levels of complexity within different levels of the nervous system, with brain stem circuitry capable of organizing quite complex integrated responses. Neilsen and Sedgwick (1949) describe an anencephalic infant who proved to have no neural tissue above the midbrain when autopsied after 85 days survival. "The patient startled in the presence of loud noises. … If we handled the patient roughly he cried weakly, but otherwise like any other infant, and when we coddled him he showed contentment and settled down in our arms. When a finger was placed into his mouth he sucked vigorously. … He would sleep after feeding and awaken when hungry, expressing his hunger by crying." Clearly this infant also had adequate respiratory, cardiovascular, and gastroenterological control, with functioning bladder and bowel even if there was no normal continence.

PRINCIPLES OF FUNCTIONAL NEUROANATOMICAL ORGANIZATION IN THE BRAIN STEM

Brain stem neuronal groups can be viewed as belonging to one of the categories described below. In this chapter every effort is made to discuss brain stem neurons according to their membership of one these categories. Cells belonging to categories 2–7, and some cells in category 1, are principle constituents of the brain stem region referred to as the reticular formation.

Categories of brain stem neurons

1. Somatic motoneurons with efferent axons distributed via the motor cranial nerves.
2. Somatic premotoneurons that function to coordinate the different striated muscles involved in integrated activities such as swallowing.
3. Parasympathetic preganglionic motoneurons with axons exiting in cranial nerves III, VII, IX, and X. The "preganglionic"epithet reflects the historical definition of autonomical neurons with respect to the peripheral ganglia.
4. Presympathetic motoneurons, with axons descending to innervate sympathetic preganglionic neurons in the thoracic and upper lumbar spinal cord.
5. Preparasympathetic neurons, with axons descending to innervate parasympathetic preganglionic neurons in the sacral spinal cord, especially those concerned with genitourinary and bowel eliminative functions. Other brain stem preparasympathetic motoneurons have intra-brain stem axons innervating cranial parasympathetic preganglionic motoneurons in the brain stem.
6. Prephrenic and prethoracic inspiratory and expiratory motoneurons.
7. Interneurons with increasing orders of complexity, capable of producing the patterned somatic and visceral effector responses involved in an integrated activity such as breathing or the crying response that occurs in infants born with no forebrain (anencephalics).
8. Secondary sensory (afferent) neurons in the various dorsally and dorsolaterally situated sensory nuclei. Projection targets of secondary sensory neurons include brain stem interneurons and premotor neurons, and motoneurons. Some interneurons (e.g., those in

the pontine parabrachial nuclei) are probably closer to the afferent than to the efferent side of the brain stem neuronal organization.

CARDIOVASCULAR FUNCTION

The guiding principle in neural regulation of cardiovascular function is that the different bodily tissues should receive a blood supply appropriate to their involvement in the various activities that constitute the individual's daily life. During ingestion of food, for example, the salivary glands require a greatly increased blood supply so that sufficient saliva can be secreted. During sexual activity, there is increased blood supply to the genital organs. In diving animals, sudden submersion in water triggers a coordinated cardiovascular response that involves extreme bradycardia and intense vasoconstriction in many of the peripheral beds. These responses are mediated by coordinated, patterned activity of the different peripheral nerves, both parasympathetic and sympathetic. The patterns are contained in neural circuitry contained in the brain stem and in the basal forebrain.

All the specifically patterned cardiovascular responses occur on a general background, which requires an adequate arterial blood pressure so that the brain itself constantly receives an adequate blood supply. In humans, if the system fails for more than a few seconds, the individual slumps to the ground unconscious. To provide early warning of such failures, sensory nerve endings with specialized pressure receptors (baroreceptors) innervate the origin of the internal carotid artery (carotid sinus) and the ascending aorta (aortic arch baroreceptors). When arterial pressure rises, increased activity in the baroreceptor primary afferents activates medullary pathways that reduce arterial pressure by inhibition of sympathetic vasomotor activity and reduce the heart rate by activation of parasympathetic cardiac vagal efferents. When arterial pressure falls, reduced baroreceptor activation leads to increased sympathetic vasomotor activity and decreased cardiac vagal activity.

Excitatory Presympathetic Neurons in the Rostral Ventrolateral Medulla

Work in animals has established that discharge of excitatory presympathetic neurons in the rostral ventrolateral medulla oblongata (RVLM) maintains activity in peripheral sympathetic vasomotor and cardiomotor nerves so that arterial pressure and heart rate are in the physiological range. The pivotal role of these neurons is summarized in Fig. 15.1, and their role in the baroreceptor–vasomotor reflex is detailed below. The relevant RVLM presympathetic vasomotor neurons may be cardiovascular pacemaker neurons, or they may constitute the final bulbospinal outflow of a pacemaker network of neurons located in the lower brain stem. In animals, damage to the RVLM neurons or to their descending bulbospinal axons causes a loss of peripheral sympathetic vasomotor and cardiomotor activity, so that arterial pressure suddenly falls to the levels observed in "spinal shock." In animals, damage to the midbrain or forebrain does not cause this cardiovascular syndrome. Clinical observation confirms that the same is true in humans, so that it is likely that the fundamental organization of cardiovascular circuitry is similar in humans and other mammals.

In animals, approximately 50% of the excitatory presympathetic vasomotor neurons in the RVLM belong to the C1 group of catecholamine-synthesizing neurons present in this medullary region. The remaining RVLM vasomotor neurons, also bulbospinal but not catecholamine synthesizing, are scattered in the same anatomical region of the medulla. At present we have no reliable histological markers for the non-catecholamine vasomotor neurons. The catecholamine cells contain tyrosine hydroxylase (TH), dopamine β-hydroxylase (DBH, the enzyme that synthesizes noradrenaline), and, in most species, phenylethanolamine N-methyltransferase (PNMT), the enzyme that converts noradrenaline to adrenaline.

Although at present there is little functional evidence that adrenaline acts as a neurotransmitter in the intermediolateral column of the spinal cord, the presence of PNMT in the presympathetic neurons in the RVLM of animals is important because there is a prominant group of PNMT-containing neurons in the region of the human medulla corresponding to the RVLM in experimental animals (Arango *et al.*, 1988; Halliday *et al.*, 1988b; Gai *et al.*, 1993). Similarly situated neurons in the human also contain neuropeptide Y (Halliday *et al.*, 1988a). Neuroanatomical studies in nonhuman primates have established that at least some RVLM PNMT-containing cells have spinal projections (Carlton *et al.*, 1987, 1989). It is therefore likely that PNMT-containing neurons in the human medullary region shown in Fig. 15.2 (see also Table 15.1) at least partially constitute the sympathoexcitatory presympathetic vasomotor neurons responsible for activity in vasomotor and cardiomotor sympathetic axons, so that arterial pressure is maintained at a reasonable level. Animal studies indicate that peripheral vascular beds controlled by RVLM presympathetic neurons, including the PNMT-positive cells, include those in skeletal muscle, in kidney, and in the gastrointestinal tract. Loss of RVLM presympathetic vasomotor neurons may contribute to the postural hypotension

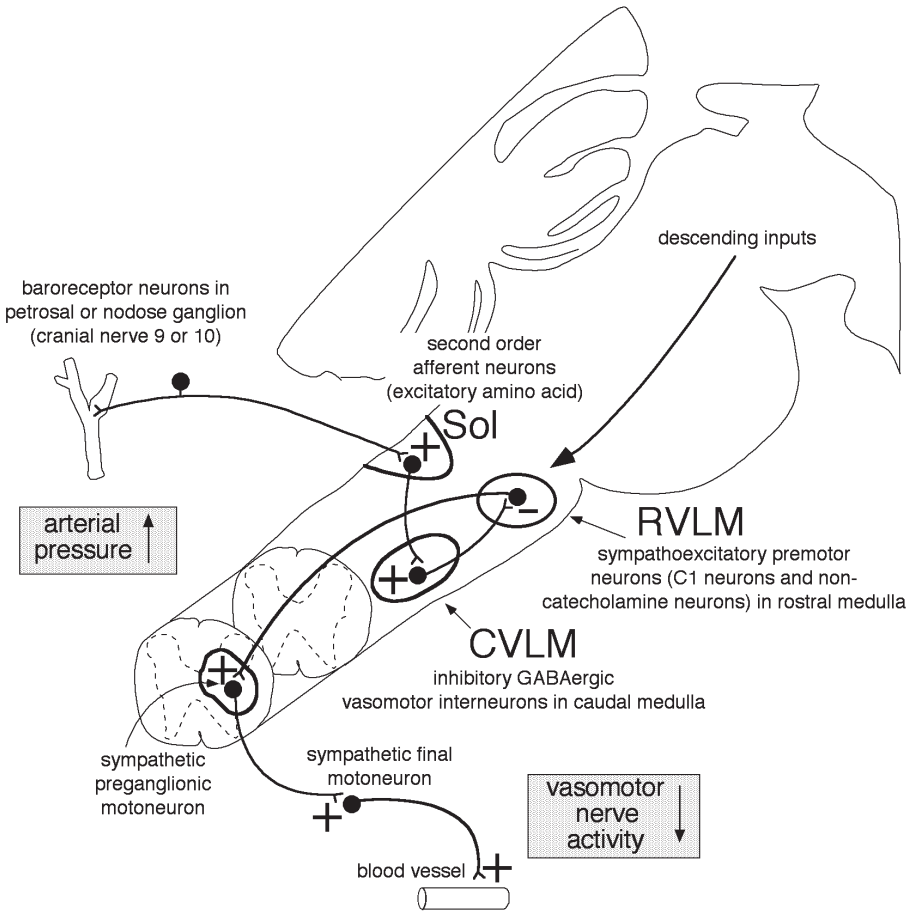

FIGURE 15.1 Diagram of central neural pathway mediating baroreceptor–vasomotor reflex. An inhibitory central link is provided by GABAergic interneurons in the caudal ventrolateral medulla (CVLM). These neurons increase their discharge when arterial pressure increases, thereby reducing the discharge of presympathetic vasomotor neurons in the rostral ventrolateral medulla (RVLM). Modified with permission from figure 5.18 of Blessing (1997b).

that sometimes occurs in patients with Parkinson's disease (Gai *et al.*, 1993) and with multiple systems atrophy with autonomic failure (Benarroch *et al.*, 1998).

Inhibitory Vasomotor Neurons Present in the Caudal Ventrolateral Medulla

In the caudal ventrolateral medulla (CVLM) region in experimental animals, there is a group of GABA-synthesizing vasomotor interneurons that tonically inhibit the RVLM sympathoexcitatory neurons by a short ascending axon. In animals the CVLM inhibitory vasomotor neurons are found intermingled with the A1 noradrenaline-synthesizing neurons, as well as in the region between the A1 cells and the ambiguus nucleus. So far there are no studies of the distribution of GABAergic neurons in the human medulla, and it is not easy to interpret clinical studies of altered arterial pressure following medullary lesions. There are reports of a patient with hypertension related to vagal rootlet–medullary compression by an arterial loop (Fein and Frishman, 1980; Jannetta *et al.*, 1985; Naraghi *et al.*, 1994) and another patient whose hypertension resolved following surgical removal of a soft-tissue mass that compressed the CVLM (Dickinson *et al.*, 1993), possibly interfering with the function of the inhibitory vasomotor neurons. The human medullary region likely to contain the inhibitory GABAergic vasomotor interneurons is shown in Figure 15.3.

Medullary Neural Circuitry Mediating the Baroreceptor–Vasomotor Reflex

A sudden rise in arterial pressure stimulates the baroreceptors in the carotid sinus and aortic arches, resulting in increased discharge in the primary afferent baroreceptor nerves entering the brain stem as part of the glossopharyngeal and vagus nerves (cranial 9 and 10). The paired nuclei of the solitary tract (Sol), particularly their caudal halves, are the principal

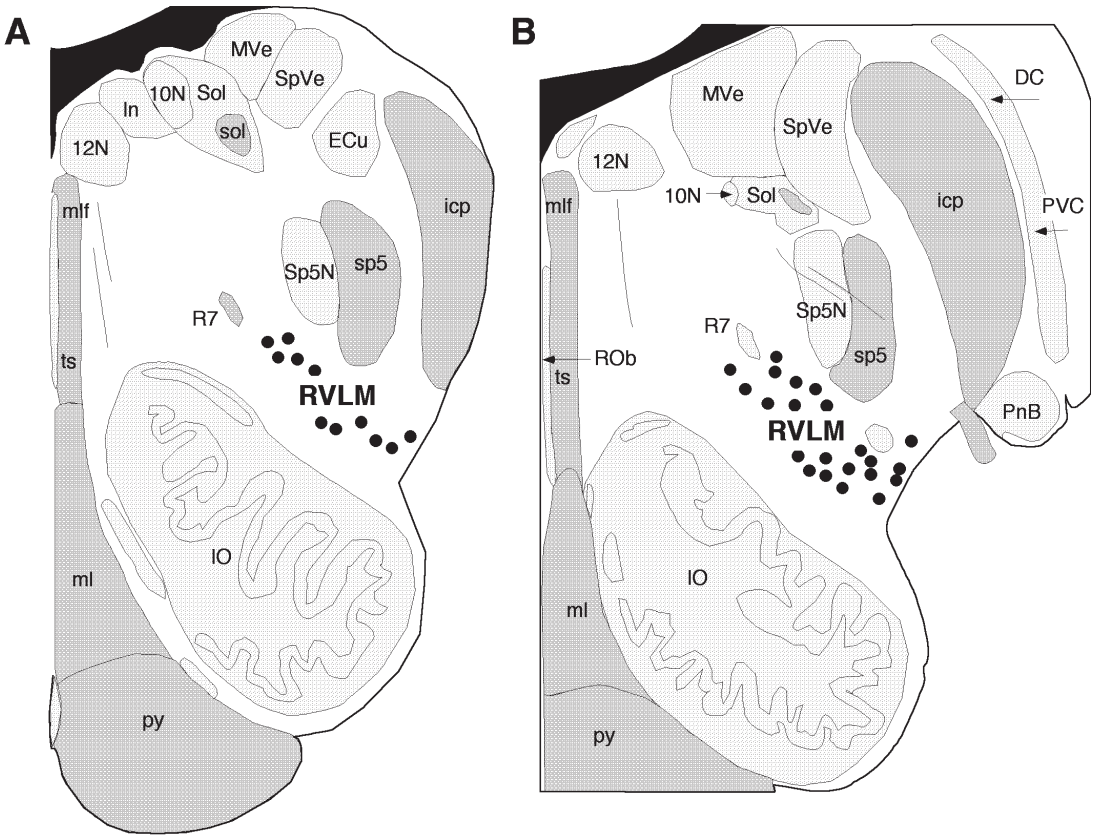

FIGURE 15.2 Distribution of PNMT-positive presympathetic (C1) neurons *(filled circles)* in the human rostral ventrolateral medulla (RVLM). The figure outlines **(A, B)** are based on figures 24 and 28 of Paxinos and Huang (1995). Abbreviations are listed in Table 15.1.

central termination sites of the baroreceptor afferents. In experimental animals, termination sites are concentrated in the dorsal and dorsolateral portions of Sol, near the border with the cuneate nucleus. Presumably this anatomical arrangement is similar in the human. Interruption of baroreceptor afferent input to Sol (or damage to secondary baroreceptor neurons in the Sol itself) would explain the fulminant hypertension sometimes observed in experimental animals and in humans with lesions near or within Sol (Reis, 1984; Doba and Reis, 1973).

As noted, in the case of sympathetic vasomotor activity, baroreceptor afferents operate in a negative-feedback fashion. Since the primary afferents excite the relevant secondary sensory neurons in Sol, there must be an inhibitory interneuron between Sol and the sympathetic preganglionic neurons in the spinal cord. The present consensus for experimental animals is that the inhibitory (GABAergic) vasomotor neurons in the CVLM fulfill this role. Thus, baroreceptor inputs to Sol activate an excitatory neuron (one that uses an excitatory amino acid as a neurotransmitter) that, by a ventrolateral projection, increases the discharge of the CVLM GABAergic neurons. This inhibits the excitatory presympathetic vasomotor and cardiomotor neurons in the RVLM (see Fig. 15.1), thereby reducing excitation of spinal preganglionic sympathetic vasomotor neurons and lowering arterial pressure.

Medullary Neural Circuitry Mediating the Baroreceptor–Cardiomotor (Vagal Efferents) Reflex

Less is known concerning the bradycardiac component of the baroreceptor reflex mediated by vagal efferents. Presumably the relevant central pathway is via a direct excitatory projection from sol to vagal parasympathetic cardiomotor neurons. In amimals these are acetylcholine-synthesizing neurons concentrated in the ambiguus nucleus at, and just caudal to, the level of the obex. They have not been definitely identified in humans but presumably are located in the region of the ambiguus nucleus region.

TABLE 15.1 Abbreviations

10N	dorsal motor nucleus of vagus	LVe	lateral vestibular nucleus
12N	hypoglossal nucleus	ml	medial lemniscus
6N	abducens nucleus	mlf	medial longitudinal fasciculus
7N	facial nucleus	MVe	medial vestibular nucleus
7n	facial nerve or its root	Pn	pontine nuclei
A5	A5 noradrenaline cells	PnB	pontobulbar nucleus
Acs5	accessory trigeminal nucleus	Pr	prepositus nucleus
Amb	ambiguus nucleus	prBo	pre-Bötzinger group of respiratory neurons
AP	area postrema	PVC	posteroventral cochlear nucleus
Ar	arcuate nucleus of the medulla	py	pyramidal tract
Ar	Arcuate nucleus	R7	retrofacial nucleus
Bo	Bötzinger group of respiratory neurons	RMg	raphe magnus nucleus
ctg	central tegmental tract	ROb	raphe obscurus nucleus

In	intercalated nucleus of the medulla	SpVe	spinal vestibular nucleus
IO	inferior olive	ts	tectospinal tract
IV	fourth ventricle	tz	trapezoid body
LRt	lateral reticular nucleus	vsc	ventral spinocerebellar tract

Parasympathetic Preganglionic Motoneurons Regulating Cerebral Vasculature

The intracranial portions of the cerebral blood vessels are densely innervated by parasympathetic postganglionic fibers arising from cell bodies in the sphenopalatine and otic ganglia. The functional role of this innnervation is still not understoood. Presumably the relevant brain stem preganglionic parasympathetic neurons are among those normally grouped together as "salivary" nuclei (see below).

Medullary Raphe Magnus/Pallidus Neurons and Sympathetic Control of the Cutaneous Circulation

A subpopulation of raphe magnus/raphe pallidus neurons function as presympathetic vasomotor neurons regulating the cutaneous vascular bed and, in rats, the production of heat by brown fat (Blessing and Nalivaiko, 2001; Morrison *et al.*, 1999). Activity of these neurons is of importance in the regulation of body temperature. In addition, their activity probably mediates the cutaneous vasoconstriction that occurs when the individual detects a painful or potentially dangerous environmental stimulus (Blessing and Nalivaiko, 2000). Although we have no evidence that medullary raphe neurons fulfil a similar function in humans, the animal findings are important because they constitute the first evidence for regulation of a specific peripheral vascular bed by a group of brain stem presympathetic neurons outside the RVLM. Serotonin is one of the neurotransmitters in the raphe bulbospinal neurons, and drugs that elevate body temperature by acting on serotonin pathways (e.g., MDMA, "ecstasy") could affect the activity of these cells. The neurotransmitter in the relevant raphe bulbospinal neurons mediating cutaneous vasocon-

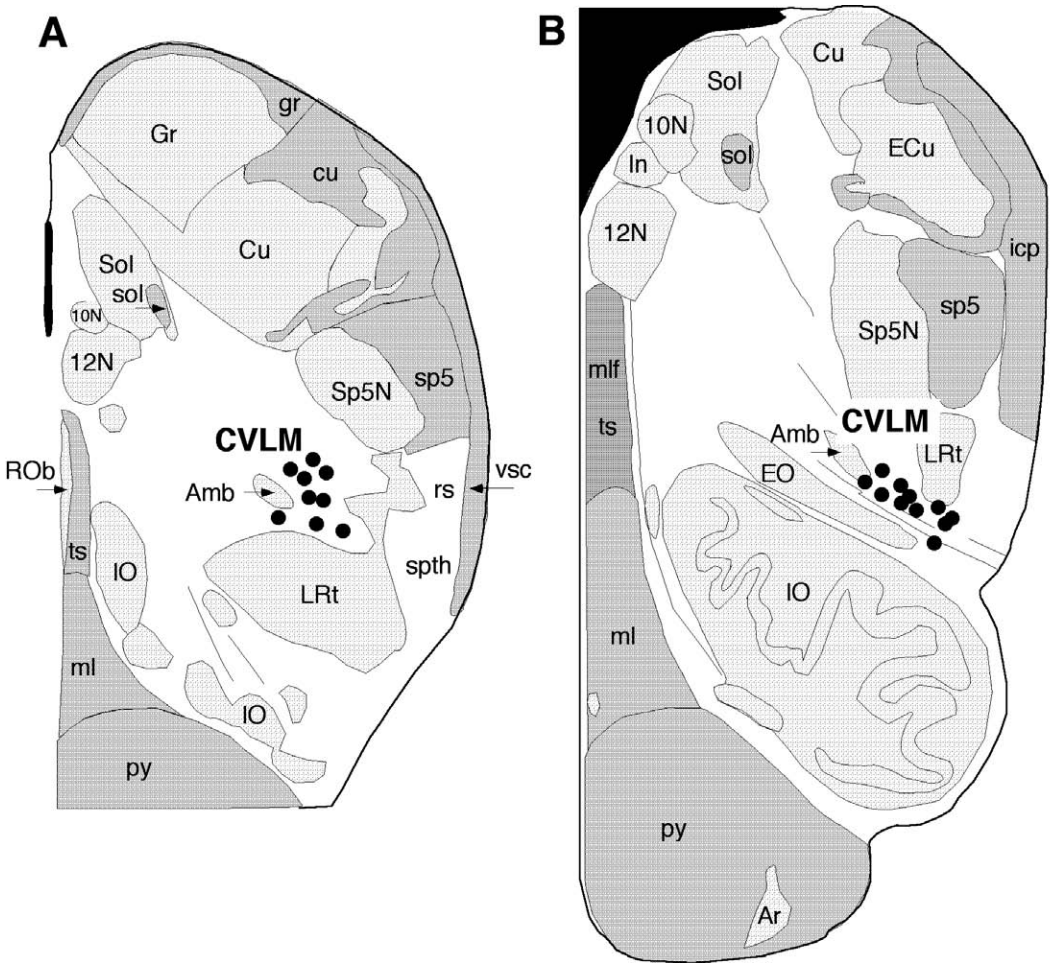

FIGURE 15.3 Human medullary region likely to contain GABAergic inhibitory vasomotor interneurons *(filled circles)* in caudal ventrolateral medulla (CVLM). The figure outlines **(A, B)** are based on figures 16 and 20 of Paxinos and Huang (1995). Abbreviations are listed in Table 15.1.

striction in response to surprising or painful stimuli in animals has not been identified. It is possible that the same neurons, by a descending projection to the dorsal horn of the spinal cord, are responsible for some of the antinociceptive functions thought to be mediated by medullary raphe neurons (Mason, 1999).

RESPIRATORY FUNCTION

Neural Circuitry Controlling Respiration

Intrathoracic pressures responsible for the to-and-fro passage of air are generated by the respiratory pump muscles. Other respiratory muscles with a valvelike function coordinate movements of the jaw, lips, tongue, pharynx, and larynx so that the airway is patent only at the appropriate time.

Inspiratory and expiratory pump muscles are innervated by somatic motor nerves (including the phrenic nerves) with cell bodies located in the C-3 and C-4 segments of the cervical spinal cord. Since lung tissue is elastic the lungs deflate by themselves, so that the first part of expiration is passive. The final part of normal expiration, as well as lung deflation during forced expiration, depends on active contraction of the expiratory muscles. Transection of the upper cervical cord isolates spinal respiratory neurons from descending control, so that respiration ceases. In contrast, breathing is maintained in patients with severe midbrain damage, but with an intact pons and medulla.

Thus, basic neural circuitry regulating respiration is present in the lower brain stem. Brain stem respiratory control was originally interpreted in terms of pneumotaxic, apneustic, inspiratory, and expiratory centers. However, these centers remained as poorly

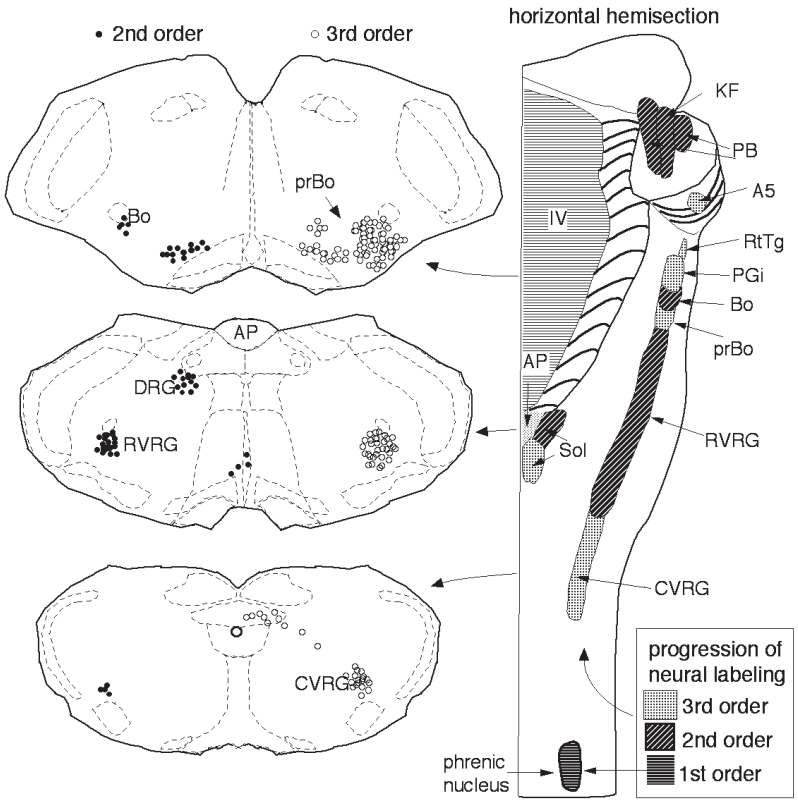

FIGURE 15.4 Transverse sections and horizontal hemisection through the medulla and lower pons, summarizing the successive distribution of virus-containing neurons after application of pseudorabies virus to one phrenic nerve. The different respiratory groups are explained in the text. Modified with permission from figure 4.3 of Blessing (1997b), based on the work of Dobbins and Feldman (1994). Abbreviations are listed in Table 15.1.

characterized hypothetical constructs, only vaguely related to actual brain stem regions. They did not provide an adequate theoretical framework for modern studies so that there is little to be gained by trying to identify these centers in the human lower brain stem. Summaries of neural circuitry mediating brain stem respiratory control can be found in Blessing (1997b) and in Dempsey and Pack (2000).

Animal studies have established that inspiratory pump premotoneurons (excitatory cells) projecting from the lower brain stem to the cervical spinal cord are located in the medulla oblongata, in the so-called rostral ventral respiratory group (RVRG). In turn, activity of RVRG neurons depends on net excitation from other medullary neurons either from the combined activity of a network of respiratory neurons or from the pacemaker activity of a particular group of respiratory neurons. These potential pacemaker cells are called pre-Botzinger cells. They are located in the ventrolateral medulla rostral to the RVRG cells.

During expiration, activity in RVRG neurons ceases so that the diaphragm and other inspiratory chest wall muscles no longer contract. These muscles are also innervated by spinal motoneurons activated by descending inputs from special expiratory motoneurons in the medulla oblongata. These inhibitory cells, discharging during expiration, are called the Botzinger group of expiratory neurons. A second group of expiratory neurons is located in the the caudal ventral respiratory group (CVRG). The distribution of the different groups in the rat is summarized in Figure 15.4.

Neurotransmitter-related antigens present in respiratory neurons are now being investigated (McCrimmon *et al.*, 1995). The pre-Botzinger cells are likely to use an excitatory amino acid as a neurotransmitter. The Botzinger cells may be GABAergic or glycinergic cells (Schreihofer *et al.*, 1999). It is not yet possible to use neurotransmitter anatomy to identify homologous neurons in the human brain. If the human system is similar to that being described in experimental animals, and if the relevant cells are located in similar regions of the human brain stem, the distribution of neurons regulating respiration may be as shown in Figure 15.5.

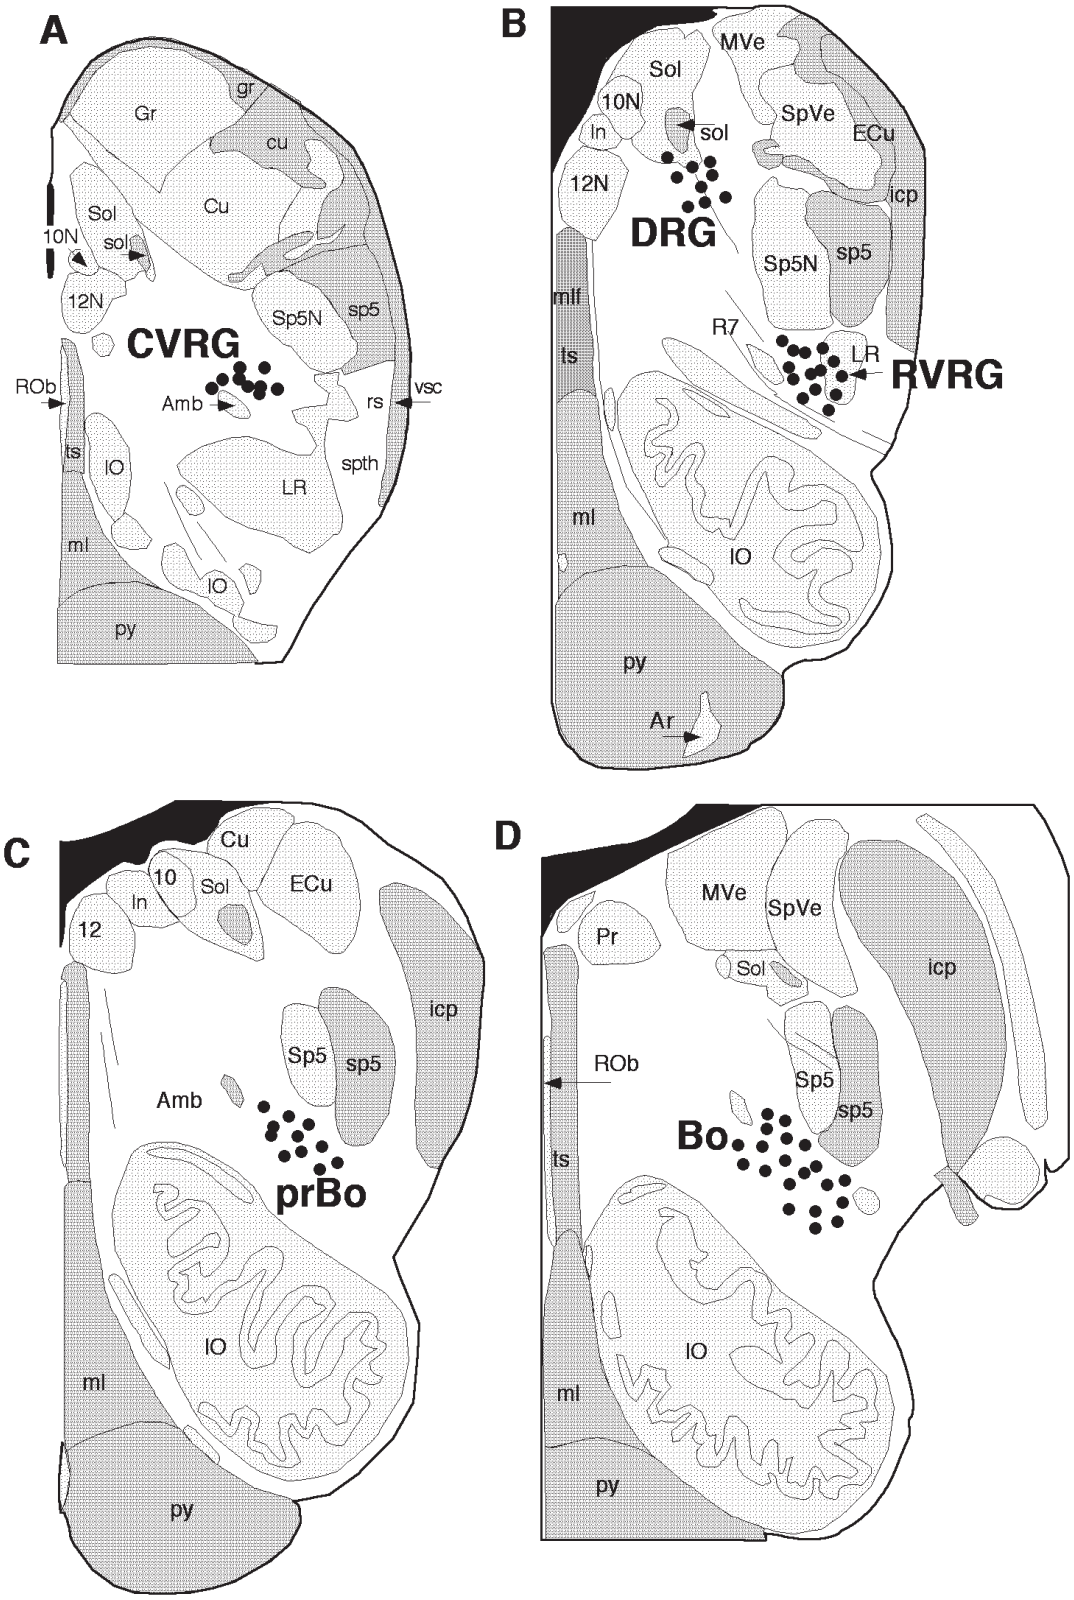

FIGURE 15.5 Human medullary regions likely to contain the different groups of respiratory interneurons and premotor neurons *(filled circles)*. The figure outlines **(A–D)** are based on figures 16, 20, 24, and 28 from Paxinos and Huang (1995). Abbreviations are listed in Table 15.1.

Responses to Hypercarbia and Hypoxia

Peripheral chemoreceptors in carotid and aortic bodies detect changes in blood levels of oxygen and carbon dixode–hydrogen ions. Primary afferent neurons in the nodose and petrosal ganglia transmit this information to the brain stem, especially to the solitary nucleus. Some primary afferents, probably chemoreceptor afferents, project beyond Sol to the ventrolateral medulla. Presumably these afferents make synaptic connections with various components of the central respiratory network, and with brain stem parasympathetic and presympathetic neurons mediating cardiovascular responses to hypercarbia and hypoxia (Guyenet, 2000).

The brain stem location of central chemoreceptors, and their cellular nature, has been the subject of many investigations in experimental animals commencing with the work of Loeschcke who studied the respiratory and cardiovascular effects of pharmacological agents applied to the ventral surface of the medulla oblongata. In recent years this approach has been supplemented by immunohistochemical demonstration of fos protein in neurons activated by appropriate respiratory-related stimuli (Sato *et al.*, 1992; Teppema *et al.*, 1997). Nattie (1999) has written a helpful review on this subject.

Ischemia of the lower brain stem, with consequent changes in tissue oxygen and carbon dioxide partial pressures and tissue acidity, elicits intense peripheral vasoconstriction and an increase in ventilation. The intense vasoconstriction is preserved after midpontine transection (Guyenet, 2000) and virtually eliminated by lesions of the presympathetic vasomotor neurons in the RVLM (Dampney and Moon, 1980). The RVLM neurons may act as the final bulbospinal pathway for sympathetic activation or could themselves have a chemosensitive function.

The arcuate nuclei are groups of small neurons scattered near the ventrolateral medulla surface, in the region medial to the corticospinal tract, and within the tract itself. The arcuate nuclei contain a subpopulation of neurons that synthesize serotonin, and they may be displaced components of raphe magnus/pallidus neurons. Kinney and colleagues have found various abnormalities in receptor binding studies focused on this region, and in the midline medullary raphe nuclei, in brains of infants dying of sudden infant death syndrome (Kinney *et al.*, 1992; Panigrahy *et al.*, 2000b; Harper *et al.*, 2000; Nachmanoff *et al.*, 1998). Studies in experimental animals also indicate that raphe serotonin cells may be chemosensitive, with a special relationship to intramedullary branches of the basilar artery, so that they sample the acidity of the blood supplying the medulla and thus act as central chemoreceptors (Iravani *et al.*, 2000).

It is possible that glial elements, as well as neurons, near the ventral surface of the medulla and in the midline raphe nuclei are sensitive to acidity and oxygen tension. Filiano and colleagues (1990) have described "thickened marginal glia" bordering the surface of the human ventrolateral medulla, associated with the clusters of small neurons identified as belonging to the arcuate nucleus.

SALIVATION, SWALLOWING, AND GASTROINTESTINAL FUNCTION, NAUSEA, AND VOMITING

Neural Circuitry Controlling Salivation

The brain stem location of preganglionic neurons regulating salivation in experimental animals is reasonably well established, thanks particularly to the work of Norgren and colleagues (e.g., Contreras *et al.*, 1980). Their findings indicate that the traditional distinction into superior and inferior salivary subnuclei is not based on firm experimental evidence. Salivary neurons with axons traveling in the facial nerve have a brain stem distribution virtually indistinguishable from that of salivary neurons with axons traveling in the glossopharyngeal nerve and its branches. The neurons are found dorsal and lateral to the facial nucleus, with scattered cells situated more dorsally, around the intramedullary fibers of the facial nerve within the caudal pons. In experimental animals, these intrapontine parasympathetic motoneurons stain strongly for NADPH and nitric oxide synthetase (NOS) (Zhu *et al.*, 1996).

In humans, neurons staining strongly for NADPH and NOS are found in corresponding regions of the pons (Gai and Blessing, 1996a), so that these cells are also presumably parasympathetic motoneurons (see Fig. 15.6 and Paxinos, *et al.*, 1999). Presumably many of the cells are salivary preganglionics, but similar neurons may also control lacrimation and secretion of nasal and paranasal mucosal cells. In addition, the neurons usually bundled together as "salivary" probably also make a major contribution to the regulation of the extra- and intracranial vasculature. The fluid in saliva is rapidly filtered from the blood, so that increased salivation is acccompanied by increased blood flow to the relevant salivary gland.

Neural Circuitry Controlling Swallowing

The lower brain stem contains neural circuitry sufficiently complex to initiate the appropriately coordinated contraction of jaw, facial, largygeal, pharyngeal,

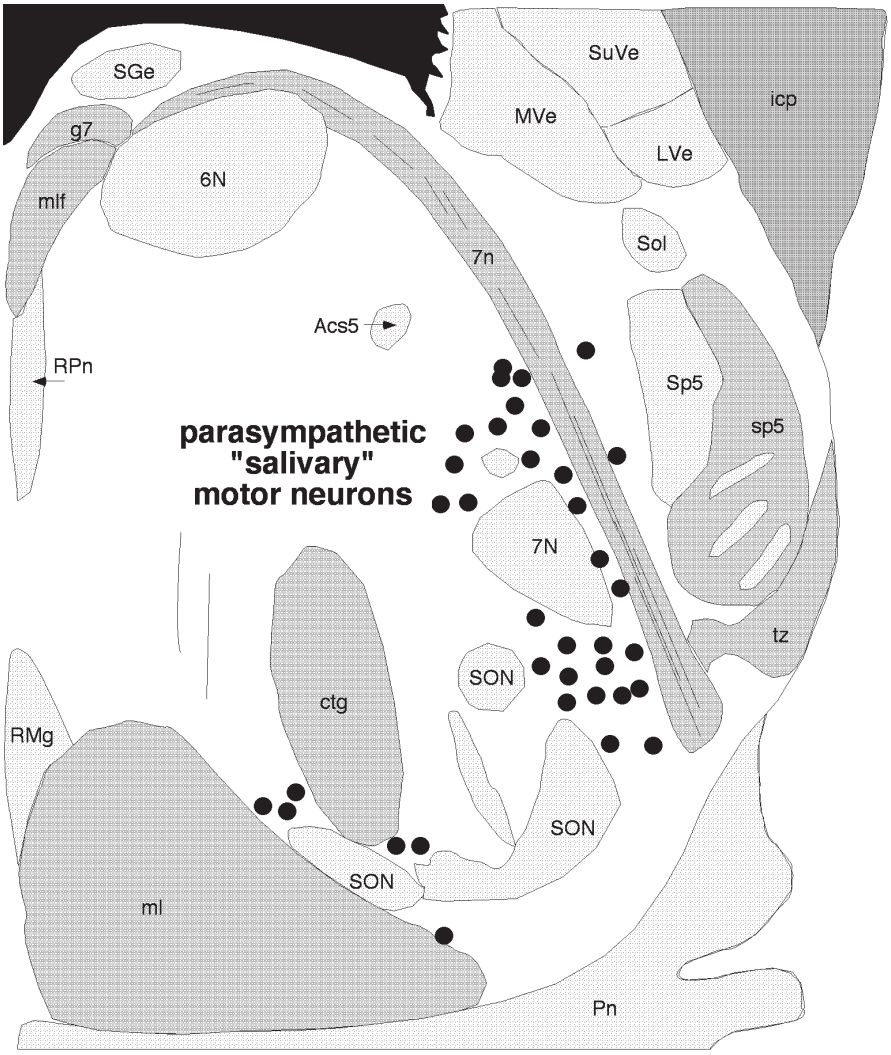

FIGURE 15.6 Human medullary regions likely to contain parasympathetic preganglionic motoneurons with axons exiting in cranial nerves 7 and 9 *(filled circles)*. The group is commonly referred to as the "salivary nucleus," but functions other than salivation are also controlled by parasympathetic motoneurons in this region. The figure outline is based on figure 33 from Paxinos and Huang (1995). Abbreviations are listed in Table 15.1.

tongue, and cervical muscles, with accompanying inhibition of respiration. Patients with severe forebrain damage can swallow if food or water is placed directly into the mouth, a stimulus that activates primary afferents in trigeminal, facial (nervus intermedius), glossopharyngeal, and vagal cranial nerves. These afferents synapse in sensory brain stem nuclei, including the principal sensory nucleus of V, the spinal nucleus of V, and the nucleus of the solitary tract (Sol). The taste afferents synapse in the rostral half of Sol. From these secondary sensory nuclei there must be projections to interneurons and premotor neurons appropriately connected to the relevant motoneurons in cranial nerves 5, 7, 9–12, and to the brain stem respiratory premotor neurons. There must be a complex degree of integration even within Sol since, in experimental animals, electrical stimulation of superior larygneal afferents can initiate swallowing.

At present there is only indirect evidence concerning the location of properties of the swallowing interneurons and premotor neurons. Live virus, applied to the hypoglossal nerve in experimental animals, spreads transneuronally from the hypoglossal nucleus to neurons (presumably premotor neurons) just lateral and a little ventral to this nucleus (Ugolini, 1995). Additional evidence from both anterograde and retrograde intraaxonal tracing studies indicates that neurons in this region have selective projections to motoneurons

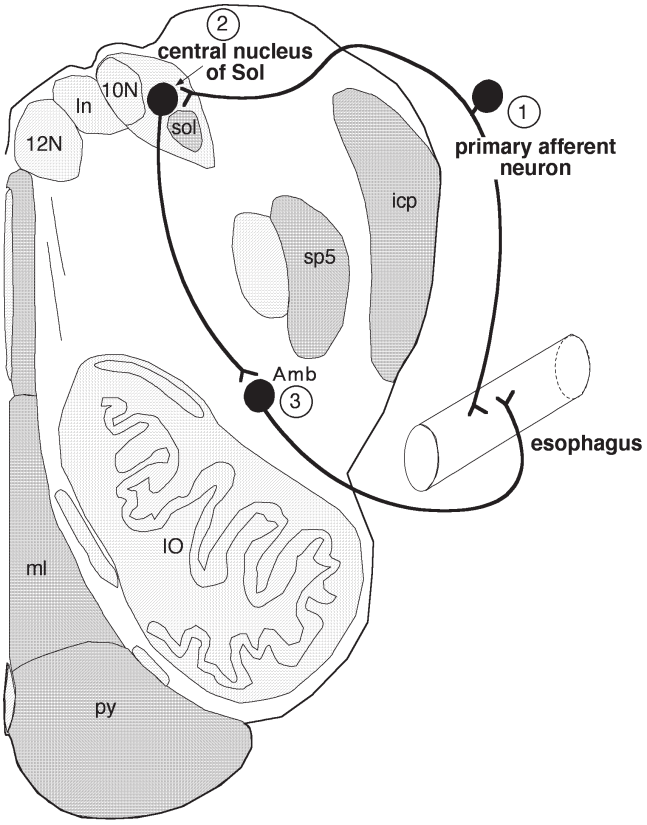

FIGURE 15.7 Diagram summarizing a single interneuron CNS pathway mediating esophago-esophageal reflexes. Neuron 1, the primary sensory neuron in the nodose ganglion, projects into the brain and synapses on neuron 2, a nitric oxide–synthesizing neuron in the central nucleus of Sol. This neuron projects directly to a nucleus ambiguus motoneuron (neuron 3), which innervates the esophageal striated muscle. Modified with permission from figure 7.6 of Blessing (1997b).

in cranial nerves 5, 7, and 9–12, so that neurons in this region lateral to the hypoglossal nucleus could function as premotor neurons regulating the integrated act of swallowing.

Vagal afferents originating in the lower esophagus synapse in a relatively newly recognized subdivision of Sol, just rostral to the obex, termed the central subnucleus of Sol. This central subnucleus contains a densely packed group of NOS-positive neurons, both in experimental animals and in humans (Gai and Blessing, 1996b). In experimental animals these cells project monosynaptically to preesophageal motoneurons in the nucleus ambiguus (Cunningham and Sawchenko, 1990; Gai *et al.*, 1995). Thus, it is likely that this central NOS-positive cell functions as a secondary sensory neuron, an interneuron, and a premotor neuron. A diagram summarizing this simple central connection is shown in Figure 15.7.

Neural Circuitry Controlling Gastric and Intestinal Function

Preganglionic parasympathetic motoneurons regulating the secretory and absorptive functions of the stomach and the intestine are located in the dorsal motor nucleus of the vagus (10). Axons project in the vagus nerve to ganglia in the wall of the gastrointestinal tract (the enteric nervous system) and to other parasympathetic ganglia located in proximity to the various abdominal viscera. Inputs to the dorsal motor nucleus of the vagus come from the adjacent Sol and other brain regions. Inputs to 10 from medullary raphe neurons [containing 5-hydroxytryptamine (5-HT), substance P, and thyrotropin-releasing factor] contribute to vagal regulation of gastric function, particularly to the regulation of gastric mucosal resistance to acid injury (Taché *et al.*, 1995). Damage to neurons in 10 in Parkinson's disease may be relevant to weight loss and gastrointestinal disturbances that may occur in this condition (Gai *et al.*, 1992).

LOWER BRAIN STEM REGULATION OF VOMITING

In both experimental animals and in humans activation of 5-HT_3 receptors on the distal terminals of abdominal vagal afferents may lead to the behavioral and physiological syndrome associated with vomiting (and with nausea in humans). These vagal afferents, originating in the lower esophagus, the stomach, or the upper small bowel, synapse in the gelatinous subnucleus of Sol. In animals there are additional inputs to the area postrema, so that cells in this specialized region are affected both by circulating factors and by vagal afferents. Nauseated humans secrete large amounts of vasopressin from the neurohypophysis. The neural pathways regulating this process are summarized in Figure 15.8 and in the following section.

LOWER BRAIN STEM REGULATION OF HYPOTHALAMOHYPOPHYSEAL SECRETION

The solitary nucleus (Sol) contains the A2 noradrenaline-synthesizing neurons and the caudal ventrolateral medulla contains the A1 noradrenaline-synthesizing neurons, present in humans as well as in experimental animals. Both these noradrenergic cell groups, via their direct axonal projections to neuro-

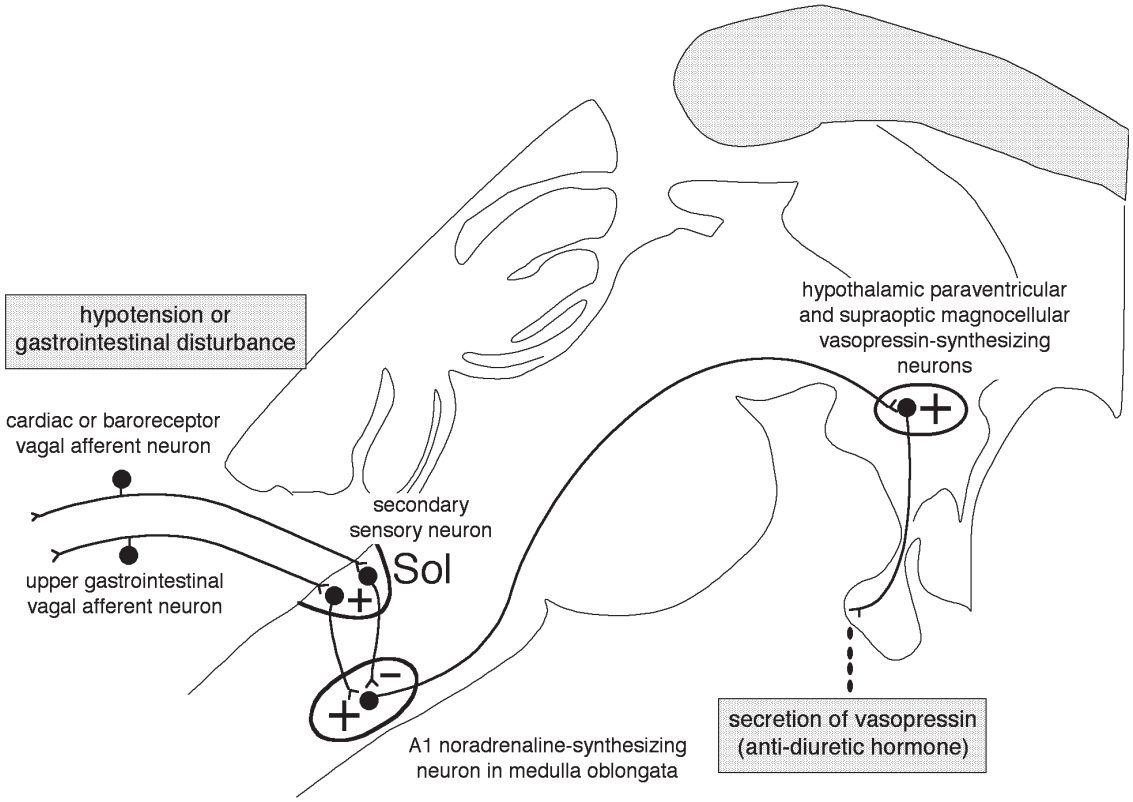

FIGURE 15.8 Central neural pathway mediating secretion of vasopressin in response to hemorrhage and in response to activation of abdominal vagal afferents. Baroreceptor afferents excite a Sol neuron (probably a GABAergic cell), which inhibits the A1 noradrenaline neurons in the caudal ventrolateral medulla. Hemorrhage causes a withdrawal of this inhibition, with consequent vasopressin secretion. Abdominal vagal afferents excite different Sol neurons, which excite the A1 cells, thereby increasing the secretion of vasopressin associated with nausea and vomiting. Modified with permission from figure 5.26 of Blessing (1997b).

endocrine cells in the paraventricular and supraoptic nuclei of the hypothalamus, regulate secretion of either vasopressin or oxytocin into the systemic circulation (Fig. 15.8).

In addition, axon terminals of A1 and A2 noradrenaline cells, as well as terminals of a subpopulation of C1 cells, innervate paraventricular neurons containing corticotrophin-releasing-factor (CRF). Activation of the medullary neurons (by internal bodily stresses reaching Sol via glossopharyngeal and vagal afferents) increases the discharge of the hypothalamic neurons so that CRF is secreted into the portal circulation. The medullary neurons thereby elicit secretion of adrenocorticotrophic hormone from the anterior pituitary in response to the internal bodily stesses.

The A1 and A2 neurons also have major inputs to luteinizing hormone–secreting cells in the medial preoptic area of the hypothalamus, so that changes in the activity of the medullary noradrenaline-synthesizing neurons are integrated into cyclical physiological changes related to the menstrual cycle.

LOWER BRAIN STEM REGULATION OF PELVIC VISCERA

Brain stem contains neurons (preparasympathetic neurons) with direct projection to either cranial or sacral parasympathetic preganglionic neurons. The latter group of neurons contributes to CNS control of pelvic visceral function, including micturition and defecation.

Existence of a pontine micturition center was initially suggested by the urinary effects of lesions of the dorsolateral pons in the cat. Modern studies in the rat (Valentino *et al.*, 1999) have identified a distinct cluster of neurons lying ventromedial to the rostral pole of the locus coeruleus and lateral to the dorsolateral tegmental nucleus. This cluser of neurons, termed Barrington's nucleus, is now known to constitute the pontine micturition center. The neurons, containing corticotropin-releasing factor (CRF) and atrial natriuretic peptide, project to the sacral column of parasympathetic preganglionic neurons, including neurons that control

the function of the urinary bladder. Transneuronal viral transport studies show that neurons in Barrington's nucleus have descending projections to sacral parasympathetic neurons controlling the function of the distal colon, the urethra and the urethral sphincter, the prostate, the penis, and the clitoris (see references in Valentino *et al.*, 1999). Thus, neurons in the "pontine micturition center" are likely to have a broad range of functions, controlling all pelvic viscera, not just the bladder. Consistent with this view, Barrington's nucleus also includes neurons that project to the dorsal motor nucleus of the vagus, innervating parasympathetic preganglionic cells with projections to ascending colon, transverse colon, and rectum.

Functional imaging studies (see references in Valentino *et al.*, 1999 and Blok and Holstege, 1998) suggest that micturition is controlled by a homologous dorsomedial pontine region in humans.

Acknowledgments

I thank Robyn Flook for help with preparation of this Chapter. My experimental work has been supported by the National Health and Medical Research Council and by the National Heart Foundation of Australia.

Reticular Formation: Eye Movements, Gaze, and Blinks

JEAN A. BÜTTNER-ENNEVER and ANJA K. E. HORN
Institute of Anatomy, Ludwig Maximilian University
Munich, Germany

The human brain stem reticular formation was first recognized as a cytoarchitectonic entity by August Forel (1877). The word *reticular* is derived from the Latin word *rete*, meaning "net", and refers to its characteristically diffuse structure, a network of loosely packed multipolar neurons, embedded in a dense neuropil. The reticular formation has no distinct cytoarchitectural boundaries, and forms the central core of the brain stem, in which other brain stem nuclei, with clearly outlined cytoarchitectural boundaries, are embedded, e.g., the red nucleus (RPC) or nucleus reticularis tegmenti pontis (RtTg). It stretches throughout the length of the brain stem, from the mesencephalon through the pons to the medulla oblongata (Fig. 16.1). In the spinal cord, the intermediate zone, i.e., Rexed's laminae V–VIII, is recognized through its cytoarchitecture as the continuation of the reticular formation into the spinal cord (see Chapter 7). There are subtle regional differences in the brain stem reticular formation cytoarchitecture, which led Jerzy Olszewski and his colleagues to subdivide it into nuclei (Olszewski and Baxter, 1954). These subdivisions have become the accepted classical standard, although the generally accepted nomenclature has evolved to include the word *reticular*, which Olszewski rigorously avoided. For example, Olszewski used the term "nucleus centralis pontis caudalis"; but presently, mostly due to the work of Brodal (1957) and Taber (1961), the same area is now usually referred to as nucleus reticularis pontis caudalis (PnC). Homologies of the subdivisions seen in the human reticular formation can be readily recognized in lower animals (for review, see Brodal, 1981). The typical wide dendritic fields of the multipolar reticular cells collect afferent signals from multiple sources (Scheibel and Scheibel, 1958) and funnel them onto nearby output structures, such as the trigeminal, facial, or oculomotor

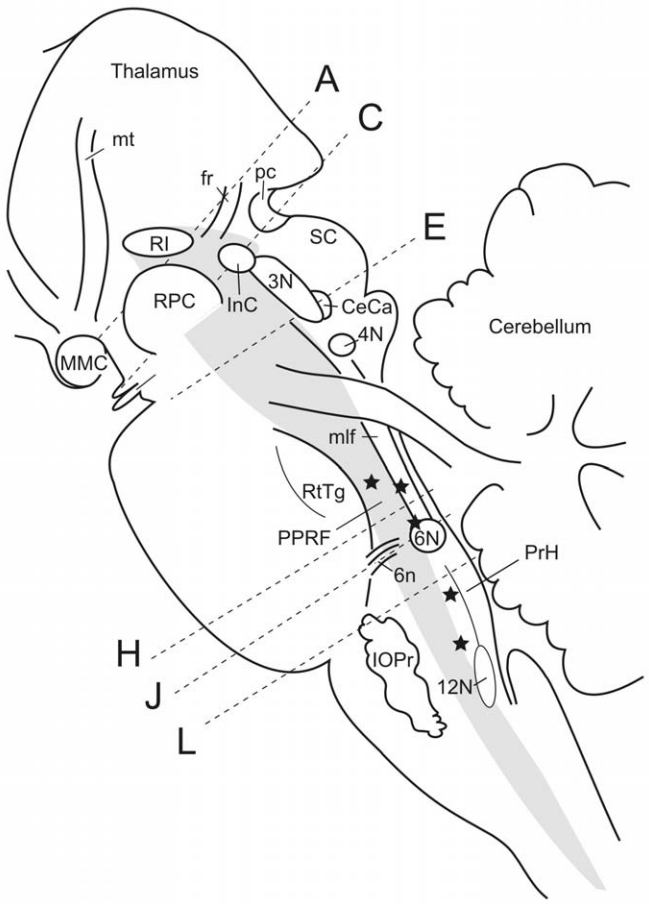

FIGURE 16.1 A sagittal view of the human brain stem showing the location of the reticular formation *(shaded area)* and several structures essential for the control of eye movements and gaze. The dashed lines indicate the levels of the transverse sections shown in Figures 16.3 and 16.4. The stars indicate the location of the cell groups of the paramedian tract (section I). Abbreviations: 3N, oculomotor nucleus; 4N, trochlear nucleus; 6N, abducens nucleus; 6n, abducens nerve; 12N, hypoglossal nucleus; CeCa, central caudal nucleus; fr, fasciculus retroflexus; InC, interstitial nucleus of Cajal; IO, inferior olive; mlf, medial longitudinal fasciculus; MMC, medial mammillary nucleus; mt, mammillothalamic tract; pc, posterior commissure; PPRF, paramedian pontine reticular formation; PrH, prepositus hypoglossal nucleus; RPC, red nucleus; RI, rostral interstitial nucleus of the medial longitudinal fasciculus; RtTg, reticulotegmental nucleus of the pons; SC, superior colliculus.

nuclei, or via descending pathways to motoneurons in the spinal cord.

Over the last years much progress has been made in the identification and characterization of functional cell groups within the reticular formation and their connectivity, either by single-cell recording in behaving animals, or with immunohistochemical and tract tracing techniques. Localized reticular cell groups, without any obvious cytoarchitectonic features, have been found to have highly specific functions and connections; therefore, in no way do they conform to the old idea that the reticular formation is part of a "diffuse arousal network" (Morruzi and Magoun, 1949), although one has to admit that it looks as though it should. Presently this concept has been replaced by the demonstration of highly localized functions within the reticular formation, while the role in arousal can be attributed to compact brain stem nuclei such as locus coeruleus (LC) or pedunculopontine tegmental nucleus (PPTg) whose cells have enormous axon terminal fields extending up to, and including, the cerebral cortex (Saper, 1987; Steckler *et al.*, 1994). In parallel to these experimental studies attempts have been made to identify the homologous cell groups in humans not only by their location and cytoarchitecture, but also by their histochemical properties, e.g., cytochrome-oxidase activity, acetylcholinesterase activity, and expression of calcium-binding proteins, such as parvalbumin (Paxinos *et al.*, 1990; Paxinos and Huang, 1995; Horn *et al.*, 1996).

The reticular formation of the pons and medulla can be divided into a lateral and a medial tegmental field (Holstege, 1991). The *lateral tegmental field* contains smaller cells, which are interneurons, or premotor neurons, for the trigeminal, facial, vagal, and hypoglossal motor nuclei. In addition it houses the premotor neurons with long descending axons to motor neurons of the spinal cord involved in respiration, abdominal pressure, micturition, and blood pressure (Holstege, 1991; see Chapter 15). The *medial tegmental field* contains the premotor circuitry for eye and head movements, and gives rise to descending pathways involved in postural orientation. These pathways are separate and distinct from the serotonergic raphe nuclei (see Chapter 13), which have widespread connections to the spinal gray matter and modulate or set, the firing level of the sensory or motor spinal circuits (for review, see Holstege 1991). The brain stem nuclei involved in the generation of eye and head movements, blinks, gaze holding, or postural orientation lie mostly in the medial tegmental field, and their functional neuroanatomy is the subject of this chapter.

EYE AND HEAD MOVEMENTS

General Concepts

The orientation of the eyes, head, and body toward a point of interest plays a central role in survival. The superior colliculus is essential for the generation of these responses, in particular the deep layers (Sparks and Hartwich-Young, 1989; for review, see Isa and Sasaki, 2002). It receives afferents from higher centers, brain stem, and spinal cord (Huerta and Harting, 1982; Harting *et al.*, 1992) and relays the commands to the

specific regions of the medial reticular formation that control the eyes, head, and postural muscles via tectoreticulospinal pathways. A rapid eye movement, called a *saccade,* is generated through the medial reticular pathways, possibly in combination with a head movement and postural adjustment, to orient the body to the object of interest. There are several different types of eye movements: saccades, vestibular ocular reflexes, optokinetic responses, smooth pursuit, vergence, and even gaze holding. Each of these is generated through circuits that are relatively separate from each other but converge at the level of the motoneuron to drive the eye movements (Büttner and Büttner-Ennever, 1988; Büttner-Ennever and Horn ,1997; Sharpe, 1998; Leigh and Zee, 1999). Although this is an oversimplification, it is an approach that enables us to schematically represent eye movements as in Figure 16.2, and to assign functions to several brain stem nuclei.

1. Saccades. A simple description of the premotor circuits for saccadic eye movements is as follows (see also Figs. 16.1 and 16.8): immediate premotor burst neurons (EBNs and IBNs), in the paramedian pontine reticular formation (PPRF) for horizontal saccades or in the rostral interstitial nucleus of the medial longitudinal fasciculus (RI) for vertical saccades, activate the eye muscle motoneurons in the abducens (6N), trochlear (4N), and oculomotor (3N) nuclei during a saccade. During slow eye movements and fixation the burst neurons are inhibited by omnipause neurons in the nucleus raphe interpositus (RIP) (for review, see Scudder *et al.*, 2002). Burst neurons and omnipause neurons receive afferents from the superior colliculus (SC), while the frontal eye fields of the cerebral cortex appear only to contact the omnipause neurons (Moschovakis *et al.*, 1996; Büttner-Ennever *et al.*, 1999).

2. The vestibuloocular reflex. The vestibuloocular reflex (VOR) is generated by sensory signals from the labyrinthine canals and otoliths, relayed through the vestibular nuclei (see Chapter 33), where the signals are modulated by the cerebellum, then fed to the extraocular muscle motoneurons in the oculomotor, trochlear, and abducens nucleus via the medial longitudinal fasciculus (mlf) or the brachium conjunctivum (Büttner-Ennever, 1992, 2000). This reflex is a slow

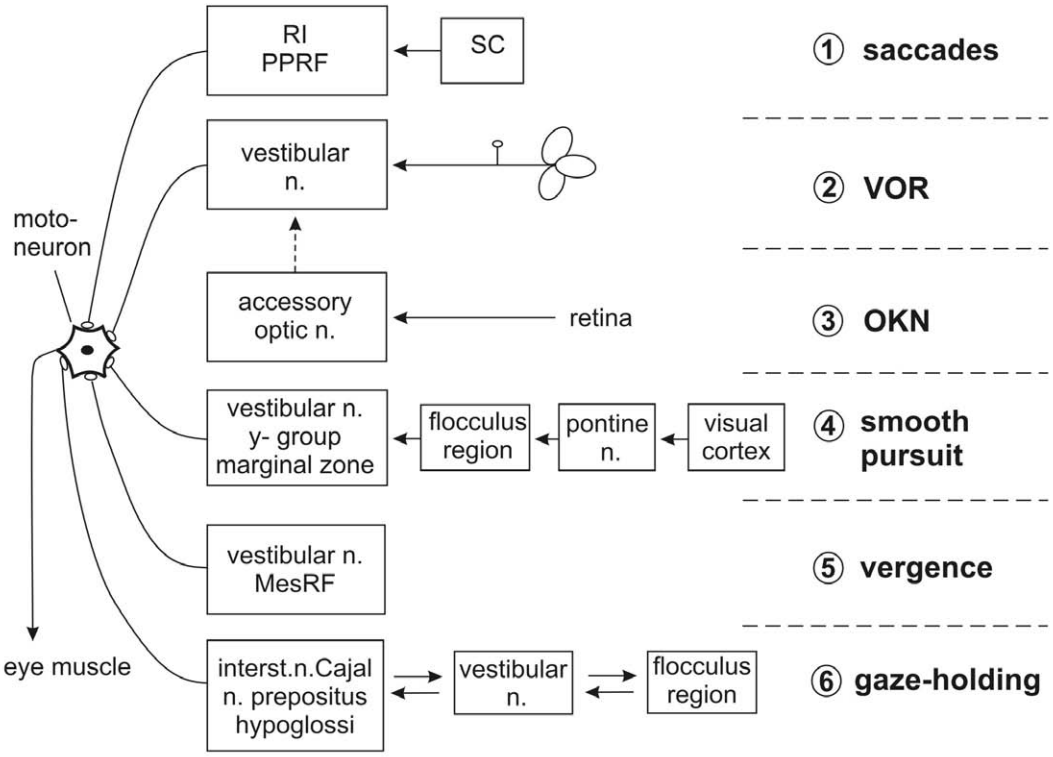

FIGURE 16.2 A simplified diagram of the premotor networks subserving five different types of eye movements, and gaze holding. All the relatively independent networks converge at the level of the motoneurons of the extraocular eye muscles. Abbreviations: MesRF, mesencephalic reticular formation; n., nucleus; OKN, optokinetic response; PPRF, paramedian pontine reticular formation; SC, superior colliculus; VOR, vestibuloocular reflex.

compensatory eye movement, and during a period of continuous stimulation it is interrupted by fast resetting saccades, giving rise to the typical fast and slow phases of vestibular nystagmus (Leigh and Zee, 1999).

3. The optokinetic response. Optokinetic responses are elicited by the movement of large visual fields across the retina, which generate responses in the retinorecipient accessory optic nuclei of the mesencephalon: the dorsal, medial, lateral, and interstitial terminal nuclei (DT, MT, LT, and IT). These nuclei, along with the nucleus of the optic tract (OT) in the pretectum, feed the information to the vestibular-oculomotor circuits through which the eye movement response, the optokinetic response, is generated (Fuchs and Mustari, 1993; Büttner-Ennever *et al.*, 1996a).

4. Smooth pursuit. Smooth-pursuit pathways receive retinal information through two parallel afferent pathways: a motion-sensitive "magnocellular pathway", and a form- and color-sensitive "parvicellular pathway" (see Chapter 35). The two inputs supply posterior parietal cortical areas with information concerning object motion in space (the dorsal stream), in contrast to the inferotemporal region more involved in the analysis of form (the ventral stream). Descending projections from the posterior parietal cortex relay in the dorsolateral pontine nuclei (May *et al.*, 1988), which project to the dorsal and ventral paraflocculus and the caudal vermis of the cerebellum. Cerebellar efferents via the vestibular complex or other relays reach the oculomotor nuclei to generate smooth-pursuit eye movements (Leigh and Zee, 1999).

5. Vergence. Vergence premotor neurons have been found in the medial mesencephalic reticular formation dorsal to the oculomotor nucleus and in the pretectum, which provide the vergence command to the oculomotor nuclei (Mays and Gamlin, 1995; for review, see Sharpe 1998). Recently, Chen-Huang and McCrea (1998) showned that a vergence signal proportional to the viewing distance during horizontal linear acceleration is carried by the ascending tract of Deiters to medial rectus motoneurons in the oculomotor nucleus. The ascending tract of Deiters originates in the rostral third of the vestibular complex (see Chapter 33).

6. Gaze holding. In addition, perhaps gaze holding, involving the velocity to position integrator, should be included in the list of eye movement types. Gaze holding is also subtended by a relatively separate group of neural circuits: the interstitial nucleus of Cajal (InC) for vertical, and the prepositus hypoglossal nucleus (PrH) for horizontal gaze holding with their reciprocal vestibular and cerebellar connections (Fukushima *et al.*, 1992; see also Chapter 33). A current hypothesis suggests that the cell groups of the paramedian tracts may provide the cerebellum with the motor feedback signal essential for maintaining gaze position (Büttner-Ennever and Horn, 1996).

In the following sections of this chapter the anatomy, histochemistry, connectivity, and functional and clinical significance are described for brain stem regions involved in the generation of eye and head movements, as well as lid movements. The line drawing in Figure 16.1 shows the location of these brain stem regions and indicates the planes of cutting for the transverse sections in Figures 16.3 and 16.4. Where possible, a reference is made to the plates in the human brain stem atlas of Paxinos and Huang (1995) or to the rhesus monkey atlas of Paxinos *et al.* (2000).

Abducens Nucleus (6N)

Structure and function

The abducens nucleus (6N) lies in the pontomedullary brain stem beneath the floor of the fourth ventricle as a round nucleus adjacent to the medial longitudinal fasciculus (Figs. 16.1 and 16.4J, K) (Paxinos and Huang, 1995, figures 31–34; Paxinos *et al.*, 2000, figures 95–100). It contains at least three functional cell groups: (1) motoneurons innervating the twitch and nontwitch muscle fibers of the lateral rectus muscle; (2) internuclear neurons, and (3) floccular-projecting neurons in the rostral cap, which belong to the paramedian tract neurons (see below; Büttner-Ennever and Horn, 1996). The motoneurons controlling the fast, twitch muscle fibers are scattered throughout the motor nucleus, but those controlling the slow, nontwitch fibers (unique to eye muscles) are arranged around the periphery of the nucleus in monkey (Büttner-Ennever *et al.*, 2001). Motoneurons and internuclear neurons exhibit the same burst-tonic firing pattern during eye movements (Fuchs *et al.*, 1988). However, only motoneurons, and not the internuclear neurons, carry conjugate- and vergence-related signals (Delgado-Garcia *et al.*, 1986; Zhou and King, 1998).

Histochemistry

In contrast to the cholinergic motoneurons, identified internuclear neurons are not cholinergic (Spencer and Bakers *et al.*, 1986; Carpenter *et al.*, 1992), but use glutamate and aspartate as transmitter (Nguyen and Spencer, 1999). The abducens nucleus receives inhibitory glycinergic afferents from inhibitory burst neurons in the contralateral dorsal paragigantocellular nucleus (DPGi) , the prepositus hypoglossi nucleus, and the ipsilateral medial vestibular nucleus (Spencer *et al.*, 1989). In addition, the motoneurons and, to a lesser extent, the internuclear neurons receive a GABAergic input, which in cat originates in part from internuclear

neurons in and above the oculomotor nucleus (de la Cruz *et al.*, 1992). The motoneurons contain the calcium-binding protein parvalbumin, but in the cat at least 80% of the internuclear neurons contain a different calcium-binding protein, calretinin, which could serve as a histological marker for internuclear neurons in this species (de la Cruz *et al.*, 1998).

Connections

The internuclear neurons of the abducens nucleus project to the motoneurons of the medial rectus muscle in the contralateral oculomotor nucleus, thereby forming the anatomical basis for conjugate eye movements (Büttner-Ennever and Akert, 1981). The motoneurons and internuclear neurons receive bilateral afferents from secondary vestibuloocular neurons in the medial vestibular nuclei, the prepositus hypoglossi nucleus (PrH), the excitatory and inhibitory saccadic burst neurons in the caudal pontine reticular nucleus (PnC) and dorsal paragigantocellular nucleus (DPGi), and from internuclear neurons of the oculomotor nucleus (Evinger, 1988).

Clinical Aspects

Lesions of the abducens nerve (6n) cause a motor paralysis of the lateral rectus muscle of the same side, resulting in horizontal diplopia (for review, see Smith, 1998; Leigh and Zee, 1999). Lesions of the abducens nucleus can be distinguished from abducens nerve palsy, since the nucleus contains not only motoneurons but also internuclear neurons that project to the medial rectus motoneurons of the contralateral side via the medial longitudinal fascicle. Therefore, damage to the nucleus results in a palsy of both muscles and an ipsilateral conjugate gaze palsy. This is often accompanied by a facial nerve palsy owing to the close proximity of the abducens nucleus (6N) and the facial genu (g7) (see Fig. 16.4J, K). A third group of neurons in the abducens nucleus, the paramedian tract neurons, which project to the flocculus, may contribute to a defect in gaze holding, if they, or their efferent or afferents inputs, are damaged (Büttner *et al.*, 1995; Büttner-Ennever and Horn, 1996).

Trochlear and Oculomotor nucleus (4N, 3N)

Structure and Function

The trochlear nucleus (4N) lies in the midbrain ventral to the aqueduct (Figs. 16.1 and 16.4A, B) (Paxinos and Huang, 1995, figures 53 and 54; Paxinos *et al.*, 2000; figures 82–84). It has been observed in human that the trochlear nucleus consists of one large group "sunken into the mlf; and several smaller groups of motoneurons further caudally" (Olszewski and Baxter, 1954). It contains only motoneurons of the contralateral superior oblique muscle. The motoneurons innervating the slow nontwitch muscle fibers lie in a tight cluster in the the dorsal cap of the nucleus (Büttner-Ennever *et al.*, 2001). The oculomotor nucleus (3N) (Figs. 16.3E, F and 16.6E, F) contains the motoneurons innervating the ipsilateral inferior rectus, inferior oblique, and medial rectus muscles and those for the contralateral superior rectus muscle. The motoneuron subgroups are organized in a topographic map (Evinger, 1988). In primates there are three clusters of medial rectus muscle motoneurons: ventrally the A group, dorsolaterally the B group, and dorsomedially at the border of the oculomotor nucleus the C group, consisting of smaller motoneurons (Büttner-Ennever and Akert, 1981). Recent experiments in the monkey show that the motoneurons of the C group innervate slow, nontwitch muscle fibers of both medial rectus and inferior rectus muscle. Small motoneurons on the midline between the oculomotor nuclei innervate the slow, nontwitch muscle fibers of the inferior oblique and superior rectus muscles (Büttner-Ennever *et al.*, 2001). In humans this region is often referred to as the nucleus of Perlia (Olszewski and Baxter, 1954); here it is termed interoculomotor nucleus (I3) (Paxinos and Huang, 1995, figures 56–58). Several populations of internuclear neurons with diverse projection targets, such as the spinal cord, the cerebellum, and the abducens nucleus, have been identified in and around the oculomotor nucleus (for review, see Evinger, 1988). So far little is known about their physiology and function.

Histochemistry

The motoneurons in the oculomotor and trochlear nuclei are cholinergic (e.g., Wang and Spencer, 1996) and express parvalbumin immunoreactivity (de la Cruz *et al.*, 1998). In contrast to the abducens nucleus, the motoneurons of vertical pulling eye muscles in the oculomotor and trochlear nuclei receive a strong GABAergic but a rather weak glycinergic input (de la Cruz *et al.*, 1992; Spencer and Baker, 1992). These results have led to the concept that inhibition in horizontal eye movement pathways is provided by glycine, whereas those for vertical eye movement pathways utilize GABA. GABAergic afferents to the oculomotor and trochlear nucleus originate from inhibitory secondary vestibuloocular neurons in the ipsilateral superior vestibular nucleus (rabbit: Wentzel *et al.*, 1995; cat: de la Cruz *et al.*, 1992; for review, see Spencer and Baker, 1992) and, at least in the cat, from the rostral interstitial nucleus of the mlf (RI) (see above; Spencer and Wang, 1996). The contralateral excitatory afferents from secondary vestibuloocular neurons in

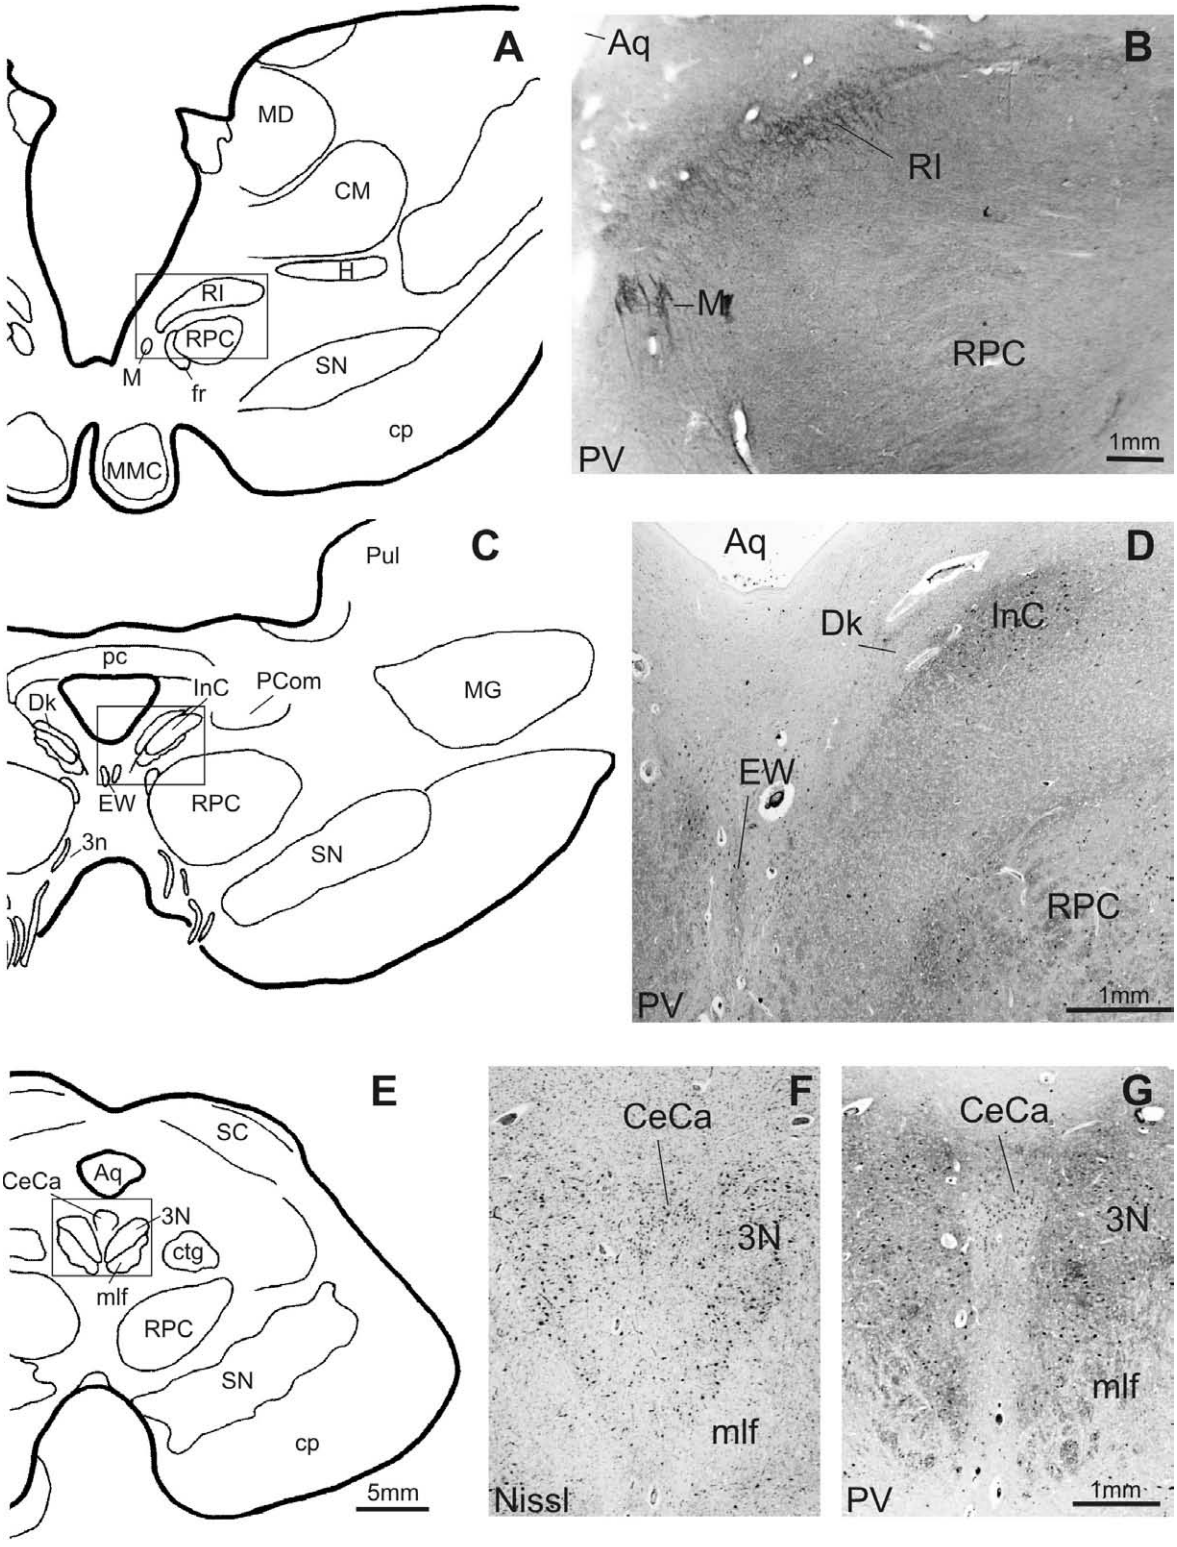

FIGURE 16.3 AND 16.4 Low-power drawings of transverse sections through the human brain stem taken from the levels indicated in Figure 16.1 (A, C, E, H, J, and L) from rostral to caudal. Adjacent, a medium-power photomicrograph with the section, stained for parvalbumin (Pv). This stain highlights several regions of the reticular formation important in the control of eye movements: In B the premotor region for vertical saccades, the rostral interstitial nucleus of the medial longitudinal fascicle (RI) and the lid premotor region (M), In D the interstitial nucleus of Cajal (InC) important for gaze holding in the vertical plane. In G the oculomotor nucleus (3N) and medially, the central caudal nucleus (CeCa) containing the motoneurons of the levator palpebrae muscle (F is taken from an adjacent Nissl-stained section). In I, the arrow marks the cluster of Pv-positive excitatory burst neurons in the dorsomedial tegmental area (DMTg) dorsomedial to the caudal pontine reticular nucleus (PnC). In K the strongly Pv-positive abducens nucleus (6N) under the facial genu (g7) and at the midline between the rootlets of the abducens nerve (6n) the nucleus raphe interpositus (RIP) consisting of Pv-immunoreactive neurons. In M, the arrow indicates darkly stained inhibitory burst neurons of the saccadic system in the dorsal paragigantocellular nucleus (DPGi). *Continued*

the medial and superior vestibular nuclei most probably use glutamate as transmitter (Dememes and Raymond, 1982). Recent anatomical studies in the cat indicate that excitation to medial rectus motoneurons from the internuclear neurons of the contralateral abducens nucleus is mediated by glutamate and aspartate, whereas the afferents from the ascending tract of Deiters use only glutamate as transmitter (Nguyen and Spencer, 1999).

Connections

The medial rectus subgroup in the oculomotor nucleus receives afferents via the medial longitudinal fasciculus (mlf) from the internuclear neurons of the contralateral abducens nucleus (Büttner-Ennever and Akert, 1981) and from the ipsilateral ascending tract of Deiters, a vestibular pathway presumably involved in the control of vergence (Baker and Highstein, 1978; Chen-Huang and McCrea, 1998). Electrophysiological recording have identified neurons in the mesencephalic reticular formation, just lateral to the oculomotor nucleus, which carry a premotor-like signal for vergence (Mays, 1984), and theoretically should project to medial and inferior rectus motoneurons; however, these cells have not yet been visualized anatomically. Secondary vestibulooculomotor projections target the motoneurons of vertical pulling eye muscles, i.e., inferior rectus, inferior oblique, superior rectus, and superior oblique muscle, via excitatory fibers from the superior and medial vestibular nuclei from the contralateral side, and via inhibitory fibers from the superior vestibular nucleus of the the ipsilateral side (for review, see Büttner-Ennever, 2000; see also Chapter 33). These vestibular pathways can be visualised with transsynaptic retrograde tract tracers (Büttner-Ennever *et al.*, 1981). In the monkey the most striking input to vertical oculomotor neurons comes from the y group. The motoneurons of vertical pulling eye muscles in the oculomotor and trochlear nuclei also receive bilateral projections from the interstitial nucleus of Cajal (InC; see "Interstitial Nucleus of Cajal"), and predominantly ipsilateral projections from the rostral interstitial nucleus of the medial longitudinal fasciculus (RI; see "Rostral Interstitial Nucleus of the Medial Longitudinal Fasciculus") (Horn and Büttner-Ennever, 1998a).

Clinical Aspects

The trochlear nucleus and nerve innervate the superior oblique muscle. Damage to the nerve accounts for most cases of acquired vertical diplopia. Lesions in either nerve or nucleus result in a vertical or oblique diplopia, which is largest when there is attempted gaze in the "down and medial" quadrant of vision. Hence, a patient with trochlear palsy frequently complains of "difficulty walking down stairs" (Henn *et al.*, 1982, for review, see Smith, 1998; Leigh and Zee, 1999). The oculomotor nucleus and nerve rootlets innervate four muscles and the levators. Lesions of this small area often cause multiple palsies in which there is insufficient resolution to distinguish between nerve or nuclear damage (for review, see Smith, 1998; Leigh and Zee, 1999). Only the superior rectus muscle has a crossed innervation. A central unilateral oculomotor lesion is rare, but it will cause bilateral superior rectus muscle palsy, because it damages both the ipsilateral motoneurons and the fibers from the contralateral motoneurons crossing through the nucleus. Damage to this area may also affect the parasympathetic fibers arising from the Edinger–Westphal complex (EW; Fig. 16.3C), that provide the preganglionic neurons innervating the ciliary ganglion in the orbit (Erichsen and May, 2002). The ciliary ganglion supplies the pupillary sphincter and ciliary muscles for lens accomodation (for review, see Leigh and Zee, 1999; Sun and May, 1993). The supraoculomotor nucleus (Su3C; Paxinos and Huang, 1995, figure 58) and the supraoculomotor cap (Su3; Paxinos and Huang, 1995, figure 58) are probably part of this poorly defined group of cells.

Rostral Interstitial Nucleus of the Medial Longitudinal Fasciculus (RI)

Structure and function

The rostral interstitial nucleus of the medial longitudinal fasciculus (RI) contains the premotor burst neurons, which are essential for generation of vertical and torsional saccades (Büttner *et al.*, 1977; Vilis *et al.*, 1989; Crawford and Vilis, 1992). In addition, this region contains premotor neurons with projections to the motoneurons of dorsal neck muscles participating in eye–head or only head movements, at least in the cat (Isa and Sasaki, 1992; Isa *et al.*, 1992; for review, see Isa and Sasaki, 2002). The rostral interstitial nucleus of the RI lies in the mesencephalic reticular formation and forms the medial part of the H fields of Forel (Figs. 16.1 and 16.3A, B) (Paxinos *et al.*, 2000, figures 68–72). In transverse sections it forms a wing-shaped nucleus ventromedial to the third ventricle and borders the parvocellular portion of the red nucleus (RPC) dorsomedially (Fig. 16.3A, B). The RI adjoins directly the rostral end of the interstitial nucleus of Cajal (InC) from which it is separated by the traversing fibers of the fasciculus retroflexus (fr). Its rostral end is roughly demarcated by the traversing fibers of the mamillothalamic tract (mt) (Büttner-Ennever and Büttner, 1988). In frontal sections the posterior thalamosubthalamic artery serves as a helpful landmark, which borders the

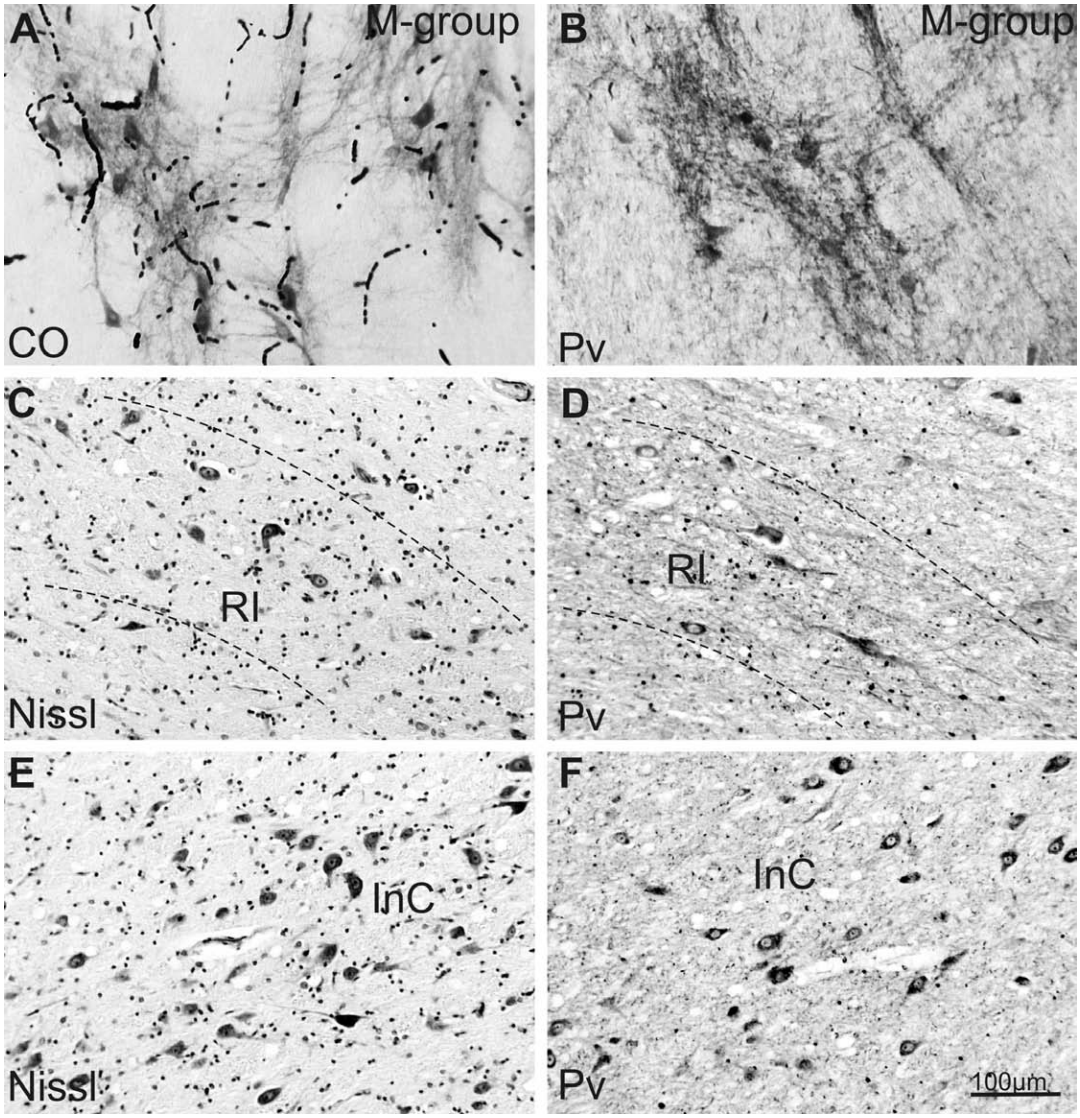

FIGURE 16.5 High-power photomicrographs of the M-group **(A, B),** the rostral interstitial nucleus of the mlf (RI) **(C, D),** and the interstitial nucleus of Cajal (InC) **(E, F),** stained for cytochrome oxidase (CO), parvalbumin (Pv), or with a Nissl stain, to show the characteristics of individual cell type.

RI dorsomedially like an eyebrow (Büttner-Ennever *et al.*, 1982). The RI is composed of several morphological cell types, enclosing small to medium-sized neurons, which are embedded in the fibers of the medial longitudinal fasciculus, resulting in its reticulated appearance (Fig. 16.5C, D; Crossland *et al.*, 1994).

Histochemistry

Recent work in monkey and human showed that the neuropil of the RI is highlighted within the mesencephalic reticular formation by its strong cytochrome oxidase activity and parvalbumin expression (Figs. 16.3B and 16.5D) (Horn and Büttner-Ennever, 1998a; Horn *et al.*, 2000). In addition, most of the parvalbumin-immunoreactive neurons in the RI express calretinin and are ensheathed by perineuronal nets as revealed by *Wisteria floribunda* agglutinin binding and chondroitin sulfate proteoglycan immunohistochemistry in monkeys and humans (Horn *et al.*, 2003). Similarly, the RI can be well visualized by immunostaining with the SMI32 antibody as shown in the atlas of Paxinos and Huang (2000; Petrides *et al.*, figure 34), where it is labeled as prerubral fields (PRFs). Anatomical studies in the RI of the cat revealed the presence of GABA-immunoreactive neurons within the dorsomedial part, which project to the oculomotor nucleus (Spencer and Wang, 1996). In contrast, the RI of the monkey contains only few small GABA-immunoreactive neurons, which

are not premotor burst neurons (Carpenter *et al.*, 1992). The RI receives a strong innervation by GABA- and glycine-immunoreactive terminals (Horn *et al.*, 1994). Combined anterograde tracing and immunocytochemical methods indicated that projection neurons from the RI to the oculomotor and trochlear nucleus use aspartate and/or glutamate as transmitter (Spencer and Wang, 1996).

Connections

The burst neurons, which make up all of the medium-sized neurons within the rostral interstitial nucleus of the mlf (RI), project monosynaptically to the motoneurons of the vertical pulling extraocular eye muscles in the oculomotor and trochlear nuclei (Moschovakis *et al.*, 1991a, b; Horn and Büttner-Ennever, 1998a; Wang and Spencer, 1996a). Additional targets are the RI of the contralateral side, the interstitial nucleus of Cajal (InC), the paramedian tract neurons (see "Interstitial Nucleus of Cajal"); and sparsely the spinal cord (Moschovakis *et al.*, 1991a, b; Wang and Spencer, 1996b; Holstege and Cowie, 1989). The burst neurons in the RI receive strong input from the inhibitory, glycinergic omnipause neurons in the pontine reticular formation (Horn *et al.*, 1994). In addition, the RI receives afferents from the interstitial nucleus of Cajal (InC) and the deep layers of the superior colliculus (Nakao *et al.*, 1990; Kokkoroyannis *et al.*, 1996). A minor projection from the medial vestibular nucleus targets mainly the mediocaudal part of the RI (Büttner-Ennever and Lang, 1981; Matsuo *et al.*, 1994).

Clinical Aspects

Unilateral experimental lesions in macaque monkeys lead to deficits of torsional saccades and produce a spontaneous torsional nystagmus (Crawford and Vilis, 1992; Suzuki *et al.*, 1995; Helmchen *et al.*, 1996b). Bilateral lesions result in a complete vertical gaze paralysis, but vertical gaze holding, vestibular eye movements, and pursuit are preserved, as are horizontal saccades (for review, see Leigh and Zee, 1999; Kömpf *et al.*, 1979; Suzuki *et al.*, 1995). In patients a rare pure isolated downgaze paralysis can be observed only after discrete bilateral lesions of the RI, whereas a combined up- and downgaze paralysis is seen after unilateral RI lesions, often but not always involving the posterior commissure (Büttner-Ennever *et al.*, 1982; Pierrot-Deseilligny *et al.*, 1982; Ranalli *et al.*, 1991; Riordan-Eva *et al.*, 1996; Helmchen *et al.*, 1998).

Interstitial Nucleus of Cajal (InC)

The Interstitial Nucleus of Cajal (InC) is elsewhere called the interstitial nucleus of the medial longitudinal fasciculus (IMLF). However, use of the term IMLF is not recommended by the authors of this chapter.

Structure and Function

The cells of the interstitial nucleus of Cajal (InC) lie within the medial longitudinal fasciculus (mlf) and form a rather well-circumscribed nucleus in the mesencephalic reticular formation lateral to the rostral pole of the oculomotor nucleus at the border of the periaqueductal gray. It consists of small to medium-sized neurons with few large polygonal cells intermingled (Figs. 16.3D and 16.5E, F) (Bianchi and Gioia, 1991) and lies just beneath the nucleus of Darkschewitsch (Dk), which contains more elongated, spindle-shaped, strongly Nissl-stained cells (Olszewski and Baxter, 1954; Bianchi and Gioia, 1990). The interstitial nucleus of Cajal is a well-known structure and has been described in many species. According to most investigations, it is clearly associated with a role in eye and head movements. In a recent description of a cell group representing the premotor center for vertical saccades, which lies immediate rostral and adjacent to InC, the name "rostral intersitial nucleus of the mlf (RI)" was chosen. Therefore, we suggest not using the name "interstitial nucleus of the mlf" for the interstitial nucleus of Cajal, because it might lead to much confusion with the RI (Figs. 16.1 and 16.3C, D) (Paxinos and Huang, 1995, figures 59–63, abbreviated as iMLF; Paxinos *et al.*, 2000, figures 72–78), as well as with some other structures, e.g., the intermediate and caudal interstitial nuclei of the mlf (Blanks 1990).

The interstitial nucleus of Cajal (InC), like the rostral interstitial nucleus of the mlf (RI), participates in vertical and torsional eye movements, but the InC is more involved in vertical gaze holding (Fukushima *et al.*, 1992) and eye–head coordination (Fukushima, 1987) rather than generation of eye movements. The InC contains several functional cell groups related to eye movements (for review, see Helmchen *et al.*, 1996a): Burst-tonic and tonic neurons encode the eye position and they are involved in the vertical integrator function (for review, see Fukushima *et al.*, 1992). Other neurons apparently participate in eye–head movements in the vertical and torsional plane, since stimulation of the InC results in an ipsilateral ocular tilt reaction consisting of an ipsilateral head tilt, with compensatory eye movements (Westheimer and Blair, 1975; Lueck *et al.*, 1991).

Histochemistry

In monkey and human the InC is highlighted by its strong parvalbumin immunoreactivity (Fig. 16.3D) and its cytochrome oxidase activity, and thereby is sharply separated from the dorsally adjacent nucleus

of Darkschewitsch (Dk), which exhibits much less parvalbumin immunoreactivity especially of the neuropil (Fig. 16.3D); (Horn and Büttner-Ennever, 1998a). Parvalbumin expression is confined to the medium-sized and large neurons in the InC, some of which are projection neurons to the motoneurons of vertical extraocular eye muscles, presumed premotor burst-tonic neurons (Fig. 16.5F) (Horn and Büttner-Ennever, 1998a). Using *in situ* hybridization methods for the detection of the messenger RNA of the GABA-synthetizing enzyme glutamate decarboxylase, there is evidence that the InC of the monkey contains numerous small and medium-sized GABAergic neurons, which in part project to the motoneurons of vertical eye muscles (Horn *et al.* 2003). The InC contains many GABA-immunoreactive terminals, some of which could arise from collaterals of the inhibitory secondary vestibulo oculomotor projections of the ipsilateral superior vestibular nucleus, which were shown to be GABAergic (De la Cruz *et al.*, 1992).

Connections

There are three main efferent projections systems leaving the interstitial nucleus of Cajal (INC) (Kokkoroyannis *et al.*, 1996): First, the ascending system has strong projections to the ipsilateral mesencephalic reticular formation, including the RI and zona incerta (ZI), weaker projections to the ipsilateral centromedian (CMn) and parafascicular (PF) thalamic nuclei and bilateral to the mediodorsal (MD), central medial (CM), and lateral nuclei of the thalamus. Second, the descending system projects through the medial longitudinal fasciculus (mlf) and innervates the ipsilateral oculomotor and trochlear nucleus, the ipsilateral paramedian pontine reticular formtion, and the rostral cap of the abducens nucleus as part of the paramedian tract groups (Büttner-Ennever *et al.*, 1989; Büttner-Ennever and Horn, 1996). Further, descending projections terminate in the vestibular nuclei, the prepositus hypoglossal nucleus, the gigantocellular portion of the reticular formation, which mediates head movements (Cowie and Robinson, 1994; Cowie *et al.*, 1994), the inferior olive, and the ventral horn of C1 to C4. The commissural system projects via the posterior commissure (pc) to the nucleus of the posterior commissure (PCom), the contralateral InC, and the contralateral oculomotor and trochlear nuclei to innervate only the motoneurons of vertical-pulling eye muscles (Kokkoroyannis *et al.*, 1996). In addition, the InC receives inputs from premotor neurons that encode eye or head velocity signals, e.g., from secondary vestibuloocular neurons (Iwamoto *et al.*, 1990) and from nucleus Y of the vestibular nuclei (Fukushima *et al.*, 1986; for review, see Leigh and Zee, 1999). Projections from the RI, presumably originating from premotor burst neurons, target most probably the burst-tonic and tonic neurons in the InC (Moschovakis *et al.*, 1991a, b).

Clinical Aspects

Unilateral lesions of the InC lead to a contralateral head tilt with torsion of the eyes to the contralateral side, but a torsional nystagmus to the ipsilateral side (Halmagyi *et al.*, 1994; for review, see Leigh and Zee, 1999). Bilateral lesions of the InC result in an upbeat nystagmus and neck retroflexion (Fukushima, 1987; Helmchen *et al.*, 1998, 2002), clinical signs characteristic of progressive supranuclear palsy (Fukushima-Kudo and Fukushima, 1987). A lesion of the posterior commissure (pc), which contains the crossing fibers of the burst-tonic and tonic neurons, leads to the inability to hold eccentric gaze after vertical saccades (Partsalis *et al.*, 1994).

Paramedian Pontine Reticular Formation

Structure and Function

Originally the term "paramedian pontine reticular formation (PPRF)" was introduced in macaque monkeys to define the brain stem site where lesions produce a horizontal gaze palsy (Fig. 16.1) (Cohen and Komatsuzaki, 1972). It includes several functional cell groups in the pontine and medullary reticular formation, which were found to be important for the generation of eye and head movements: excitatory and inhibitory burst neurons for horizontal eye movements, as well as omnipause neurons and saccadic long-lead burst neurons that participate directly in the generation of horizontal saccadic eye movements. Reticulospinal neurons are involved in eye–head movements, and paramedian tract neurons may have a role in gaze stabilization.

Anatomically, the paramedian pontine reticular formation is composed of the oral pontine reticular nucleus (PnO), and the caudal pontine reticular nucleus (PnC), including the dorsomedial tegmental area (DMTg). The PnO begins rostrally at the caudal end of the trochlear nucleus and extends caudally to the level of the caudal end of the locus coeruleus (LC) (Paxinos and Huang, 1995, figures 37–49). The caudal pontine reticular nucleus (PnC) adjoins the PnO caudally and extends to the caudal pole of the facial nucleus (7N), and the dorsomedial tegmental area (DMTg) stretches throughout the dorsal paramedian pontine reticular formation (Paxinos and Huang, 1995, figures 33–36; Paxinos *et al.*, 2000; figures 94–96). The PnC and the PnO consist of small to medium-sized cells. An additional few large reticulospinal neurons are scattered in the PnC, whereas the PnO is characterized by the presence

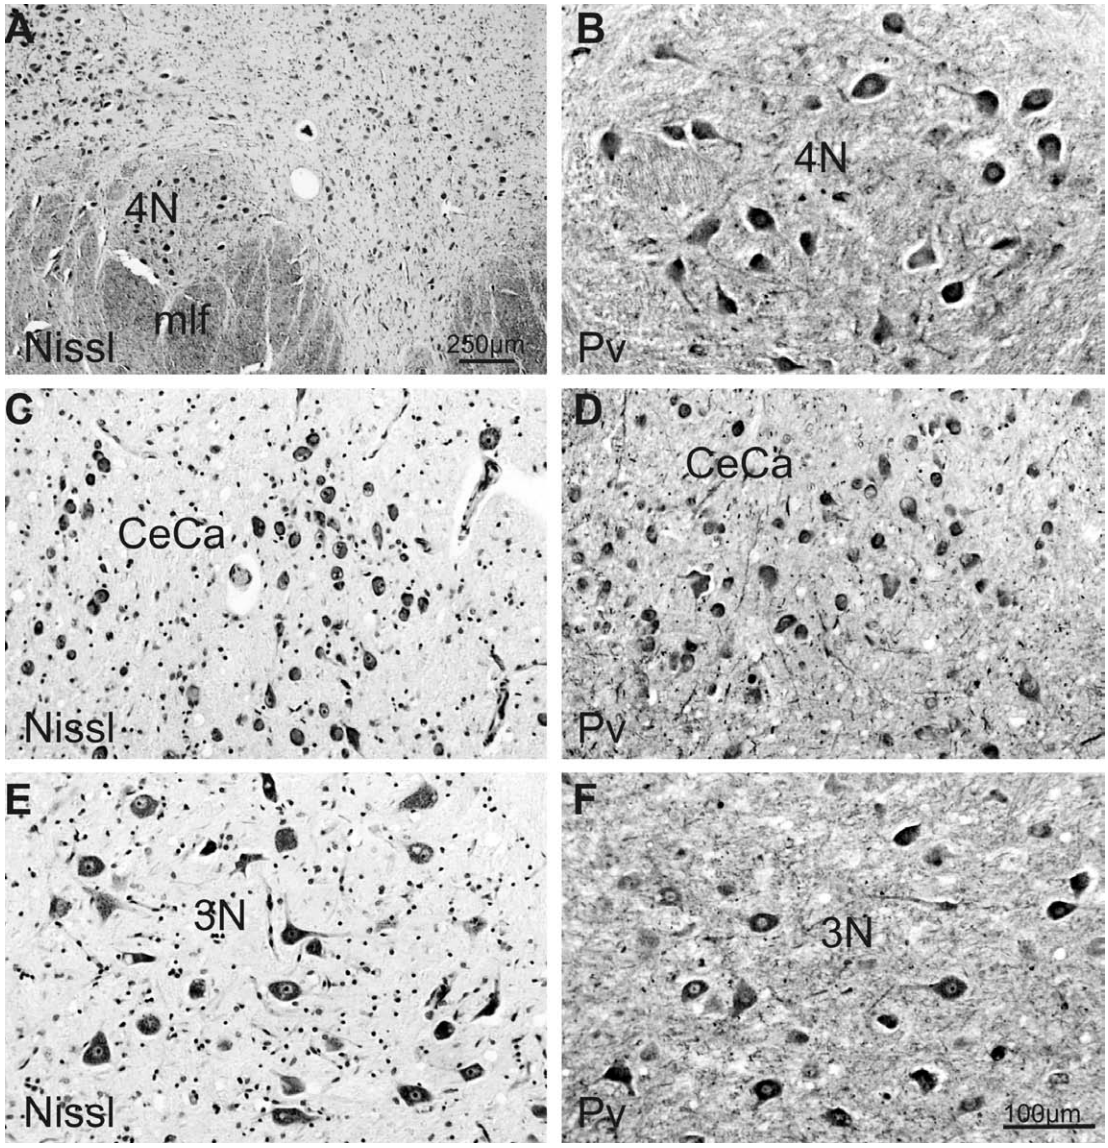

FIGURE 16.6 High -power photomicrographs to show the characteristics of individual cell types: **A,** (Nissl) and **B,** (Pv) the superior oblique muscle motoneurons in the trochlear nucleus (4N); in **C** (Nissl) and **D** (Pv), the levator palpebrae muscle motoneurons in the central caudal nucleus (CeCa); and in **E** (Nissl) and **F** (Pv), the extraocular muscle motoneurons in the oculomotor nucleus (3N).

of plump neurons and a more cellular appearance in Nissl-stained sections (Olszewski and Baxter, 1954; Martin and Holstege, 1990).

Saccadic Burst Neurons There are several types of saccade-related burst neurons in the PPRF (Figs. 16.7 and 16.8) (for review, see Leigh and Zee, 1999; Scudder *et al.*, 2002). Excitatory (EBNs) and inhibitory burst neurons (IBNs) exhibit a high-frequency burst during horizontal saccades and are otherwise silent being inhibited by omnipause neurons (OPNs). EBNs excite the motoneurons and internuclear neurons in the ipsilateral abducens nucleus, thereby also activating the medial rectus motoneurons in the contralateral oculomotor nucleus, which results in a saccade to the ipsilateral side (Fig. 16.8). At the same time IBNs are driven by the EBNs, and they inhibit the motoneurons in the contralateral abducens nucleus in order to evoke a conjugate saccade (Strassman *et al.*, 1986b). Saccade-related long-lead burst neurons (LBNs) exhibit an additional irregular low-frequency activity before the saccade-related burst, and they presumably activate the premotor burst neurons (for review, see Moschovakis *et al.*, 1996).

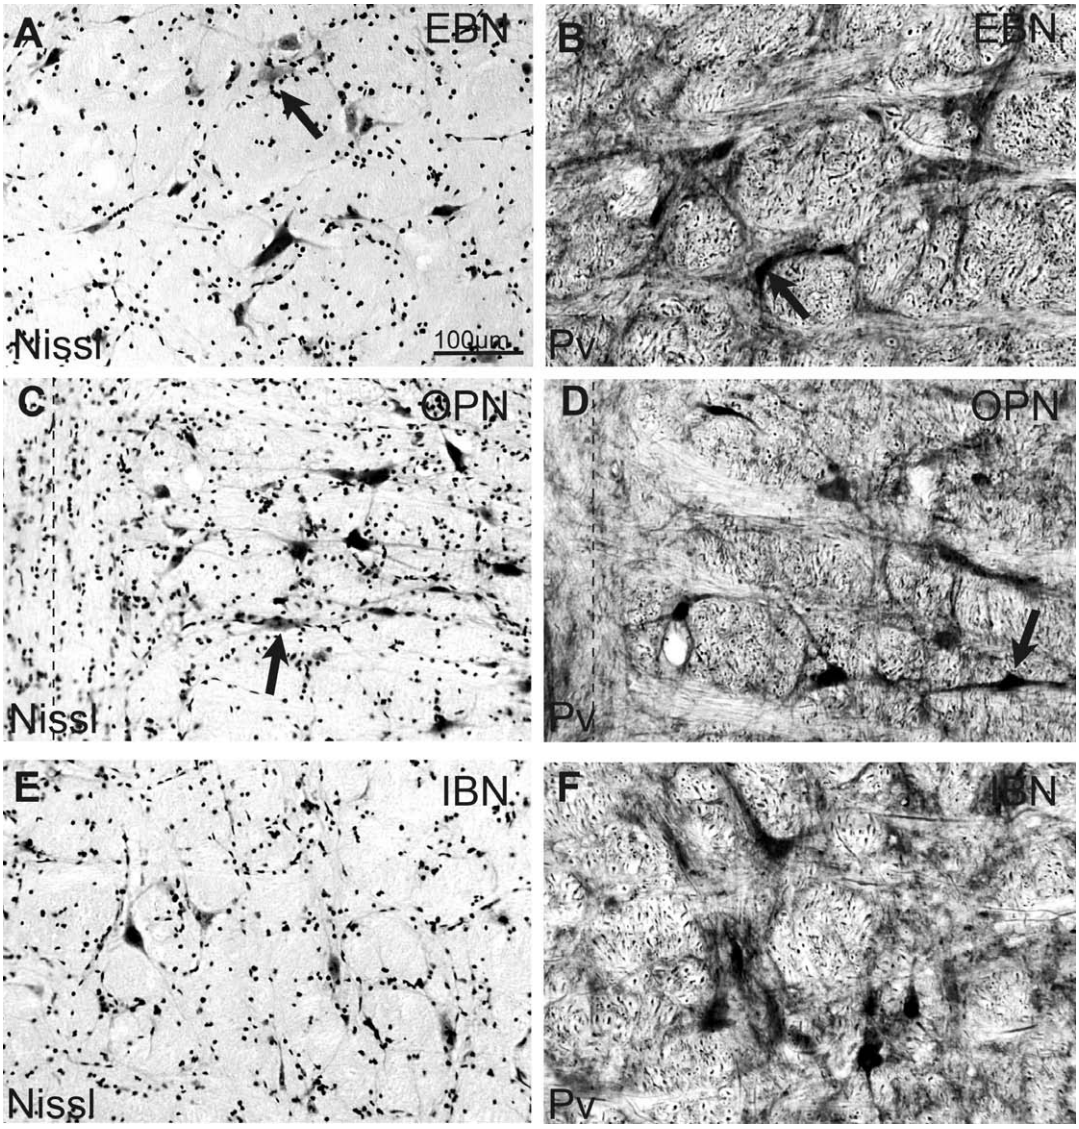

FIGURE 16.7 High-power photomicrographs of the excitatory burst neurons (EBNs; *arrow*) in the caudal pontine reticular nucleus **(A, B),** the omnipause neurons (OPNs) in the nucleus raphe interpositus (**C, D;** *arrows*), and the inhibitory burst neurons (IBNs) in the dorsal paragigantocellular nucleus **(E, F)** in either Nissl- or parvalbumin (Pv)–stained transverse sections, to show the characteristics of each individual cell type. Dotted lines in C and D indicate the midline.

Excitatory burst neurons (EBNs) Tract tracing experiments in the monkey showed that the excitatory burst neurons for horizontal saccades lie as a compact group within the dorsomedial part of the caudal pontine reticular nucleus (PnC) just rostral to the saccadic omnipause neurons (Fig. 16.4H, I) (Strassman *et al.*, 1986a; Langer *et al.*, 1986; Horn *et al.*, 1995). The burst neurons belong to the medium-sized cell population, which in addition express parvalbumin (Fig. 16.7A, B) (Horn *et al.*, 1995). Based on the parvalbumin-immunostaining pattern the homologue of the EBN area was described in humans, as an area of about 2.5 mm width and 2 mm height adjacent to the medial longitudinal fasciculus (mlf) that corresponds to the dorsomedial tegmental area (DMTg) (Paxinos and Huang, 1995, figure 35) (Fig. 16.4H, I, *arrow;* Horn *et al.*, 1995, 1996).

Inhibitory burst neurons (IBN) In monkey the premotor inhibitory neurons for horizontal saccades are located ventromedially to the abducens nucleus in the dorsal paragigantocellular nucleus (DPGi). They belong to the medium-sized cell population that expresses parvalbumin immunoreactivity and helped

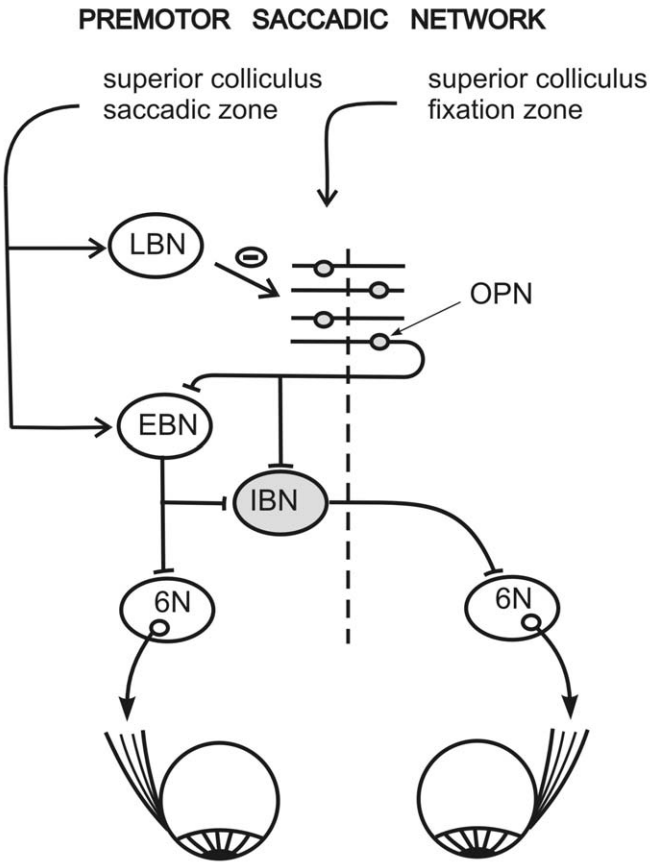

FIGURE 16.8 A simplified diagram of the arrangement of the excitatory burst neurons (EBNs), the glycinergic omnipause neurons (OPNs), and the glycinergic inhibitory burst neurons (IBNs) that constitute the premotor circuitry in the paramedian pontine reticular formation controlling the generation of horizontal saccades. The shaded elements are inhibitory neurons. 6N, abducens nucleus; LBN, long-lead burst neurons.

to outline the homologue region in human as well (Fig. 16.4L, M, *arrow;* Fig. 16.7E, F) (Horn *et al.*, 1995, 1996; Paxinos and Huang, 1995, figures 30–31).

Long-lead burst neurons (LBNs) Saccadic long-lead burst neurons are found at several locations in the brain stem (Fig. 16.8): pontine LBNs lie within the nucleus reticularis pontis caudalis (PnC), intermingled with premotor excitatory burst neurons, and more rostrally in the nucleus reticularis pontis oralis (PnO). They also lie in the reticulotegmental nucleus of the pons (RtTg) (Scudder *et al.*, 1996b) and intermingled with inhibitory burst neurons in the dorsal paragigantocellular nucleus (DPGi) (Scudder *et al.*, 1988).

Reticulospinal neurons In the cat, another class of excitatory saccade-related neurons in the PPRF was described, the reticulospinal neurons (for review, see Martin and Holstege, 1990; Grantyn *et al.*, 1992). They project via the medial reticulospinal tract to the spinal cord and give off collaterals to the abducens nucleus. The reticulospinal neurons are activated during eye movements and neck muscle activity during gaze shifts to the ipsilateral side (Grantyn *et al.*, 1987). Reticulospinal neurons were found in the vicinity of the abducens nucleus and in the nucleus reticularis pontis caudalis (PnC) intermingled with EBNs (Grantyn *et al.*, 1987). In the monkey, gaze-related neurons were recorded in the DPGi, the PnC, and the oral pontine reticular nucleus (PnO), which might have projections to the spinal cord with collaterals to the abducens nucleus (Whittington *et al.*, 1984; May and Porter, 1992; Robinson *et al.*, 1994).

Omnipause neurons (Fig. 16.7C, D) Saccadic omnipause neurons (OPNs) act as triggers for the initiation of saccadic eye movements in all directions (Fuchs *et al.*, 1985). During fixation and slow eye movements the OPNs exert a tonic inhibition on premotor burst neurons in the pontine reticular formation (see above) and the rostral interstitial nucleus of the mlf (RI). During a saccade the OPNs are inhibited, thereby enabling an activation of the burst neurons from the superior colliculus (for review, see Moschovakis and Highstein, 1994; Scudder *et al.*, 2002). The basic circuitry for the generation of horizontal saccades is shown in Figure 16.8. In cat OPNs not only trigger saccadic eye movement, but participate in gaze control, i.e., combined eye and head movements (Paré and Guitton, 1990, 1998). However, in primates the OPNs apparently control only that portion of gaze movement, that involves the eye movement (Phillips *et al.*, 1999). In addition, OPNs may form a link to the premotor circuit of the blink system, since stimulation of the OPNs suppresses reflex blinks (see "Blink–Saccade Interaction") (for review, see Sibony and Evinger, 1998).

Combined physiological and anatomical experiments showed that the saccadic omnipause neurons lie within a distinct nucleus at the ventrocaudal border of nucleus raphe pontis (RPn) and dorsal to the nucleus raphe magnus (RMg), which was termed nucleus raphe interpositus (RIP) (Figs. 16.4J, K and 16.7C D) (Paxinos and Huang, 1995, figures 33–34; Paxinos *et al.*, 2000, figures 93 and 94, Büttner-Ennever *et al.*, 1988). In monkey the RIP forms two vertical columns adjacent to the midline, consisting of medium-sized neurons, which are horizontally oriented with well-developed dendrites reaching across the midline. In all species so far studied, including humans, the RIP lies at the level where the traversing fibers of the abducens nerve (6n) rootlets appear (Fig. 16.4J, K) (Büttner-Ennever *et al.*, 1988; Horn *et al.*, 1994).

Histochemistry

There are only few reports on the histochemistry of the functional cell groups within the pontine reticular formation. Excitatory (EBNs) and inhibitory (IBNs) saccadic burst neurons and omnipause neurons (OPNs) are parvalbumin-immunoreactive and express cytochrome oxidase activity (Büttner-Ennever *et al.*, 1988; Horn *et al.*, 1994, 1995). The nucleus raphe interpositus shows positive staining for acetylholinesterase activity (see Paxinos and Huang, 1995, figure 34). The transmitter of the EBNs, RSNs, and LBNs is not known, but the IBNs use glycine as a transmitter (Spencer *et al.*, 1989). In contrast to its neighboring raphe nuclei, nucleus raphe interpositus (RIP), which is composed of OPNs, does not contain 5-HT-immunoreactive neurons (Büttner-Ennever *et al.*, 1988; Horn *et al.*, 1994; see also Chapter 13). Immunocytochemical studies in monkey showed that the neurons of the RIP are glycinergic, and that they receive a similar strong supply of glycine- and GABA-immunoreactive terminals on their somata and proximal dendrites, whereas glutamatergic afferents are confined to the dendrites (Horn *et al.*, 1994). Although embedded in a network of 5-HT and catecholaminergic fibers, only few immunostained varicosities are associated with RIP neurons (Horn *et al.*, 1994). In addition, the neurons of the RIP are ensheathed with prominent perineuronal nets (Horn *et al.*, 2003).

Connections

The excitatory burst neurons (EBNs) project directly to the motoneurons and internuclear neurons in the abducens nucleus and to the inhibitory burst neurons (IBNs) in the dorsal paragigantocellular nucleus (DPGi) of the same side, thereby providing the neuroanatomical basis for conjugate horizontal saccades (Fig. 16.8) (Strassman *et al.*, 1986a). In addition, the EBNs and IBNs send projections to the paramedian tract neurons (Strassman *et al.*, 1986a, b; Büttner-Ennever and Horn, 1996).

Recent work in monkey showed that the DPGi and PnC containing IBNs, EBNs, and reticulospinal neurons receive a strong afferent input from the intermediate layers of the superior colliculus motor map mediating large horizontal saccades, which could be accompanied by head movements (Büttner-Ennever *et al.*, 1999).

The omnipause neurons in the nucleus raphe interpositus (RIP) of the monkey project directly to the vertical burst neurons in the rostral interstitial nucleus of the mlf (RI) , the horizontal burst neurons (EBN) in the dorsomedial nucleus reticularis pontis caudalis (PnC), and the dorsal paragigantocellular nucleus (DPGi) (Fig. 16.8) (Ohgaki *et al.*, 1989; Strassman *et al.*, 1987; for review, see Moschovakis *et al.*, 1996). Axons of the majority of omnipause neurons cross the midline. In the monkey, the omnipause neurons receive direct afferents from the deep layers of the rostral superior colliculus, which represents the fixation area (Büttner-Ennever *et al.*, 1999; Everling *et al.*, 1998). Only a few omnipause neurons project to the spinal cord (Robinson *et al.*, 1994). Single-cell reconstructions of horseradish peroxidase–filled, electrophysiologcially identified saccadic long-lead burst neurons (LBNs) in the oral pontine reticular nucleus (PnO) of the monkey revealed projections to the dorsomedial part of the PnC and the DPGi, which correspond to the EBN and IBN area, respectively, the nucleus reticularis tegmenti pontis (RtTg), and the nucleus reticularis gigantocellularis (Gi), which contains premotor neurons for head movements (Cowie *et al.*, 1994; Scudder *et al.*, 1996b).

Clinical Aspects

Experimental unilateral lesions of the saccadic burst neuron region in the pontine reticular formation result in ipsilateral gaze paralysis (Henn *et al.*, 1984; for review, see Zee, 1998). Selective experimental and pharmacological lesions of the omnipause neurons in monkey resulted in slowed saccades but not oscillations (Kaneko, 1996; Soetedjo *et al.*, 2002). From clinicopathological studies in human, it is not clear whether the slowing of saccades is due to lesions of the omnipause neurons or the adjacent excitatory burst neurons (Johnston *et al.*, 1993; Hanson *et al.*, 1986; Kato *et al.*, 1994). Theoretically, it is also possible that restricted lesions of the omnipause neurons may result in oscillations (ocular flutter and opsoclonus) (Leigh and Zee, 1999; Schon *et al.*, 2001). On the other hand, the analysis of cases with opsoclonus in patients who had suffered from lung carcinoma did not reveal any significant deficits of omnipause neurons (Büttner-Ennever and Horn, 1994; Wong *et al.*, 2001).

Nucleus of the Posterior Commissure (PCom)

Structure and Function

The nucleus of the posterior commissure (PCom) lies rostral to the deep layers of the colliculus superior and is closely associated with the fibers of the posterior commissure (Fig. 16.3C) (Paxinos and Huang, 1995, figures 63 and 64). Based on the cytoarchitecture and relationship to the fibers of the posterior commissure, five different cell groups were identified in the PCom of monkey and human (Kuhlenbeck and Miller, 1949; Carpenter and Peter, 1970): the principal part, the medially adjacent magnocellular part, which borders on the periaqueductal gray; and the rostral, subcommissural, and infracommissural parts, which all lie

within the periaqueductal gray. Usually in the oculomotor literature the term "nucleus of the posterior commissure" refers to the two largest groups, the magnocellular and principle parts. All parts consist of small and medium-sized neurons; only in the magnocellular part are large cells predominant (Bianchi and Gioia, 1993).

On the basis of clinical observations, the nucleus of the posterior commissure (PCom) has long been suspected as being involved in the generation of upward eye movements, since lesions in patients resulted in upward gaze paralysis (Christoff, 1974). To date the role of the PCom in vertical gaze has not been fully explained. In addition, lesions of the PCom result in lid retraction, indicating a role in the premotor control of the upper eyelid (Schmidtke and Büttner-Ennever, 1992; Averbuch-Heller, 1997).

Recording experiments in the macaque monkey revealed neurons in the PCom, which fire with upward saccades. In contrast to the burst neurons in the rostral interstitial nucleus of the mlf (RI), these saccade-related PCom neurons do not project to motoneurons of extraocular eye muscles but target on neurons in the contralateral PCom, the InC, the RI, and intralaminar thalamic nuclei. They are thought to play a role in modulating the vertical gaze integrator (Moschovakis *et al.*, 1996). The PCom has moderate acetylcholinesterase activity (Paxinos and Huang, 1995, figures 63 and 64). It contains GABAergic neurons, which project to the superior colliculus in the cat (Appell and Behan, 1990).

Connections

Fibers of the magnocellular part of the PCom project through the ventral part of the posterior commissure to the contralateral interstitial nucleus of Cajal (InC), the magnocellular part of the PCom, the rostral interstitial nucleus of the mlf (RI), and the supraoculomotor area (Su3), which is the region immediately dorsal to the oculomotor nucleus (Carpenter *et al.*, 1970; Grantyn, 1988, Büttner-Ennever and Büttner, 1988). In addition, descending fibers terminate in the paramedian pontine reticular formation, but sparsely in the spinal cord at cervical levels (Benevento *et al.*, 1977; Holstege, 1988; Satoda *et al.*, 2002). The PCom has reciprocal connections with the superior colliculus, and receives a strong input from the frontal eye fields of the cortex and the dentate nucleus of the cerebellum (Huerta and Harting, 1982; Leichnetz, 1982; Sugimoto *et al.*, 1982; Grantyn, 1988; Stanton *et al.*, 1988).

Clinical Aspects

In macaque monkeys experimental lesions of the PCom lead to an upward gaze paralysis often combined with lid retraction (Pasik *et al.*, 1969; Carpenter *et al.*, 1970). The same symptoms were observed in patients with lesions of the Pcom (Christoff, 1974). The reanalysis of clinicopathological cases with vertical gaze paralysis and lid retraction showed that the common lesioned area involved the posterior commissure and the PCom, whereas the lesions in cases with only vertical gaze paralysis and no lid retraction spared the nuclei and the fibers of the posterior commissure (Schmidtke and Büttner-Ennever, 1992).

Central Mesencephalic Reticular Formation

Structure and Function

A specific area of the mesencephalic reticular formation lateral to the oculomotor nucleus has been distinguished on account of its involvement in the control of saccades and was designated as central mesencephalic reticular formation (cMRF) (for review, see Cohen *et al.*, 1986). The cMRF lacks distinctive boundaries, but the saccade-related region lies caudal to the posterior commissure (pc) and overlaps the rostral portion of nucleus subcuneiformis in monkeys (Waitzman 2000a). It has been recently visualized, at least in part, by Chen and May (2000) using retrograde tracer substances: its rostral pole lies dorsolateral to the anterior tip of the red nucleus and ventrolateral to the interstitial nucleus of Cajal (InC). Stimulation in cMRF induces contralateral saccadic eye movements, and lesions cause transient deficits in contralateral gaze shifts (Cohen and Büttner-Ennever, 1984; Waitzman *et al.*, 1996). Single-unit recordings and the microinjection of a reversible inactivator (muscimol) revealed two subregions of the mesencephalic reticular formation (Waitzman, 2000a, b). The first was a ventrocaudal region corresponding to cMRF, from which inactivation caused contraversive, upward saccade, hypermetria, as well as destabilization of gaze fixation and head tilts. The more rostral subregion lay in the mesencephalic reticular formation lateral to the interstitial nucleus of Cajal (InC), and inactivation there caused hypometria of vertical saccades. The functional role of cMRF in gaze control is not clear, but three different hypotheses have been put forward: (1) saccade triggering; (2) a feedback system informing the superior colliculus about dynamic changes in gaze; or (3) a feedforward system from superior colliculus to pontine gaze centers. It may be that there are multiple functions connecting this region with cell populations supporting several different functions. As is often the case, descending afferents from the limbic structures have been seen to avoid the oculomotor-related regions of the reticular formation (Büttner-Ennever and Holstege, 1986; Holstege, 1990; figure 55). There is some evidence supporting the GABAergic nature of some neurons within cMRF (Chen and May, 2000).

Connections

A study of the efferent projections from the mesencephalic reticular formation in cat was reported by Edwards and de Olmos (1975). The cMRF has been shown to be a major target for superior colliculus output (Cohen and Büttner-Ennever, 1984; Harting *et al.,* 1980; Huerta and Harting, 1984; Chen and May, 2000), and reciprocal connections back to the superior colliculus were emphasized by Moschovakis *et al.* (1988a, b) and Chen and May (2000)—features that have an important role in the feedforward or feedback hypotheses. Additional afferents to cMRF arise from the paramedian pontine reticular formation (PPRF), and in the light of more recent research cMRF efferents are seen to project to the omnipause neurons (Büttner-Ennever, personal observation).

Superior Colliculus (SC)

Structure and Function

The superior colliculus (Fig. 16.1) is essential for the generation of an orienting response to an object of visual or auditory interest (Grantyn *et al.,* 1993). Pathways from the superior colliculus to the saccade generator and reticulospinal cells groups generate the eye and head movements, and have been documented in many studies (Harting, 1977; Harting *et al.,* 1980; Moschovakis, 1996; Moschovakis *et al.,* 1996; Olivier *et al.,* 1993; Isa and Sasaki, 2002). Electrical stimulation and recording studies in the superior colliculus demonstrate a topographical motor map for the saccadic eye movements (Robinson, 1972). Large saccades are represented caudally and small saccades rostrally, and rostrolaterally lies the "rostral pole of the saccadic motor map," a region described as the fixation zone in behavioral experiments (Munoz and Guitton, 1991; Munoz and Wurtz, 1993; Paré *et al.,* 1994). These physiological studies in cat and monkey report regional specializations in the rostral pole considered to promote gaze fixation, and there is some neuroanatomical evidence supporting this (Büttner-Ennever *et al.,* 1999; Sato and Ohtsuka, 1996; Ohtsuka and Nagasaka, 1999).

Histochemistry

The superior colliculus of monkeys and humans contains numerous neurons immunoreactive for the calcium-binding proteins calretinin, calbindin, and parvalbumin, but with differing distribution patterns throughout the layers (Leuba and Saini, 1996; McHaffie *et al.,* 2001; Soares *et al.,* 2001). Whereas the small calbindin-positive neurons represent predominantly interneurons, some of which are GABAergic, many of the large and medium-sized parvalbumin-containing neurons in the deep layers of the superior colliculus are projection neurons including predorsal bundle fibers, which innervate neurons of the saccadic premotor network in the pontine reticular formation (Mize, 1992, 1996). The deep layers of the superior colliculus contain fiber patches seen with acetylcholinesterase histochemistry (see Paxinos and Huang, 1995, figure 58). These patches overlap with neuron clusters that give rise to the tectoreticular pathways controlling the orientation of eye and head to alerting stimuli (Jeon and Mize, 1993; Mize, 1996). These neuron clusters were shown to receive transmitter specific afferents from the pedunculopontine tegmental nucleus (PPT) associated with attention (Zweig *et al.,* 1987), which contain acetylcholine and nitric oxide, and from the GABAergic cells in the substantia nigra pars reticulata (Harting *et al.,* 1991, 1992, 1997), which impose a tonic inhibition on the superior colliculus that pauses during saccades (Hikosaka and Wurtz, 1983). In cat, equal numbers of tectotectal fibers are GABAergic or glutamatergic with identical topographical distribution within the contralateral SC (Olivier *et al.,* 1993; Hardy, 2000).

Connections

The intermediate and deep layers of the superior colliculus are the origin of the tectospinal system. The descending collicular fibers decussate below the oculomotor nucleus in the "dorsal tegmental decussation" and run close to the midline in the "predorsal bundle." Collicular terminals were found in the nucleus reticularis tegmenti pontis (RtTg), the caudal pontine reticular nucleus (PnC), and the medullary reticular formation mainly ipsilaterally (Sparks and Hartwich-Young, 1989), and they project directly to upper cervical motoneurons in the spinal cord (May and Porter, 1992). Ascending projections target the interstitial nucleus of Cajal (InC) and the rostral interstitial nucleus of the mlf (RI). The premotor neurons of the levator palpebrae muscle in the M-group receive afferents only from the medial part of the SC, which mediates upgaze (Horn and Büttner-Ennever, 1998b). Afferents to the superior colliculus arise from many regions: cortical areas, thalamus, sensory trigeminal nucleus (including afferents related to the blink system), pedunculopontine tegmental nucleus, and substantia nigra. The afferents terminate in specific tiers, or sublayers, of the superior colliculus intermediate layer, and also are arranged in discrete clusters, whereby the sensory- and motor-related terminal clusters are interdigitated.

Clinical Aspects

In general, the superior colliculus has very little clinical significance, and drastic cell loss is not an unusual finding in geriatric material. Theoretically the degeneration of the superior colliculus should severely

affect the generation of saccades and postural changes during orienting responses. This is the case in "progressive supranuclear palsy" (PSP), where the superior colliculus is known to degenerate early in the course of the disease. PSP patients have severe difficulty in orienting to alerting stimuli (Rafal *et al.*, 1988).

Theoretically, the loss of fixation and occurrence of square-wave jerks reported in PSP patients (Fisk *et al.*, 1982) could also be a result of the degeneration of the superior colliculus in the "fixation zones"; but this association has not been investigated. Experiments have demonstrated that bicuculine injections into the rostral superior colliculus block the effects of GABA on superior colliculus neurons and cause intrusion saccades (Munoz and Wurtz, 1993).

Prepositus Hypoglossi Nucleus

Structure and Function

The prepositus hypoglossal nucleus (PrH) lies in the floor of the fourth ventricle between the abducens and the hypoglossal motor nuclei (Figs. 16.1 and 16.4L, M) (Brodal, 1983; Paxinos and Huang, 1995, figures 25–30; Paxinos *et al.*, 2000; abbreviated as Prin; figures 101–108). Caudally it contains two distinct regions. One consists of small neurons and merges into the nucleus intercalatus of Staderini (In; Paxinos and Huang, 1995, figures 20–24). The second is a large-celled region that joins with the nucleus of Roller (Ro; Paxinos and Huang, 1995, figures 21–25). The ubiquitous connections of prepositus to and from oculomotor structures have earned it the nickname "nucleus preposterous." These studies, along with physiological studies of cell activity in behaving animals, have led to the hypothesis that the PrH has an important roll in stabilizing horizontal components of eye movements, i.e., is part of the velocity-to-position integrator (McCrea, 1988; for review, see Fukushima and Kaneko, 1995).

Histochemistry

Immunocytochemical staining revealed few GABAergic small neurons scattered throughout the PrH in cat and monkey, but a high density of GABAergic terminals (Yingcharoen *et al.*, 1989; Straube *et al.*, 1991). Some GABAergic neurons might send projections to the superior colliculus (cat: Appell and Behan, 1990) or the dorsal cap of the inferior olive (de Zeeuw *et al.*, 1993). A major GABAergic projection from the PrH to the locus coeruleus is only shown in rat so far (Aston-Jones *et al.*, 1991). The Purkinje cells of the cerebellar flocculus provide one source of GABAergic afferents to the PrH (Yamamoto, 1978). In cat, approximately 30% of the neurons the PrH are glycine (GLY)–immunoreactive, most of them being small neurons representing local circuit and commissural neurons (McCrea and Baker, 1985; Yingcharoen *et al.*, 1989). Medium-sized glycinergic neurons in the PrH were shown to project to the contralateral abducens nucleus (Spencer *et al.*, 1989). Glycinergic terminals are found throughout the PrH deriving from intrinsic commissural connections, but also from saccadic inhibitory burst neurons of the dorsal paragigantocellular nucleus and the ipsilateral medial vestibular nucleus (Spencer *et al.*, 1989). The PrH of the monkey contains cholinergic neurons, some of which might represent projection neurons to the oculomotor nucleus (Carpenter *et al.*, 1992). In addition, a cholinergic projection from the PrH to the contralateral inferior olive has been demonstrated in rat and monkey (Barmack *et al.*, 1993), and to the contralateral cerebellar flocculus and ventral paraflocculus in rat and rabbit (Barmack *et al.*, 1992). Interestingly, numerous neurons in the PrH of cat and monkey express nitric oxide synthetase immunoreactivity, a marker for nitric oxide–releasing neurons (Satoh *et al.*, 1995; Moreno-Lopez *et al.*, 2001), which is required for the correct performance of eye movements (Moreno-Lopez *et al.*, 1996).

Connections

The small cells in the PrH are predominantly commissural or interneurons; the larger cells give rise to the projections to the oculomotor cell groups, such as the vestibular nuclei, the inferior olive, the superior colliculus, and the motor nuclei. Prepositus afferents supply the cerebellum and terminate in the vermis (lobuli VII, IX, and X), the flocculus ventral paraflocculus (tonsilla), and fastigial nuclei (McCrea, 1988; Belknap and McCrea, 1988). All areas that project to the abducens nucleus also project to the prepositus hypoglossal nucleus. In addition, it receives afferents from the fastigial nucleus, the pregeniculate nucleus of the diencephalon—which controls the flow of information entering and leaving the visual striate pathways via the lateral geniculate nucleus (see Chapter 33).

Clinical Aspects

A unilateral muscimol injection in the PrH of the cat resulted in a bilateral gaze-holding failure (Mettens *et al.*, 1994). Lesions involving the PrH in humans often lead to an upbeat or horizontal gaze-evoked nystagmus (for review, see Leigh and Averbuch-Heller, 1998).

Paramedian Tract Neurons

Structure and Function

Paramedian tract neurons (PMTs) are defined as groups of cerebellar-projecting neurons that lie around the midline fiber bundles of the pons and medulla. The

PMT groups have been brought to the attention of oculomotor neuroanatomists on account of their projection to the flocculus and ventral paraflocculus region, demonstrated in experimental tract-tracing experiments (Sato *et al.*, 1983; Blanks *et al.*, 1983; Langer *et al.*, 1985; Blanks, 1990). The homologue of the cell groups has not been described in humans, although nucleus pararaphales of Olszewski and Baxter (1954) may be part of it. The PMT groups could provide the flocculus and ventral paraflocculus of the cerebellum and other areas of the brain with a motor efference copy of the oculomotor output signal. Damage could lead to a disturbance in gaze holding (Büttner *et al.*, 1995).

There are at least six relatively separate PMT groups scattered in the medial longitudinal fasciculus, rostral to, and even within, the abducens nucleus. They continue back to the level of the hypoglossal nucleus (stars in Fig. 16.1). In cat, rat, and monkey they have been given different names by different investigators; we use the individual terms introduced by Langer and colleagues. The use of the nomenclature "medial" and "caudal" interstitial nuclei of the mlf for the PMT groups rostral or caudal to the abducens nucleus is unsatisfactory (as well as unwieldy), partly because they overlook fine differences in the cell grouping, at least in the primate, and also because often the prefix "medial" or "caudal" is dropped and then there is total confusion with the vertical premotor neurons of the rostral interstitial nucleus of the mlf (RI) and interstitial nucleus of Cajal (InC) (see "Interstitial Nucleus of Cajal").

Histochemistry

The transmitter content of the PMT groups is unknown: however, we have found that the cell somata are not serotonergic or catecholaminergic (Büttner-Ennever and Horn, personal observation). In addition, the PMT groups contain high levels of cytochrome oxidase and acetylcholinesterase. The neurons are chromophilic, medium-sized cells that lie immediately lateral to the smaller-celled raphe nuclei. The difference between them can be demonstrated by immunocytochemical stainings with serotoninantibodies, the raphe nuclei are labeled but the PMT groups are not.

Connections

Aside from their projection to the flocculus and ventral paraflocculus, the PMT groups have been shown to receive an afferent input from all the premotor brain stem nuclei known to project to oculomotor motoneurons (Büttner-Ennever and Büttner, 1988; Büttner-Ennever *et al.*, 1989; Büttner-Ennever and Horn, 1996). Several projections from oculomotor or vestibular structures to the PMT groups are mistakenly described in the literature as projections to raphe nuclei (e.g., nucleus raphe obscurus; see Chapter 33).

Clinical Aspects

Theoretically the PMT cell groups are thought to contribute to gaze holding (Büttner-Ennever and Horn, 1996). Lesions of the midline brain stem often cause nystagmus, and in some cases it is likely to be due to lesions of the PMT neurons rather than "lesions of vestibular structures," which is the usual hypothesis put forward (Baloh and Yee, 1989; Janssen *et al.*, 1998). Recently, reversible chemical lesions to PMT cell groups in cat caused a nystagmus, which fits well to the above hypothesis (Nakamagoe *et al.*, 1998). Therefore, PMT cell groups should be taken more into account in future clinical analyses of brain stem nystagmus.

EYELID AND BLINK

In humans and monkeys the oculomotor system interacts with the eyelid system: (1) Blink-evoking stimuli elicit transient eye closure, along with movements of the eye (e.g., Collewijn *et al.*, 1985; Evinger *et al.*, 1984). (2) Blinks coincide with large saccades, combined with head movements (Evinger *et al.*, 1991, 1994) and may affect vergence movements as well (Rambold *et al.*, 2002). (3) Vertical eye movements are accompanied by synchronous movements of the upper eyelid (Becker and Fuchs, 1988).

The function of the eyelids is to protect the eyeball without interfering with vision and to keep the eyes wet, which is achieved by intermittent spontaneous brief blinks in the alert state, or by lid closing during sleep. The eyelids are mainly moved by the interaction of two muscles: the levator palpebrae muscle, which elevates the lid, and the orbicularis oculi muscle, which closes the eye. A third muscle, the smooth superior tarsal muscle (Müller`s muscle), contributes to retraction of the upper lid and is innervated by the sympathetic superior cervical ganglion (Van der Werf *et al.*, 1993; for review, see Sibony and Evinger, 1998). In the awake state the levator palpebrae motoneurons receive a tonic excitatory input (of unknown origin), which keeps the eye open. With increasing fatigue the activity of levator palpebrae motoneurons drops, resulting in eye closure, and indicating a change in the influence of the afferent limbic signals on levator palpebrae motoneurons. On top of this basic behavior the levator palpebrae motoneurons receive excitatory signals that synchronize lid movements with vertical eye movements, which are only interrupted during blinks. Whereas some data on the premotor circuitry of the eye closing orbicularis oculi muscle are available, information about the premotor control of the levator

palpebrae muscle during different types of lid movements is still scarce (Fig. 16.9A, B).

Lid–eye Movements (Fig. 16.9A)

During all types of vertical eye movements the upper eyelid closely follows the globe, providing protection but avoiding obstruction of vision. Thereby, the upper eyelid is elevated by activation of the levator palpebrae muscle, but lowered exclusively by passive downward forces resulting from a decrease in levator palpebrae activity without involvement of the orbicularis oculi muscle (for review, see Sibony and Evinger, 1998). The close coordination of lid movements with vertical eye movements must be mediated by common premotor neurons. Recently, a premotor cell group was identified in the rostral mesencephalon, termed M-group, which projects to motoneurons of the upper eyelid and those of upward pulling eye muscles and is therefore proposed as a structure controlling lid–eye coordination in upgaze (Figs. 16.3A, B and 16.5A, B) (Horn *et al.*, 2000).

Blinks (Fig. 16.9B)

In mammals blinking occurs through the interaction of two lid muscles, the levator palpebrae muscle and the orbicularis oculi muscle. During a blink the nervous system briefly inhibits the tonic activity of the levator palpebrae motoneurons, which is followed by a transient activity burst in the motoneurons of the orbicularis oculi muscle resulting in a fast eye closure. When the orbicularis oculi motoneurons cease discharging, the levator palpebrae motoneurons resume their tonic activity (for review, see Sibony and Evinger, 1998). The orbicularis oculi muscle response in the (trigeminally evoked) blink reflex consists of two electromyographic components, an early R1 and a late R2 response, which are both generated by the same orbicularis oculi muscle motoneurons, with the R2 component producing most of the lid closure in human (Shahani and Young, 1972). Both components are mediated by different routes: an oligosynaptic path through the sensory trigeminal nuclei for R1 and a polysynaptic path involving neurons in the reticular formation for R2 (for review, see Sibony and Evinger, 1998). A blink can be evoked by different stimuli, e.g., auditory, visual, or tactile, all of whose pathways project on premotor neurons of the orbicularis oculi muscle lying in the trigeminal nuclei, in the lateral part of the pontine reticular formation, in the medullary reticular formation, and in the red nucleus (for review, see Holstege, 1990, 1991; Sibony and Evinger 1998. Since the primates do not have a retractor bulbi muscle, which is present in most mammals and pulls the eyes back into the orbit during blinks, the connections of its motoneurons are not considered here (for review, see Holstege, 1990).

Central Caudal Nucleus (CeCa)

Structure and Function

In primates, the levator palpebrae motoneurons lie in the central caudal nucleus (CeCa), a compact unpaired nucleus situated dorsal to the caudal pole of the oculomotor nucleus in human (Schmidtke and Büttner-Ennever, 1992) (Fig. 16.1; Fig. 16.3E–G; Fig. 16.6C, D). Within the CeCa the motoneurons of both eyelids appear intermixed. There are conflicting reports as to whether some levator palpebrae motoneurons innervate the muscles of both sides (Sekiya *et al.*, 1992; van der Werf *et al.*, 1997), or whether each motoneuron innervates only the levator palpebrae of one side (Porter *et al.*, 1989).

Histochemistry

The central caudal nucleus (CeCa) is discernible in parvalbumin immunostaining, with less involvement of the neuropil compared to the motoneurons of the extraocular eye muscles (Fig. 16.6D). In addition, the motoneurons in the CeCa neurons are smaller than those of the extraocular eye muscles (Figs. 16.3F, G and 16.6C, D). The motoneurons receive a strong supply of GABA-immunoreactive terminals and are very specifically associated with glycine transporter immunoreactivity, indicating glycinergic afferents (Horn, personal observations).

Connections

In the primate the central caudal nucleus was shown to receive afferents from the interstitial nucleus of Cajal, from the nucleus of the posterior commissure (May, 1995), and from a small group medial to the rostral interstitial nucleus of the mlf (RI), which was called M-group (Fig. 16.3A, B) (Horn *et al.*, 2000). Studies in rabbit and monkey revealed projections from neurons at the rostral border of the principal and spinal trigeminal nucleus (pars oralis) to the central caudal nucleus, which presumably provide the inhibition during blinks (May, 1995).

Clinical Aspects

Midbrain lesions affecting the central caudal nucleus lead to ptosis, which is usually bilateral (Averbuch-Heller, 1997; Büttner-Ennever *et al.*, 1996b). A lesion anywhere in the brain stem sympathetic chain or superior cervical ganglion affects the innervation of

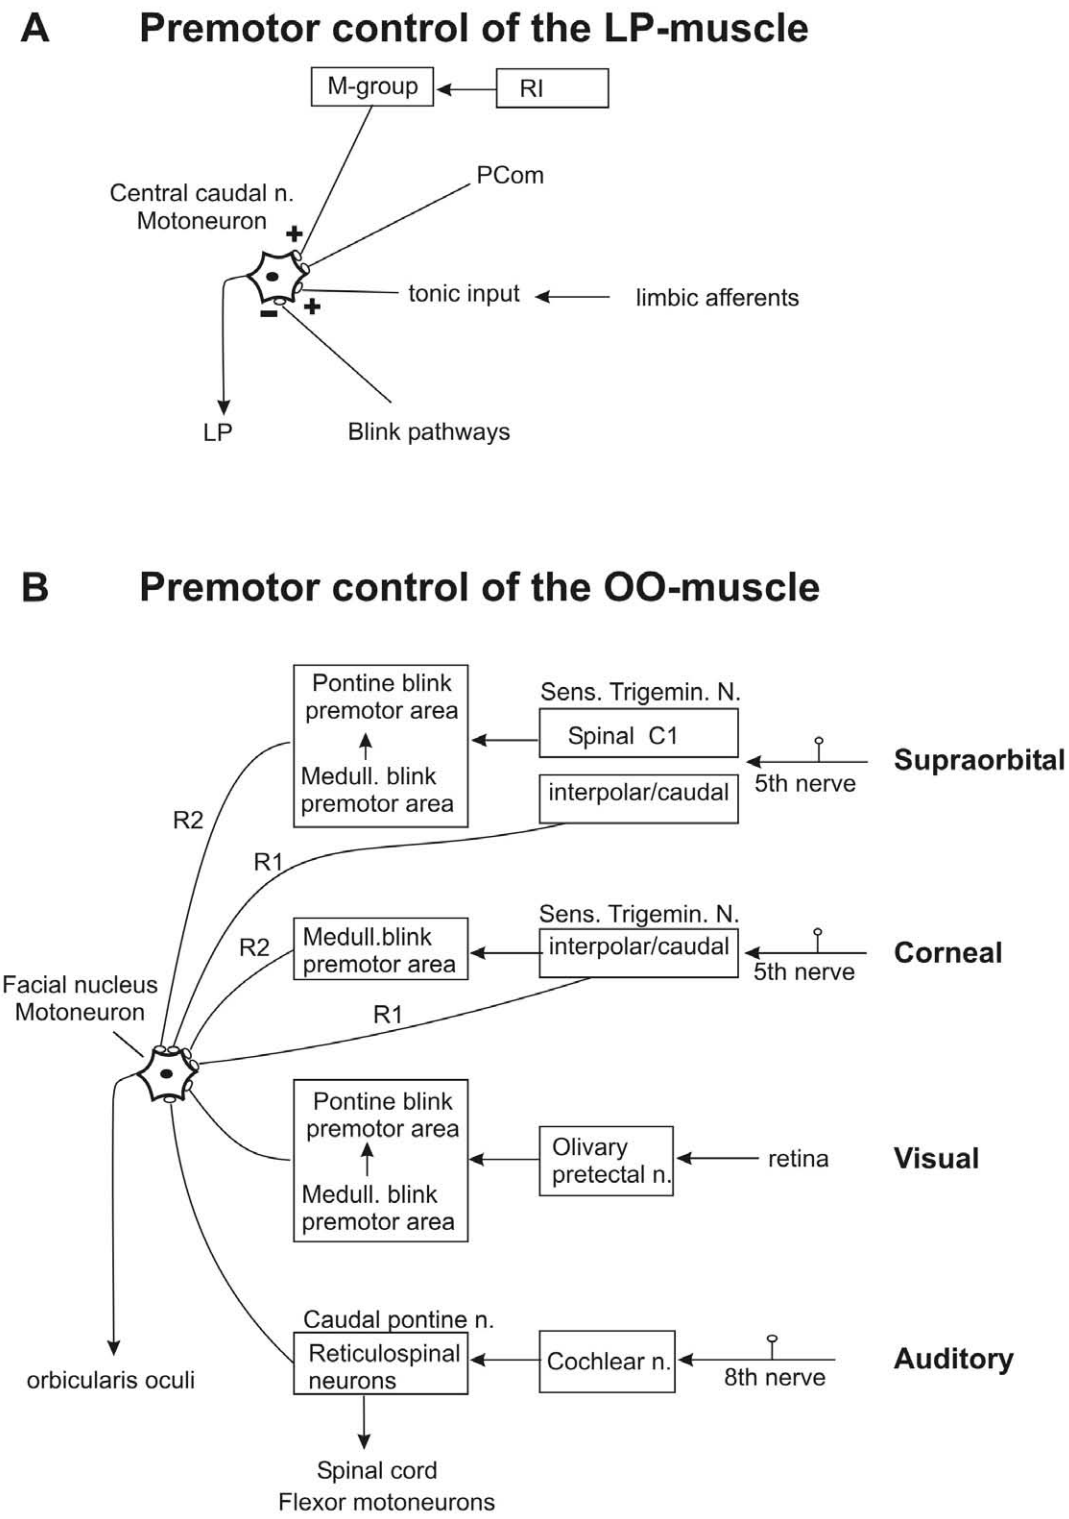

FIGURE 16.9 **A:** Diagrammatic representation of the premotor inputs controlling levator palpebrae motoneurons. **B:** A summary diagram of the premotor networks controlling the orbicularis oculi muscle in blink reflex generation. The blink response of the supraorbitally and corneally evoked blink reflex consists of a short-latency R1 response mediated by a three-neuron arc, whereas the long-latency R2 response uses polysynaptic connections for activation of the orbicularis oculi muscle. LP, levator palpebrae muscle; N., nucleus; PCom, nucleus of the posterior commissure; RI, rostral interstitial nucleus of the medial longitudinal fascicle.

the superior tarsal muscle (Müller`s muscle) and produces Horner`s syndrome, which is characterized by a mild, unilateral ptosis (for review, see Sibony and Evinger, 1998).

Facial Nucleus (7N)—Orbicularis Oculi Motoneurons

Structure and Function

The facial nucleus (7N) lies in the caudal pontine tegmentum lateral and ventral to the abducens nucleus (6N), medial to the spinal trigeminal nucleus, and dorsal to the nuclei of the superior olive (Fig. 16.4J, M) (Paxinos and Huang, 1995, figures 31–33). It is divided into several groups extending through the rostrocaudal length of the nucleus, each containing the motoneurons of the ipsilateral individual facial muscles. All subnuclei contain small and large neurons, presumably representing γ motoneurons innervating muscle spindles and α-motoneurons, respectively (Welt and Abbs, 1990). Retrograde tracing experiments in macaque monkeys demonstrated that the motoneurons of the orbicularis oculi muscle lie in the rostral two-thirds of the nucleus within the dorsal subgroup (Satoda *et al.*, 1987; Porter *et al.*, 1989; Welt and Abbs, 1990), those for the frontalis muscle in the dorsomedial subdivision (Welt and Abbs, 1990). Using the nomenclature of Courville, the motoneurons of the orbicularis oculi muscle lie in the intermediate nucleus in human (Courville, 1966; Paxinos and Huang, 1995, figure 31; Olszewski and Baxter, 1954, plate 18).

Histochemistry

As other motor nuclei, the facial nucleus can be easily identified by its strong acetylcholinesterase activity pattern (Paxinos and Huang, 1995, figure 32). The nucleus expresses moderate cytochrome oxidase activity, primarily in the neuropil. The parvalbumin immunoreactivity of the neurons is more confined to the cell bodies and does not involve the neuropil as in the oculomotor nuclei (Fig. 16.4M). The neurons of the facial nucleus of the cat receive catecholaminergic afferents from the locus coeruleus and nucleus parabrachialis lateralis, cholinergic afferents from an area ventral to the nucleus of the solitary tract, and methionine-, enkephalin-, and substance P–immunoreactive afferents (Fort *et al.*, 1989). In addition, the facial nucleus receives a dense supply with serotonergic fibers and terminals, which originate from neurons in the raphe magnus, raphe obscurus, and raphe pallidus and may adjust the excitability of facial motoneurons (McCall and Aghajanian, 1979; Fort *et al.*, 1989; Aghajanian and McCall, 1980).

Connections

There is anatomical evidence that the facial nucleus contains not only motoneurons innervating the facial muscles but also smaller neurons projecting to the cerebellar flocculus (Roste, 1989), which mainly arise from caudal parts of the facial nucleus in the monkey (Langer *et al.*, 1985). Retrograde tracing studies in different animals revealed several pools of neurons in the brain stem, which innervate the facial nucleus. Here only those projecting to orbicularis oculi motoneurons are considered (for review, see Sibony and Evinger, 1998; Holstege, 1990): the ventrolateral part of the spinal trigeminal nuclei, the dorsolateral pontine tegmentum, the ventral part of the lateral pontine tegmental field, the medial tegmentum at levels of the hypoglossal nucleus, and the red nucleus (Holstege *et al.*, 1986a, b). A recent transneuronal study in the rat describes a stronger input from the reticular regions than from trigeminal nuclei, in addition to afferents from the parabrachial nuclei, from the interpositus nucleus of the cerebellum, and from the dorsolateral quadrant of the red nucleus (Morcuende *et al.*, 2002). In the rat, facial motoneurons receive collaterals from descending fibers, which originate in giant neurons in the caudal pontine reticular formation and activate motoneurons of the flexors in the spinal cord. These giant reticular neurons receive direct projections from the cochlear nucleus and may represent part of the afferent limb of the circuit for auditory evoked blink reflexes as part of a more general startle response to loud noises (Fig. 16.9B) (for review, see Sibony and Evinger, 1998).

M-Group

Structure and Function

Recently, a small cell group was identified in the rostral mesencephalon of the primate, which contains premotor neurons of the upward-pulling extraocular eye muscles, superior rectus and inferior oblique muscles, and of the levator palpebrae muscle, which elevates the upper eyelid, as well as the frontalis muscle motoneurons. The premotor cells were termed M-group (Fig, 16.3A, B) (Horn *et al.*, 2000). The observed projection pattern implicates a role in the coordinated activation of the upper eyelid during vertical eye movements.

In macaque monkeys and humans the M-group lies as a separate cell group immediate medially to the caudal third of the rostral interstitial nucleus of the mlf (RI), whereas in cat the homologue premotor neurons were identified within the medial RI (Chen and May, 2002) (Fig. 16.3A, B). In contrast to the neurons of

the RI, which belong to the mesencephalic reticular formation, the M-group is part of the central gray, which surrounds the third ventricle and is composed of more densely packed cells. As the RI the M-group is highlighted by its strong cytochrome oxidase activity and its high parvalbumin content mainly of the neuropil, which was used to identify the homologue in the human brain as well (Figs. 16.3B and 16.5A, B) (Horn *et al.*, 2000).

Connections

Anterograde tract tracing experiments in macaque monkeys showed that the M-group projects to the motoneurons of the levator palpebrae muscle in the central caudal nucleus and the motoneurons of the superior rectus and inferior oblique muscle, that elevate the eye, but not those that depress the eye. Additional weaker projections target the dorsomedial group of the facial nucleus containing motoneurons of the frontalis muscle, which participates in extreme upward gaze (Welt and Abbs, 1990; Sibony and Evinger, 1998; Horn *et al.*, 2000). The M-group receives a strong projection from the medial part of the deep layers of the superior colliculus, which encodes upward saccades. Additional weaker afferent projections arise from the medial and superior vestibular nuclei and the interstitial nucleus of Cajal (Horn and Büttner-Ennever, 1998b).

Clinical Aspects

A selective destruction should lead to a dissociation of lid and eye movements, manifesting as pseudoptosis on attempted downgaze or lid lag during vertical gaze, as is indeed seen in a patient with a lesion involving the M-group region (Galetta *et al.*, 1996). The post-mortem analysis of a case with downgaze paralysis and ptosis, but preserved upgaze, revealed a partial RI lesion, which included the M-group. Since upgaze was not affected, these results show that the M-group is not alone generating upward eye movements (Büttner-Ennever *et al.*, 1996b).

Sensory Trigeminal Nuclei

Structure and Function

The sensory trigeminal complex is composed of several nuclei, from rostral to caudal: the principal sensory nucleus (Pr5) lying lateral to the motor trigeminal nucleus (Paxinos and Huang, 1995, figures 35–37) and the spinal trigeminal nucleus consisting of the oral part (Sp5O), the interpolar part (Sp5OI) (Paxinos and Huang, 1995, figures 17–30), and the caudal part (Sp5C) (Paxinos and Huang 1995, Appendix Liu, figures 6–16, see Chapters 29 and 28).

Primary afferents from the cornea terminate heavily in the ventrolateral portion at the junction of the interpolar and caudal spinal trigeminal nuclei, and only sparsely in the dorsal horn of the spinal cord of C1–C3, and not in the principal trigeminal nucleus (Panneton and Burton, 1981). The afferents from the supraorbital nerve supplying periocular structures terminate also primarily at the junction of the interpolar and caudal spinal trigeminal nucleus, but in addition to the principal trigeminal nucleus and the spinal cord dorsal horn at C1. The principal oral and interpolar parts of the sensory trigeminal nuclei are interconnected and send direct projections to the orbicularis oculi muscle motoneurons in the facial nucleus (Fig. 16.9B), representing the central link of the three-neuron arc, which contributes to the early R1 component of the blink response. The late R2 response is presumably initiated at the dorsal horn of the spinal cord at C1 and involves polysynaptic pathways involving the medullary reticular formation (for review, see Sibony and Evinger, 1998). In humans the principal trigeminal nucleus is suspected to be the source of afferents to the orbicularis oculi muscle motoneurons (Ongerboer de Visser, 1983).

Connections

In general, the principal and spinal trigeminal nucleus projects to the thalamus, the cerebellar cortex and the nucleus interpositus, the dorsal red nucleus, and the deep layers of the superior colliculus (Holstege *et al.*, 1986b). Neurons in the interpolaris and caudal part of the spinal trigeminal nucleus project to the orbicularis oculi motoneurons in the facial nucleus (Fig. 16.9) (Tamai *et al.*, 1986; Pellegrini *et al.*, 1995) This pathway is presumably excitatory, since no glycinergic or GABAergic projection neurons to the facial nucleus were found in the rat (Li *et al.*, 1997). Anterograde tracing experiments in the rabbit revealed projections from the principal sensory trigeminal nucleus and interpolar part of the spinal trigeminal nucleus to orbicularis oculi muscle motoneurons in the facial nucleus *and* to the region of levator palpebrae motoneurons in the oculomotor nucleus (van Ham and Yeo, 1996). The trigeminofacial projections in cat lack a parallel input to levator palpebrae motoneurons (Holstege, 1990). The blink interneurons in the sensory trigeminal nuclei are modulated by inhibitory inputs from serotoninergic projections from the nucleus raphe magnus, which in turn is controlled by afferents from the superior colliculus (for review, see Sibony and Evinger, 1998).

Clinical Aspects

Lesions involving the spinal trigeminal nucleus at the interpolaris/caudalis border and the adjacent reticular formation disrupt corneal reflex blinks in

human (Ongerboer de Visser, 1980, 1983). In Parkinson's disease, the blink rate is increased, presumably due to an increased excitability of the facial motoneurons. The following hypothesis is suggested: The dopamine deficit in the substantia nigra results in an increased inhibition of the superior colliculus by the GABAergic projections from the substantia nigra pars reticulata. This results in reduced excitation of the raphe magnus from the superior colliculus leading to reduced inhibition of the spinal trigeminal nucleus from the serotonergic neurons of the raphe nuclei, which produces increased excitability of the trigeminally evoked blink reflex (Basso and Evinger, 1996a; Basso *et al.*, 1996b; for review, see Sibony and Evinger, 1998).

Pontine Lateral Tegmental Field (Pontine Blink Premotor Area)

Structure and Function

Retrograde tracer injections in the facial nucleus, including the orbicularis oculi subdivision, revealed premotor neurons in the ventrolateral pontine tegmental field at the level of the motor trigeminal nucleus ventral to it, but not in the sensory trigeminal nuclei (Holstege, 1990). This area was called the pontine blink premotor area (Holstege *et al.*, 1986a) and together with the medullary blink premotor area is proposed to contribute to the R2 response.

Connections

In the rabbit neurons of the lateral pontine tegmental field *(pontine blink premotor area)* and the ventral sensory trigeminal nucleus project to levator palpebrae and superior rectus motoneuronal groups in the oculomotor nucleus (Guerra-Seijas *et al.*, 1993). A similar projection is described in cats and primates arising from neurons forming a continuous column at the rostral border of the principal and oral part of the sensory trigeminal nuclei (May, 1995). Data from the rat and cat suggest that this projection is inhibitory (Li *et al.*, 1997) and could provide the inhibition of levator palpebrae motoneurons during blinks.

In cat the pontine blink premotor area receives inputs from the olivary pretectal nucleus, which is innervated by retinal afferents, and may function as a luminance detector (Gamlin *et al.*, 1995), thereby forming the afferent arc of the visually evoked blink reflex (Takada *et al.*, 1984) (see Fig. 16.9B). In all nonprimate species the pretectal olivary nucleus has direct projections to facial motoneurons (Takada *et al.*, 1984). In addition, the pontine blink premotor area receives afferents from the facial motor cortex (for review, see Sibony and Evinger, 1998).

Medullary Medial Tegmental Field (Medullary Blink Premotor Area)

Structure and Function

In the cat the medullary medial tegmental field containing premotor neurons of the orbicularis oculi muscle lies ventral to the hypoglossal nucleus around the midline, and was called medullary blink premotor area (Holstege, 1990). Like the *pontine blink premotor area,* it does not include the spinal trigeminal nucleus. Lesion studies in humans (Kimura and Lyon, 1972; Ongerboer de Visser and Kuypers, 1978) and experimental studies (Pellegrini *et al.*, 1995) indicate that this region along with the *pontine blink premotor area* is important for the generation of the R2 response.

Connection

The medullary medial tegmental field, which might include the *medullary blink premotor area,* receives afferent projections from the intermediate and deep layers of the superior colliculus (for review, see Holstege, 1990). In addition, the medullary medial tegmental field projects to the *pontine blink premotor area,* mainly bilateral (Holstege *et al.*, 1986b). A strong afferent input to the *medullary blink premotor area* arises from the paramedian pontine reticular formation and the upper medullary medial tegmentum. Both structures receive afferent projections from the superior colliculus, thereby forming a possible anatomical link for blink–saccade interaction (for review, see Holstege, 1990; Sibony and Evinger, 1999).

Red Nucleus

Structure and Function

The red nucleus (RPC) is a large round cell group in the mesencephalon dorsomedial to the substantia nigra (Figs. 16.1 and 16.3C). It is composed of a magnocellular part, which is very small in the human, occupying only the caudal pole, and a parvocellular part, from which a dorsomedial portion with more densely packed cells can be separated (Paxinos and Huang, 1995, figure 63). Experimental data suggest that the red nucleus is more involved in the learned blink response, after classical conditioning with neutral stimuli (visual, auditory), since lesions of the red nucleus abolish the conditioned, but not the unconditioned, blink reflex (for review, see Holstege, 1991).

Connections

Tracing studies (for review, see Holstege, 1991) in the cat revealed a weak projection from the dorsal part of the red nucleus, which corresponds to the facial

part of the red nucleus, to the *pontine* and *medullary blink premotor areas* areas. In addition, a weak direct projection to the orbicularis oculi muscle portion of the facial nucleus was found in the cat (Holstege and Tan, 1988). The dorsolateral part of the red nucleus receives afferent projections from the trigeminal nucleus and the interpositus nucleus of the cerebellum, thereby providing a pathway for the conditioned blink response (Holstege *et al.*, 1986b).

Blink–Saccade Interaction

Large saccadic gaze shifts are accompanied by blinks (Evinger *et al.*, 1991, 1994). Several observations in patients indicate an interaction between blink and saccadic circuits; a blink can induce oscillations in saccades (Hain *et al.*, 1986), or patients with abnormally slow saccades can facilitate their saccadic eye movements with voluntary blinks (Leigh *et al.*, 1983; Zee *et al.*, 1983). Although the circuits for gaze-evoked blinks are unknown, there is some evidence that saccadic omnipause neurons (OPNs; see "Pontine Lateral Tegmental Field Britine Blink Premotor Area") may act on blink circuits: microstimulation of OPNs suppresses reflex blinks in monkeys (Mays and Morrisse, 1995) and rats (Basso *et al.*, 1996a) and the activity of OPNs pauses during blinks in the same way as during saccades (Mays and Morrisse, 1994). Recent data indicate that the blink circuits may act at the level of the superior colliculus, since the activity of saccade-related burst neurons in the deep layers of the superior colliculus is transiently suppressed if a reflex blink is evoked (Goossens and van Opstal, 2000a, b). Electrical stimulation studies showed that the least effective site in the superior colliculus for eliciting blink suppression is the rostral pole—a region associated with fixation and accommodation and possessing direct projections to the OPNs (Gnadt *et al.*, 1997; Ohtsuka and Nagasaka, 1999; Büttner-Ennever *et al.*, 1999).

CHAPTER

17

Hypothalamus

CLIFFORD B. SAPER

Department of Neurology and Program in Neuroscience
Beth Israel Deaconess Medical Center, Harvard Medical School
Boston, Massachusetts, USA

An enormous amount of information has been obtained about the organization of the hypothalamus in general, and the human hypothalamus in particular, since the first edition of this book was published. As a result of the gains in understanding over the last decade, the organization of this chapter in the last edition, which was strictly along the lines of cytoarchitecture, fiber connections, and chemoarchitecture, would no longer be appropriate. Instead, the current chapter focuses to a much greater extent than was possible in the past on the *functional organization* of the hypothalamus.

In taking this leap, this chapter will rely to a great extent on data that have been derived over the last decade in other species, most commonly in rodents. In some cases, where parallel data on monkeys or human exist, this will be emphasized. However, the functions of the hypothalamus are so basic that its plan and organizational patterns have, to a great degree, been conserved throughout the mammalian spectrum. As a result, even when data in humans or monkeys are still sketchy, it is useful to view what we know in a functional context that is derived in large part from other sources.

It is particularly appropriate to review the hypothalamus from this functional perspective in a book that emphasizes structure because the methods used to dissect the functions of the hypothalamus have relied heavily on new ways to localize physiologically driven gene expression at specific sites in the brain. This revolution, which has largely taken place in the last decade, has extended our ability to make structure–function correlations. Our functional knowledge about the hypothalamus has relied so heavily on morphological approaches because of the extraordinarily small size and functional complexity of this region. Occupying just 4 g of the approximately 1200 to 1400-g adult human brain weight, or just a fraction of 1% of the brain (Le Gros Clarke, 1938), the hypothalamus contains the integrative systems that support life, including such activities as fluid and electrolyte balance, food ingestion and energy metabolism, thermoregulation and immune response, and, of course, emotional expression and reproduction. All of these functional systems have in common a wide variety of sensory inputs; a set of specific types of regulatory drives and setpoints; and a range of specific types of effector mechanisms.

These complex mechanisms are subserved by an equally complicated array of cell groups and fiber pathways, packed into a very small space. As a result, studying the function of the hypothalamus requires placing it into anatomical context, and the current

generation of methods, which allow a cellular level of resolution of function, have finally allowed us to make headway in understanding the functional organization of the hypothalamus.

The sections that follow will first review the overall plan of the cytoarchitecture and the major fiber pathways of the hypothalamus. The following sections will focus on the functional organization of the hypothalamus. Current knowledge about the chemoarchitecture of the hypothalamus will be integrated, to the greatest extent possible, into that context.

CYTOARCHITECTURE OF THE HUMAN HYPOTHALAMUS

The cytoarchitectural plan of the human hypothalamus has been well understood for many years, although the exact terminology has often been controversial. The most exhaustive description of the human hypothalamus is that of Brockhaus (1942), who divided the hypothalamus into many more subdivisions than can be justified on the basis of the material used to prepare this chapter. Braak and Braak (1987) employed the method of pigmentoarchitectonics, identifying several additional cell groups that are poorly distinguished in Nissl-stained preparations. While recognizing these antecedants, the terminology to be used here will follow, insofar as possible, that of Nauta and Haymaker (1969). This system of nomenclature is largely derived, in turn, from that of Gagel (1927), Grünthal (1933), LeGros Clark (1936, 1938), and Rioch *et al.* (1939). For comparison with the nomenclature of early workers, the reader is referred to the extensive tables of terminologies prepared by Laruelle (1934) and Koikegami (1937).

One major reason for the differences in nomenclature in descriptions of the human hypothalamus is that the nuclear masses in this part of the brain are rarely as well differentiated as in most other mammalian species. LeGros Clark (1936), who was the first to distinguish among the medial hypothalamic nuclei in humans, relied extensively on preparations from the human fetus, where these cell groups are much better defined (see also Koutcherov *et al.*, 2002).

A second major problem in delineating cell groups in the human hypothalamus is the extreme variability of the plane of section. The human skull is foreshortened in the anteroposterior direction, in comparison with other mammalian species. As a result, the pituitary gland lies directly under the hypothalamus rather than posterior to it. In addition, the foreshortening of the face results in the rather abrupt decussation of the optic fibers in the chiasm almost as soon as they exit the optic foramen. This landmark limits the anterior extent of the hypothalamus. The effect of these two anatomical restrictions is that, depending on the exact shape of the skull, the pituitary stalk and the attached tuberal hypothalamus may be retroflexed, virtually straight, or even anteroflexed. Thus, there is as much as a 45-degree variation in the angle at which the tuberal part of the hypothalamus is cut, even if great pains are taken to block the forebrain in a standard plane.

As in other species, the human hypothalamus can be divided in Nissl-stained material into three major regions in the anteroposterior direction, and also into three zones in the mediolateral direction (Fig.17.1). The most anterior part of the hypothalamus, bordered rostrally by the lamina terminalis and caudally by the posterior edge of the optic chiasm, is the preoptic division. In the human brain the anterior wall of the third ventricle, containing the ventral part of the preoptic area, is often quite thinned and may extend for several millimeters between the dorsal surface of the optic chiasm and the floor of the septal region (Fig.17.2). Neurosurgeons have used this anatomical feature to place ventriculostomy incisions to drain the cerebrospinal fluid from the third ventricle. The next more caudal portion of the hypothalamus is the tuberal division. This gray swelling (tuber cinereum in Latin) along the base of the brain gives rise in the midline to the pituitary stalk. The lateral surface of the tuberal region may be raised by small bumps, representing the surface protrusions of the lateral tuberal nuclei (see LeGros Clark, 1936). Finally, the level of the mammillary bodies defines the posterior hypothalamic division. The mammillary recess, a small extension of the third ventricle trapped ventrally between the mammillary bodies in the midline, is common in other species but generally absent in humans.

Periventricular Zone

The most medial part of each of the anterioposterior divisions of the hypothalamus is the periventricular zone, bordering the wall of the third ventricle. At the level of the preoptic area, the organum vasculosum of the lamina terminalis is seen at the anteroventral end of the third ventricle, a vascularized area containing medium-sized, medium-staining cells. The organum vasculosum merges dorsally with the median preoptic nucleus and laterally with the anteroventral periventricular nucleus, both of which are composed of similar-appearing neurons. In rodents, the median preoptic nucleus can be followed dorsally, over the anterior surface of the anterior commissure, along the lamina terminalis, to the subfornical organ, but this

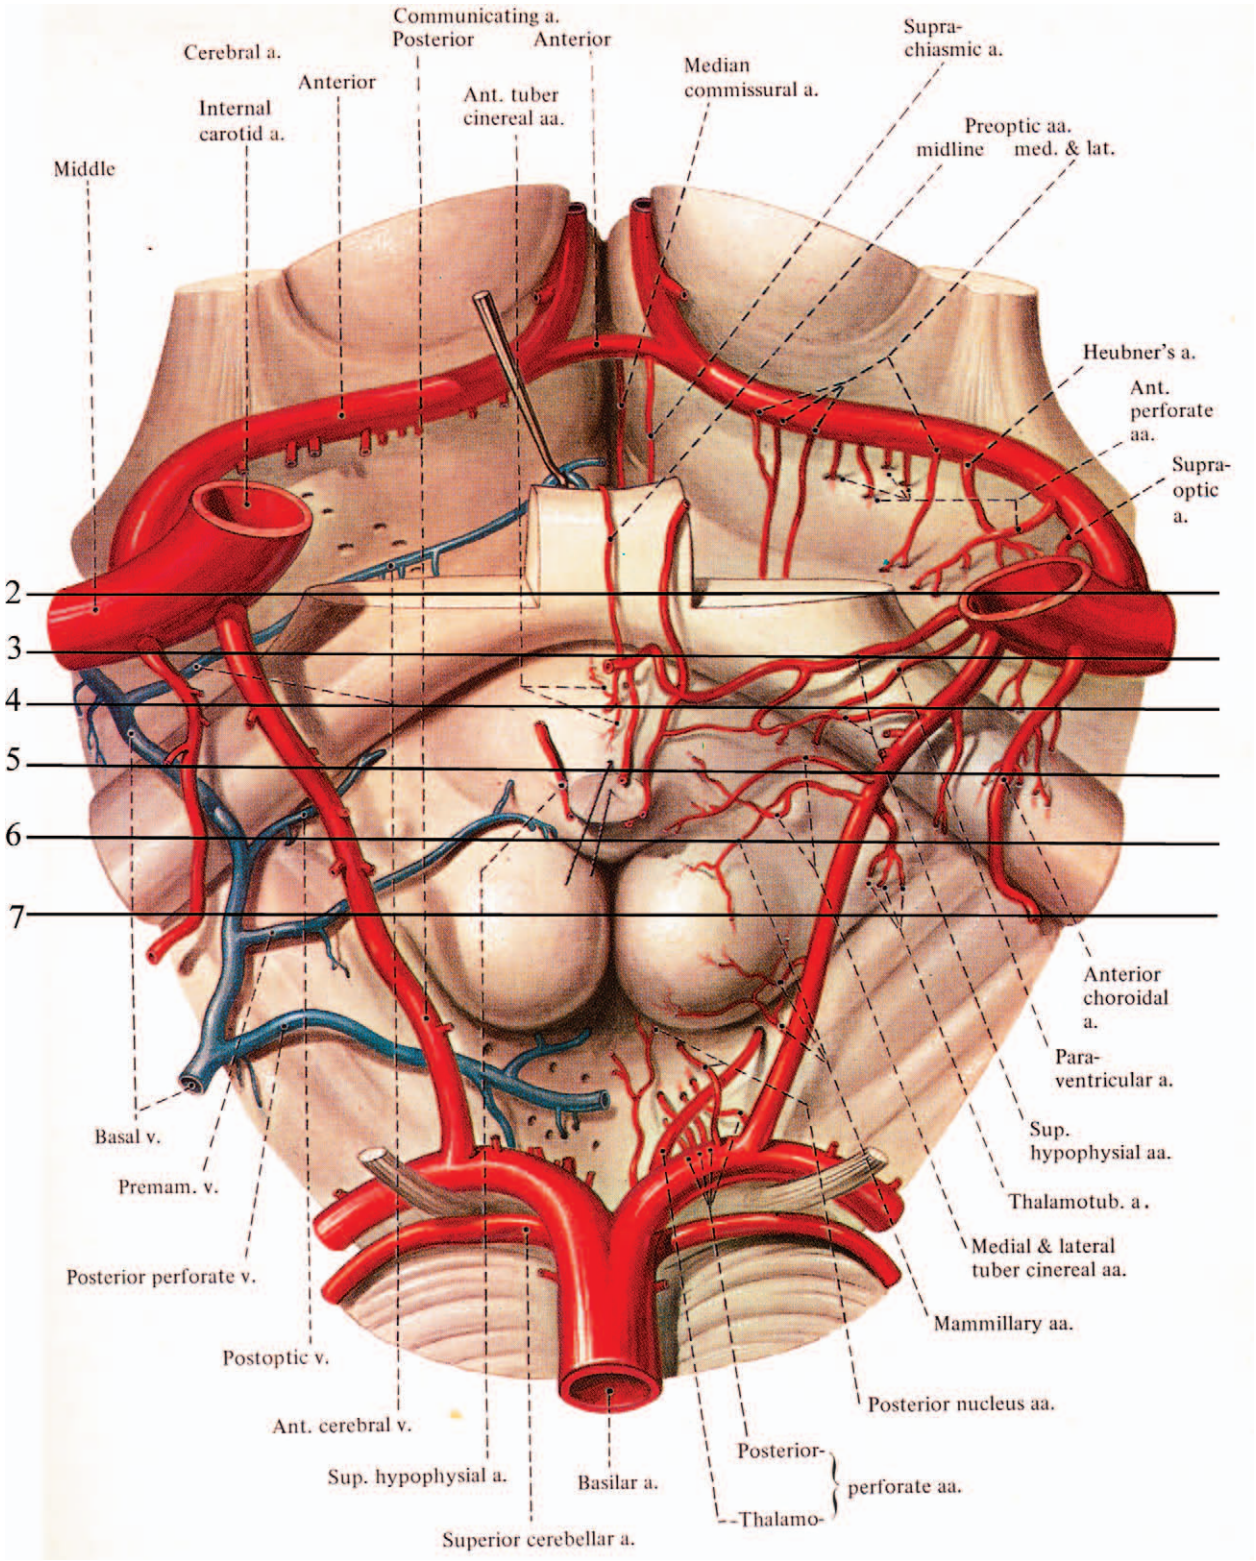

FIGURE 17.1 A drawing of the base of the brain, emphasizing the relationship of the hypothalamus to the circle of Willis. The approximate levels of the sections depicted in Figures 17.2–17.7 are shown. Modified from Nauta and Haymaker, 1969 with permission.

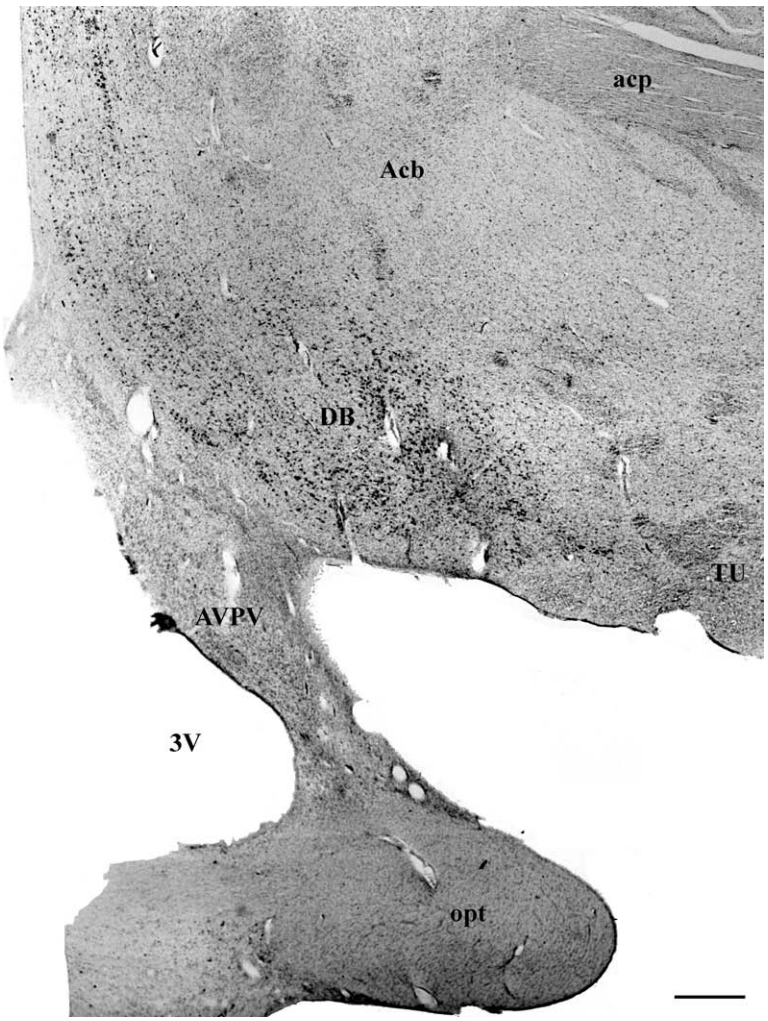

FIGURE 17.2 A photomicrograph taken at the level of the most rostral tip of the third ventricle. The preoptic area begins as an expansion of the tissue separating the optic chiasm from the base of the telencephalon. Scale = 1 mm.

extension is usually not apparent in humans. Both the subfornical organ and the organum vasculosum lack a blood–brain barrier (see Chapter 19). In rats there is evidence that angiotensin, and perhaps other blood-borne hormones, may act on neurons in these regions, which in turn project to the hypothalamus (Lind *et al.*, 1982, 1984).

At the foot of the third ventricle, just above the optic chiasm in the most rostral part of the preoptic area, lies a condensation of small, medium-staining neurons, the suprachiasmatic nucleus (Fig. 17.3). This cell group is less impressive in humans than in many other mammalian species and may be difficult to recognize in Nissl-stained material. The homology of this cell group with the suprachiasmatic nucleus, which is responsible for maintaining circadian rhythms in other species, was questioned until the application of immunohistochemical and pigmentoarchitectonic methods (Braak and Braak, 1987; Lydic *et al.*, 1980; Stopa *et al.*, 1984; Swaab *et al.*, 1985; Mai *et al.*, 1991). The shape of this cell group has been reported to be elongated in females and more spherical in males (Swaab *et al.*, 1985), although other investigators have not reported any sexual dimorphism in its structure (Braak and Braak, 1992).

The remainder of the periventricular zone in the preoptic area (Fig. 17.3) consists of a narrow strip of medium-sized to small, medium-staining neurons, the periventricular preoptic nucleus, which merges imperceptibly with the hypothalamic periventricular nucleus at the tuberal level. At the foot of the third ventricle in the tuberal region there is marked lateral

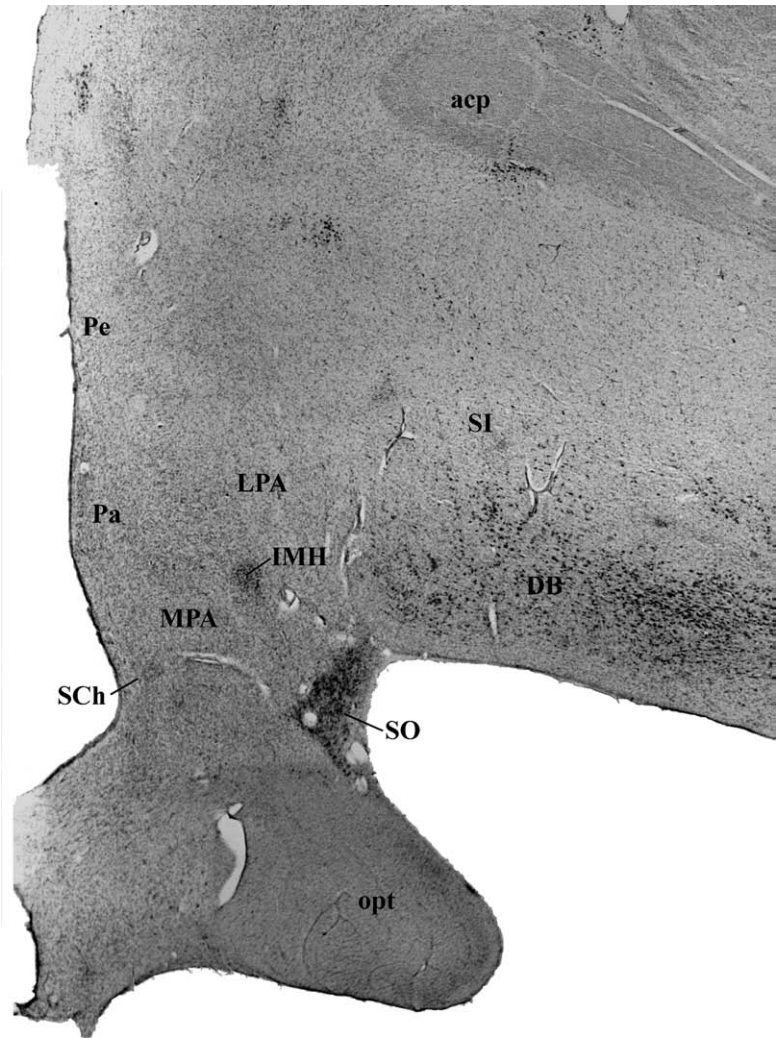

FIGURE 17.3 A photomicrograph taken at the level of the preoptic area, showing the most rotral portions of the supraoptic and paraventricular nuclei. The suprachiasmatic nucleus and the intermediate nucleus are also clearly seen at this level. Scale = 1 mm.

extension of the periventricular cell group, the arcuate nucleus (Figs. 17. 4 and 17.5). The arcuate nucleus overlies the median eminence, which forms the floor of the third ventricle at this level. Some arcuate neurons can be followed down into the median eminence itself. Unlike many other mammalian species, the median eminence in primates (including humans) does not form a neatly laminated structure; rather, the limited anteroposterior extent causes the neurohemal contact zone containing the hypophysial portal vessels to form a ball-like structure, whereas the axons of the neurohypophysial tract course along the surface of the infundibulum, toward the posterior pituitary gland.

At the posterior hypothalamic level, the periventricular zone expands laterally to become the posterior hypothalamic area (Figs. 17.6 and 17.7). This region is invaded along its lateral border by large, darkly staining neurons from the lateral hypothalamic area and the fields of Forel. Many of these neurons belong to the orexin- and melanin-containing hormone-containing populations (Elias *et al.*, 1998), which at tuberal levels occupy mainly the lateral hypothalamic area. The posterior hypothalamic area becomes continuous dorsally and caudally with the periventricular gray matter of the caudal third ventricle and the periaqueductal gray matter. Similarly, there is a well-defined cell group termed the supramammillary nucleus in rats, which lies between the posterior hypothalamic area and the dorsal surface of the mammillary body. However, in humans, there is no clear distinction between the supramammillary area and the posterior hypothalamic area.

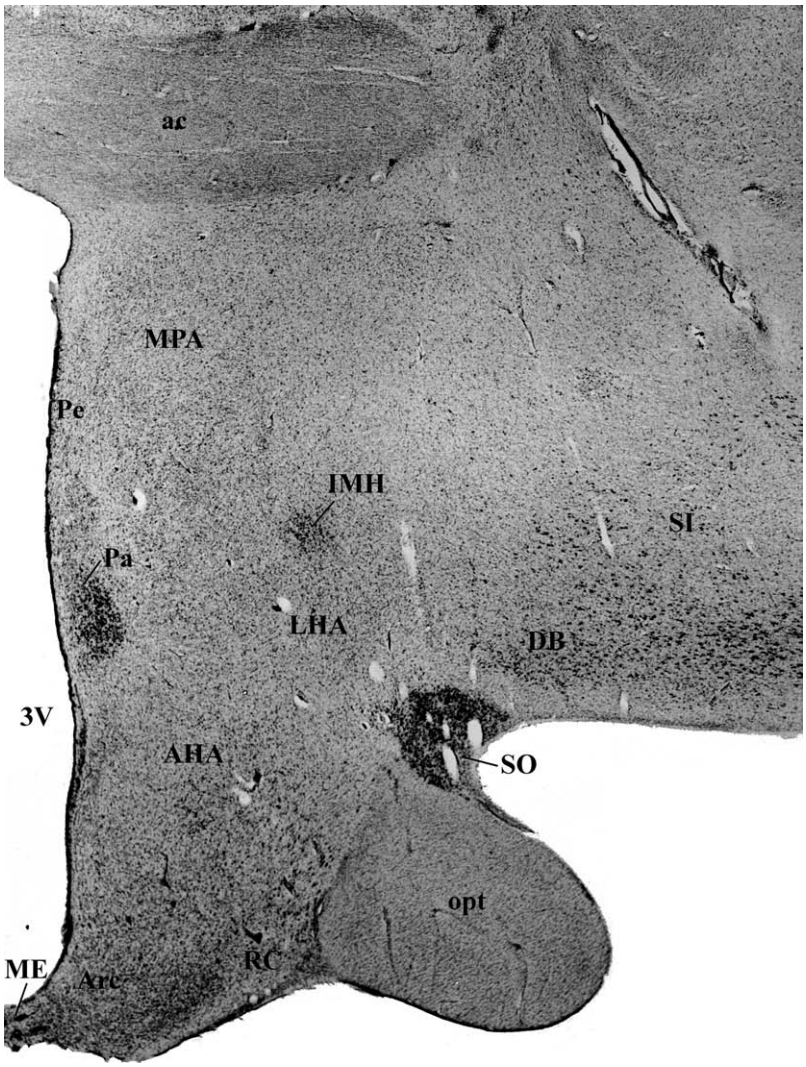

FIGURE 17.4 A photomicrograph taken at the level of the anterior hypothalamic area and the crossing of the anterior commissure. The section is slightly angled so that the dorsal part is roughly at the same anteroposterior level as Figure 17.3, while the ventral portion is closer to the level of Figure 17.5. This disparity in the orientation of the hypothalamus in the coronal plane is typical of human brains, in which the position of the pituitary stalk in relation to the optic chiasm may cause substantial topographical deformation of the relationship of the nuclei. Scale = 1 mm.

Medial Zone

The next more lateral portion of the hypothalamus, the medial zone, contains the most well-differentiated cell groups in the hypothalamus. At the preoptic level, the paraventricular nucleus can be seen near the foot of the third ventricle (Fig. 17.3). More caudally, the paraventricular nucleus appears to rise along the wall of the third ventricle, reaching nearly to the hypothalamic sulcus, which demarcates the hypothalamus from the thalamus at tuberal levels (Figs. 17.4–17.6). The paraventricular nucleus contains both large, darkly staining neurons as well as smaller, medium-staining cells. Unlike rodents, where these populations form discrete subnuclei, the subdivisions of the paraventricular nucleus in the human brain are not clear-cut. However, a number of homologies at the subnuclear level do exist (Koutcherov *et al*., 2000). For example, the larger neurons (the magnocellular neurosecretory cells that secrete oxytocin and vasopressin from their terminals in the posterior pituitary gland) tend to congregate most densely in the ventrolateral quadrant of the nucleus, generally avoiding the area just adjacent to the third ventricle (see Fig. 17.8).

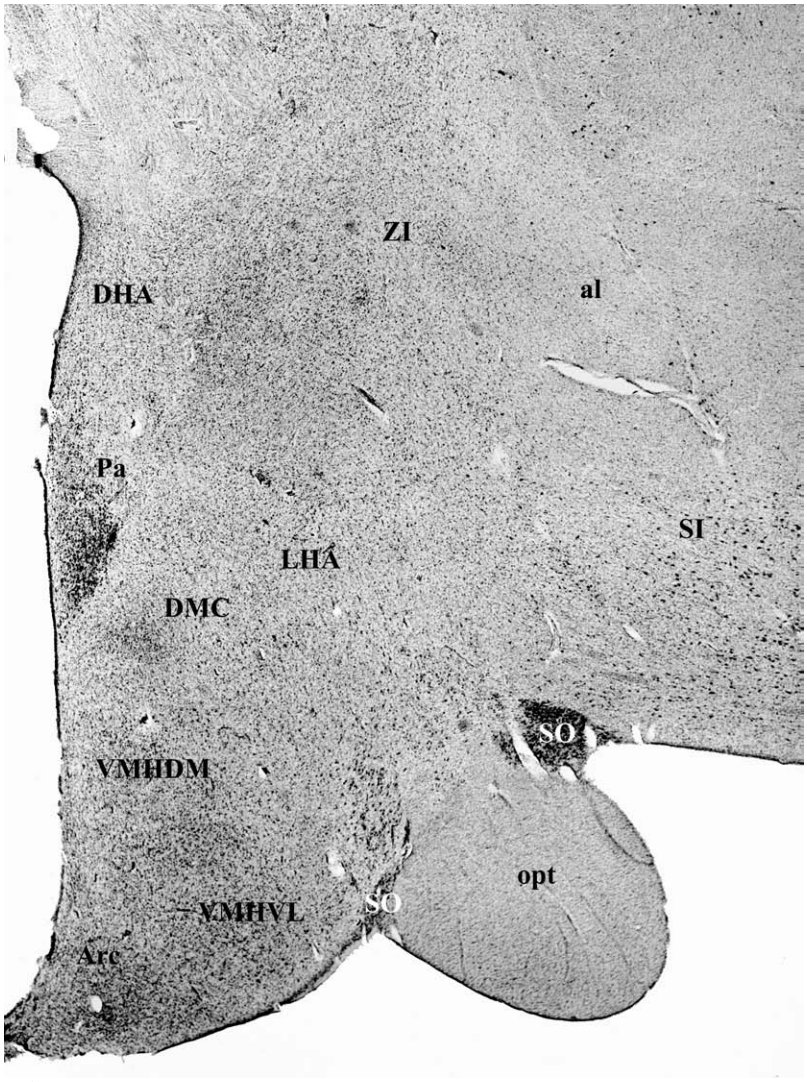

FIGURE 17.5 A photomicrograph taken at the level of the ventromedial nucleus of the hypothalamus. The dorsomedial and ventrolateral components of the ventromedial nucleus can be clearly seen, as can the compact portion of the dorsomedial nucleus of the hypothalamus. Scale = 1 mm.

Similar large, darkly staining neurons, without admixed smaller cells, are seen in the supraoptic nucleus. In humans, the largest part of the supraoptic nucleus is contained in a single well-defined cluster of neurons just dorsolateral to the optic tract. Additional supraoptic neurons are found spilling medially over the optic tract, to form a smaller cluster just ventromedial to the optic tract. Numerous scattered neurons are seen in the retrochiasmatic area, along the floor of the tuberal region.

At the rostral preoptic level, the supraoptic and paraventricular nuclei come to lie nearly adjacent to one another, reflecting their origin from the same embryological anlage. Here one often sees clusters of accessory neurosecretory neurons, running along the surface of penetrating blood vessels, bridging the gap between the two magnocellular nuclei (Figs. 17.3 and 17.4). It has been recognized since the work of Gagel (1927) that the main bodies of the paraventricular and supraoptic nuclei are also unusually heavily vascularized. This vascular relationship of magnocellular neurosecretory neurons, which is also seen in other species, may reflect their role in regulating blood osmolarity and electrolyte composition.

Just dorsal and medial to the supraoptic nucleus, another cluster of darkly staining neurons must be distinguished from the accessory neurosecretory nuclei. These cells are not quite as large as the magnocellular neuroendocrine neurons, nor is their cytoplasm as coarsely granular. Unlike the latter perikarya,

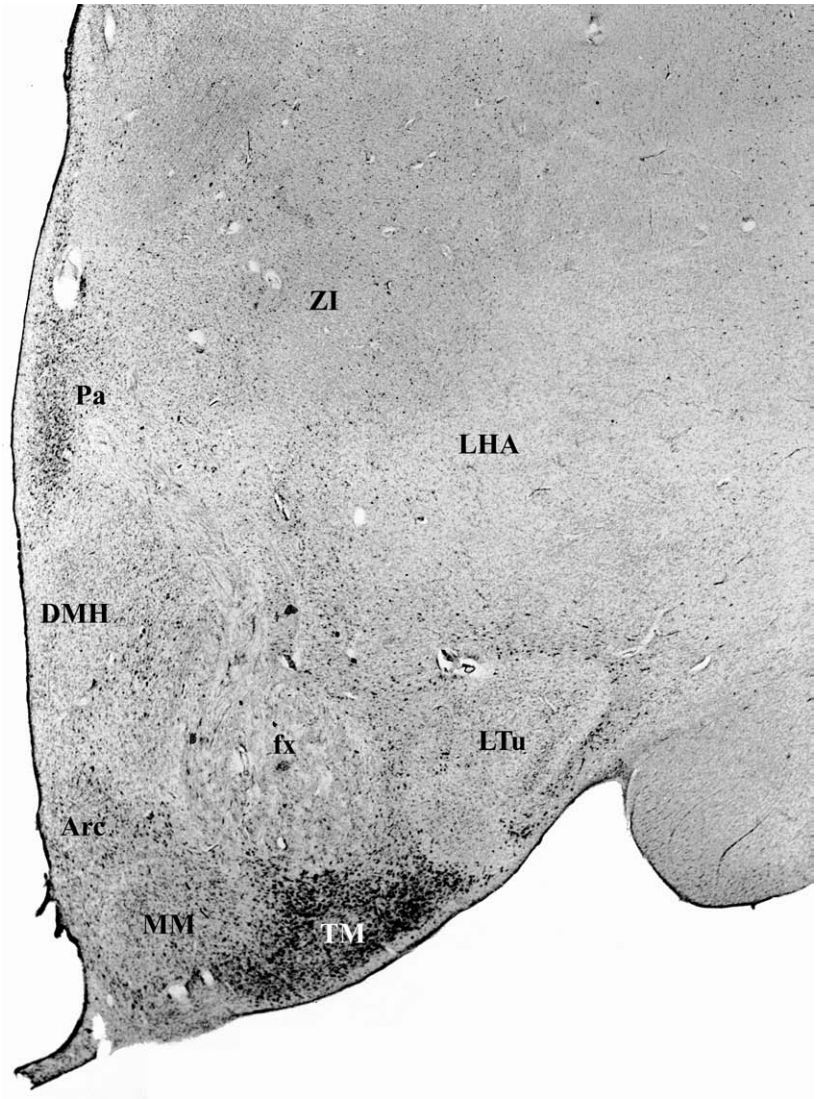

FIGURE 17.6 A photomicrograph taken at the premammillary level of the hypothalamus, demonstrating the tuberomammillary nucleus. Scale = 1 mm.

they do not stain immunohistochemically for posterior pituitary hormones, and they stand out as unstained with the aldehyde fuchsin stain for lipofuchsin pigment. Brockhaus (1942) and Braak and Braak (1987) termed this group the intermediate nucleus. This cell group, which is clearly seen in Nissl preparations, is often mistaken for a component of the accessory neurosecretory system, although its neurons are different in appearance and tend to become displaced progressively more dorsally at caudal preoptic levels (Fig. 17.3). Recent work has demonstrated that the neurons of the intermediate nucleus contain galanin mRNA, suggesting that they may represent the homologue of the ventrolateral preoptic nucleus, a cell group involved in sleep regulation (see below).

In the medial preoptic area of other species, there is considerable sexual differentiation of the pattern of innervation and cellular formations (see Simerly *et al.*, 1986, for review). Swaab and Fliers (1985) identified a sexually dimorphic nucleus in the human preoptic area, which has roughly twice as many neurons in men as in women. This cell group appears identical with the intermediate nucleus of Brockhaus (1942) and Braak and Braak (1987) and with the interstitial nucleus of the anterior hypothalamus 1 (INAH 1) of Allen and Gorski (1982). Allen and Gorski also described three other very small cell clusters in the medial preoptic region in humans, which they called INAH 2–4. They reported finding differences between the sexes in the size only of INAH 2 and INAH 3. LeVay (1991) found

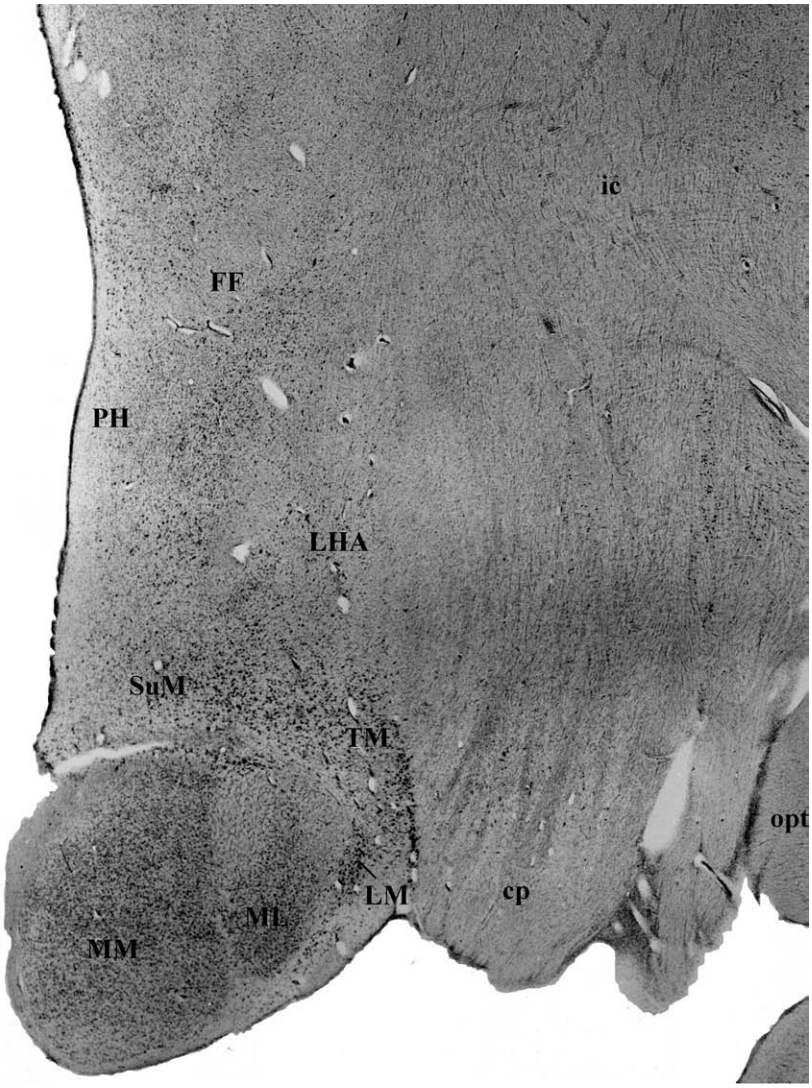

FIGURE 17.7 A photograph taken at the level of the midportion of the mammillary body, illustrating the relationships of the different mammillary nuclei. Scale = 1 mm.

no gender-based difference in the overall area of the INAH 1, 2, or 4 groups, but did confirm an increase in the size of INAH 3 in heterosexual males compared to females. LeVay also reported that INAH 3 in homosexual males was smaller than in heterosexual males, and about the same size as in females (who were not characterized for their gender preference). Byne and coworkers (2000) confirmed the sexually dimorphic nature of INAH 3, but not INAH 1.

The remainder of the medial preoptic area in the human brain is relatively undifferentiated. The ventromedial preoptic nucleus, a cell group that has been associated with thermoregulation in rats (Elmquist *et al.*, 1996), is not clearly demarcated in human brains. Ventral to the paraventricular nucleus, the anterior hypothalamic area blends with the medial preoptic area rostrally and with the dorsomedial hypothalamic nucleus caudally.

At the tuberal level, the ventromedial nucleus forms a dense cellular condensation, bordered ventromedially by the arcuate nucleus and dorsally by the dorsomedial nucleus. The ventromedial nucleus has a relatively cell-poor capsule (Fig. 17.5), and in some humans can be seen to form dorsal and ventral cell aggregations, as in other species (see Saper *et al.*, 1976b, 1979). In rats and monkeys, these subdivisions have distinct connections, with most of the long efferents of the ventromedial nucleus arising from the ventrolateral part. In monkeys, neurons in this same area bind sex steroids (Keefer and Stumpf, 1975).

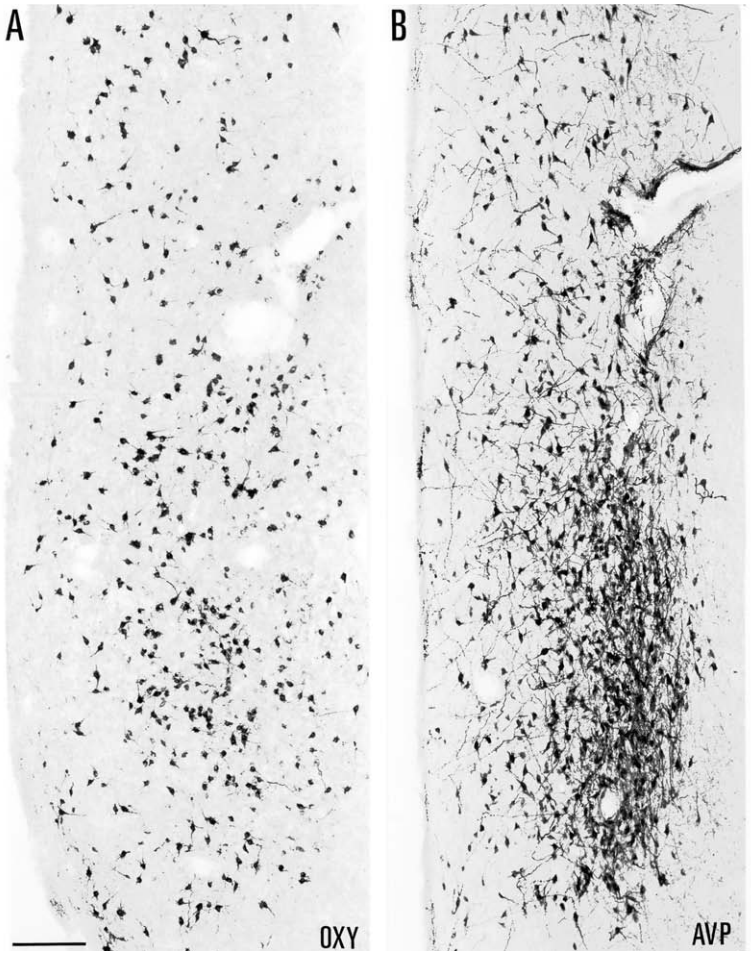

FIGURE 17.8 A pair of photomicrographs illustrating the distribution of oxytocin **(A)** and vasopressin **(B)** neurons in the human paraventricular nucleus. Note that the vasopressin cells form a dense cluster in the ventrolateral quadrant of the paraventricular nucleus, whereas the oxytocin neurons tend to avoid this region, instead clustering along its borders. Scale = 250 μm.

Immediately dorsal to the ventromedial nucleus and ventral to the caudal extension of the paraventricular nucleus lies the dorsomedial nucleus. This cell group is poorly differentiated in the human brain, consisting of loosely organized medium-sized, medium-staining neurons, so that it is best defined by its borders with neighboring structures. Its lateral margin can be arbitrarily marked at the edge of the fornix, although at this border the nucleus is often invaded by larger neurons from the lateral hypothalamus. Conversely, some dorsomedial nucleus cells spill over laterally past the descending column of the fornix. As in other species, embedded within the diffuse part of the dorsomedial nucleus is a cluster of smaller, more darkly staining and densely packed neurons, the compact part of the dorsomedial nucleus (Fig. 17.5). In humans the dorsomedial nucleus is clearly seen in acetylcholinesterase preparations (Koutcherov *et al.*, 2002).

At the caudal tuberal level, just rostral to the appearance of the mammillary nuclei, rodents such as rats show clearly defined dorsal and ventral premammillary nuclei. Similar cell groups cannot be adequately delineated in human brain with current data. However, like the suprachiasmatic nucleus, which was difficult to define on a cytoarchitectonic basis before it could be stained for characteristic chemical markers, it is possible that advances in determining the chemoarchitecture of these nuclei may make it possible to identify them within the tuberal hypothalamic gray level.

The mammillary body is the most prominent component of the medial hypothalamus at the posterior level (Figs. 17.1, 17.6 and 17.7). In human brains, the medial portion of the medial mammillary nucleus reaches prodigious proportions, causing the bulging shape in the floor of the hypothalamus that gave this region its suggestive name. The lateral part of the medial

mammillary nucleus forms a much smaller cluster that is often split off from the lateral margin of the medial subnucleus by a sheet of fornix fibers (Fig. 17.7). The neurons in the lateral part of the medial mammillary nucleus are identical in size (medium), shape (multipolar), and staining characteristics (moderately dense, relatively granular Nissl substance) to those in the medial part of the nucleus. Nevertheless, they have frequently been identified as a separate cell group: Gagel (1927), Grünthal (1933), and LeGros Clark (1936) called this the "lateral mammillary nucleus." This term is unfortunate because it suggests homology with the lateral mammillary nucleus in other species (such as rats), in which the lateral mammillary neurons are much larger and more darkly staining than those in the medial mammillary nucleus. In addition, the lateral mammillary nucleus in rodent species has distinct connections (e.g., a bilateral projection to the anterodorsal nucleus of the thalamus; see "Fiber Connections of the Hypothalamus"). The anterodorsal thalamic nucleus is not distinct in humans, and the lateral mammillary nucleus similarly is much less prominent. In our own material, a collection of larger, more darkly staining neurons located along the lateral edge of the medial mammillary nuclei can be distinguished (Fig. 17.7). This cluster of cells, which is of variable size and distinctiveness, has been designated the lateral mammillary nucleus.

Surrounding the mammillary body along its rostroventral, lateral, and caudodorsal borders is a diffuse population of slightly larger, intensely staining neurons (Figs. 17.6 and 17.7). This latter cell group, which first appears along the floor of the hypothalamus at the premammillary level (Fig. 17.6), was originally named the mammilloinfundibular nucleus by Malone in 1910. Later, he changed the name to the tuberomammillary nucleus (see Malone, 1916) because it was more closely related to the lateral tuberal region than the infundibulum. Several authors have, in fact, included the tuberomammillary nucleus within the mammillary complex, referring to it as the "nucleus intercalatus" (LeGros Clark, 1936; Brockhaus, 1942), whereas others have applied this same term to what is here called the lateral mammillary nucleus (Gagel, 1927; Malone, 1916). It seems preferable, in light of this confusion, to adopt a terminology that is similar to that used in other species and avoid the term "nucleus intercalatus" entirely.

Some authors have followed the suggestion of Bleier *et al.* (1979), who termed the tuberomammillary nucleus the "caudal magnocellular nucleus," to emphasize its cytological similarity to the more rostrally situated magnocellular neurons of the supraoptic nucleus. Malone noted this same similarity in 1916 but pointed out that the two structures could be distinguished on cytological grounds. Recent connectional and immunohistochemical observations in rats support this view. The supraoptic nucleus consists of oxytocin and vasopressin neurons that project to the posterior pituitary gland (Swanson and Kuypers, 1980). In contrast, tuberomammillary neurons stain immunohistochemically for a variety of neurotransmitters or their related enzymes, including histamine, adenosine deaminase, γ-aminobutyric acid (GABA), and galanin (Köhler *et al.*, 1985; Staines *et al.*, 1987). Furthermore, the tuberomammillary nucleus gives rise to widespread connections that are reminiscent of other monoamine cell groups, including innervation of the entire cortical mantle. For these reasons, the term "tuberomammillary nucleus" introduced by Malone is preferred.

In Malone's (1910, 1916) original descriptions, and the later ones of Grünthal (1933), LeGros Clark (1936), and Brockhaus (1942), the tuberomammillary nucleus was described as including similar cells located more dorsally in the tuberal and posterior lateral hypothalamus (Figs. 17.6 and 17.7). Although these populations appear continuous with the tuberomammillary nucleus in human brains, connectional studies in other species and immunocytochemical studies in humans indicate that they can be separated into several distinct cell groups (see "Functional Organization of the Hypothalamus").

Lateral Zone

The most lateral part of the hypothalamus, the lateral zone, comprises a continuum that runs from the lateral preoptic area rostrally through the anterior, tuberal, and posterior parts of the lateral hypothalamic area caudally. The large and relatively diffusely organized neurons of the lateral hypothalamic area are interspersed among the fibers of the medial forebrain bundle, which run longitudinally through the lateral hypothalamus, connecting the autonomic and limbic regions of the forebrain above with the hypothalamus and the brain stem below. The large lateral hypothalamic neurons also provide much of the long projections from the hypothalamus to the cerebral cortex and the brain stem (see "Fiber Connections of the Hypothalamus").

At the tuberal level, two distinctive cell groups can be seen embedded in the lateral hypothalamus. The lateral tuberal nuclei consist of several fiber-encapsulated clusters of small, medium-staining, parvalbumin-immunoreactive neurons embedded in a gelatinous-appearing matrix (Fig. 17.6). The lateral tuberal nuclei form small bulges along the floor of the caudal lateral hypothalamus that, in favorable cases, can be seen as distinct bumps on the surface of the

brain (LeGros Clark, 1936). The lateral tuberal nucleus can be identified on the basis of its staining for a variety of chemical markers, including corticotropin-releasing factor, somatostatin, and muscarinic cholinergic receptors (Kremer, 1994). This cell group also contains heavy staining with the Alz-50 antibody (Rye *et al.*, 1993; Kremer, 1994), but this is most likely cross-reactivity for somatostatin (Nelson and Saper, 1995). The lateral tuberal nucleus shows cytoskeletal pathology in Pick's disease and in argyrophilic grain disease, but only occasional Lewy bodies in Parkinson's disease and no characteristic changes in Alzheimer's disease (Braak and Braak, 1998; Schultz *et al.*, 1998; Kremer, 1994). A homologous structure has been identified in rhesus monkeys (Narkiewicz *et al.*, 1994; Paxinos *et al.*, 2000), and a similar-appearing cluster of parvalbumin-immunoreactive neurons has been identified in rats (Celio and Saper, 1999). Bleier and Byne (1986) also used this name for a cell group in rats, but it probably is a distinct nucleus not related to the human lateral tuberal nucleus.

A second feature of the tuberal lateral hypothalamus is the abrupt appearance of large, darkly staining neurons with coarse cytoplasm that are seen scattered throughout the region and invading the lateral edges of the medial nuclei. Similar-appearing cells can be followed caudally through the posterior level of the lateral hypothalamic area, where they invade the lateral part of the posterior hypothalamic area in large numbers. In Nissl-stained sections, these cell groups merge imperceptibly with the tuberomammillary nucleus, and with a collection of large, darkly staining neurons in the fields of Forel that encroaches on the lateral part of the posterior hypothalamic nucleus. In rats, similar-appearing cell groups are better differentiated from one another, and have distinct immunohistochemical properties (see "Functional Organization of the Hypothalamus"). In rats, all four groups (large neurons in the tuberal lateral hypothalamus, posterior lateral hypothalamus, tuberomammillary nucleus, and fields of Forel) project upon the cerebral cortex (see "Functional Organization of the Hypothalamus"). The apparent expansion of these cell groups in human brains is consistent with their role in innervation of the cerebral cortex in humans as well (see "Fiber Connections of the Hypothalamus").

FIBER CONNECTIONS OF THE HYPOTHALAMUS

The synaptic connections of the hypothalamus will be reviewed below in the context of their functions. However, it is useful first to gain an overview of the layout of hypothalamic connections. In addition, we still do not understand the functions of some of the most prominent fiber pathways of the hypothalamus. The larger myelinated hypothalamic pathways, in particular, would be otherwise overlooked if reviewed only in a functional context.

Afferents

The hypothalamus receives three main sources of neuronal input. *Descending* pathways originate in the cerebral cortex, hippocampal formation, septum, and extended amygdala. *Ascending* pathways arise from a variety of spinal and brain stem sources, including prominent inputs from brain stem sensory and monoaminergic systems. *Intrinsic connections,* meanwhile, connect the different hypothalamic nuclei with one another, allowing them to carry out their carefully orchestrated integrative functions.

Descending Pathways from the Forebrain

The input to the hypothalamus from the *hippocampal formation* forms one of the most heavily myelinated and easily identified fiber bundles in the brain, i.e., the fornix. The course of the fornix includes a long arching pathway that is a remnant of the developmental history of the hippocampal formation. The development of the temporal lobe in the primate brain carries the hippocampal formation, which occupies the most medial extreme of the cortical mantle in the embryonic brain, far from its site of origin near the lamina terminalis. As a result, the fimbria of the fornix recapitulates this migration. At the foramen of Monro, the fornix takes a sharp turn, bending back in a stately column that brushes past the posterior margin of the anterior commissure. The column of the fornix appears to form a solid structure as it pierces the hypothalamus, running slightly laterally as it moves caudally and inferiorly toward the dorsal surface of the mammillary body. Microscopic examination, by contrast, shows that the column of the fornix consists of rather loosely organized bundles of heavily myelinated axons. In rats (Guillery, 1955; Powell *et al.*, 1957; Swanson and Cowan, 1977; Canteras and Swanson, 1995; Canteras and Swanson, 1992; Kishi *et al.*, 2000) and in monkeys (Valenstein and Nauta, 1956), many axons lose their myelination and peel off the fornix to innervate the medial hypothalamic nuclei and lateral hypothalamic area.

Although the hippocampus proper is often considered to be the origin of the fornix projection, most of the axons that originate in the hippocampus travel no further than the septal nuclei in rodents. The projections to the hypothalamus, particularly the dense projections to the shell of the ventromedial nucleus

and to the mammillary body, originate primarily from the subiculum in both rats and monkeys, although the presubiculum may also contribute in primates (Swanson and Cowan, 1975; Krayniak *et al.*, 1979; see also Chapter 23).

Septal afferents to the hypothalamus originate mainly from the lateral septal nucleus. Although there is an extensive projection from the lateral septal nucleus to the hypothalamus in rats, including the medial preoptic, anterior hypothalamic, and lateral hypothalamic and preoptic areas, as well as the shell of the ventromedial nucleus and the ventral premammillary nucleus (Risold and Swanson, 1997), this structure has not received similar study in primates. There are also afferents, primarily to the lateral hypothalamic area, from the shell region of the nucleus accumbens in rats and cats (Powell and Leman, 1976; Mogenson *et al.*, 1983; Groenewegen and Ruschen, 1984; Heimer *et al.*, 1991; Zahm and Heimer, 1993; Usuda *et al.*, 1998); similar pathways have been reported in monkeys (Haber *et al.*, 1990), but these have not been studied in comparable detail.

The main inputs from the *amygdala* to the hypothalamus in rodents arise from the corticomedial and central nuclei. The cortical, medial, basomedial, and posterior nuclei innervate the medial preoptic and anterior and lateral hypothalamic areas and the ventromedial and ventral premammillary nuclei (Coolen and Wood, 1998; Canteras *et al.*, 1992, 1995; Gomez and Newman, 1982; Petrovich *et al.*, 1996). These pathways have been implicated in relaying the olfactory influence on reproductive behavior (Lehman and Winans, 1982). The central nucleus mainly projects to the lateral hypothalamic area (Krettek and Price, 1978; Price and Amaral, 1981) and has been implicated in the amygdaloid influence on the autonomic system (Schwaber *et al.*, 1982). In rats, fibers from the amygdala reach the hypothalamus via two pathways: a short, direct projection over the surface of the optic tract (the ventral amygdalofugal pathway, a component of the ansa peduncularis) and a long, looping projection through the stria terminals. The latter fiber bundle runs through the floor of the lateral ventricle just across from the free edge of the fornix. It then passes through (and extensively innervates) the bed nucleus of the stria terminalis before residual fibers enter the medial forebrain bundle, through which it distributes largely to the medial preoptic and hypothalamic nuclei. The organization of these pathways is similar in monkeys (Nauta, 1961; Price and Amaral, 1981), although the stria terminalis projection could not be followed as far caudally as the tuberal hypothalamus. Little is known about the functional significance of these pathways in primates. Lesions of the stria terminalis combined with interruption of the fimbria of the fornix in monkeys have been reported to impair visual memory (Mishkin, 1982), but it is not clear that it is the hypothalamic portion of these pathways that is important for this function.

The bed nucleus of the stria terminalis provides extensive projections to the hypothalamus in rodents that largely overlap those from the amygdala (see Numan and Numan, 1996; Dong *et al.*, 2000). However, this region has received little study in primates. The dorsal part of the substantia innominata also projects to the lateral hypothalamic area in monkeys (Kim *et al.*, 1976). In rats, the dorsal part of the substantia innnominata has projections consistent with its role as a part of the extended amygdala, innervating the medial preoptic and anterior hypothalmic areas, and the paraventricular, dorsomedial, ventromedial, arcuate, and ventral premammillary nuclei (Grove, 1988).

Cortical inputs to the hypothalamus in rats arise primarily from insular, lateral frontal, infralimbic, and prelimbic fields (Kita and Oomura, 1982; Saper, 1982; Tucker and Saper, 1984; Sesack *et al.*, 1989). In addition, there are afferents from olfactory cortical areas, including the primary olfactory cortex and anterior olfactory nucleus (see below and Chapter 32). Projections from the prelimbic and infralimbic areas in monkeys (areas 32 and 25) most heavily innervate the anterior hypothalamic area, perifornical region, and ventromedial nucleus, whereas the orbitoinsular area (including areas 13a, 12o, and Iai) projects to the lateral hypothalamic area most densely (Ongur *et al.*, 1998; Friedman *et al.*, 2000; Rempel-Clower and Barbas, 1998; Barbas *et al.*, 2000). Frontal cortical projections to the ventromedial nucleus and mammillary body have been reported in Glees-stained specimens from frontal leukotomy patients. However, it appears probable that this result was an artifact of the method used (see Nauta and Haymaker, 1969, for discussion). Nevertheless, corticohypothalamic projections similar to those described above in monkeys are likely to exist in humans as well.

The cortical and olfactory inputs to the hypothalamus form the anterior roots of the *medial forebrain bundle.* This fiber pathway, which runs longitudinally through the lateral hypothalamic area linking the hypothalamus with the forebrain rostrally and the brain stem caudally (Veening *et al.*, 1982), is really misnamed. Although it is medial to the internal capsule (the "lateral forebrain bundle"), the medial forebrain bundle is actually quite laterally placed in the hypothalamus. It also does not form a "bundle" in the strict sense. Most of the fibers are unmyelinated, and they are difficult to pick out in myelin-stained preparations. The axons of the medial forebrain bundle are widely dispersed across the lateral hypothalamus, intercalating themselves among the

neuronal populations, rather than forming a discrete fiber bundle (e.g., like the column of the fornix). Finally, some prominent components of the medial forebrain bundle have little to do with the hypothalamus, e.g., the nigrostriatal bundle.

Ascending Pathways from the Brain Stem

The ascending inputs to the hypothalamus from the brain stem originate in a wide variety of sources, including the nucleus of the solitary tract and ventrolateral reticular formation in the medulla; the parabrachial nucleus, locus coeruleus, and raphe nuclei in the pons; and the periaqueductal gray matter and ventral tegmental area in the midbrain. Each of these will be discussed in more detail below. These ascending pathways enter the hypothalamus via three main pathways. Many of the axons form the ascending root of the *medial forebrain bundle.* Afferents from monoaminergic and sensory systems, discussed below, contribute to this pathway. Another important component of the lateral hypothalamic ascending system is the *ventral supraoptic commissure* pathway. The ventral supraoptic commissure refers to axons that cross the midline of the hypothalamus along the caudal edge of the optic chiasm, then follow the optic tract back through the lateral hypothalamus (Nauta and Haymaker, 1969). Axons from a various sensory systems, particularly those concerned with pain (Cliffer *et al.*, 1991; see also Chapter 30), reach the hypothalamus from the brain stem by passing just medial to the lateral geniculate nucleus and following the medial surface of the optic tract back into the hypothalamus. Some hypothalamic intrinsic pathways also cross the midline in this path.

A third major pathway for brain stem afferents to the hypothalamus is the *periventricular fiber system* (Sutin, 1966). This tract was originally termed the dorsal longitudinal fasciculus of Schütz, on the basis of myelin-stained material, but most of the axons are not myelinated, and they do not form a bundle nor are they dorsally located. Rather, they penetrate diffusely through the periaqueductal gray matter of the midbrain into the periventricular third ventricular white matter. Some older textbooks still use the archaic term, but the more descriptive name proposed by Sutin is preferable.

A classical myelinated ascending input to the mammillary body, the mammillary peduncle, arises from the dorsal and ventral tegmental nuclei in the midbrain in rats (Cowan *et al.*, 1964). The mammillary peduncle is difficult to identify in the human brain, but just caudal to the mammillary body a myelinated bundle can be seen on the ventral surface of the midbrain, just medial to the cerebral peduncle. These fibers appear to enter the capsule of the mammillary body, although it is not possible to trace them caudally to their origin.

Each of the classes of monoamine cell groups in the rat brain stem provides innervation to the hypothalamus through both the medial forebrain bundle and the periventricular pathways. The origins and distribution of noradrenergic projections from the locus coeruleus and the medulla to the hypothalamus in rats has received considerable study (Sawchenko and Swanson, 1982; Tucker *et al.*, 1987). The organization of both noradrenergic and serotonergic cell groups in the brain stems of monkeys (Felten *et al.*, 1974; Garver and Sladek, 1975; Sladek *et al.*, 1982) and humans (Saper and Petito, 1982; J. Pearson *et al.*, 1983, 1990) is quite similar to that of rats, but little is known about the hypothalamic projections of these fiber systems in primates.

Projections to the hypothalamus from brain stem autonomic areas may be organized somewhat differently in monkeys than in rats. Both the nucleus of the solitary tract and the parabrachial nucleus project extensively to the lateral hypothalamic area, and the dorsomedial, paraventricular, and median preoptic nuclei in rats (Ricardo and Koh, 1978; Saper and Loewy, 1980; Bester *et al.*, 1997). There is also a separate projection from the parabrachial nucleus to the ventromedial nucleus (Fulwiler and Saper, 1984, 1985; Bester *et al.*, 1997). In monkeys, the projections from both the nucleus of the solitary tract and the parabrachial nucleus to the hypothalamus have been described as less intense than in rats (Beckstead *et al.*, 1980; Pritchard *et al.*, 2000). However, both of these studies employed the transport of tritium-labeled amino acids, which is less sensitive than modern tracer methods, so it is possible that these projections may be more extensive than earlier studies could demonstrate.

The periaqueductal gray matter in monkeys projects to the hypothalamus mainly via a periventricular route (Mantyh, 1983). The axons innervate most of the medial hypothalamic nuclei, including the medial preoptic, the anterior and posterior hypothalamic areas, and the ventromedial and dorsomedial nuclei, as well as the lateral hypothalamic area.

Intrinsic Connections of the Hypothalamus

Most studies of hypothalamic connections have concentrated on long-range connections in rodents. Often nearby connections are either obscured by the spread of tracer from the injection site or not emphasized in the analysis. Unfortunately, even less is known about hypothalamic intrinsic connections in primates. However, studies in rats, particularly those using the anterograde tracer *Phaseolus vulgaris* leucoagglutinin, have demonstrated some features of intrahypothalamic connections.

The structures in the medial part of the preoptic region in rats, including the median preoptic, medial preoptic, anteroventral periventricular, ventromedial preoptic, and periventricular preoptic nuclei, primarily project to the medial tuberal hypothalamus, including the paraventricular, ventromedial, and arcuate nuclei (Saper and Levisohn, 1986; Simerly and Swanson, 1988). The suprachiasmatic nucleus projects extensively into the medial part of the anterior hypothalamic area (the "subparaventricular zone") and back into the dorsomedial nucleus (Watts *et al.*, 1987), and similar projections have been confirmed by postmortem tracing in human brains (Dai *et al.*, 1998b; Abrahamson *et al.*, 2001). The anterior hypothalamic area projects into the perifornical part of the lateral hypothalamic area, as well as to the ventromedial and dorsal premammillary nuclei and the posterior hypothalamic area (Risold *et al.*, 1994). Smaller numbers of fibers enter the dorsomedial nucleus and the retrochiasmatic area. At the tuberal level, the arcuate nucleus projects to the paraventricular nucleus and lateral hypothalamic area both in rats and in humans (Elias *et al.*, 1998; Broberger *et al.*, 1998). The dorsomedial part of the ventromedial nucleus projects into the anterior hypothalamic area (including the subparaventricular zone), while the ventrolateral part projects to the medial preoptic and ventral premammillary nuclei as well as the lateral hypothalamic area (Canteras *et al.*, 1994; Saper *et al.*, 1979b; Elmquist *et al.*, 1998). The dorsomedial nucleus projects heavily to the paraventricular nucleus and less intensely to the median preoptic, medial preoptic, and anteroventral periventricular nuclei, and the lateral hypothalamic and retrochiasmatic areas (Thompson *et al.*, 1996; Elmquist *et al.*, 1998). The dorsal premammillary nucleus primarily projects to the anterior hypothalamic area (Canteras and Swanson, 1992), and the ventral premammillary nucleus to the ventrolateral part of the ventromedial nucleus and the medial preoptic nucleus (Canteras *et al.*, 1992).

In general, much less is known about intrinsic hypothalamic connections in humans or monkeys, although what is known suggests that they are similar to those documented in rats. The medial hypothalamic nuclei in monkeys provide the greatest amount of intrinsic connections, whereas the lateral hypothalamus is the major source of long ascending and descending projections (Saper *et al.*, 1978, 1979). Sketchy information available on the projections of the ventromedial nucleus of monkeys (Saper *et al.*, 1979a) is consistent with that from rats but relies on information from autoradiographic studies that are less sensitive than modern tracers. Recent studies of the chemically defined projections containing agouti-related protein, neuropeptide Y, or α-melanocyte-stimulating hormone, from the arcuate nucleus to the lateral hypothalamic area in human brain, shows that this pathway to orexin and melanin-concentrating neurons is virtually identical to that found in rats (Elias *et al.*, 1998).

Efferents

The efferent projections from the hypothalamus, like the afferents, consist of both ascending and descending projections. Both projections include components that follow the medial forebrain bundle, as well as periventricular components.

The ascending projections from the hypothalamus to the *cerebral cortex* have been examined using retrograde transport in both rats and monkeys (Kievet and Kuypers, 1975; Köhler and Swanson, 1984; Mesulam *et al.*, 1983; Porrino and Goldman-Rakic, 1982; Saper, 1985; Shiosaka *et al.*, 1984; Tigges *et al.*, 1983; Rempel-Clower and Barbas, 1998). In rats, four separate hypothalamocortical cell groups can be distinguished (see Saper, 1985): (1) Tuberal lateral hypothalamic neurons innervate the entire cortical mantle, including the hippocampal formation and the amygdala, in a crudely topographical manner. As we will discuss below, many of these neurons contain either melanin-concentrating hormone or orexin/hypocretin peptides. (2) The posterior lateral hypothalamus contains a separate population of neurons whose neurotransmitters are not yet known but that similarly project to the entirety of the ipsilateral cortex. The posterior lateral hypothalamic projection is organized in a strictly topographical manner. (3) Cortically projecting neurons in the fields of Forel have the narrowest range, innervating only the ipsilateral frontal and paralimbic fields in a loosely topographical fashion. (4) By contrast, tuberomammillary neurons on each side of the brain innervate the entire cortical mantle bilaterally but are not topographically organized. The tuberomammillary neurons contain histamine, as well as GABA, and galanin in both rats (Panula *et al.*, 1984; Vincent *et al.*, 1983; Staines *et al.*, 1986) and humans (Chan-Palay and Jentsch, 1992; Panula *et al.*, 1990).

Anterograde tracing studies in rats demonstrate that hypothalamic neurons project to the cerebral cortex via the medial forebrain bundle (Saper, 1985). At the level of the preoptic area, one group of fibers turns laterally, running ventral to the globus pallidus and the putamen, to enter the external capsule from which they are distributed to the cortex of the lateral wall of the hemisphere, including much of the temporal lobe outside the hippocampus. The remaining hypothalamocortical fibers follow the medial forebrain bundle rostrally, run along the dorsal surface

of the diagonal band nucleus, and then rostrally and dorsally. One bundle of axons enters the fornix and travels along back along it to innervate the hippocampal for mation. The other bundle runs over the genu of the corpus callosum into the cingulate bundle, from which its axons are distributed to the cortex of the medial wall of the cerebral hemisphere.

In several species of monkeys, investigators have noted retrogradely labeled neurons in the tuberal and posterior lateral hypothalamus (probably including the tuberomammillary nucleus, although this has not been separately identified) following injections into the frontal, parietal, and occipital cortex (Kievet and Kuypers, 1975; Porrino and Goldman-Rakic, 1982; Tigges *et al.*, 1983; Mesulam *et al.*, 1983; Rempel-Clower and Barbas, 1998). Although the data are less extensive than in rats, the medial-to-lateral topography of the lateral hypothalamic projection to the cerebral cortex appears to be preserved in monkeys (Rempel-Clower and Barbas, 1998). By staining melanin-concentrating hormone, orexin/hypocretin, and histaminergic neurons immunocytochemically in human brains, it has been possible to confirm the origins and pathways for these portions of the hypothalamocortical projection (Elias *et al.*, 1998 and unpublished observations; Panula *et al.*, 1990). The neurons of each of these populations are more widely dispersed in humans than in rats, occupying an overlapping region of the tuberal and posterior lateral hypothalamus (Fig. 17.9). However, the orexin- and melanin-concentrating hormone-containing neurons form interlacing clusters of cells rather than diffusely overlapping one another's distribution (Elias *et al.*, 1998). The ascending fiber pathways, and even the diffuse terminal distribution, favoring the deeper layers of the cerebral cortex, are much the same in human and rat brain.

Many hypothalamic nuclei also provide inputs to *the septum* or to *the extended amygdala*, including the bed nucleus of the stria terminalis and the substantia innominata. The ventromedial nucleus in monkeys projects to the capsule of the central nucleus of the amydgala, the substantia innominata (including the basal nucleus of Meynert), and the lateral part of the bed nucleus. The ventromedial nucleus also projects to the ventral lateral septal nucleus, whereas the lateral hypothalamic area projects to the medial septal nucleus (Saper *et al.*, 1979a).

The hypothalamus also provides afferents to the *thalamus* in rats (Risold *et al.*, 1997). Many of the medial nuclei project through the periventricular pathway to the paraventricular nucleus of the thalamus. These same cell groups give off collaterals to the nucleus reuniens, midline thalamic nuclei, and intralaminar nuclei as well. In addition, the lateral preoptic area sends a projection through the *stria medullaris* to the lateral habenular nucleus, in the epithalamus.

However, the most prominent hypothalamic projection to the thalamus is the mammillothalamic tract. These fibers leaves the mammillary body from its dorsomedial surface in a shallow ascending arc. Many of these axons bifurcate, giving rise to the mammillotegmental tract in rats (Fry and Cowan, 1972); similar studies have not been done in primates. The mammillothalamic fibers run in a dense bundle dorsally into the internal medullary lamina before entering the anterior thalamic nuclei. Unlike other species, the human anterior thalamic nuclei are not easily separated into distinct cell groups (Armstrong, 1990; see also Chapter 1). This lack of differentiation may reflect the fact that the most cytologically distinctive component of the anterior nuclei in other species, the anterodorsal nucleus, which primarily receives the output of the lateral mammillary nuclei, has not been identified in adult human brains. Comparative studies indicate that the mammillary body, the mammillothalamic tract, and the anterior thalamic nuclei reach their greatest state of development in anthropoids (see Armstrong, 1986, 1990). However, the increase in size primarily involves the medial mammillary nucleus, while the lateral nucleus remains quite small, its very existence being controversial (see above). Therefore it seems likely that the anterior thalamic nuclei of the human brain represent primarily the anteroventral, anteromedial, and laterodorsal nuclei, which receive medial mammillary inputs (Veazey *et al.*, 1982).

Although these pathways have received only limited study in primates, the projections from the ventromedial nucleus and anterior hypothalamic area to the midline and intralaminar thalamic nuclei have been confirmed (Saper *et al.*, 1978; 1979a). The projections from the medial mammillary nucleus to the anteroventral, anteromedial, and laterodorsal thalamic nuclei, and from the lateral mammillary nucleus to the anterodorsal nucleus, have also been identified in monkeys (Veazey *et al.*, 1982), and the mammillothalamic tract is among the most easily identified myelinated pathways in human brains.

The *descending projections* from the hypothalamus through the *periventricular* pathway originate widely from virtually all of the medial and periventricular hypothalamic nuclei in monkeys, much as they do in rats (Saper *et al.*, 1978, 1979a). These axons descend through the peraqueductal gray matter, but most terminate before the aqueduct opens into the fourth ventricle. Some axons via this pathway may reach as far as the rostral pole of the locus coeruleus.

The bulk of the descending pathway from the hypothalamus travels through the medial forebrain bundle

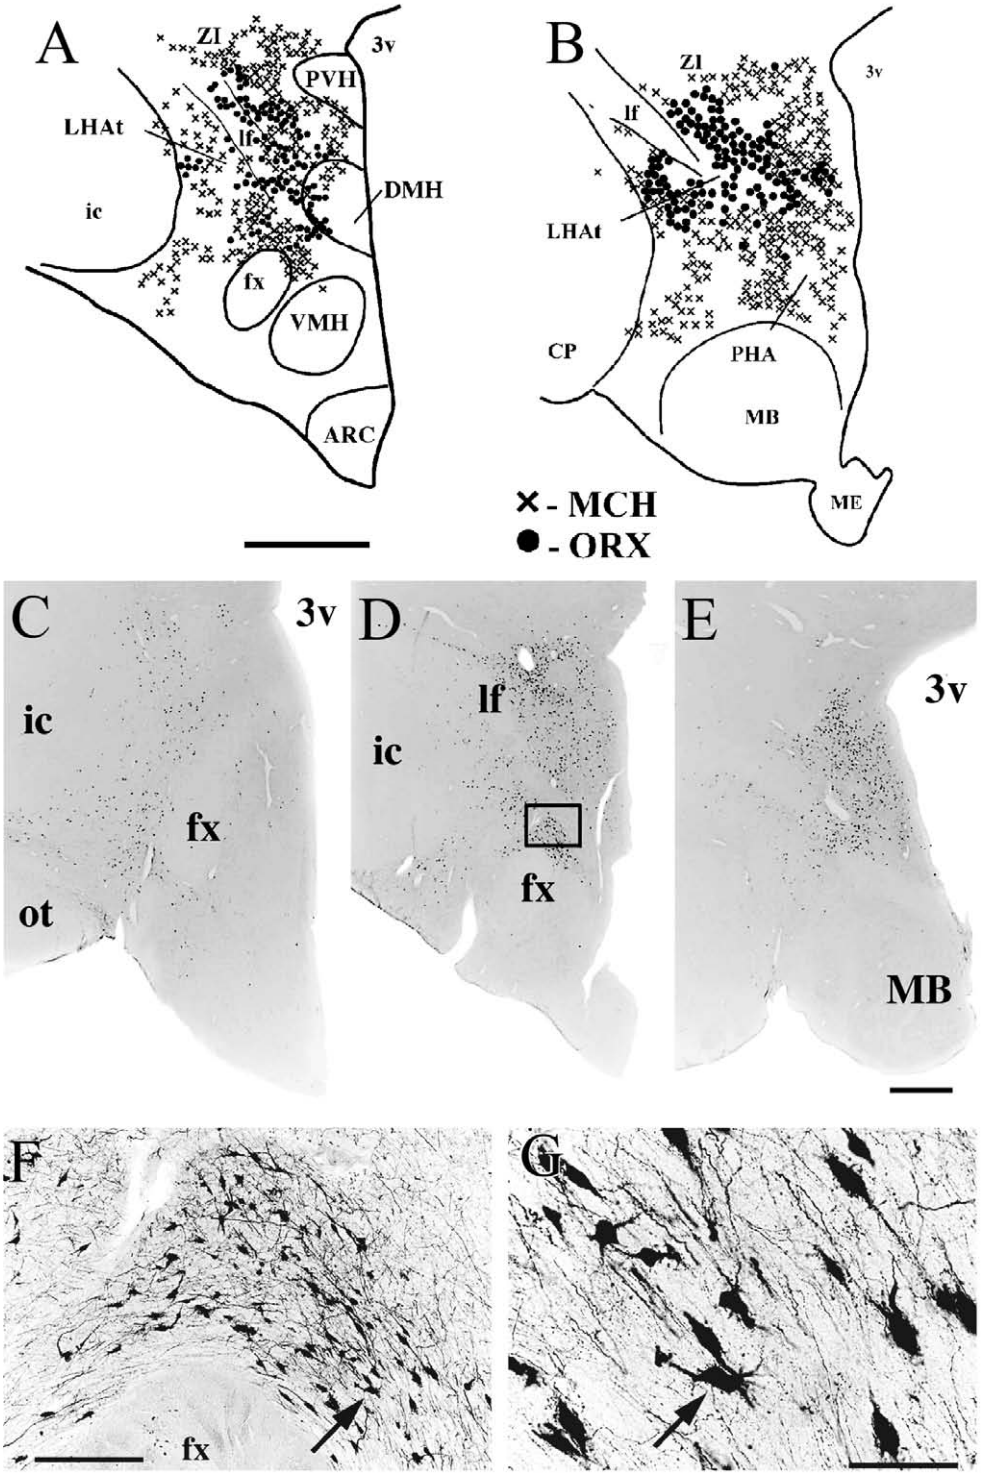

FIGURE 17.9 A series of drawings **(A, B),** and photomicrographs **(C–G)** illustrating the melanin-concentrating hormone and orexin neurons in the human lateral hypothalamus. In panels A and B, the distribution of neurons that are immunoreactive for the two peptides has been plotted from adjacent sections onto a single plane. Note that clusters of neurons containing each peptide are interlaced with clusters containing the other peptide. Panels C–D show the pattern of melanin-concentrating hormone neurons at low magnification in a series of sections roughly corresponding to Figures 17.5–17.7. Panel F shows a magnified view of the boxed area in panel D, and panel G shows a higher magnification of the area indicated by the arrow in panel F. Note the clustering of these neurons in the perifornical region. Scales = 3 mm for A; 2.4 mm for B; 1.5 mm in C–E; 200 μm in D; 100 μm in E. Modified from Elias *et al.*, 1998, with permisson.

and runs laterally at the level of the ventral tegmental area, to take a lateral position within the brain stem tegmentum. These fibers travel along the dorsal surface of the substantia nigra, and some may communicate with neurons of the ventral tegmental area or the substantia nigra (Saper *et al.*, 1978, 1979a). Many axons from medial hypothalamic cell groups such as the ventromedial nucleus terminate in the midbrain reticular formation, dorsal to the substantia nigra.

Only a relatively modest number of hypothalamic cell groups provide axons that descend further to the lower brain stem and the spinal cord. In rats, many of these axons terminate in autonomic or somatic sensory nuclei, such as the nucleus of the solitary tract, the parabrachial nucleus, or the outer laminae of the trigeminal or spinal dorsal horn, where they may modulate ascending afferents. Others end in the ventrolateral reticular formation or the spinal intermediate gray matter, where they may be involved in the modulation of brain stem or spinal reflexes, particularly those involved in autonomic and respiratory control. A similar pathway has been observed after large injections of anterograde tracers into the lateral hypothalamus and the paraventricular nucleus in monkeys (Saper *et al.*, 1976). The hypothalamic projections to the parasympathetic and sympathetic preganglionic cell groups in rats have been studied by retrograde transport (Saper *et al.*, 1976a; Swanson and Kuypers, 1980; Cechetto and Saper, 1988; Elias *et al.*, 2000; Zhang *et al.*, 2000) and viral transneuronal transport (Jansen *et al.*, 1992, 1997). This projection originates from the paraventricular and dorsomedial nuclei and the lateral hypothalamic area, as well as the lateral part of the arcuate nucleus and the adjacent retrochiasmatic area. In monkeys, similar studies have been done only using the less sensitive horseradish peroxidase retrograde tracing method. Nevertheless, these observations have confirmed projections from the paraventricular and dorsomedial nuclei and the lateral hypothalamic area to the medullary and spinal preganglionic cell groups (Saper, 1976a).

Likewise, studies tracing the hypothalamo-autonomic pathways in the anterograde direction have not been repeated using more sensitive modern tracers in primates. In monkeys, the descending projection from the hypothalamo-autonomic cell groups has been examined using very large injections of tritiated amino acids into the paraventricular nucleus and adjacent lateral hypothalamus (Saper *et al.*, 1976a). As in rats and cats, the descending pathway runs through the medial forebrain bundle into the lateral part of the brain stem tegmentum. One branch innervates the parabrachial nucleus in the pons, while the other traverses the ventrolateral medulla (just dorsolateral to the inferior olivary complex) to enter the dorsal lateral funiculus of the spinal cord. Fibers turn dorsally from this pathway in the medulla to innervate the nucleus ambiguus, the nucleus of the solitary tract, and the dorsal motor vagal nucleus. In the spinal cord, hypothalamic fibers can be traced to the sympathetic and parasympathetic preganglionic cell columns in the thoracic and sacral intermediolateral columns. The details of this spinal projection in monkeys have been demonstrated in the greatest detail by immunohistochemical staining for one of its neurotransmitters, oxytocin (see next section). The existence of a similar pathway in humans can be inferred from the presence of an ipsilateral sympathetic deficit following injury to the hypothalamus, lateral brain stem tegmentum, or spinal lateral funiculus (Nathan and Smith, 1986).

FUNCTIONAL ORGANIZATION OF THE HYPOTHALAMUS

The functional organization of the hypothalamus can be best appreciated in terms of its role as an *integrative* structure. By nature, it receives a wide variety of different afferent inputs which modulate specific drive states, and it controls autonomic, endocrine, and behavioral outputs which allow it to accomplish those goals. This section will describe circuitry along the same lines, beginning with the different sensory inputs, and how they are used to assess *homeostatic*, *allostatic*, and *circadian* needs. It will then review briefly what is known about the circuitry underlying regulation of autonomic, endocrine, and behavioral responses. Finally, it will review several functional systems, including feeding and energy metabolism; fluid and electrolyte control; reproduction; thermoregulation and fever; and wake–sleep regulation.

Sensory Afferent Inputs to the Hypothalamus

Although it was once thought that sensory afferents reach the hypothalamus only through multisynaptic and rather indirect pathways (see Nauta and Haymaker, 1969), work in recent decades has identified direct sensory inputs to the hypothalamus from nearly every sensory system. Much of this work was originally done in rodents, but in some cases correlative studies have been done in monkey or human brains.

Olfactory input arrives in the hypothalamus in rodents via relays in the olfactory tubercle, anterior olfactory nucleus, corticomedial amygdala, and olfactory cortex (Lehman and Winans, 1982; Switzer *et al.*, 1986; Price *et al.*, 1991), although in primates the main olfactory relays may include the nucleus accumbens and

septal nuclei (Tazawa *et al.*, 1987; see also Chapter 32). Olfactory afferents terminate throughout the lateral hypothalamus. In rodents there is an especially dense projection to the gemini nuclei in the premammillary part of the lateral hypothalamus from the polymorphic layer of the olfactory tubercle (Price *et al.*, 1991). A homologous projection has been identified in monkeys (Veazey *et al.*, 1982) but has not yet been described in humans (see also Chapter 32). In rodents, which have a well-developed vomeronasal organ that samples pheromones, the accessory olfactory system relays in the cortical and medial nuclei of the amygdala to provide inputs to the medial preoptic and ventromedial nuclei (Lehman and Winans, 1982; Coolen and Wood, 1998). Although it has recently been established that humans also have a vomeronasal organ, very little is known of its central connectivity (Jhanke and Merker, 2000; see Chapter 22, for additional discussion of this issue).

Visual afferents reach the hypothalamus via a direct retinal projection. In all mammalian species, including humans, some retinal fibers leave the optic chiasm and pass dorsally into the hypothalamus, where they innervate the suprachiasmatic nuclei (Sadun *et al.*, 1984; Moore, 1993; Dai *et al.*, 1998a). In addition, in rodents many retinal fibers bypass the suprachiasmatic nucleus and distribute more widely in the subparaventricular zone, the ventrolateral preoptic nucleus, and the lateral hypothalamic and retrochiasmatic areas (Johnson *et al.*, 1988; Lu *et al.*, 1999). Similar pathways have been described in nonhuman primates (Costa *et al.*, 1999; Reuss and Fuchs, 2000) and, to a lesser extent, in humans (Dai *et al.*, 1998a).

Somatic sensory information reaches the hypothalamus via a direct route: a projection to the lateral hypothalamic area from wide-dynamic-range mechanoreceptive and thermoreceptive neurons in the spinal and trigeminal dorsal horn has been reported in both rats and monkeys (Burstein *et al.*, 1987). These afferents have been traced anterogradely in rats, in which they reach the hypothalamus via the ventral supraoptic commissure pathway and provide afferents to the medial preoptic region and the lateral hypothalamic area (Cliffer *et al.*, 1987).

Visceral sensory inputs to the hypothalamus, including taste, arise from the nucleus of the solitary tract, which projects directly to the hypothalamus in rats (Ricardo and Koh, 1978). Similar experiments using injections of tritiated amino acids in monkeys have failed to provide evidence for such a projection (Beckstead *et al.*, 1980; see also Chapter 31), although studies using modern and more sensitive tracers have not been reported. Visceral sensory information from the nucleus of the solitary tract may, however, be relayed to the hypothalamus via projections of the solitary nucleus to the ventrolateral medullary reticular formation, the parabrachial nucleus, or the periaqueductal gray matter. The projection from the ventrolateral medulla to the hypothalamus arises predominantly from noradrenergic and adrenergic neurons in the A1 and C1 cell groups in rats (Tucker *et al.*, 1987) but has not received similar study in primates. The projection from the nucleus of the solitary tract to the parabrachial nucleus is very substantial both in rats and in monkeys (Beckstead *et al.*, 1980; Ricardo and Koh, 1978). The parabrachial projection to the hypothalamus is quite extensive in rats (Saper and Loewy, 1980; Fulwiler and Saper, 1984; Bester *et al.*, 1997). Evidence from experiments tracing the pathway with tritiated amino acid suggest a more restricted distribution in monkeys (Pritchard *et al.*, 2000), including dense inputs mainly to the lateral hypothalamic area, dorsomedial and ventromedial nuclei, and the preoptic area, and only light innervation of the arcuate and paraventricular nuclei. However, it is possible that more sensitive methods may demonstrate more extensive parabrachial projections to the hypothalamus in primates. For example, one recent study that used immunohistochemical staining of calcitonin gene–related protein to trace parabrachial projections to the forebrain in humans (de Lacalle and Saper, 2000) demonstrated more extensive projections to the thalamus, amygdala, and bed nucleus of the stria terminalis than were reported in monkeys. The projection from the nucleus of the solitary tract to the periaqueductal gray matter originates mostly from noradrenergic neurons in the A2 catecholamine cell group (Herbert and Saper, 1992). The periaqueductal gray matter, in turn, provides extensive projections to the nuclei of the medial hypothalamus in monkeys (Mantyh, 1983; see also Chapter 12).

Despite extensive study, no direct projection to the hypothalamus from the *auditory* system has been identified (LeDoux *et al.*, 1985). Nevertheless, it is clear that auditory information, like visual and somatic sensory input, may influence the firing of hypothalamic neurons in both rats and monkeys (Burstein *et al.*, 1987; Fisher and Almli, 1984; Oomura *et al.*, 1983; Rolls *et al.*, 1976). Many hypothalamic neurons respond best to complex sensory stimuli, suggesting that the sensory information that drives them is highly processed (Oomura *et al.*, 1983; Rolls *et al.*, 1976). It is likely, therefore, that much of the sensory information that reaches the hypothalamus travels by polysynaptic routes involving convergence of cortical sensory pathways in the amygdala, hippocampus, and cerebral cortex (Jones and Powell, 1970; Turner *et al.*, 1980; van Hoesen *et al.*, 1972).

Circuitry Supporting Hypothalamic Drive States

Homeostatic drives require both access to sensory inputs from the body, as described above, as well as *interoceptors,* or neuronal receptors that are internal to the brain. These include neurons within the hypothalamus that are especially responsive to local temperature (Boulant and Bignall, 1973; Hori *et al.,* 1986), glucose (Oomura, 1988; Shiraishi *et al.,* 1999; Lee *et al.,* 1999), osmolality (Bourque and Oliet, 1998), or sodium (Voisin *et al.,* 1999), as discussed below. In addition, the brain must have access to information about the levels of various nutrients and hormones in the bloodstream. Direct access for these molecules to the brain is prohibited by the blood–brain barrier, consisting of tight junctions between capillary endothelial cells that lack fenestrations. This arrangement prevents any hydrophilic compounds from entering the brain from the bloodstream unless they are specifically transported in. To overcome this barrier, the brain maintains a set of small "windows" on the circulation. These *circumventricular organs* are specialized neurohemal contact zones, along the borders of the ventricular system of the brain (Broadwell and Brightman, 1976; see also Chapter xx). The subfornical organ at the foramen of Monro, the organum vasculosum of the lamina terminalis at the anteroventral tip of the third ventricle, the median eminence at the midline in the floor of the tuberal hypothalamus, and the area postrema at the caudal end of the fourth ventricle all have fenestrated capillaries. Even large proteins in the bloodstream can enter the circumventricular organs, where they can interact with neurons that are just outside the blood–brain barrier (Broadwell and Brightman, 1976). Small amounts of blood-borne substances can penetrate the borders of the circumventricular organs and enter the brain for 1–2 mm, but most of the substances that gain entry are washed away in the cerebrospinal fluid. Specific homeostatic signals and their targets will be discussed below as we consider different functional systems in the hypothalamus.

Circadian rhythms in the brain are organized by the suprachiasmatic nucleus. This structure is difficult to identify in Nissl-stained sections of human brain, as it is far less prominent than it appears in rats and even in other primate brains (Moore, 1997). However, many neurons in the suprachiasmatic nucleus in rats contain vaspressin or vasoactive intestinal polypeptide, and the same peptide may be used as a marker for identifying the human suprachiasmatic nucleus as well (Stopa *et al.,* 1984; Mai *et al.,* 1991; Hofman *et al.,* 1996; Dai *et al.,* 1997).

Lesions of the suprachiasmatic nucleus result in loss of daily rhythms of wake–sleep activity, feeding, body temperature, and a variety of hormones, including melatonin and cortisol (see Moore, 1997). However, humans (e.g., shift workers) and animals (e.g., when food availability is restricted to normal sleeping hours) can entrain to activity cycles that are dictated by social or physiological necessity, rather than the light cycle. These observations suggest that, while the suprachiasmatic nucleus may be the pacemaker for circadian activity, there may be mechanisms downstream that are capable of modifying the output of the circadian clock and reorganizing activity, metabolic, and hormonal patterns.

One candidate for this function is the subparaventricular zone. In rats, the suprachiasmatic nucleus projects massively to the subparaventricular zone, which stretches from the dorsal surface of the suprachiasmatic nucleus, back into the area just ventral to the paraventricular nucleus, and caudally into the dorsomedial nucleus (Watts *et al.,* 1987). A similar pathway has been identified using postmortem tracing in human brains (Dai *et al.,* 1998). This column of tissue receives intense input from the suprachiasmatic nucleus throughout its course. Recent work in rodents suggests that lesions in the subparaventricular zone can profoundly interrupt circadian cycles of wakefulness and sleep, activity, and body temperature (Lu *et al.,* 2001). However, similar work in primates is so far lacking.

Allostatic drives are activated by perception of physiological challenges that are discrete and potentially of overwhelming importance (as opposed to the graded and often smaller challenges that constitute homeostatic challenges). McEwen (2000) defines allostatic challenges as those that produce stress, and which require change rather than return to equilibrium. Attack by a predator or competitor could be examples of allostatic challenges, but so could the presence of a potential mate. Such external allostatic challenges are detected by the classical sensory systems and identified by higher cognitive systems in the cerebral cortex. Access to the hypothalamus in primates is likely to involve cortical, amygdaloid, or hippocampal pathways.

Other allostatic challenges may be of internal origin. For example, extensive tissue injury or blood loss is sensed by visceral afferent systems. However, responses to invading microorganisms require additional sensory mechanisms. In response to a variety of immune challenges, white blood cells in various parts of the body make cytokines (see Breder and Saper, 1994). These hormones, which attract and recruit other immune system cells to battle the invader, also act on

the nervous system. Prostaglandins play a key role in this process, as inhibiting their synthesis blocks most of the CNS response to inflammation (Elmquist *et al.*, 1997). Prostaglandins made in various organs may act on local sensory branches of the vagus nerve, thus signaling the brain. In addition, circulating cytokines or other inflammatory signals may cause secretion of prostaglandins by the endothelial cells and perivascular microglia lining small venules at the borders of the brain (Laflamme *et al.*, 1999). Prostaglandins are lipids, and they can diffuse across the blood–brain barrier to activate CNS responses, which will be described below.

Autonomic and Endocrine Efferents of the Hypothalamus

The hypothalamus controls the autonomic nervous system by means of a series of both direct and relayed inputs to the parasympathetic and sympathetic preganglionic neurons in the medulla and the spinal cord. The origins of this pathway, in the paraventricular nucleus, arcuate nucleus, and lateral hypothalamic area, are described in the section on descending pathways above, as is the course of the pathway to the brain stem and the spinal cord. Oddly, the same pattern of retrograde labeling is seen in the hypothalamus from injections of retrograde tracers at virtually every spinal level in both rats and monkeys (Saper *et al.*, 1976a; Saper and Cechetto, 1988). Injections of pseudorabies virus for retrograde transneuronal labeling have demonstrated only minor variations in the pattern of retrograde labeling in the paraventricular nucleus after injections into different peripheral targets (Bamshad *et al.*, 1998; Smith *et al.*, 1998; Jansen *et al.*, 1997, 1992; Haxhiu *et al.*, 1993; Schramm *et al.*, 1993; Spencer *et al.*, 1990; Strack *et al.*, 1989). Recent studies in rats, however, have found that different patterns of hypothalamospinal neurons show Fos protein expression after specific physiological stimuli. For example, after injection of leptin, nearly all of the hypothalamospinal cells that show Fos expression are found in the arcuate nucleus (Elias *et al.*, 1998), whereas after administration of an immune stimulus such as lipopolysaccharide, nearly all of the hypothalamospinal cells that show Fos expression are in the dorsal parvicellular part of the paraventricular nucleus (Zhang *et al.*, 2000). These studies suggest that the unit of functional organization of the hypothalamic projection to the preganglionic nuclei may be functional, with neurons that participate in a specific response clustering together in one of the cell groups that constitute the hypothalamospinal system. These cells appear to project down the entire length of the sympathetic preganglionic column, specifically innervating those neurons necessary for that response at multiple spinal levels. Such a plan of organization would be consistent with widespread retrograde transport from any single organ (which can be involved to a greater or lesser degree in a wide range of physiological responses).

The neurons in the different cell groups that give rise to the hypothalamospinal pathway contain distinct peptide transmitters. The spinally projecting neurons in the paraventricular nucleus in the rat mainly contain oxytocin or vasopressin. Early immunohistochemical studies in rats found that fewer than 5% of cell bodies that project to the spinal cord stained for these peptides (Swanson and Sawchenko, 1983). However, unlike the magnocellular oxytocin and vasopressin neurons, which project to the pituitary gland but not the spinal cord (Swanson and Kuypers, 1980) (Fig. 17.8), the hypothalamospinal neurons are much smaller, and they are much less intensely stained for vasopressin or oxytocin. After colchicine administration, a much larger number of paraventriculospinal neurons stain for these peptides: about 25% of the retrogradely labeled neurons stained for oxytocin and up to 35% for vasopressin (Cechetto and Saper, 1988). Studies using *in situ* hybridization have found that about 40% of paraventriculospinal neurons contains vasopressin (Hallbeck and Blomqvist, 1999), suggesting that the immunocytochemical methods employed in most earlier studies were not adequately sensitive. Immunocytochemical studies in both rats (Teclemariam-Mesbah *et al.*, 1997; Motawei *et al.*, 1999) and monkeys (Swanson and McKellar, 1979) confirm that large numbers of oxytocin and vasopressin terminals appose sympathetic preganglionic neurons.

In contrast, many of the neurons in the arcuate nucleus that project to the spinal cord contain both proopiomelanocortin and its derivatives (such as α-melanocyte stimulating hormone (α-MSH) and β-endorphin) as well as the peptide known as CART (cocaine and amphetamine–regulated transcript) (Elias *et al.*, 1998). Early studies on the lateral hypothalamic projection to the spinal cord in rats showed that they stain with certain antisera against α-MSH (Cechetto and Saper, 1988). However, these cells did not not stain with other antisera against proopiomelanocortin derivatives, and many α-MSH antisera did not recognize them (see Saper *et al.*, 1986), suggesting that this staining represented cross-reactivity with an unidentified protein. More recently, it has been shown that many lateral hypothalamic neurons that project to the spinal cord contain either orexin/hypocretin or MCH (Bittencourt and Elias, 1998; van den Pol, 1999; Date *et al.*, 2000). A large percentage of the latter

neurons also contain CART (Broberger, 1999). The roles of these different peptides in the spinal cord have received only limited attention. Both oxytocin and vasopressin in the hypothalamospinal projection are probably excitatory (Ma and Dun, 1985; Desaulles *et al.*, 1995: Kolaj and Renaud, 1998), as is orexin/hypocretin (van den Pol, 1999).

None of these pathways has been studied in similar detail in primates. The best data are available for the oxytocin pathway, which has been described by the use of immunohistochemistry in monkeys (Swanson and McKellar, 1979). The distribution of oxytocin terminals in the intermediolateral cell column varies markedly at different levels of the thoracic and sacral spinal cord. This inhomogeneous distribution may reflect the uneven dispersion of preganglionic cell bodies along the column, or it may be due to oxytocin fibers innervating preferentially only certain functional classes of preganglionic neurons.

The hypothalamic control of the endocrine system is mediated by three main mechanisms. First, *magnocellular neuroendocrine* neurons in the paraventricular and supraoptic nuclei send their axons directly to the posterior pituitary gland, where they release these peptides from their terminals. Both types of neurons are found in both nuclei (Saper, 1990; Ishunina and Swaab, 1990; Koutcherov *et al.*, 2000) (see Fig. 17.8). In humans as in other species, the vasopressin neurons tend to cluster in the ventrolateral quadrant of the paraventricular nucleus, whereas the oxytocin neurons tend to surround this cluster and are more diffusely organized. Within the supraoptic nucleus the neurons of each type tend to cluster, but the topography of their mixing is more complex. Axons from the paraventricular nucleus run laterally, around the fornix, and then arch toward the supraoptic nucleus, with whose axons they merge on the way to the median eminence. The magnocellular axons form the hypothalamohypophysial tract, which runs in rat brain through the inner layer of the median eminence. The primate median eminence is a more complex spherical structure, with the hypothalamohypophysial axons coursing along the surface. Many additional peptides have been found to colocalize with oxytocin or vasopressin neurons in the hypothalamus of rats (Meister *et al.*, 1990), but similar data are not available for humans.

The *parvicellular neuroendocrine* neurons are those that contain peptides that are secreted into the hypothalamohypophysial portal circulation to control the anterior pituitary gland. In rats, retrograde transport studies demonstrate that these neurons are located in the periventricular zone of the hypothalamus and preoptic area (Lechan *et al.*, 1982; Swanson *et al.*, 1982). Similar studies have not been performed in other species.

Another approach has been the use of antisera for the immunohistochemical localization of the releasing hormones. The greatest amount of information is available for the rat. Each releasing factor investigated has been found within a spatially distinct population of neurons in the periventricular zone. The axons contribute to the tuberoinfundibular tract, which can be traced to the median eminence, where immunoreactive axons contact hypophysial portal vessels that carry the releasing hormones to the anterior pituitary gland. In most cases these releasing hormones are also found in other CNA pathways, where they are presumably used as neuromodulators. Thus, the pattern of immunohistochemical staining (where it can be applied in humans) does not, of itself, delineate the parvicellular neurosecretory system (i.e., those cells that secrete releasing hormones into the portal circulation). Nevertheless, this method provides the opportunity for establishing homology with other species in which connectional studies can be done.

Several releasing hormones have been localized immunohistochemically in human brains. Growth hormone–releasing hormone (GRH) has a rather limited distribution (Bloch *et al.*, 1984; Pelletier *et al.*, 1986). The only immunoreactive cell bodies seen in the human brain are in the arcuate nucleus, extending dorsally into the periventricular nucleus and laterally into the retrochiasmatic area. Occasional cells invade the borders of the ventromedial and lateral tuberal nuclei. GRH-immunoreactive fibers are seen in the periventricular region and in the neurovascular region of the median eminence.

Neurons that are immunoreactive for luteinizing hormone–releasing hormone (LHRH) are also found mainly in the hypothalamic periventricular and arcuate nuclei (Barry, 1977; Dudas *et al.*, 2000). Additional LHRH-immunoreactive cells are found extending rostrally through the periventricular preoptic area as far as the lamina terminalis and up into the septum. Other LHRH-immunoreactive cells are found extending caudally into the premammillary area and into the retromammillary region and the rostral midbrain. LHRH-immunoreactive fibers contribute to the tuberoinfundibular tract, ending on portal vessels in the median eminence, and among the capillaries of the organum vasculosum of the lamina terminalis (Barry, 1977). There is an increase in LHRH mRNA in the arcuate neurons in women who have undergone menopause (Rance and Uswandi, 1996).

Corticotropin-releasing hormone (CRH)–immunoreactive parvicellular neuroendocrine neurons are found primarily in the paraventricular nucleus in humans (Kruseman *et al.*, 1984; Mouri *et al.*, 1984; Pelletier *et al.*, 1983). The population of small CRH-immunoreactive cells is distinct from the magnocellular neurons that

secrete oxytocin and vasopressin. In rats, following adrenalectomy, some of the small CRH-immunoreactive neurons can be stained with antisera against vasopressin (Sawchenko and Swanson, 1985). It is not known if the content of these peptides is regulated in a similar fashion in humans.

In humans and other primates, somatostatin-(SOM-) and prosomatostatin-immunoreactive neurons are also found in the typical hypophysiotrophic distribution, in the arcuate and periventricular nuclei, with fibers extending into the neurohemal contact zone in the median eminence (Bennett-Clarke and Joseph, 1986; Bouras *et al.,* 1987; Filby and Gross, 1983). However, both SOM-immunoreactive cell bodies and fibers are also far more widely distributed. Immunoreactive cell bodies are found in the medial septal/diagonal band nuclei and magnocellular basal nucleus, the striatum and the bed nucleus of the stria terminalis, as well as in the amygdala, the periaqueductal gray matter, and the brain stem reticular formation (Bouras *et al.,* 1987). SOM-immunoreactive innervation is widespread throughout the basal forebrain, striatum, and brain stem tegmentum (Bouras *et al.,* 1987). Using autoradiography, SOM binding sites have been localized in most of these same sites in the human brain (Reubi *et al.,* 1986).

Dopamine also serves as a releasing hormone, inhibiting the secretion of prolactin by the anterior pituitary gland. It is possible to identify dopaminergic neurons in the human hypothalamus either by their content of melanin or by their immunoreactivity for the catecholamine synthetic enzyme tyrosine hydroxylase (Saper and Petito, 1982; Spencer *et al.,* 1985). In human brains these neurons are found in two clusters in the periventricular zone, corresponding to the A12 and A14 cell groups in rat and monkey (Saper and Petito, 1982; Spencer *et al.,* 1985). Other tyrosine hydroxylase–immunoreactive neurons are found extending more laterally into the zona incerta, possibly corresponding to the A11 catecholamine group in rats. Many immunoreactive neurons are also found in the supraoptic nucleus.

Finally, the hypothalamus also exerts influence over the endocrine system by means of autonomic innervation of the endocrine organs. For example, both sympathetic and parasympathetic innervation of the pancreas can influence secretion of insulin and glucagon (Havel *et al.,* 1994; Ahren, 2000). However, the central organization of this control system has not received much study in primates.

Behavioral Efferents of the Hypothalamus

The mechanisms by which the hypothalamus controls behavior remain among the least understood aspects of hypothalamic function. Early conceptualization of the hypothalamus containing specific behavioral "centers" that would independently elicit complex behaviors is almost certainly too simplistic (Stellar and Corbit, 1973). Rather than organizing full-blown behaviors, as one might conceive the cerebral cortex doing in a primate, the hypothalamus may more accurately be conceived as influencing behaviors by means of a range of efferent projections.

It has been tempting to assume that ascending projections to thalamus or cortex might mediate behavioral responses from the hypothalamus. Certainly the extensive projections to the cerebral cortex, reviewed above, could subserve the activation of specific behaviors. However, the cortical projections from the hypothalamus are widespread and diffusely organized, rather than being focused on specific cortical areas that might produce a discrete behavior. Even the projections from the lateral hypothalamic area, which are roughly topographic, are not organized in a way that indicates a major role in directly eliciting a specific behavior, such as feeding. Rather, the hypothalamocortical and hypothalamothalamic projections appear to be more important in regulating the level of cortical arousal and perhaps behavioral responsiveness (Risold *et al.,* 1997). This influence may be of importance in specific behaviors. For example, a hungry animal must be both awake and restless, so that it is stimulated to forage for food.

Descending hypothalamic projections to the brainstem reticular formation may play a role in facilitating specific behavioral responses. For example, a decerebrate rat, with no nervous system above the midbrain, can still chew and swallow if food is placed in its mouth (Kaplan *et al.,* 2000). The pattern generators for oropharyngeal behaviors that are associated with eating are located in the reticular areas around the cranial nerve (facial, trigeminal, hypoglossal, and ambiguus) motor nuclei that produce these movements (Travers *et al.,* 2000). By facilitating these movements and reducing the threshold for their production, the hypothalamus may be able to increase the probability of feeding, reduce its latency, and prolong its course (Stellar and Shrager, 1985).

Finally, the importance of autonomic responses in behavioral regulation cannot be overlooked. Among the most important cues for drinking is dryness of the mouth, which is due to reduced salivary outflow under hypothalamic control (Brunstrom *et al.,* 2000). Similarly, humans find that "hunger pangs," which consist of gastric motility and acid secretion, are important cues for feeding (Martyn *et al.,* 1984; Stricker and Verbalis, 1991). These sensory signals are thought to reach conscious appreciation through the pathway from the nucleus of the solitary tract to the parabrachial

nucleus to the visceral sensory thalamic nucleus and relay to the visceral sensory cortex in the insular area (Cechetto and Saper, 1987; de Lacalle and Saper, 2000). These relevant sensory stimuli may then be used by the cerebral cortex to plan specific behaviors.

While the concept that the hypothalamus mechanistically biases behavior toward specific outcomes may be less romantic and satisfying than "behavioral centers" that can produce full-blown and complex behaviors, the former view is almost certainly more accurate. There are very few studies of these problems in primates, but recent studies using functional imaging indicate that even simple behaviors in humans are supported by the activation of widespread networks of cortical and subcortical neurons (Tataranni *et al.*, 1999; Gordon *et al.*, 2000). It is unlikely that a hypothalamic "command neuron" can produce the complex sequence of responses necessary to drive specific behaviors in humans. Nevertheless, the ability of hypothalamic projections to influence behaviors ranging from seeking a warmer environment to feeding to sexual behavior is almost certainly as profound and pervasive in humans as it is in other mammalian species.

Organization of Specific Functional Systems

Feeding

The earliest view on the role of the hypothalamus in feeding came from observations of patients with Froehlich's syndrome, consisting of obesity and lack of sexual maturation (see review in Elmquist *et al.*, 1999). These patients were shown to have pituitary tumors impinging on the medial basal hypothalamus. Whereas such luminaries as Harvey Cushing thought that the disorder was due to the pituitary lesion, others argued that it only appeared when the lesions damaged the overlying hypothalamus. The issue was finally settled in studies done by Hetherington and Ranson (1939) who placed stereotaxic lesions in the medial basal hypothalamus in rats. Although the hyperphagia and obesity they produced has often been called the "ventromedial nucleus syndrome", and it has been observed in many other species, including man (Reeves and Plum, 1969), Hetherington and Ranson were careful to indicate that the region that produced the syndrome was considerably larger than the ventromedial nucleus, including the arcuate, dorsomedial, and ventral premammillary nuclei. Other studies showed that small focal lesions, primarily confined to the ventrolateral part of the ventromedial nucleus, do not cause hyperphagia or obesity (see Elmquist *et al.*, 1999, for review). However, lesions in the lateral hypothalamic area dramatically reduced feeding.

These observations can now be explained by a dramatic series of findings in the late 1990s, beginning with the identification of the gene defect in the *obese* mouse as a functional deletion of the hormone leptin (see Halaas *et al.*, 1995; Elmquist *et al.*, 1999 for reviews). Leptin is released by white adipose tissue during times of metabolic substrate availability. Absence of leptin causes profound hyperphagia, reminiscent of the ventromedial nucleus syndrome. When the distribution of the leptin receptor was mapped in the brain, neurons containing the highest levels of receptor were found to cluster in a group of nuclei that are located within about 1 mm of the median eminence, in the arcuate nucleus, dorsomedial part of the ventromedial nucleus, posterior dorsomedial nucleus, and ventral premammillary nucleus (Elmquist *et al.*, 1998), i.e., precisely the same region in which Hetherington and Ranson found the lesions cause hyperphagia and obesity.

Subsequent studies have confirmed that systemic leptin enters the CNS via the median eminence and binds in this same region (Banks *et al.*, 1996). The leptin receptor belongs to a family of cytokine receptors that use the JAK-Stat signaling system (Bjorbaek *et al.*, 1998; Hübschle *et al.*, 2001). Activation of theses receptors simultaneously causes transcription of members of the SOCS (suppressors of cytokine signaling) family. Leptin causes translocation of STAT3 to the cell nucleus and expression of SOCS-3 in cells whose receptors have been activated. It also activates expression of Fos protein in many (but not all) cells that show STAT3 or SOC-3 expression (Elias *et al.*, 1999, Hübschle *et al.*, 2001). By mapping the expression of these transcription factors after administration of intravenous leptin, it has been possible to show that leptin acts in part by stimulating neurons in the arcuate nucleus that contain both α-MSH and CART (Fig. 17.10), as well as by inhibiting neurons that contain both neuropeptide Y (NPY) and agouti-related protein (AgRP) (Fig. 17.11) (Elias *et al.*, 2000).

The α-MSH neurons are important for suppressing feeding, as demonstrated by the hyperphagia and obesity shown by animals that lack the melanocortin-4 receptor (Huszar *et al.*, 1997), for which α-MSH is the preferred agonist. Interestingly, AgRP is an antagonist at this same receptor (Fan *et al.*, 1997; Elmquist *et al.*, 1999). Animals that overexpress agouti protein, which also blocks the MC-4 receptor, are also obese. The α-MSH- and AgRP-containing neurons in the arcuate nucleus project to overlapping terminal fields in the paraventricular nucleus and the lateral hypothalamic area (Figs. 17.10–17.12), where they are believed to have mutually antagonistic effects (Elias *et al.*, 1998, 2000; Broberger *et al.*, 1998). The paraventricular nucleus is

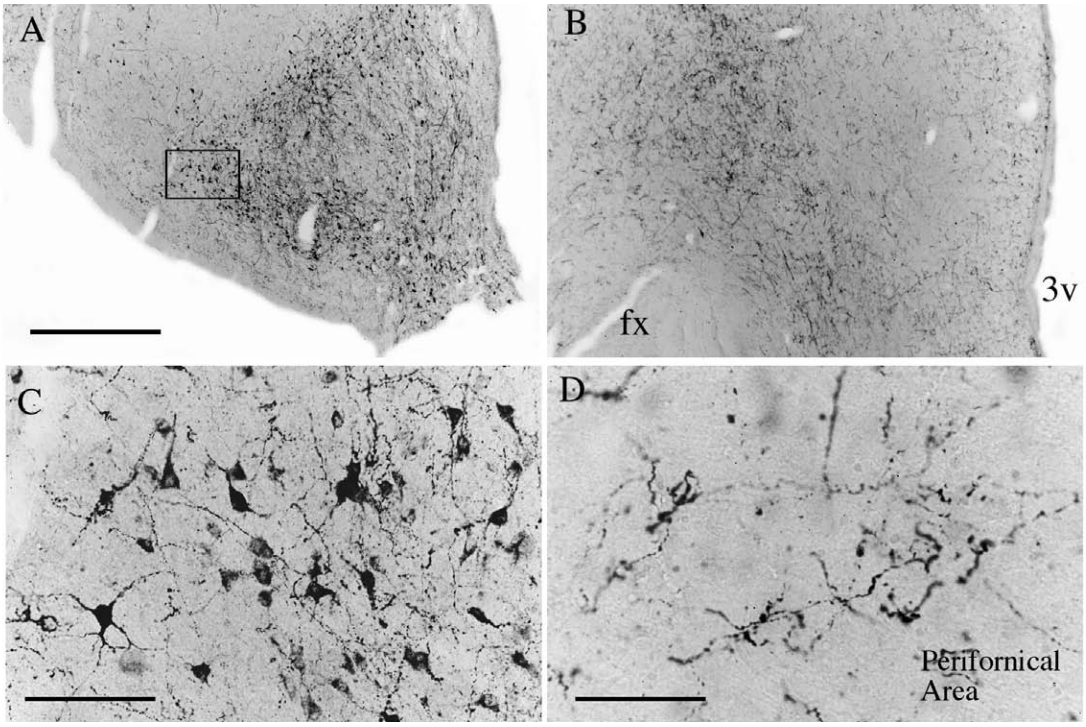

FIGURE 17.10 A series of photomicrographs illustrating α-melanocyte-stimulating hormone–immunoreactive neurons in the human hypothalamus. Note that nearly all immunoreactive cell bodies are in the arcuate nucleus and adjacent retrochiasmatic area **(A, C).** Immunreactive axons and terminals are distributed densely in the perifornical region **(B, D).** C is a higher magnification of the boxed area in panel A; D is a higher magnification of panel B. Scales = 750 μm in A and B; 100 μm in C; 50 μm in D. Modified from Elias *et al.,* 1998, with permission.

thought to be important in promoting feeding, as the injection of NPY and AgRP into it can increase feeding (Yokosuka *et al.,* 1999; Wirth and Giraudo, 2000), whereas α-MSH or CART injections decrease feeding (Wang *et al.,* 2000; Wirth *et al.,* 2001). Interestingly, transection of the vagus nerve below the diaphragm can abrogate the overeating response to ventromedial nucleus lesions (Cox and Powley, 1981). Thus, the projections from the medial basal hypothalamus through the autonomic control system are probably of great importance in the regulation of feeding.

The lateral hypothalamic area contains two separate populations of neurons that express peptides: orexin/hypocretin and melanin-concentrating hormone (MCH) (Figs. 17.9 and 17.12) (Elias *et al.,* 1998), whose transcription is increased during starvation, and decreased during food repletion or following leptin administration (Qu *et al.,* 1996; Sakurai *et al.,* 1998). Orexin/hypocretin knockout animals have minimal changes in feeding (Chemelli *et al.,* 1999). However, transgenic animals in which the orexin promoter drives the ataxin-3 gene, causing death of the orexin cells, are hypophagic but have an increased body weight (Hara *et al.,* 2001). In contrast, animals in which the MCH gene is deleted show hypophagia and decreased body weight (Shimada *et al.,* 1998). Thus, both the orexin/hypocretin and the MCH neurons, which are confined to the lateral hypothalamus, are involved in feeding and metabolism; both are also innervated by both the α-MSH/CART and the AgRP/NPY neurons in the arcuate nucleus (Fig. 17.12) (Elias *et al.,* 1998; Broberger *et al.,* 1998).

Although most of this work has been done in rats, the validity of its application to humans has been strikingly confirmed by observations showing that the same projections from the α-MSH/CART and the AgRP/NPY neurons in the arcuate nucleus project to both the orexin/hypocretin and the MCH neurons in the human hypothalamus (Figs. 17.11 and 17.12) (Elias *et al.,* 1998). The presence of the same chemically defined systems in the same relationships in the human brain provides strong evidence for the conservation of circuitry regulating feeding and body weight among mammals.

Reproduction

Evidence from the leptin system also suggests that reproductive pathways are highly conserved between

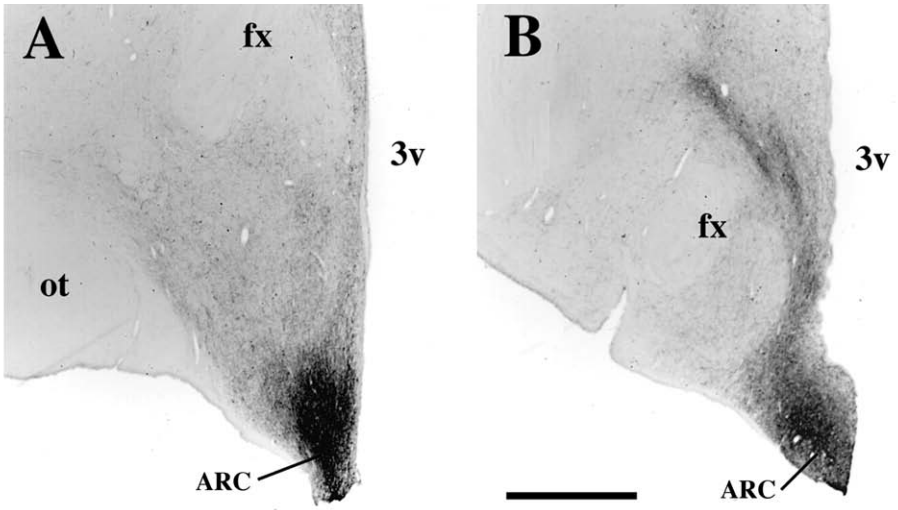

FIGURE 17.11 A pair of photomicrographs illustrating the immunostaining in the human hypothalamus with antiserum against agouti-related protein. Note the dense collection of cell bodies and fibers in the arcuate nucleus, which is the only source of this peptide in human brains. A dense bundle of fibers can be traced into the paraventricular nucleus **(A)** and the perifornical region of the lateral hypothalamus **(B).** Scale = 2 mm. Reproduced from Elias *et al.,* 1998, with permission.

humans and other mammals. Animals with absence of leptin or its receptor are both hyperphagic and hypogonadotropic, similar to the original description of Froehlich's syndrome (see Elmquist *et al.,* 1999, for review). Similarly, women who are marathon runners often have low body fat (and hence low leptin levels), which may contribute to loss of menstrual cycling (Shangold and Levine, 1982). This relationship presumably reflects the importance of adequate food supplies for reproduction. This response is thought to represent the influence of leptin-responsive neurons in the ventral premammillary, ventromedial, and arcuate nuclei on gonadotropin-releasing hormone neurons in the arcuate and periventricular regions (Rance *et al.,* 1994).

The medial preoptic nucleus in rats and other rodents contains a sexually dimorphic population of neurons, which are more prominent in males (Arendash and Gorski, 1983; Simerly *et al.,* 1986; Byne and Bleier, 1987). There is also a sexual dimorphism in monoaminergic innervation of this region rats (Simerly *et al.,* 1985, 1986). The identification of a homologous region of sexual dimorphism in the human hypothalamus has been controversial. Swaab and colleagues reported that there are about twice as many neurons in the intermediate nucleus in male compared to female human brains, and that the suprachiasmatic nucleus was more elongated in women and more spherical in men (Swaab and Fliers, 1985; Swaab *et al.,* 1985). Swaab and Hoffman later reported that the suprachiasmatic nucleus also had about twice as many neurons in homosexual as in heterosexual men (Swaab and Hofmann, 1990). However, Allen and Gorsky reported finding four interstitial nuclei of the anterior hypothalamus, or INAH groups, in human hypothalamus. Their INAH-1 corresponds to the intermediate nucleus, but they did not find any sexual dimorphism in this cell group. On the other hand, INAH-2 and INAH-3 were at least twice as large (as measured by volume) in male than in female brains (Allen *et al.,* 1989). LeVay (1991) subsequently reported finding that INAH-3 has about twice the volume in heterosexual men than women, with no difference in INAH-1 or INAH-2. In homosexual men, however, INAH-3 was the same size as in female brains. Byne (1998) confirmed that of the INAH cell groups, only INAH-3 is sexually dimorphic in both humans and rhesus monkeys. While the role of INAH-3 as a sexually dimorphic nucleus in humans seems secure, its correspondence with the sexually dimorphic preoptic nuclei in rat, which has been much more carefully studied, remains conjectural. In addition, the INAH-1 and INAH-2, each has been found to be sexually dimorphic by one group but not by two or three others. However, the age and reproductive status of the subjects may have affected the results, as may the disorders from which they eventually succumbed (as the subjects died of varying causes).

Physiological studies in rats and monkeys indicate that the sexually dimorphic medial preoptic nucleus is critical for male sexual performance (Arendash and Gorski, 1983; Lloyd and Dixson, 1988). Single cell recordings from the medial preoptic area in male and female monkeys (Oomura *et al.,* 1983; Aou *et al.,* 1988)

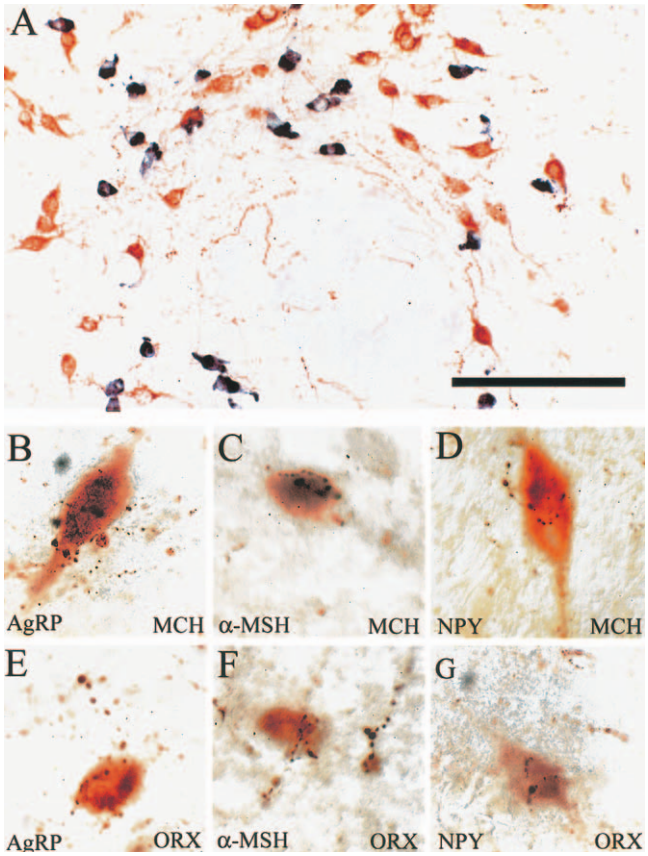

FIGURE 17.12 A series of color micrographs illustrating the melanin-concentrating hormone (MCH) and orexin (ORX) neuron systems in the hypothalamus. Panel **A** illustrates the mixing of neurons that stain with antiserum against ORX (brown) and with a digoxygenin-labeled probe for MCH mRNA (blue) in the perifornical region of a rat. Although the two types of neurons cluster closely with one another around the edge of the fornix, there is virtually no colocalization within individual neurons. Panels **B–G** illustrate the close relationship of axons that stain immunohistochemically for agouti-related protein (AgRP, panels B, E), α-melanocyte-stimulating hormone (α-MSH, panels C, F), or neuropeptide Y (NPY, panels D, G), with cell bodies in human brains that are immunoreactive for MCH (B–D) and ORX (E–G). Scale = 100 μm in A; 25 μm in panels C–G. Modified from Elias *et al.*, 1998, with permission.

have likewise shown a close relationship of neuronal firing with sexual behavior.

In rats, the medial preoptic nucleus is reciprocally connected with the ventrolateral part of the ventromedial nucleus and the ventral premammillary nucleus (Canteras *et al.*, 1992, 1994). Recordings from the ventromedial nucleus in female monkeys demonstrate that neuronal firing increases during sexual stimulation (Auo *et al.*, 1988). Lesions in the ventrolateral part of the ventromedial nucleus disrupt lordosis behavior in female rats (Pfaff and Sakuma, 1979). This response is thought to be mediated by projections from the ventromedial nucleus to the periaqueductal gray matter (Canteras *et al.*, 1994; Kow and Pfaff, 1998). There is also a high concentration of gonadotrophic steroid receptors in the preoptic area and ventromedial and arcuate nuclei in monkey and human brain, a pattern that is highly conserved across mammalian species (Pfaff *et al.*, 1976; Clancy *et al.*, 1992: Herbison *et al.*, 1995; Michael *et al.*, 1995; Choate *et al.*, 1998).

Thermoregulation and Fever

The medial preoptic region in rats and in monkeys is also enriched in neurons that respond to local brain temperature (Hardy and Boulant, 1974; Griffin and Boulant, 1995; Hori *et al.*, 1987). All neurons are temperature sensitive to some extent because the biophysical processes that account for neuronal firing increase in rate with temperature. However, a subset of preoptic and anterior hypothalamic neurons are especially warmth sensitive, increasing their firing rate more than 1 Hz for each 0.8°C of local warming. A large proportion of these warmth sensitive neurons also respond to skin temperature, lending support to their function as warmth receptive (Hardy and Boulant, 1974). Interestingly, a small proportion of preoptic neurons in intact animals is also found to be cold sensitive, increasing their firing with cooling of the local brain. However, very few such neurons are found in hypothalamic slice preparations, suggesting that this activity pattern results from axonal connections that are severed in a slice, e.g., inputs from warmth sensitive neurons that inhibit the firing of tonically active cells (Dean and Boulant, 1989).

The importance of the medial preoptic region in thermoregulation in humans is hinted at by a rare disorder, i.e., paroxysmal hypothermia (van Uitert and Plum, 1980). This disorder consists of intermittent attacks of decreased body temperature, to as low as 27°C. It typically occurs in individuals who have had a developmental lesion of the anterior wall of the third ventricle, which includes the medial preoptic region.

The mechanisms by which the preoptic neurons regulate body temperature still are poorly understood. There is evidence both in rats and in humans that medial preoptic neurons serve a thermostatic set point function. Lesions of this tissue cause loss of the fine regulation of body temperature, although crude thermoregulation, within a much broader range, is preserved (Satinoff *et al.*, 1982; Johnson *et al.*, 1990; Kubota *et al.*, 1991; Lu *et al.*, 2000). In rats, there is evidence that the descending pathways from the preoptic area that regulate thermogenesis involve projections through the ventrolateral part of the lateral hypothalamic area to the periaqueductal gray matter (Zhang *et al.*, 1997; Chen *et al.*, 1998). The periaqueductal

gray matter in turn innervates the medullary raphe nuclei (Hermann *et al.*, 1997), which have a profound effect on thermoregulation (Morrison, 1999). It is likely that a similar set of polysynaptic pathways plays a role in thermoregulation in primates, but thus far specific evidence for many of these steps is lacking.

While body temperature does not respond to heating or cooling the posterior hypothalamic area, electrical or chemical stimulation in this region can produce shivering and thermogenesis (Refinetti and Carlisle, 1986; Thornhill and Halvorson, 1994; Chou and Saper, unpublished observations). Similar studies in primates would be of great interest.

Fever is a hypothalamically mediated increase in body temperature in response to an inflammatory stimulus. Recent work, primarily in rats, shows that when a variety of immune stimuli, ranging from lipopolysaccharide to cytokines such as interleukin-1β and tumor necrosis factor-α, reach the brain, they cause endothelial cells and perivascular microglia along venules at the edges of the brain to express cyclooxygenase-2 (COX-2) (Elmquist *et al.*, 1997; Rivest *et al.*, 2000). COX is the key enzyme in the synthesis of prostaglandins, and COX-2 is the form that is produced in response to inflammatory stimuli. COX-2 synthesizes prostaglandin H_2, which is rapidly converted to prostaglandin E_2 in the same cells that express COX-2 (Yamagata *et al.*, 2001). Prostaglandin E_2 acts on EP receptors located in the preoptic area to produce a fever response (Scammell *et al.*, 1996, 1998). Recent studies in rats indicate that there are four different EP receptors, of which three (EP1, 3, and 4) are expressed in the hypothalamus (Oka *et al.*, 2000). Gene deletion studies have indicated that deletion of the EP3 receptors, but not the EP1 or EP4 receptors can prevent the production of fever with either an intravenous interleukin-1 or intracerebroventricular prostaglandin E_2 stimulus (Ushikubi *et al.*, 1998). Neurons that express the EP3 receptor cluster around the anteroventral tip of the third ventricle, in the median preoptic nucleus (Oka *et al.*, 2000; Ek *et al.*, 2000). Similarly, in monkeys there is binding of prostaglandin E_2 along the anteroventral tip of the third ventricle (Watanabe *et al.*, 1988) suggesting a similar locus for the pathogenesis of prostaglandin-mediated fever in primates.

Further experiments in rats have attempted to map the pathways involved in producing a fever response by examining the pattern of expression of the immediate early gene, Fos, after either intravenous injection of lipopolysaccharide or interleukin-1β (Ericsson *et al.*, 1994; Elmquist *et al.*, 1996). There is expression of Fos protein in the ventromedial preoptic nucleus, the paraventricular nucleus of the hypothalamus, and the nucleus of the solitary tract and ventrolateral medulla, at all time points and dosages of lipopolysaccharides that produce a fever (Elmquist *et al.*, 1996). The Fos expression in the ventromedial preoptic nucleus is colocalized with EP4 expression (Oka *et al.*, 2000). However, lesions of the ventromedial preoptic nucleus do not prevent fever responses (Lu *et al.*, 2000). In the paraventricular nucleus, Fos-positive neurons also express EP4 receptors (Oka *et al.*, 2000). In fact, there is an increase in EP4 receptor expression in the paraventricular nucleus after intravenous lipopolysaccharides (Zhang and Rivest, 1999; Oka *et al.*, 2000). Lesions of the paraventricular nucleus substantially block fever responses (Horn *et al.*, 1994; Lu *et al.*, 2000). Thus, the fever response appears to rely on a relay from the medial preoptic region to the paraventricular nucleus (Levisohn and Saper, 1983).

To identify the source of input to sympathetic preganglionic neurons during a fever, Zhang and colleagues (2000) combined retrograde transport from the sympathetic preganglionic column in the spinal cord with Fos staining after intravenous administration of lipopolysaccharides. Of the hypothalamic cell groups that were retrogradely labeled from the spinal cord, only neurons in the dorsal parvicellular subnucleus of the paraventricular nucleus were double labeled in these experiments. This same pattern of double labeling was present after injections of retrograde tracer at each level of the spinal cord. These observations suggest that the pattern generator for the sympathetic response associated with a fever may reside in a small population of paraventricular neurons that innervate multiple pools of preganglionic neurons involved in producing a fever response. Unfortunately, comparable data are not available for primates.

Sleep

Unlike many areas of neuroscience, in which discoveries made in experimental animals are applied to humans, the study of hypothalamic lesions that produce alterations of sleep was initiated by studies in humans. During World War I, there was a worldwide pandemic of a presumed viral illness that had not been reported before, and has not been seen since, known as *encephalitis lethargica*. The illness was studied closely by an Austrian physician, Baron Constantin von Economo (1930), who reported that victims with lesions of the posterior lateral hypothalamus and the adjacent midbrain would fall into a deep, sleeplike state, from which they could be transiently awakened. However, they would sleep most of the day, for up to several weeks. A second group of victims, who had lesions in the basal forebrain including the lateral preoptic area, showed the opposite response, demonstrating prolonged wakefulness or insomnia.

Subsequent lesion studies in rats (Nauta, 1946), cats (Sterman and Clemente, 1964), and monkeys (Ranson, 1939) confirmed von Economo's observations. Electrical recording studies demonstrated sleep-active neurons in the lateral preoptic area and adjacent basal forebrain (Alam *et al.*, 1995; Szymusiak *et al.*, 1998) and wake-active neurons in monoaminergic nuclei whose axons pass through the lateral hypothalamic area, including the noradrenergic locus coeruleus (Aston-Jones and Bloom, 1981; Rajkowski *et al.*, 1994), the serotonergic dorsal and median raphe nuclei (Trulson and Jacobs, 1979; Rasmussen *et al.*, 1994), and the histaminergic tuberomammillary nucleus (Steininger *et al.*, 1999). However, the exact source of neither the waking nor the sleeping influences from the hypothalamus were located until the last few years.

By studying afferents to the tuberomammillary nucleus, two different sets of hypothalamic neurons with important influences on the regulation of wakefulness and sleep were pinpointed (Sherin *et al.*, 1996). One group of neurons was located diffusely in the lateral hypothalamus. The other was clustered in the ventrolateral preoptic nucleus (VLPO). The VLPO neurons were also found to show Fos expression specifically during sleep, and about 80% of them contained both GABA and the inhibitory peptide transmitter, galanin (Sherin *et al., 1998*). Although many of the neurons with these properties were located in a dense cluster, almost half were found scattered dorsally and medially from the cluster, in a formation called the extended VLPO (Lu *et al.*, 2000). Excitotoxic amino acid lesions of the VLPO demonstrated that the loss of neurons in the VLPO cluster correlated with loss of non-REM sleep, which exceeded 70% in some animals. Loss of neurons in the extended VLPO correlated with a similar degree of loss of REM sleep. Recent observations have identified a set of sleep-active, galanin-containing neurons in the VLPO in mice, degus (a diurnal rodent), and cats (Gaus *et al.*, 2001). A homologous galanin-containing cell group has been identified in monkeys and in humans, verifying von Economo's observations.

The second source of afferents to the tuberomammillary nucleus consists mainly of orexin/hypocretin and MCH neurons (see Figs. 17.9 and 17.12) in the lateral hypothalamic area (Peyron *et al.*, 1998; Bittencourt *et al.*, 1998; Chemelli *et al.*, 1999). Although animals with MCH gene deletion do not have an obvious deficit of sleep or waking (Qu *et al.*, 1996), mice with deletion of the orexin/hypocretin gene (Chemelli *et al.*, 1999), or dogs with mutations in the orexin-2 receptor (Lin *et al.*, 1999), show a complex sleep disturbance known as narcolepsy. These individuals have sudden sleep attacks during their waking periods, in which they rapidly fall into REM sleep. They also have episodes of cataplexy, in which they show the atonia associated with REM sleep, against a waking background. Both of these traits are characteristic of humans with narcolepsy. Recent studies show that human narcoleptics have low levels of orexin/hypocretin in their spinal fluid (Nishino *et al.*, 2000), and that they lack orexin-producing neurons in the lateral hypothalamus, although MCH neurons are intact (Thannickal *et al.*, 2000) (Fig. 17.13). However, few human narcoleptics have mutations of either the orexin/hypocretin or orexin-2 receptor genes (Peyron *et al.*, 2000). Rather the loss of neurons in the lateral

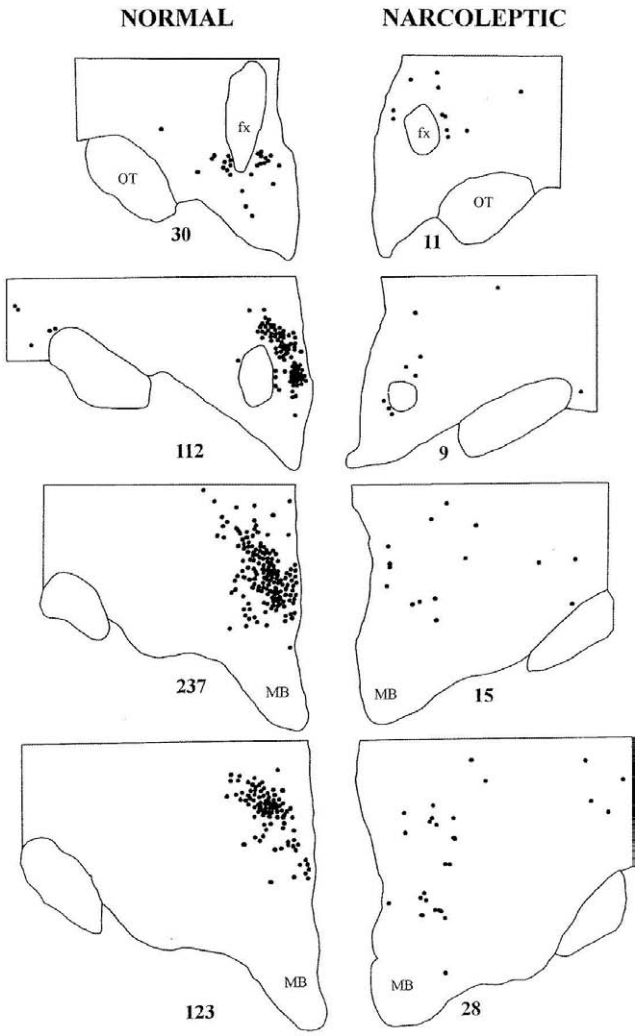

FIGURE 17.13 A series of drawings illustrating the numbers of orexin-immunoreactive neurons in a series of sections through the hypothalamus a normal individual **(left)** and in a similar series of sections through the brain of an individual with narcoleptic **(right).** Note the profound loss of orexin neurons in the narcoleptic brain. Reproduced from Thannickal *et al.*, 2000, with permission.

hypothalamus appears to be a degenerative process (occurring in the second or third decade of life).

Because both the MCH and orexin/hypocretin neurons can be identified by immunohistochemistry in normal human autopsy brains (Figs. 17.9–17.12), both the location of these neurons and many of their connections can be observed directly in humans (Elias *et al.*, 1998). The remarkable conservation of the details of this circuitry throughout the mammalian line, up to and including humans, underscores its importance. As with many hypothalamic neuronal systems that subserve basic life-supporting functions, the information available from study of animals is likely to be applicable to understanding human neuroanatomy and physiology.

The pituitary, the master gland and conductor of the endocrine orchestra, is located in the sella turcica in close approximation to several vital structures such as the brain, vessels, nerves, bone, and connective tissue. Thus, it is not surprising that pituitary lesions can cause several local symptoms which, if not properly treated, may induce irreversible tissue damage, may be life threatening, and may even lead to the demise of the patient. Pituitary abnormalities are common. Numerous lesions may arise in or spread to the sella turcica and to the pituitary gland. The most frequently occurring pituitary abnormalities are the various types of pituitary adenomas. Small adenomas can be found in approximately 20% of unselected adult autopsies.

The pituitary gland is composed of several cell types and produces several hormones, which regulate the endocrine activities of the thyroid, adrenal cortices, and gonads. Beside affecting hormone secretion of these peripheral endocrine organs, the pituitary influences practically every function in the body, including growth, water and electrolyte balance, and protein, carbohydrate, and lipid metabolism. It influences sleep, sexual activity, muscle strength, and immune functions. In pituitary-related studies unprecedented progress was achieved during the last decade. Application of modern cellular and molecular methods increased our understanding on the pathogenesis of various pituitary lesions, shed light on their progression and prognosis, and obtained a deeper insight into structure–function correlations and treatment. Although advances were spectacular, the novel findings raised many new questions that are still unresolved at present.

ANATOMY OF THE HYPOPHYSIS

Gross anatomy

The hypophysis or pituitary is a small, bean-shaped endocrine gland measuring approximately 4 × 6 × 8 mm and weighting about 500–600 mg in adults. There are no major size differences between genders in adults (Kovacs and Horvath,1986). The hypophysis is located in the sella turcica, a depression in the superior

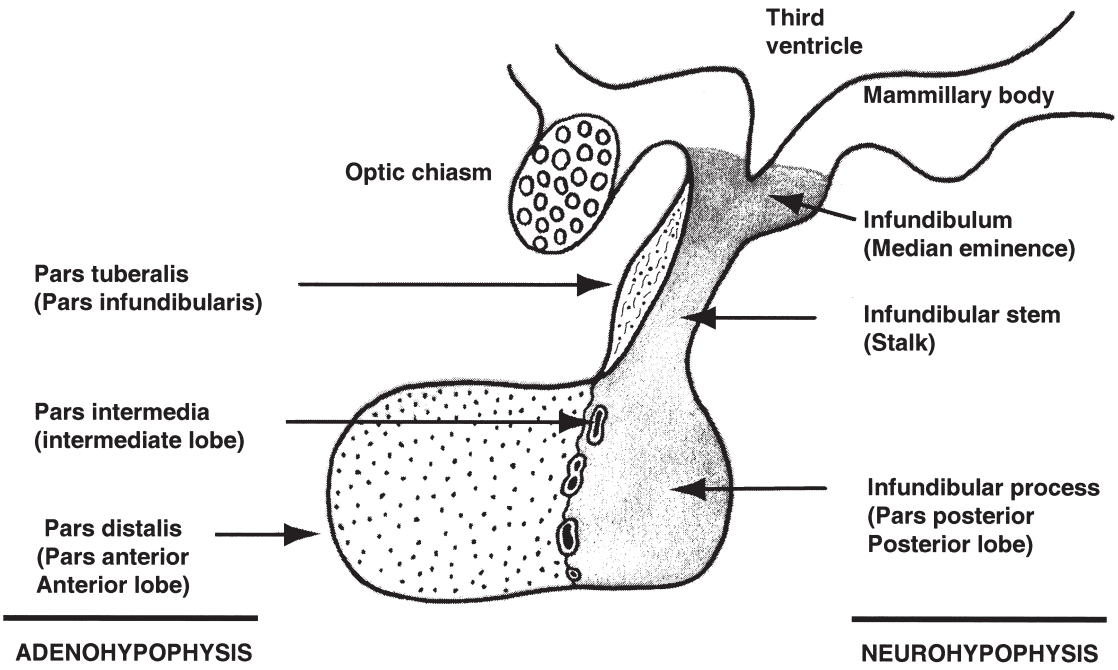

FIGURE 18.1 Diagram of the anatomical components of the hypophysis.

surface of the sphenoid bone. The gland is connected to the hypothalamus by the pituitary stalk through a small central opening of the diaphragma sellae, which forms the roof of the sella turcica. The hypophysis is in proximity to the optic chiasm and cranial nerves III, IV, V, and VI. Anatomically, the pituitary is divided into the adenohypophysis or anterior pituitary comprising approximately 80% of the gland and of the neurohypophysis or posterior pituitary. Anterior and posterior pituitaries represent two separate compartments of different embryology, anatomy, and structure. The adenohypophysis consists of three parts: the pars distalis (anterior lobe or pars glandularis), the pars intermedia (intermediate lobe), and the pars tuberalis (pars infundibularis). The adenohypophysis is of ectodermal origin and develops from an evagination of Rathke's pouch growing upward from the oral cavity. The neurohypophysis arises from the brain and also consists of three parts: the infundibulum, a funnel-shaped downgrowth projection of the tuber cinereum; the pituitary stalk; and the posterior lobe or pars nervosa (Fig. 18.1). The posterior lobe abuts the median wedge.

Blood Supply

The adenohypophysis has a highly dense and complex vascular network. The arterial supply is scarce, whereas the majority of blood reaches the parenchyma through the portal veins (Fig. 18.2). Pairs of the superior and inferior hypophysial arteries, both branches of the internal carotid arteries, enter the median eminence and form the superficial external plexus that gives rise to a network of capillaries and the gomitoli (also named internal plexus). Gomitoli are 1- to 2-mm-long arteries surrounded by a thick layer of muscle and capillaries. The internal plexus gives rise to long veins that contribute to the formation of the portal system. The long portal vessels originate in the proximal part of the hypophysial stalk and terminate in fenestrated capillaries within the pars distalis. The long portal vessels supply the adenohypophysis with 70–90% of blood and carry the hypothalamic releasing and inhibiting hormones that regulate secretion and multiplication of hormone-producing cells. The short portal vessels arise in the lower part of the stalk and in the posterior lobe. They provide the adenohypophysis the remaining 10–30% of the blood. The neurohypophysis receives arterial supply from the middle hypophysial (loral) arteries. They also provide arterial blood to the capsule of the pituitary and the superficial cells of the adenohypophysis. Given that capillaries of the pituitary are fenestrated, they lie outside the blood-brain barrier. Pituitary veins drain the blood from the pituitary to the cavernous sinus (Bergland and Page, 1978, 1979; Gorczyca and Hardy, 1987).

Innervation

Except for a few sympathetic nerve fibers along the vessels, the adenohypophysis has practically no innervation.

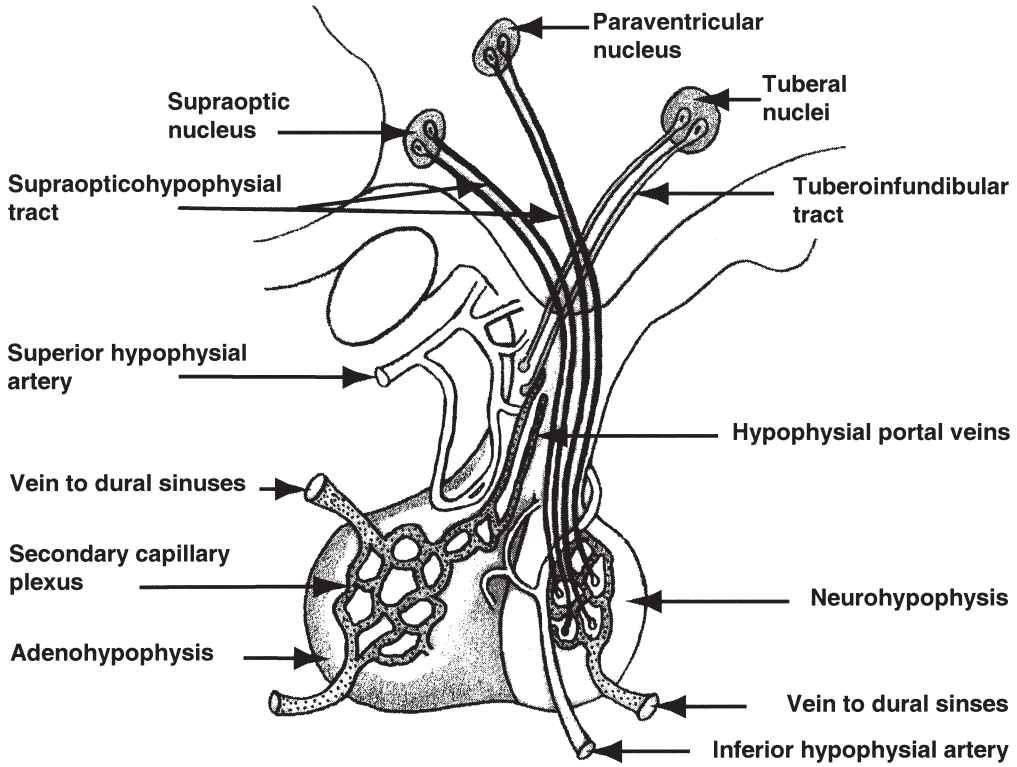

FIGURE 18.2 Diagram of the hypophysial portal system, supraopticohypophysial tract, and tuberoinfundibular tract.

IMAGING OF THE HYPOPHYSIS

Magnetic resonance images (MRI) can easily differentiate the two pituitary lobes of the hypophysis in adults. The adenohypophysis shows similar signal intensity to cerebral white matter on all pulse sequences (Fig. 18.3a, b). The fact that the hypophysis receives both arterial and venous blood can explain the different enhancement rate on dynamic scans after intravenous administration of contrast agents (Kucharczyk *et al.*, 1996). In pregnancy the adenohypophysis shows a hyperintense signal on T1-weighted images; the signal intensity ratio is positively correlated with the gestational age (Miki *et al.*, 1993). The neurohypophysis is markedly hyperintense on T1-weighted images. Both neurohypophysis and pituitary stalk show enhanced

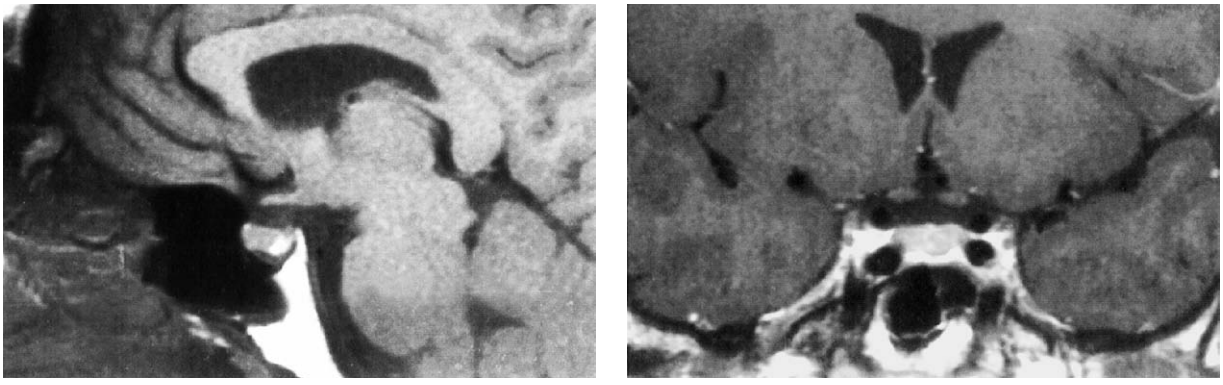

FIGURE 18.3 Midline sagittal T1-weighted **(a)** and coronal T1-weighted **(b)** MRI of the skull base of an adult. The adenohypophysis is approximately isointense to cerebral white matter whereas the neurohypophysis shows a markedly hyperintense signal.

intensity after intravenous contrast administration. Interestingly, the fetal hypophysis is hyperintense on T1-weighted MR images like the posterior lobe. In neonates the anterior lobe is brighter than in adults; 2 months later this brightness starts diminishing and by about 6 months of age becomes similar to that of adults (Kucharczyk *et al.*, 1996).

Imaging studies show that the size of pituitary gland increases progressively during fetal life. At puberty, particularly in females, the gland is significantly enlarged. During pregnancy the hypophysis enlarges and may reach 10 mm. At the immediate postpartum period the gland may measure up to 12 mm, but beyond the first week of postpartum it rapidly returns to normal size regardless the status of breast-feeding (Elster *et al.*, 1991).

HISTOLOGY

Anterior Pituitary (Adenohypophysis)

The adenohypophysis is divided by fibrous trabeculae into two lateral wings and the central mucoid wedge area, which can be seen on horizontal cross-section. The anterior lobe is composed mainly of hormone-producing cells grouped in acini delineated by a basement membrane, a delicate reticulin network, and capillaries. On hematoxylin and eosin (H&E)–stained sections, three types of cells can be distinguished: the acidophils disposed especially in the lateral wings, the basophils localized mainly in the mucoid wedge region, and the chromophobes scattered throughout the anterior lobe (Fig. 18.4). Immunocytochemistry for adenohypophysial hormones identifies five main cell types: growth hormone (GH) cells, prolactin (PRL) cells, adrenocorticotropin (ACTH) cells, thyrotropin (TSH) cells, and gonadotropin (follicle-stimulating hormone and luteinizing hormone) cells.

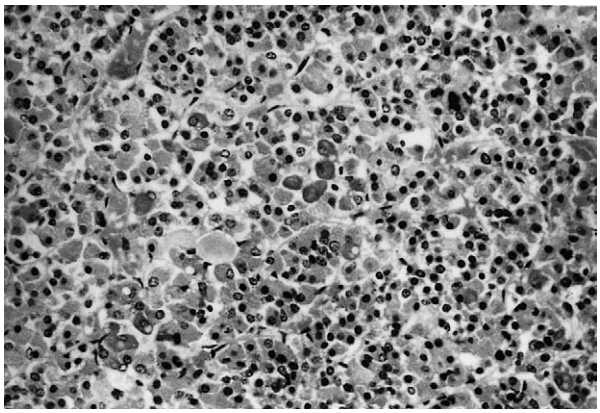

FIGURE 18.4 Hematoxylin and eosin–stained section of an autopsy pituitary shows the presence of acidophilic, basophilic, and chromophobic cells forming acini and a follicle.

GH cells or somatotrophs, situated mainly in the lateral wings, are acidophilic on H&E preparations, negative with periodic acid–Schiff (PAS) stain, and represent 40–50% of the cells (Fig. 18.5a, b). PRL cells, also called lactotrophs or mammotrophs are chromophobic or acidophilic on H&E-stained sections and PAS negative. PRL cells are distributed all over the anterior lobe, and are abundant especially in the posterolateral rim of adenohypophysis (Fig. 18.5c, d). The number of PRL cells varies in function of sex, age, parity and hormonal status (15–25%) (Asa *et al.*, 1982). Mammosomatotrophs, which are bihormonal cells that secret GH and PRL, are present in normal pituitary (Lloyd *et al.*, 1988). The increased number of mammosomatotrophs during pregnancy supports the concept of transformation of GH cells into PRL cells (Stefaneanu *et al.*, 1992). ACTH cells (corticotrophs) are located primarily in the central mucoid wedge and constitute 10–15% of adenohypophysial cells (Fig. 18.5e, f). ACTH is derived from the precursor protein proopiomelanocortin (POMC). These basophilic cells are easily identified with PAS stain. Enigmatic bodies located in the vicinity of nuclei correspond to large phagolysosomes at ultrastructural level and are useful markers of these cells. The number and size of enigmatic bodies increases with age (Sano *et al.*, 1993). The inhibited corticotrophs have a special feature in human hypophysis, the progressive accumulation of type 1 microfilaments, known as Crooke's hyalinization. The filaments are immunoreactive for cytokeratin. TSH cells (thyrotrophs), accounting for 5% of the adenohypophysial cells, are distributed preferentially in the anteromedian zone of the mucoid wedge (Fig. 18.5g, h). They are angular or polyhedral cells, stained by basic dyes. PAS stains small cytoplasmic globules corresponding ultrastructurally to phagolysosomes. They are immunoreactive for TSH-β and the α subunit of glycoprotein hormones. Gonadotropin cells (gonadotrophs) are basophilic and represent about 15–20% of adenohypophysial cells. The majority of gonadotrophs are bihormonal cells that can be demonstrated by immunocytochemistry for β subunits of follicle-stimulating hormone (FSH-β) and luteinizing hormone (LH-β) (Fig. 18.6). They are situated in the lateral wings and central mucoid wedge intermingled with other cell types and often are closely apposed to lactotrophs. The functional status of FSH/LH-immunoreactive cells is altered by age, sex, and various phases of the menstrual cycle.

Folliculo stellate (stellate) cells are nongranulated cells with a star shape due to long, thin cytoplasmic processes surrounding hormone-producing cells. S-100

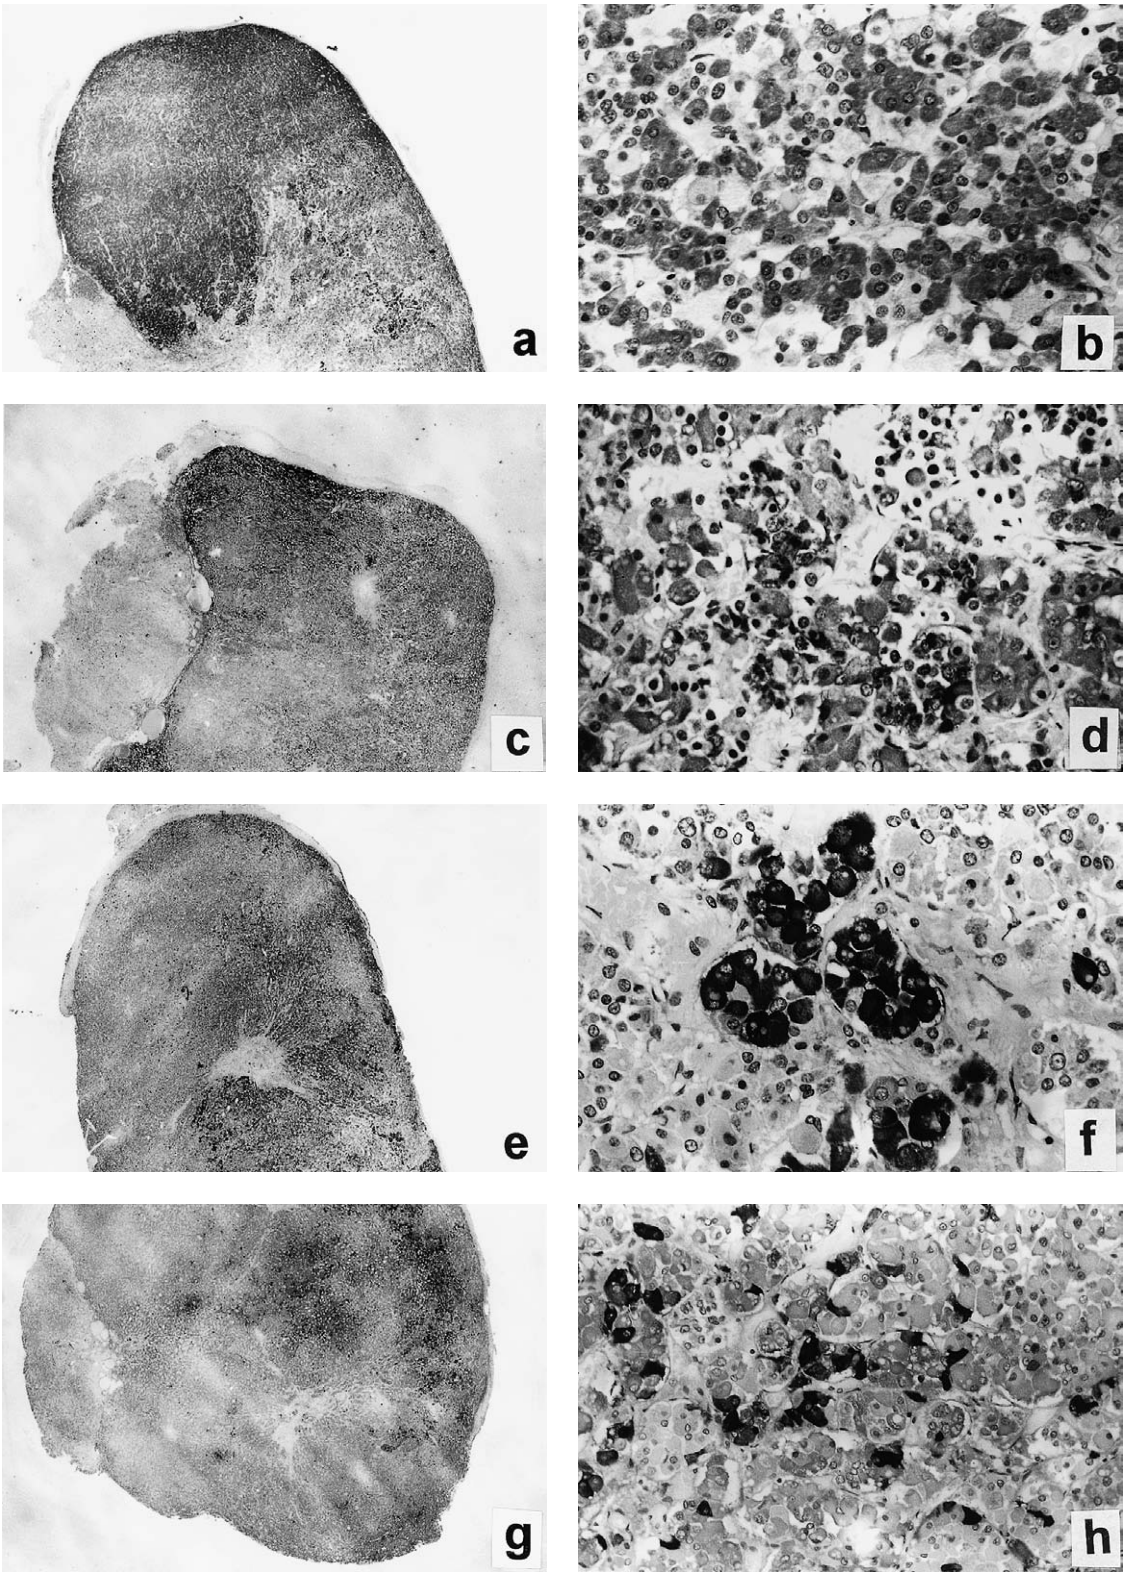

FIGURE 18.5 Horizontal cross-section of an autopsy pituitary depicts the preferential disposition of GH-immunoreactive cells in the lateral wing **(a);** GH-immunoreactive cells are middle sized with polyhedral or round contour **(b);** PRL-immunoreactive cells are distributed throughout the adenohypophysis but are especially abundant in the posterolateral wings **(c);** they are angular or polyhedral cells with the PRL immunoreactivity as a paranuclear dot or diffuse in the cytoplasm **(d);** horizontal cross-section of an autopsy pituitary shows the disposition of ACTH-immunoreactive cells in the mucoid edge **(e);** ACTH cells are polyhedral or ovoid and are often seen in cluster **(f);** TSH-immunoreactive cells are found in the mucoid edge that is shared with ACTH cells **(g);** TSH cells are angular or polyhedral with long cytoplasmic processes **(h).**

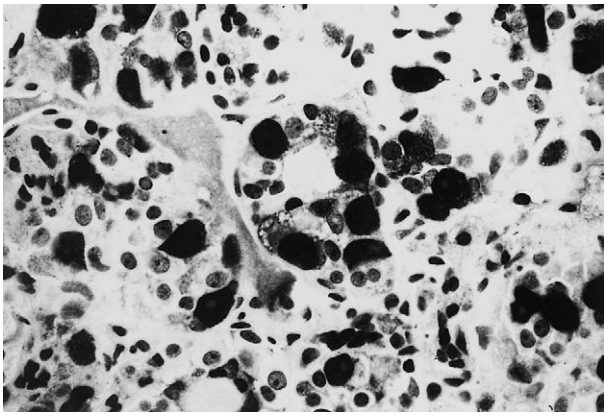

FIGURE 18.6 Gonadotrophs depicted by immunocytochemistry for LHβ are scattered throughout the adenohypophysis, and frequently participate to follicle formation.

protein is a useful immunocytochemical marker of this cell type (Fig. 18.7). It was suggested that stellate cells have phagocytic, paracrine, immune, and supporting roles (Inoue *et al.*, 1999; Marin *et al.*, 1992).

The pars intermedia (intermediate lobe) is part of the adenohypophysis located between the pars distalis and the posterior lobe. In the fetal and newborn pituitary the intermediate lobe is a distinctive structure of the pituitary, which in adults is assumed to be represented by cells scattered throughout the pars distalis (Horvath *et al.*, 1999; McNicol, 1986). They are immunoreactive for ACTH and other POMC-derived peptides. In aging people, the asymptomatic hyperplasia of these cells is more common in men than women (Horvath *et al.*, 1999). Some basophils immunoreactive for POMC peptides, and considered to represent intermediate lobe cells, extend into the posterior lobe. This process, referred to as "basophil invasion," may become prominent with age. At the border of anterior and posterior lobes, there are a variable number of heterogeneous cysts considered to be remnants of Rathke's pouch or vestigial intermediate lobe structures.

The pars tuberalis (tuberal lobe) surrounds the distal portion of the stalk, especially its anterior surface, and is covered by the arachnoid membranes. Pars tuberalis is formed by hormone-producing cells disposed along the longitudinally oriented portal vessels embedded in a loose connective tissue. The cells are immunoreactive for FSH and LH and occasionally for TSH or ACTH. Nests of squamous cells are also present.

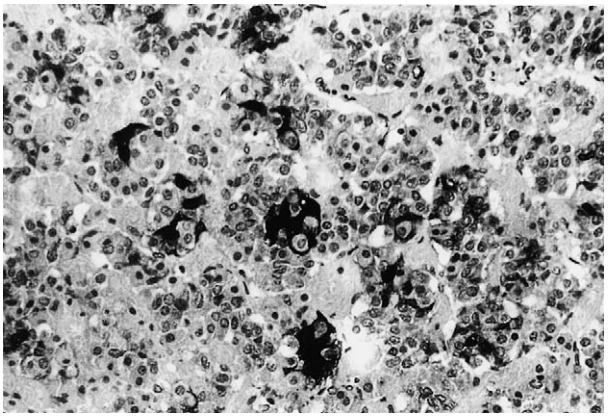

FIGURE 18.7 Folliculostellate cells demonstrated by immunocytochemistry for S-100 protein are angular with long cytoplasmic processes disposed among hormone-secreting cells.

Posterior Pituitary (Neurohypophysis)

The posterior lobe of the neurohypophysis is composed mainly of pituicytes that are glial cells with a supporting role. The pituicytes are inconspicuous on routinely stained sections and can be easily recognized by immunostaining for glial fibrillary acidic protein. These elongated cells possess long cytoplasmic processes and in aging people contain yellow brown pigment granules. Unmyelinated nerve fibers originating in the supraoptic and paraventricular nuclei of the hypothalamus are intermingled with the pituicytes and capillaries. The vasopressin (antidiuretic hormone) and oxytocin are transported by neurophysin carrier proteins along the axons and can be visualized by immunocytochemistry in the dilated axon terminals called Herring bodies.

ULTRASTRUCTURE

Somatotrophs are mostly middle-sized ovoid cells; the large polyhedral forms are less common. The rough endoplasmic reticulum (RER) occurs as slender cisternae; the Golgi apparatus is globoid and contains immature secretory granules. Most somatotrophs are densely granulated displaying an unusually wide range of granule sizes (200–1000 nm) (Horvath and Kovacs, 1988). The enormous GH cell population probably represents more subsets, which ultrastructurally overlap and blend into a virtual continuum. The most common type is ovoid with spherical, evenly electron dense secretory granules measuring up to 500 nm (Fig. 18.8). If the granule sizes are larger (exceeding 600 nm), ovoid and irregular forms and those with uneven electron density occur as well. This variant may show exocytosis (granule extrusion) suggesting mammosomatotroph differentiation. At the other end of the spectrum, immunoelectron microscopy may

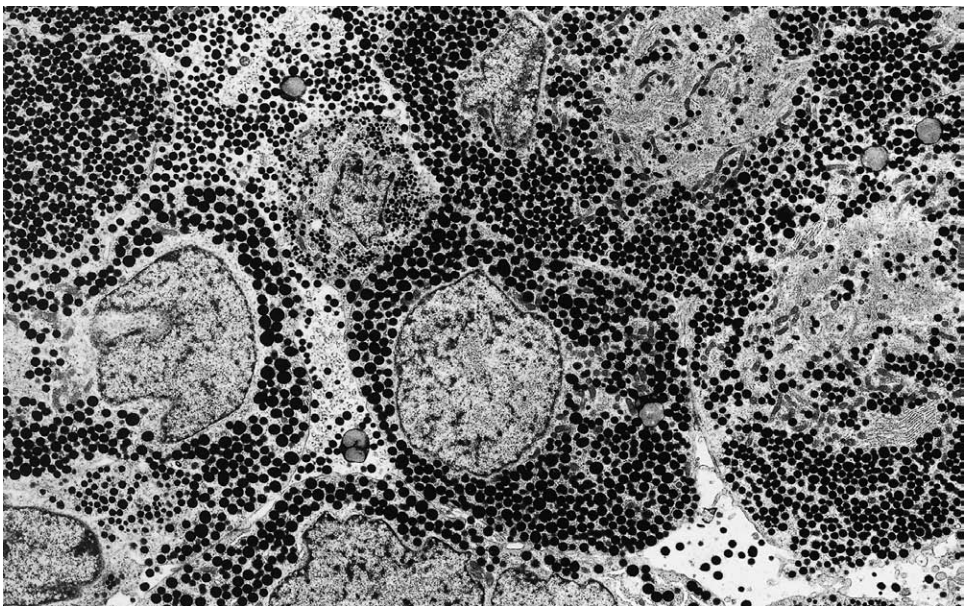

FIGURE 18.8 Ultrastructurally, the GH cells are filled with electron-dense secretory granules of 400–500 nm and well-developed Golgi apparatus; ×3800.

detect small, sparsely granulated cells possessing 100- to 200-nm GH-immunoreactive granules, further widening the range (Horvath and Kovacs, 1988). Functional stimulation or suppression of GH cells results in only subtle alterations of their ultrastructure.

Somatotrophs are assumed to represent a reserve cell type with potential for taking up hormonal functions of the other cell types (Childs, 2000). In the human gland, the best example is gestational PRL cell hyperplasia; many of the PRL-producing cells are recruited from the GH cell population (Stefaneanu *et al.*, 1992). Similar transdifferentiation occurs in cases of idiopathic or secondary PRL hyperplasia (Horvath, 1988), whereas transformation of GH cells into thyroid deficiency cells (stimulated thyrotrophs) takes place in hypothyroid subjects (Vidal *et al.*, 2000).

Lactotrophs are small to middle-sized polyhedral cells localized in the central part of acini, whereas their cytoplasmic processes extend to the basal lamina. Their cytoplasm contains parallel arrays of slender RER cisternae and juxtanuclear Golgi complex harboring spherical as well as pleomorphic (fused) granules and sparse, mostly spherical secretory granules ranging up to 300 nm (Fig. 18.9). Extrusion of secretory granules may take place along both basal and lateral cell membranes. PRL cells respond briskly to changing functional demand (Horvath and Kovacs, 1988). Stimulation results in enlargement of cytoplasm due chiefly to accumulation of RER and increased size of highly active Golgi complex containing most of the secretory granules. Functional suppression (presence of PRL cell adenoma, treatment with dopaminergic drugs) leads to dramatic shrinkage of cytoplasm owing to severe involution of RER and Golgi complex. Recently, it was shown that in GH cell hyperplasia due to ectopic overproduction of growth hormone–releasing hormone, PRL cells become bihormonal producing GH as well (Vidal *et al.*, 2001).

POMC-producing cell population of the pars distalis includes the corticotrophs as well as the more elusive, functionally yet uncharacterized pars intermedia–derived cells (Horvath *et al.*, 1999). Due to overlaps in their morphology and immunocytochemical profiles, clear distinction of these cell types is rarely possible (Horvath *et al.*, 1999).

Corticotrophs reside chiefly in the anterior two-thirds of the median wedge. The middle-sized ovoid cells have relatively electron opaque cytoplasm, moderately developed and unevenly dilated RER, fairly prominent Golgi complex, and a large heterogeneous lysosomal body. The secretory granules, ranging up to 500 nm, are not only numerous but characteristic being spherical as well as notched, irregular, and heart shaped. The other marker of the cell type is the presence of cytokeratin filaments first appearing in the perinuclear cytoplasm (Fig. 18.10) (Horvath and Kovacs, 1988).

Functional stimulation is not known to alter the ultrastructure of corticotrophs, whereas suppression (intrinsic or extrinsic hypercortisolism) results in the

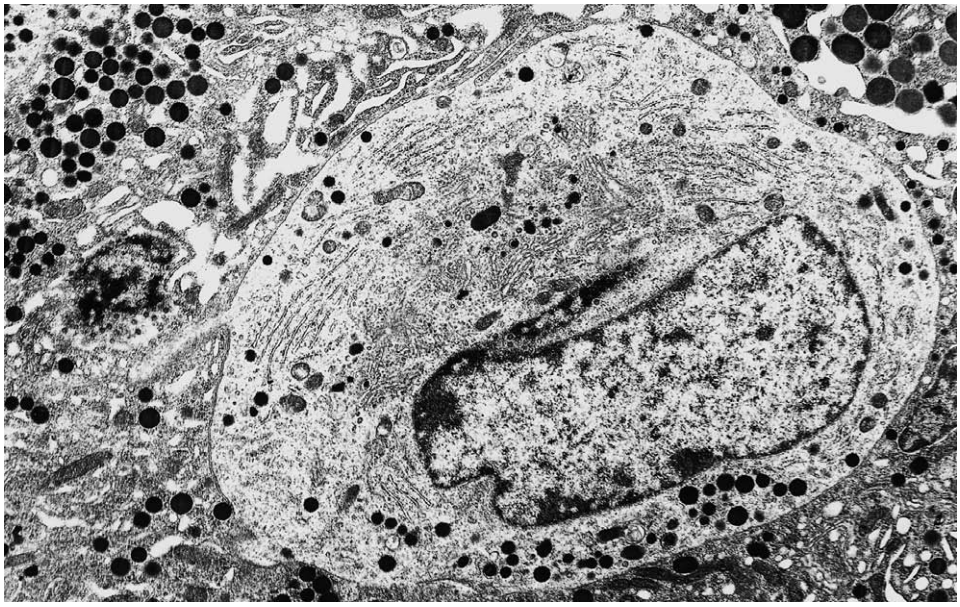

FIGURE 18.9 By electron microscopy, the PRL cells contain a few secretory granules, some seen in the process of formation inside the Golgi apparatus, and prominent rough endoplasmic reticulum in parallel arrays; ×6300.

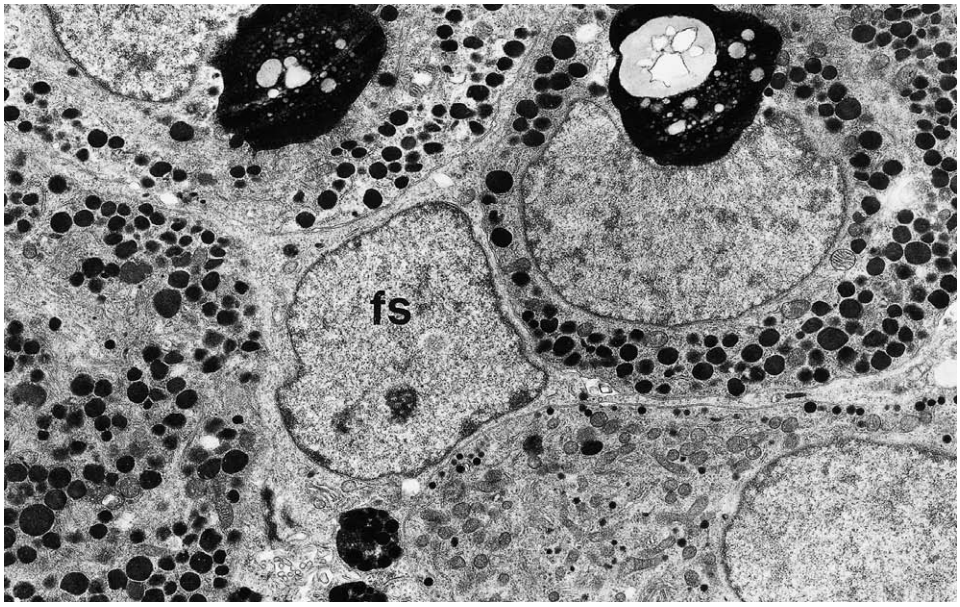

FIGURE 18.10 Ultrastructurally, the ACTH cells are easily recognized due to the presence of bundles of type 1 microfilaments and the prominent phagolysosome in the vicinity of the nucleus; the abundant secretory granules of about 500 nm have irregular contour. Note the presence of a folliculostellate cell (fs) sending slender processes among granulated cells; ×6900.

excessive accumulation of cytokeratin filaments known as Crooke's hyalinization (Fig. 18.11) (Horvath and Kovacs, 1988).

Pars intermedia–derived cells, which can be reliably identified within the posterior lobe, isolated from other adenohypophysial cell types, are morphologically indistinguishable from corticotrophs.

Thyrotrophs represent the least popular cell type and are largely restricted to the anteromedial rim of the pars distalis. The middle-sized to large, characteristically

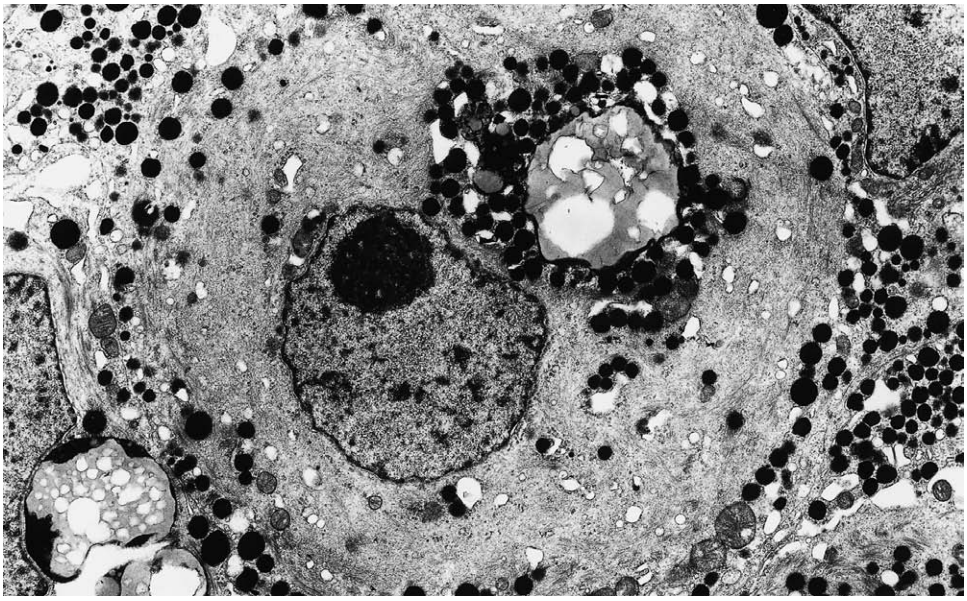

FIGURE 18.11 Ultrastructurally, the Crooke's cells are characterized by a large cytoplasm occupied by the microfilaments that push the secretory granules at the periphery; some secretory granules are engulfed by phagolysosomes; ×6900.

FIGURE 18.12 TSH cell with euchromatic nucleus, well-developed cytoplasm containing small secretory granules, prominent Golgi apparatus, and a few phagolysosomes is commonly seen; ×7800.

angular cells often lie on the basal lamina. They have a spherical nucleus with low heterochromatin content. The RER may be slightly dilated; the roughly spherical Golgi region includes numerous tiny Golgi vesicles. The well-defined secretory granules are small, ranging up to 250 nm. If sparse, they tend to form a single layer beneath the plasmalemma. Groups of heterogeneous lysosomes are often noted (Fig. 18.12).

Long standing hypothyroidism, i.e., sustained stimulation, results in hyperplasia comprising the highly characteristic thyroid deficiency cells (Vidal *et al.*, 2000). The cells possess a spherical euchromatic

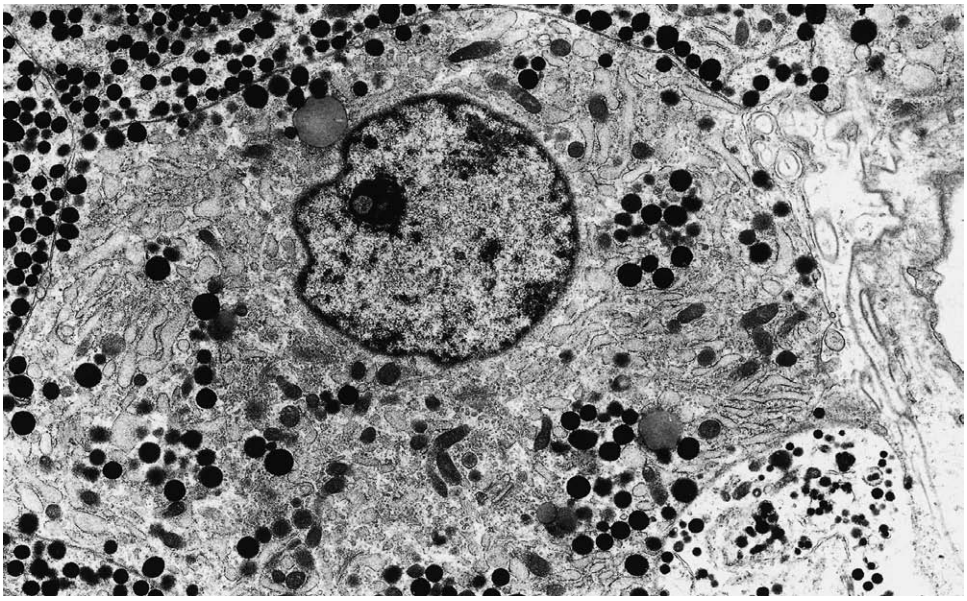

FIGURE 18.13 A gonadotroph with ovoid shape contains typical short, slightly dilated cisternae of rough endoplasmic reticulum and several secretory granules with variable electron density; ×7800.

nucleus, as well as enormous cytoplasm occupied chiefly by hyperplastic, markedly dilated RER filled with low-density proteinaceous substance. The prominent Golgi apparatus harbors few developing granules; packaging of secretory material appears to be bypassed in the highly stimulated cells. Accordingly, the number of cytoplasmic secretory granules diminishes as the hyperplastic changes progress. Thyroid deficiency cells usually harbor large, electron-dense lysosomal bodies readily noted as PAS-positive globules at the light microscopic level. In functional suppression (hyperthyroidism, presence of TSH-producing tumor) thyrotrophs become uncharacteristic: the small cells are packed with lysosomes and have few, small secretory granules and poorly developed membranous organelles.

Gonadotrophs, the cells of various sizes producing FSH and LH, are ovoid, have a large interface with the epithelial basal lamina, and are often surrounded by PRL cells (Horvath and Kovacs, 1988). Gonadotrophs have largely euchromatic spherical nucleus, slightly dilated RER with a nearly homogeneous content of low electron density, prominent ring-shaped Golgi apparatus and variable numbers of 250- to 600-nm secretory granules. The latter are spherical or slightly irregular with a variably electron dense, often uneven matrix (Fig. 18.13).

Functional stimulation (primary hypogonadism, ablation of gonads) leads to development of gonadal deficiency or castration cells (Horvath, 1988). Similar to thyroidectomy cells, castration cells display enlargement of cytoplasm and marked proliferation of dilated RER. With advancing change, the degree of dilation progresses, often leading to formation of a single large vacuole ("signet ring cell"). The number of secretory granules also decreases with time. The ultrastructure of hormonally inactive gonadotroph (seen in hypogonadotropic hypogonadism) is not sufficiently studied.

Folliculo stellate cells (FSCs), joined by terminal bars at their apical portion and projecting slender processes between hormone-producing cells, are essential parts of the acini of the human pituitary. The FSC are not demarcated by basal lamina, but they join directly the hormone-producing cells. The FSC are simple cells having unremarkable elongate nucleus, few RER membranes, small Golgi complex, fair number of mitochondria, and sometimes fine vimentin-like filaments. Lysosomal bodies may be present (Fig. 18.10). The activated form of FSC seen, for instance, in lymphocytic hypophysitis (Horvath *et al.*, 2001) is characterized by enlarged, rounded nucleus harboring prominent inclusions (spheridia), enlarged cytoplasm containing increased quantity of RER and free polyribosomes, sometimes copious amounts of filaments possibly including both vimentin and cytokeratin, variable number of lysosomes, and, less frequently, glycogen β particles.

The subfornical organ (SFO), vascular organ of the lamina terminalis (OVLT), median eminence, neurohypophysis, pineal gland, subcommissural organ, area postrema, and choroid plexus compose the circumventricular organs (CVOs) of the human brain (Fig. 19.1 and 19.2). They are a group of specialized structures within the brain, so named because they occupy strategic positions along the surface of the brain ventricles (Hofer, 1958). In lower vertebrates, a number of other structures, including the saccus vasculosus, paraventricular organ, and paraphysis, have also been classified in this grouping of CVOs but are not found in adult mammalian brain. Kuhlenbeck (1970) subdivided the mammalian CVOs into two groups, namely, paraependymal CVOs and ependymal CVOs. The paraependymal CVOs are the subfornical organ, OVLT, neurohypophysis, median eminence, pineal gland, and area postrema. They are characterized in regard to their neuroectodermal component by subependymal elements that differ considerably from the ependymal cells. The paraependymal CVOs have been further categorized by Gross and Johnson (1990) into sensory (subfornical organ, OVLT, and area postrema) and secretory circumventricular organs

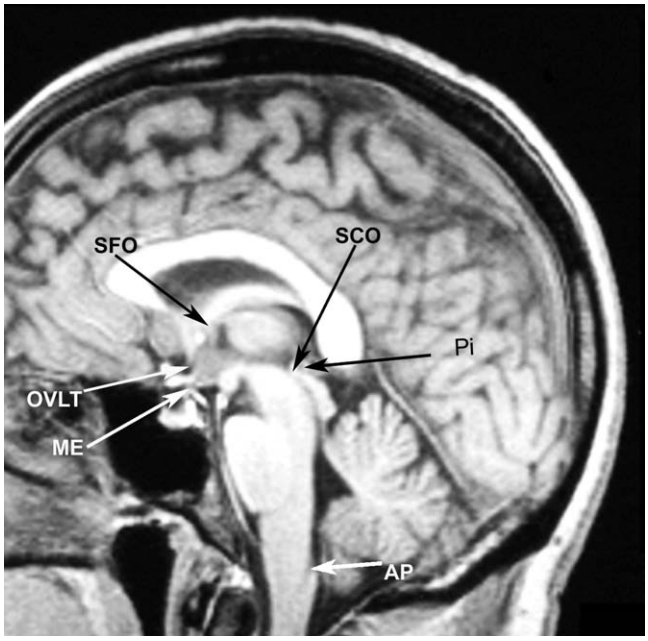

FIGURE 19.1 The position of human circumventricular organs *(arrowed)* on a midsagittal magnetic resonance image of the human brain. AP, area postrema; ME, median eminence; OVLT, vascular organ of the lamina terminalis; Pi, pineal gland; SCO, subcommissural organ; SFO, subfornical organ.

(neurohypophysis, median eminence, and pineal gland). The ependymal CVOs are the choroid plexus and subcommissural organ. They are characterized by one or more layers of ependymal cells which may be modified and vascularized.

All the CVOs of mammalian brains lie along the midline of the brain ventricular system, except for the lateral wings of the area postrema and parts of the choroid plexus, which extend to the lateral and fourth ventricles. CVOs are made up of neural, glial, and ependymal elements derived from the neuroectoderm, combined with leptomeningeal and vascular tissue of mesodermal origin. A number of morphological features characterize these structures.

1. The ependymal cells are irregular, flattened, or elongated columnar cells that contrast with the regularly apposed cuboidal cells of most of the surface of the ventricular system. In addition, they lack or have very few cilia, unlike the ciliated ependymal cells of other regions (Kuhlenbeck, 1970; Leonhardt, 1980; Weindl, 1973).
2. CVOs are highly vascularized structures with unusual vascular arrangements and capillary loops reaching almost to the ependymal surface (Duvernoy and Koritke, 1964; Hofer, 1957; Weindl, 1973).
3. With the exception of the subcommissural organ (Weindl and Joynt, 1973), the blood–brain barrier is absent due to fenestrations in the capillary endothelium of CVOs (Leonhardt, 1980; Weindl, 1973; Wislocki and Leduc, 1952).
4. Extensive perivascular spaces surround many of the capillary beds (Leonhardt, 1980; Weindl and Joynt, 1971).
5. Tight junctions between adjacent ependymal cells of these structures form a circumventricular organ–cerebrospinal fluid barrier (Krisch *et al.*, 1978; Weindl, 1973).
6. Supraependymal cells are often observed at the ventricular surface of CVOs (Brizzee and Klara, 1984; McKinley *et al.*, 1987b; Weindl, 1973).

In early studies of the CVOs, a major factor leading to their identification in animals was the feature of having an altered blood–brain barrier. It was discovered that intravitally administered colloidal dyes (e.g., trypan blue) stained such regions but not the remainder of the brain (Behnsen, 1927; Wislocki and King, 1936; Wislocki and Putnam, 1920). While the overwhelming bulk of evidence pertaining to the lack of a blood–brain barrier comes from experiments in animals, there is indirect evidence that the blood–brain barrier is also absent in human CVOs. This comes from postmortem observations that ingested silver salts, or iron pigments in hemochromatosis patients, are deposited in human CVOs but not in most other brain regions (Cammermeyer, 1947a; Landas *et al.*, 1985). Some investigators term the CVOs *neurohemal regions* because they provide an effective interface for exchange of substances between the blood "milieu" and the central nervous system (CNS). Some CVOs are sites of neurosecretion where substances synthesized in the brain can be delivered via the circulation to the periphery, e.g., median eminence, OVLT. There is also exchange of substances from the circulation to the brain in these organs, and it is likely that CVOs are sites of sensors whereby changes in the composition of the blood can be detected by the CNS. The CVOs are also receptor regions where certain humoral agents from the periphery (e.g., angiotensin II, atrial natriuretic peptide, relaxin) can act on the brain to exert centrally mediated effects (McKinley and Oldfield, 1998; Simpson, 1981; Weindl, 1973).

SUBFORNICAL ORGAN

General Characteristics and Comparative Studies

Located in the dorsal aspect of the midline anterior wall of the third ventricle, the subfornical organ is a prominent feature in coronal sections of the nonhuman

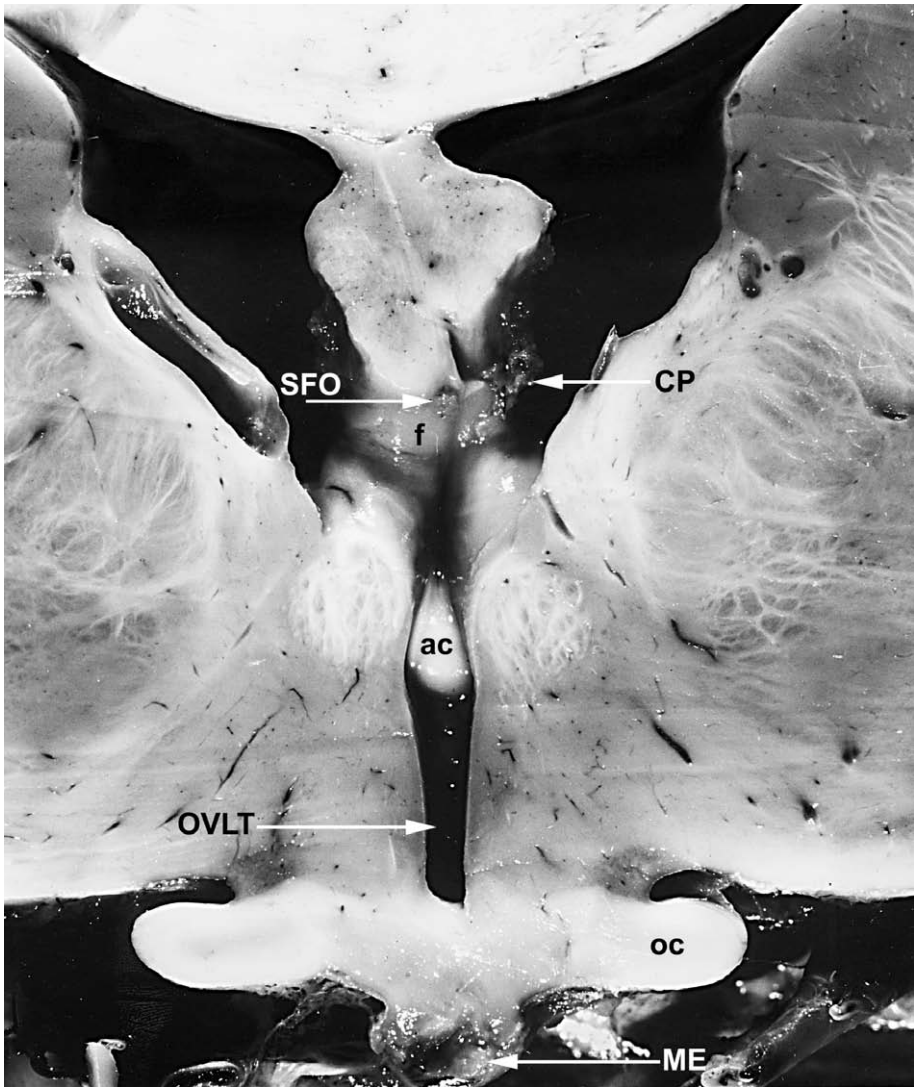

FIGURE 19.2 The position of the subfornical organ (SFO), choroid plexus of the lateral ventricle (CP), vascular organ of the lamina terminalis (OVLT) and median eminence seen in a coronally sectioned human brain. ac, anterior commissure; oc, optic chiasm.

mammalian brain at the level of the interventricular foramen. Bulging into the third ventricle at the confluence of the two interventricular foramina and ventral to the junction of the two fornical columns (Fig. 19.2 and 19.3A), this highly vascularized structure develops from the dorsal extremity of the lamina terminalis. Akert *et al*. (1961) made a comparative study of the subfornical organ that included a description of it in a primate, the squirrel monkey. They distinguished three distinct zones: the dorsal stalk, which comes in contact with the tela choroidea; the main body of the organ, which bulges into the ventricle; and a ventral stem merging into the median preoptic nucleus. Rostrally, the subfornical organ is bounded by the nucleus triangularis of the septum and hippocampal commissure. There have been many investigations into the cytological and ultrastructural characteristics of the subfornical organ of animals and these have been comprehensively reviewed (Dellman and Simpson, 1979; Dellman, 1998). In summary, four neuronal subtypes have been identified in the subfornical organ, despite earlier proposals that it lacked neuronal perikarya. Like other CVOs, glial cells are plentiful and the ependyma of the subfornical organ is modified. The ependymal cells either lack or have few cilia at their ventricular surface. Although there is considerable species variability in the appearance of the ependymal surface of the subfornical organ, and not all species have been shown to have fenestrated capillary endothelium (Weindl, 1973), a rich vascularization is

always observed. The arterial sources to the subfornical organ form a capillary network with capillary loops reaching near to the ependymal surface, especially in the central part of the organ.

Human Subfornical Organ

Location

The subfornical organ in the human brain is much less prominent than that of many species in that, relative to overall brain size, it occupies less space. Putnam (1922) gave one of the early descriptions of the human subfornical organ, or intercolumnar tubercle as he called it, describing it as a rounded, pearly gray translucent nodule bulging into the third ventricle. It is found in the midline anterior wall of the third ventricle at the level of the superior border of the interventricular foramina (of Monro) (Mai *et al.*, 1997). Being adjacent to the tela choroidea, the subfornical organ is concealed by the overhanging choroid plexus (Fig. 19.3A), but if this is retracted it can be directly viewed ventral to the point where the two columns of the fornix meet (Duvernoy and Koritke, 1969b). The human subfornical organ is more easily seen in unfixed brains, in which it retains its pearly gray translucent character, making it stand out against the white matter of the fornix (Mark and Farmer, 1984; Putnam, 1922). It is ellipsoid with a diameter of only 1 mm, which caused Mark and Farmer (1984) to describe it as "miniscule". It has been observed at gestational week 16 and does not reach full structural and cytological development until the neonatal period (Castaneyra-Perdomo *et al.*, 1992).

Cellular Elements

The subfornical organ in humans (Fig. 19.3B) comprises a loose fibrillary network containing many neurons and glial cells (Castaneyra-Perdomo *et al.*, 1992; Mark and Farmer, 1984; Putnam, 1922). Typical neuronal perikarya of this structure are large and triangular, having round or ovoid nuclei with an eccentrically placed nucleolus. The cytoplasm stains faintly for Nissl. The ultrastructure of cells in the subfornical organ of the human has been examined by Mark and Farmer (1984). Many unmyelinated axons and dendrites are present and axodendritic and axosomatic synapses are plentiful, with presynaptic clear vesicles of 20–45 nm diameter and occasional larger granulated vesicles (80–150 nm). Nonsynaptic axonal dilatations are also noted to contain dense core granules of 100–175 nm.

The ependyma of the human subfornical organ is modified into flattened, squamous cells (Kuhlenbeck, 1955), and this can be seen in Fig. 19.3B. Astrocytes are numerous throughout the subfornical organ, particularly near blood vessels. Fewer oligodendrocytes and microglia are present. Channels lined by ciliated ependymal cells with microvilli have also been observed to infiltrate this organ (Mark and Farmer, 1984).

Vasculature

Branches of the anterior cerebral artery and posterior choroidal artery anastomose to form the capillary network of the subfornical organ. The network is particularly dense in the central part of the organ where groups of capillary loops extend toward the ependyma, coming close to the ventricular surface (Duvernoy and Koritke, 1964; Putnam, 1922). These capillaries exhibit extensive perivascular spaces and drain laterally into a wide vein on each side of the fornix, which eventually leads to the great cerebral vein. Arterioles in the subfornical organ of the human exhibit thick smooth muscle sheaths (Weindl, 1973). Some authors report vascular connections with the adjacent choroid plexus in certain species (Duvernoy and Koritke, 1964; Krisch and Leonhardt, 1980); however, this is not so in the human subfornical organ (Duvernoy and Koritke, 1969b; Putnam, 1922).

Neural Connectivity

Afferent Connections

The subfornical organ has both afferent and efferent neural projections and they are summarized in Table 19.1. The earliest indication of the nature of these projections came from the studies of Lewis and Shute (1967), who demonstrated in the rat that, acetylcholinesterase-containing fibers originating in the septum entered the subfornical organ. Many of the subsequent studies of its connections have involved experimental procedures, including placement of lesions with degeneration and silver impregnation techniques, axonal transport of tracers, and electrophysiological manipulations. Therefore, the most detailed information has necessarily arisen from experimental animals rather than postmortem human material. Hernesniemi *et al.* (1972) used lesion techniques as well as Golgi methods to study neural afferents to the subfornical organ, and found projections from the nucleus triangularis (of the septum) and the median preoptic nucleus. This projection from the median preoptic nucleus to the subfornical organ has subsequently been confirmed by both anterograde and retrograde transport of injected horseradish peroxidase into the subfornical organ (Lind *et al.*, 1982) and the median preoptic nucleus (Oldfield *et al.*, 1986), respectively. Other afferents to the subfornical organ arise from the medial septal nucleus, the OVLT, the medial preoptic area, hypothalamic para-

ventricular nucleus, anterior hypothalamus, and thalamic nuclei, including the paraventricular nucleus of the thalamus and the reuniens nucleus (Lind *et al.*, 1982). Of these, the projections from the perifornical region of the lateral hypothalamus as well as the rostral zona incerta and thalamic reuniens nucleus utilize angiotensin II and enter the organ via the columns of the fornix or along the lamina terminalis (Lind *et al.*, 1984; Tanaka *et al.*, 1986).

Efferent Connections

The efferent neural pathways of the subfornical organ have been well documented by anatomical (Lind *et al.*, 1982, 1984; Miselis, 1981; Miselis *et al.*, 1979; Saper and Levisohn, 1983; Swanson and Lind, 1986) and electrophysiological (Sgro *et al.*, 1984; Ferguson, 1997; Tanaka *et al.*, 1986) techniques, and there is generally close agreement on the trajectory of fibers and the areas innervated. Fibers emanating from the subfornical organ essentially take either of two courses. The first is a precommissural pathway and involves fibers that leave the organ via its ventral stalk and travel toward the median preoptic nucleus passing rostral to the anterior commissure. A few fibers split off at this point to innervate the medial preoptic area, whereas the major bundle continues to the OVLT,

suprachiasmatic nucleus, and supraoptic nucleus. The neurons giving rise to these fibers are found mainly around the periphery of the subfornical organ, while a group of neurons in the core of the subfornical organ sends a prominent efferent projection to the bed nucleus of the stria terminalis (Swanson and Lind, 1986).

The postcommissural pathway, on the other hand, travels with the columns of the fornix and the medial corticohypothalamic tract to innervate areas in the hypothalamus, including the paraventricular nucleus. Electrophysiological studies have indicated that efferents from the subfornical organ to the paraventricular and supraoptic nuclei change the excitability of vasopressin and oxytocin neurons projecting to the neurohypophysis (Ferguson *et al.*, 1984a; Sgro *et al.*, 1984) and, in the case of the paraventricular nucleus, vasopressin-containing neurons projecting to the dorsomedial medulla (Ferguson *et al.*, 1984b). More recent studies combining neural pathway tracing with immunohistochemical identification of Fos (the protein encoded by the immediate early gene *c-fos*, which is a marker of increased neuronal activity) in the rat show that neurons in the periphery of the subfornical organ that project to the supraoptic and paraventricular nuclei can be activated by hypertonicity or the circulating hormones angiotensin II and relaxin (Larsen and Mikkelsen, 1995; Oldfield *et al.*, 1994; Sunn *et al.*, 2001). Other regions found to be innervated by the subfornical organ were the infralimbic area of the prefrontal cortex, septal region, substantia innominata, zona incerta, and lateral hypothalamus (Swanson and Lind, 1986).

Tracing studies in the rat, which utilized injections of the neurotropic virus pseudorabies into peripheral sites, have shown that there are polysynaptic neural pathways from the subfornical organ and other parts of the lamina terminalis to many peripheral organs and tissues (Hubschle *et al.*, 1998; Sly *et al.*, 1999; Westerhaus and Loewy, 1999). These data indicate that neurons in the subfornical organ may influence sympathetic nerves supplying many peripheral organs, being an integral part of a visceral neuraxis as proposed by Miselis *et al.* (1987).

Function

As previously mentioned, experimental evidence of passage of intravenously administered horseradish peroxidase or intravitally administered dyes (Broadwell and Brightman, 1976; Weindl, 1973; Wislocki and Leduc, 1952) into the subfornical organ suggests that there is an altered permeability of the blood–brain barrier at this site. Such permeability of the vasculature to circulating agents provides the basis for its function as a site of receptors (AT_1 receptors) for circulating angiotensin II (Giles *et al.*, 1999). This octapeptide, which does not cross the blood–brain barrier (Ganten *et al.*, 1976), should be able to gain access to the subfornical organ from the circulation, and increased neuronal activity (shown by *c-fos* expression) occurs in neurons of the rat subfornical organ following intravenous infusion of angiotensin II (McKinley *et al.*, 1992). Physiological studies in animals have established that the subfornical organ is a site of receptors which are stimulated by circulating angiotensin II to induce water drinking, vasopressin secretion, and a centrally mediated pressor response (Simpson *et al.*, 1978, 1981). Consistent with these physiological findings is autoradiographic evidence of high-affinity binding of radiolabeled angiotensin II to the subfornical organ in animals and humans (Fig. 19.4D) (Allen *et al.*, 2000; McKinley *et al.*, 1987a; Mendelsohn *et al.*, 1984; Speth *et al.*, 1985), and both immunohistochemical and *in situ* hybridization histochemical evidence of high concentrations of angiotensin AT_1 receptors in the subfornical organ of the rat (Giles *et al.*, 1999; Lenkei *et al.*, 1997). In regard to angiotensin, significant levels of angiotensin-converting enzyme (ACE) are found in the human subfornical organ (Chai *et al.*, 1990), suggesting that local generation of angiotensin II within the subfornical organ may be of importance. Consistent with this notion is evidence in rats that circulating ACE inhibitors such as captopril or enalapril, at concentrations that are effective at inhibiting peripheral conversion of angiotensin I to angiotensin II, are ineffective in the subfornical organ. As a consequence, high levels of blood-borne angiotensin I reach the subfornical organ and are there converted to angiotensin II. This results in the activation of neurons in this CVO and stimulation of thirst (McKinley *et al.*, 1997). Binding sites in the subfornical organ of rats for other circulating hormones, such as somatostatin, atrial natriuretic peptide, calcitonin, and relaxin (Osheroff and Phillips 1991; Patel *et al.*, 1986; Quirion *et al.*, 1984; Rouleau *et al.*, 1984), have also been demonstrated, suggesting that angiotensin II may not be the only blood-borne agent acting at this site. Relaxin, a hormone secreted during pregnancy, directly stimulates neurons of the subfornical organ (Sunn *et al.*, 2001). Nitric oxide synthase (NOS) is also abundant in the rat subfornical organ, and NO donors depress the activity of the subfornical organ (Rauch *et al.*, 1997). In addition to being a receptor zone, morphological evidence suggests that hormones such as luteinizing hormone–releasing hormone (LHRH), somatostatin, or angiotensin II (of central origin) may be released by neurosecretion into the bloodstream by the subfornical organ (Krisch and Leonhardt, 1980; Lind *et al.*, 1985; Oldfield and McKinley, 1989).

VASCULAR ORGAN OF THE LAMINA TERMINALIS

General Characteristics and Comparative Studies

Situated in the anterior wall of the third ventricle between the optic chiasm and anterior commissure is another CVO, the vascular organ of the lamina terminalis or OVLT (an abbreviation derived from its Latin designation *organon vasculosum laminae terminalis*). Other terms that have been used for the OVLT are supraoptic crest, preoptic organ, medial (vascular) prechiasmatic gland, and Sclussplattenorgan (terminal plate organ). This region, initially described by Behnsen (1927) and then by Wislocki and King (1936) on the basis of its selective permeability to intravitally administered trypan blue, has been observed in many vertebrate species of fish, reptiles, birds, and mammals (McKinley *et al.*, 1987b; Weindl, 1973; Wenger and Tork, 1968).

While there is considerable variation between species in the morphology of the ependymal cells and

in the proportion of the lamina terminalis ventral to the anterior commissure that is occupied by the OVLT (McKinley *et al.*, 1987b), the general structural elements of the OVLT are quite similar throughout vertebrates (Wenger and Tork, 1968). Situated in the lamina terminalis immediately dorsal to the optic chiasm, the OVLT is characterized by a special vascular arrangement. This CVO separates two cerebrospinal fluid–containing spaces, the prechiasmatic cisterna rostrally and the optic recess of the third ventricle caudally, and has characteristics somewhat reminiscent of the median eminence, particularly the rich intrapial plexus of blood vessels of the OVLT which gives rise to a network of capillary loops with fenestrated endothelial cells and extensive perivascular spaces (Duvernoy and Koritke, 1964; Hofer, 1957; Wenger and Aros, 1971). While the precise functions of the OVLT have yet to be fully elucidated, the similarity in organization of this region to the median eminence has led several authors to suggest a neurosecretory role for the OVLT (Weindl, 1973), particularly in the release of LHRH (Wenger *et al.*, 1981).

Recent studies in a number of species have suggested that OVLT has (1) a sensor role as an osmoreceptor (McKinley *et al.*, 1982; Oldfield *et al.*, 1994; Thrasher and Keil, 1987), (2) a role as a mediator of the febrile (fever) response (Blatteis *et al.*, 1983, 1987), and (3) a receptor role for blood-borne angiotensin II and relaxin to stimulate the CNS (Johnson, 1985; McKinley *et al.*, 1992, 1997; Giles *et al.*, 1999).

Human OVLT

Location and Structural Organization

In humans, the OVLT is at its greatest extent in the lamina terminalis approximately midway between the optic chiasma and anterior commissure (Fig. 19.3A). Kuhlenbeck (1954) first described the human OVLT as a slight thickening in the lamina terminalis. He divided it into two zones, an outer one situated beneath the pia mater lining the prechiasmatic cisterna and an inner zone reaching to the ependymal lining of the optic recess of the third ventricle (Fig. 19.3C). He observed in the superficial lamina of the external zone a rich vascular plexus of sinusoidal vessels. Deeper to this lamina are the cellular elements of the external zone, while in the inner zone densely packed cells and a network of fibers running at right angles abutted the modified ependymal surface (Kuhlenbeck, 1970). Like other CVOs, the ependymal cells of the OVLT are flattened and have few, if any, cilia. Channels or canals lined by ependymal cells extending into the body of the OVLT have been reported (Wenger and Torö, 1971), and these also occur in the subfornical organ (Mark and Farmer, 1984).

Vasculature

Duvernoy *et al.* (1969) made a detailed study of the vascular architecture of the human OVLT and found that it received its arterial supply from four sources: (1) a superior median source branching from the anterior communicating artery, (2) and (3) two lateral sources coming from arteries which branch off from each anterior cerebral artery below the anterior communicating artery, and (4) an inferior median source ascending from below the optic chiasm (Fig. 19.5A). These sources anastomose and branches twig off to enter the pia mater and supply a dense superficial capillary network in the external zone of the OVLT. From this superficial network, a secondary deep capillary network extends into the body of the OVLT in the form of sinusoidal capillary loops and coils (Fig. 19.5B). This deep network, which drains the superficial capillary network, is denser in the inferior zone of the OVLT. There many anastomoses unite the capillary loops of the deep network (Fig. 19.5C). The venous drainage of the deep network is in a lateral direction to veins coming from adjacent hypothalamus and proceeding to the anterior cerebral veins (Duvernoy *et al.*, 1969).

Extensive perivascular spaces of 0.1–0.3 μm width may surround the blood vessels of the rich vascular network that extends from the pia mater into the organ. Unlike other species, fenestrations in the capillary endothelial cells have not been observed in the human OVLT (Wenger and Torö, 1971). However, reports of selective entry into the OVLT and other CVOs of endogenous iron deposits observed postmortem in cases of hemochromatosis (Cammermeyer, 1947a) and entry of imbibed silver (for cosmetic purposes) into the OVLT (Landas *et al.*, 1985) suggest altered blood–brain barrier characteristics in the human OVLT. The junctional complexes joining ependymal cells have not been studied.

Cellular Elements

With regard to its cellular elements, many glial cells can be seen in the deeper layer of the external zone. Neither Kuhlenbeck (1968) nor Wenger and Torö (1971) were able to discern neuronal cell bodies in the human OVLT; however, Landas and Phillips (1987) report the presence of small "primitive neurons" in the OVLT of humans analogous to those observed in the rabbit, the so–called parenchymal cells (Weindl *et al.*, 1968).

Neural Connectivity

Afferent Connections

Based on the few studies in experimental animals (e.g., rat, sheep) utilizing the axonal transport of marker molecules such as tritiated amino acids and horseradish peroxidase, which have investigated the neural connectivity of the OVLT (summarized in Table 19.2), this CVO appears to be part of a neural network within the lamina terminalis and hypothalamus that is involved in the regulation of fluid balance (McKinley *et al.*, 1996, 1999; Miselis, 1981; Thrasher and Keil, 1987). The major afferent inputs to the OVLT appear to come from the subfornical organ (Camacho and Phillips, 1981; Miselis, 1981), locus coeruleus, central gray, medial preoptic, median preoptic, lateral preoptic, and anterior, lateral, dorsomedial, and ventromedial hypothalamic nuclei (Camacho and Phillips, 1981; Palkovits *et al.*, 1978; ter Horst and Luiten, 1986).

Efferent Connections

The efferent fibers emanating from neurons within the OVLT have not been studied in detail; however, it is clear from studies in the rat that there are strong projections to the median preoptic nucleus immediately dorsal to the OVLT and to the supraoptic nucleus (Camacho and Phillips, 1981; Gu and Simerly, 1997; Miselis, 1981; Oldfield *et al.*, 1986; Saper and Levisohn, 1983; Sunn *et al.*, 2001). Camacho and Phillips (1981) have suggested that the strong projection from the OVLT to the adjacent lateral preoptic region may be of more significance than the aforementioned pathways. Using anterogradely transported tritiated amino acids or horseradish peroxidase that had been microinjected into the OVLT of the rat, they also described projections to the limbic system via fibers that travel to the septum and spread out to continue to the hippocampus and cingulate cortex. Some terminate there in the dentate gyrus; however, these connections have yet to be confirmed by experiments using retrogradely transported neural tracers injected into these regions. There are also efferent projections to both magnocellular and parvocellular parts of the hypothalamic paraventricular nucleus (Sunn *et al.*, 2001) and also to the lateral hypothalamic region, lateral septal nucleus, parastrial nucleus of the preoptic region, bed nucleus of the stria terminalis, periaqueductal gray, and lateral parabrachial nucleus (Gu and Simerly, 1997; Uschakov *et al.*, 2001). Transneuronal viral tracing studies show that neurons in the OVLT may also be connected

polysynaptically to the autonomic nervous system (Hubschle *et al.*, 1998; Sly *et al.*, 1999; Westerhaus and Loewy, 1999).

Functions

Studies in animal species have suggested that the OVLT is of importance as a neurohemal neurosecretory and/or receptor zone. There are very few functional investigations in humans, although LHRH has been detected in the human OVLT (Okon and Koch, 1977). Consistent with neurosecretion into the bloodstream are reports that LHRH, angiotensin II–, somatostatin–, and atrial natriuretic peptide–immunoreactive fibers terminate in the OVLT (Barry and Carette, 1975; Kawata *et al.*, 1985; Lind *et al.*, 1985; Zimmerman and Antunes, 1976), and that there are dense core vesicles in nerve endings near perivascular spaces (Weindl and Schinko, 1975). Using *in vitro* autoradiography, we have observed dense binding of radioiodinated analogs of angiotensin II to the human OVLT (Fig. 19.4C) (Allen *et al.*, 2000; McKinley *et al.*, 1987a). This is similar to findings in animal species showing high concentrations of angiotensin AT_1 receptors in the OVLT (Allen *et al.*, 2000; McKinley *et al.*, 1986; Mendelsohn *et al.*, 1984; Speth *et al.*, 1985) and is consistent with the notion that the OVLT is a site at which blood-borne angiotensin II may act on the CNS to influence the regulation of fluid balance and arterial blood pressure (Camacho and Phillips, 1981; Johnson, 1985; McKinley *et al.*, 1992). Very high levels of ACE are observed in the human OVLT (Chai *et al.*, 1989), indicating that local generation of angiotensin II may occur there.

Experimental studies in animals using lesioning techniques, electrophysiology, and immunohistochemical identification of Fos show that the OVLT is a major osmoreceptor site for vasopressin secretion and thirst (McKinley *et al.*, 1988, 1994; Oldfield *et al.*, 1994; Richard and Bourque, 1993; Thrasher and Ramsay, 1987). Lack of thirst in some rare conditions reported in humans with either surgical damage, tumors, or cysts in the region of the OVLT (Robertson, 1991) is consistent with this view. The OVLT is also a site at which blood-borne relaxin directly stimulates neurons (Sunn *et al.*, 2001), consistent with the presence of relaxin binding sites in this CVO (Osheroff and Phillips, 1991). Neuronal NOS is also at a high level in the rat OVLT (Alm *et al.*, 1997), as are binding sites for peptides such as amylin, atrial natriuretic peptide, calcitonin, calcitonin gene–related peptide (CGRP), interleukin-1, endothelin, somatostatin, and vasopressin (Eriksson *et al.*, 1995; Murone *et al.*, 1997; Patel *et al.*, 1986; Saavedra *et al.*, 1992; Tribollet *et al.*, 1992; Sexton *et al.*, 1986, 1994).

MEDIAN EMINENCE AND NEUROHYPOPHYSIS

General Characteristics and Comparative Studies

In nonprimate mammalian species, the term *median eminence* refers to that tissue that is midline, immediately caudal to the optic chiasm and rostral to the mamillary bodies. Its name accords to the median position and the fact that it forms a protruberance from the surface of the brain. It is connected to the pituitary stalk. The median eminence includes the neural tissue that lies below the ependyma of the floor of the third ventricle. Two recesses are found in the ventricle at this level: the infundibular recess and the mamillary recess. The former is a central indentation of the median eminence. Diagrammatic representation of the ovine median eminence with photomicrographs is shown in Figure 19.6. The innermost layer of the median eminence (internal zone) contains cells of the arcuate nucleus in most nonprimate mammalian species. The nerve fibers of the hypothalamoneurohypophysial tract (traveling from the cell bodies of the magnocellular neurons to the posterior lobe of the pituitary) traverse the median eminence at this level. These axons of the oxytocin and vasopressin neurons, originating from the hypothalamic supraoptic and paraventricular nuclei, project to the neurohypophysis and secrete into the peripheral blood system. The next layer of the median eminence is the external zone (sometimes called the palisade layer because of its histological appearance). It is into this layer that the hypophysiotropic neurons project and come in close proximity to the primary plexus of the hypothalamohypophysial portal blood system. The cell bodies of the hypophysiotropic neurons are found in various nuclei of the hypothalamus and preoptic area and project to the external zone of the median eminence. In addition, there are projections from the arcuate nucleus and other regions as far away as the brain stem of nonhypophysiotropic neuropeptides (e.g., neuropeptide Y and substance P) and monoamines (Palkovits, 1984; Mai *et al.*, 1986). Secretion from these nonhypophysiotropic systems into the portal blood appears to vary between species, since there is good evidence for the secretion of significant levels of neuropeptide Y into the portal system of the rat (Sutton *et al.*, 1988) but not in the sheep (Clarke *et al.*, 1993). On the other hand, there is good evidence that noradrenaline is secreted directly into the portal system (Thomas *et al.*, 1989). While there is substantial evidence that dopamine is released into the portal blood of rats and serves as a prolactin inhibiting factor (Pan, 1996), there

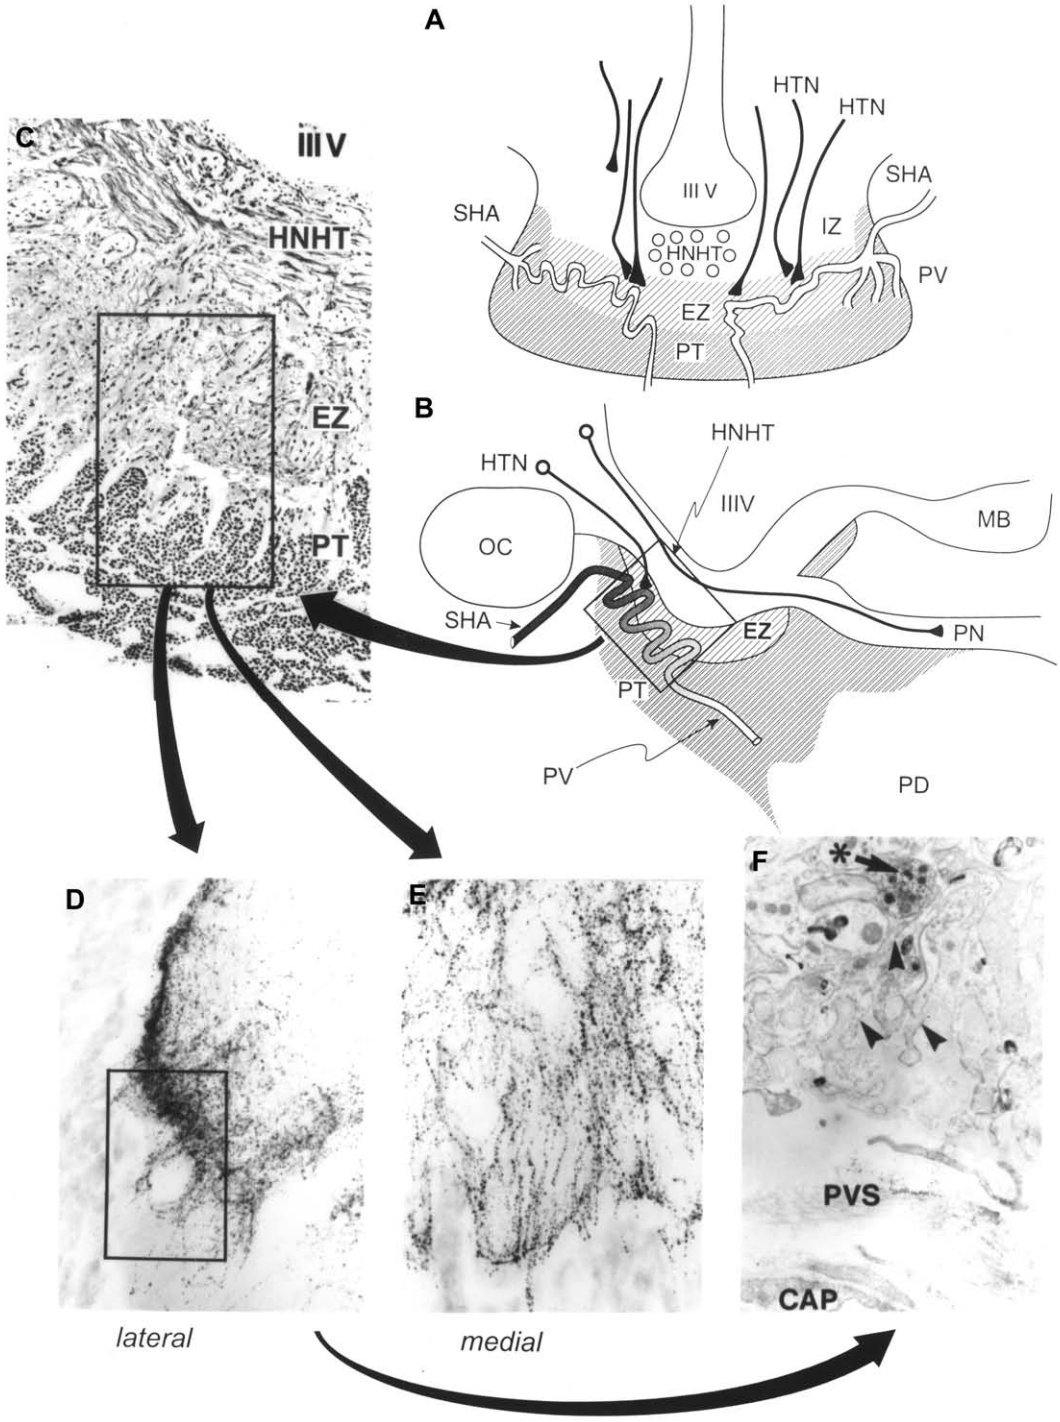

FIGURE 19.6 The ovine median eminence. **A.** Diagram of a frontal section of the sheep median eminence showing the processes of the hypophysiotrophic neurons (HTN) terminating in the external zone (EZ). The hypothalamoneurohypophysial tract (HNHT) is shown in the internal zone (IZ) en passant to the pars nervosa (neurohypophysis) of the pituitary gland. The pars tuberalis (PT) wraps around the entire structure. The portal vessels (PV) arise from the superior hypophysial artery (SHA). IIIV, third ventricle. **B.** Diagram of the sheep median eminence in saggital section. OC, optic chiasma; PD, pars distalis; PN, pars nervosa; MB, mamillary body. **C.** Sagittal section through the sheep median eminence showing the neurosecretory external zone (EZ) (see part B). The HNHT can be seen coursing through the IZ of the median eminence. The distinctive appearance of EZ is largely due to the portal vessels that loop through this region to come into close proximity to the terminals of HNT (×280) **D.** Lateral region of the median eminence showing fibers immunostained for GnRH in the EZ (×840). **E.** Medial region of the median eminence showing fibers immunostained for GnRH in the EZ (×840). **F.** Electron micrograph taken from the lateral region of the median eminence (see D) showing an immunreactive GnRH terminal (*). These terminals are generally surrounded by glial processes *(arrowheads)* that extend to the perivascular space (PVS) that is seen between the neural tissue and the fenestyrated capillaries (CAP). (×10,000).

are a number of discrepancies that require careful consideration before this doctrine is unequivocally accepted. These include sex differences and inconsistent relationships between the levels of dopamine in the median eminence/portal blood and peripheral prolactin levels. In the sheep, a differential in the plasma levels of dopamine cannot be demonstrated between the portal and peripheral circulation (Thomas *et al.*, 1989). In spite of this, dopamine is a highly effective inhibitor of prolactin secretion in a wide range of species, including man.

There is some degree of regionalization of projections from hypophysiotropic neurons into the median eminence. For example, the gonadotropin-releasing hormone terminals are found predominantly in the lateral regions of the external zone whereas the terminals of the somatostatin neurons are found mainly in the medial region. The neuronal terminals of the hypophysiotropic neurons are surrounded by glial elements (Fig. 19.6), and there is some degree of rearrangement under normal physiological conditions, e.g., across the seasons in seasonally breeding animals (Xiong *et al.*, 1997). In general, the terminals are found some distance from the fenestrated capillaries of the primary plexus, so that secreted stimulatory and inhibitory factors need to traverse an extravascular space prior to uptake into the primary plexus capillaries. Most hypophysiotropic hormones are secreted in a pulsatile manner (Clarke, 1996) and the presence of degrading enzymes in the median eminence (Smith *et al.*, 1997) might be a mechanism whereby such pulsatile secretion is maintained as a discrete rather than a prolonged signal to the anterior pituitary gland.

The outermost layer of the median eminence is the pars tuberalis, which is of nonneural origin and an upgrowth of the pituitary gland. The pars tuberalis is of a different embryonic origin to the pars distalis and contains cells that have a distinct profile. For example, the homeobox gene *Pit1* is expressed in the pars tuberalis to a much greater extent than in pars distalis cells (Lin *et al.*, 1994), and the cells of the pars distalis also express melatonin receptors at a very high level (Morgan, 2000).

The median eminence and the neurohypophysis (pars nervosa or posterior pituitary gland) contain a common neurohypophysial capillary bed (Page and Bergland, 1977). The hypophysial portal system arises from the superior hypophysial artery that supplies the primary capillary bed in the external zone of the median eminence. The superior hypophysial artery arises from both internal carotid arteries (Page and Bergland, 1977). Within the external zone of the median eminence the capillaries of the primary plexus of the portal system form loops, giving rise to the palisade appearance of the structure. These capillaries then drain into the portal vessels that travel through the pars tuberalis and pituitary stalk to the pars distalis of the pituitary gland; these are the long portal vessels (Xuereb *et al.*, 1954b). At the level of the pars tuberalis there is further opportunity for the secretion of factors that might influence the function of the cells of the pars distalis. Indeed, current work indicates that the cells of the pars tuberalis secrete a factor that regulates prolactin secretion (Morgan, 2000) and melatonin action on the pars tuberalis cells appears to mediate seasonal changes in prolactin secretion in sheep (Lincoln and Clarke, 1998). Vascular casts of the hypophysial portal system in a variety of species may be found in Page (1978). The inferior hypophysial artery supplies blood to the caudal end of the neurohypophysial capillary bed, but the capillaries of the median eminence and the neurohypophysis are confluent, allowing for variations in flow between the two, depending on the relative pressure with which blood is delivered via the superior and inferior hypophysial arteries (Page, 1987). A dense bed of short portal vessels connects the neurohypophysis to the pars distalis of the pituitary gland (Daniel and Prichard, 1975). The blood supply to the median eminence and neurohypophysis constitutes the sole blood supply to the pituitary gland and hypophysial stalk section results in substantial infarction of the pars distalis (Clarke *et al.*, 1983). The degree to which this occurs depends on the extent to which blood is supplied by the inferior hypophysial arteries in different species (Daniel and Prichard, 1975).

The median eminence is a masterpiece of physiology. Very small quantities of hypophysiotropic hormone (pg/mL levels) are secreted into the portal system to act on pituitary cells that then secrete large amounts of hormone (achieving peripheral concentrations in the order of ng/mL). The secondary bed of this portal system is the sinusoids of the pars distalis, where each hypophysiotropic signal can interact with the relevant cell type. Not only does this allow for substantial signal amplification, but the pulsatile nature of hypophysiotropic hormone secretion allows for fine modulation of both frequency and amplitude of pulsatile release of hormone. In this way the median eminence translates a neural signal into an hormonal signal. The portal system is able to carry multiple signals from the different hypophysiotropic systems and yet achieve specificity at the level of the pars distalis; each pituitary cell type responds specifically to the relevant releasing/inhibiting factor by way of specific receptors. Detailed dissertations on the significance of the junction between the brain and the endocrine system by way of the median eminence and the hypophysial

portal system can be found in Donovan (1978) and Flerko (1980).

Human Median Eminence

Location and Structural Organization

While the arrangement of the human median eminence follows the aforementioned general pattern, a number of modifications have evolved to give it distinct features worthy of comment. In its gross anatomy, the eminence on the brain surface that is equivalent to the median eminence of lower mammals is no longer evident in the ventral surface of the human hypothalamus. As a result of the increase in size of the human forebrain, the long axis of the infundibulum from hypothalamus to pituitary shifts its orientation so that it runs forward (see Chapter 17) and becomes elongated (Fig. 19.3A), and is not a caudally directed column as in nonprimates. Thus, the surface eminence disappears and the median eminence becomes incorporated into the upper part of the infundibular stem (Daniel and Pritchard, 1975). Unlike many species, there is no strict delineation of this region into internal and external zones in the developed human brain. However, there has been designation of an upper infundibular stem located in a suprasellar region and a lower infundibular stem which is the part of the infundibulum that is adjacent to the adenohypophysis and which has fibers leading in a caudal direction to the infundibular process (Daniel and Pritchard, 1975; Xuereb *et al.*, 1954a). The pars tuberalis forms the most rostral surface boundary of the median eminence (Figs. 19.3D, E), and the stalk of the infundibulum passes through an opening in the diaphragma sellae, an extension of the dura mater that closes over the pituitary fossa. At the caudal joining of the infundibular stem to the brain, a superficial layer termed the neurovascular zone extends in the midline postinfundibular eminence toward the mammillary body (Fig. 19.3E). At the junction of the neurohypophysis with the pars distalis, a pars intermedia can be discerned in many species; however, in the human pituitary gland, this feature is not present and cystic spaces and epithelial cells are observed in the analogous region (Daniel and Pritchard, 1975).

Vasculature

Perhaps the most distinguishing feature of the human neurohypophysis and median eminence is the specialized configuration of the vascular arrangement that pervades the neural tissue of the median eminence, which is so important for its neuroendocrine function. The blood supply to these regions comes from the superior hypophysial and inferior hypophysial arteries that arise from the internal carotid arteries. Some branches of the superior hypophysial artery descend within the pars tuberalis along the rostral and lateral surface of the infundibulum and give rise to arterioles, which enter the infundibulum and bend upward toward the median eminence to form complex capillary loops in both the superficial and deeper parts of the infundibulum (Fig. 19.5D). These capillary arrangements form the primary capillary complex of the median eminence in the upper infundibular stem. The continuation of these capillary coils gives rise to the long portal veins from their lower end which deliver blood to the pars distalis (Fig. 19.5D). These portal veins travel down the surface (pars tuberalis) and interior of the infundibulum to supply the sinusoids of the pars distalis (Xuereb *et al.*, 1954a, b). Other descending branches of the superior hypophysial artery break up into a capillary plexus within the pars tuberalis, the so-called mantle plexus from which some superficial capillary loops enter the infundibulum. Although the long portal veins are the major venous drainage of the median eminence, a few veins pass back to the pars tuberalis and reach surface retrochiasmatic veins and the hypothalamus (Fig. 19.5D). Similar capillary plexuses also occur in the caudal part of the median eminence, where there is a superficial plexus in the neurovascular zone of the postinfundibular eminence and arterioles giving rise to a deep network of capillary coils that drain into long portal vessels that supply the pars distalis (Duvernoy, 1972). A group of portal vessels is also found in the lower infundibular stem. These are the short portal vessels that arise from capillary loops in the neural tissue adjacent to the pars distalis and that supply the sinusoids of this tissue. The associated capillary loops receive their arteriolar input from the artery of the trabecula which links the inferior and superior hypophysial arteries.

The portal blood vessels which emanate from the median eminence and neurohypophysis provide the exclusive blood supply of the pars distalis (adenohypophysis) (Xuereb *et al.*, 1954a). The hypothalamic releasing factors and inhibitory agents secreted from nerve endings in the vicinity of capillary loops are delivered to the pars distalis by the portal vessels to influence the secretion of hormones by this gland. Histologically, the capillaries of the primary plexus are easily observed, being surrounded by extensive fibrous reticulum sheaths and bundles of nerve fibers of the neurohypophysial tract. Long processes from specialized ependymal cells (tanycytes) that line the floor of the infundibular recess also pass into this tissue.

Human Neurohypophysis (see also Chapter 18)

Location

The infundibular process of the neurohypophysis (posterior pituitary, pars nervosa) is situated in the most caudal part of the pituitary fossa. It is here that the majority of axons of the hypothalamoneurohypophysial tract terminate to release oxytocin and vasopressin. This most distal part of the neurohypophysis is characterized by rich vascularity, nerve endings, Herring bodies, and pituicytes.

Cellular Elements and Vasculature

The distribution of pituicytes (which may be analogous to astrocytes) varies within the neurohypophysis. Ultrastructurally, these cells have large nuclei and sparse perinuclear cytoplasm with processes that terminate near perivascular spaces (Lederis, 1965). The capillaries within the infundibular process receive a blood supply directly from numerous arteries of lateral and medial branches of the inferior hypophysial arteries, and the capillaries drain into venous channels to enter the systemic circulation via the posterior intracavernous sinus or a posterior venous network or the vein accompanying the inferior hypophysial artery (Green, 1957; Xuereb *et al.*, 1954a). These capillaries have fenestrated endothelial cells and extensive perivascular spaces containing collagen fibers and occasional fibroblasts surrounded by a basement membrane. Numerous nerve endings are found in this region together with pituicyte processes. The nerve endings contain elementary granules that are 90–200 nm in diameter and also some smaller vesicles, 20–50 nm in diameter, which may contain the neurosecretory products of the hypothalamoneurohypophysial tract (Bergland and Torack, 1969; Lederis, 1965).

Neural innervation of the Median Eminence and Neurohypophysis (see also Chapter 17)

The infundibulum or pituitary stalk receives neural input from two major fiber pathways. The first of these is the neurohypophysial tract or magnocellular system. The second neural input to the infundibulum is the tuberoinfundibular tract or parvocellular system. The neurohypophysis does not contain neuronal perikarya. Thus, the projections to the neurohypophysis/median eminence are of a neurosecretory nature. The neurohypophysial tract has its origin in the magnocellular neurons of the supraoptic and paraventricular nuclei in the hypothalamus and accessory internuclear cells in the bridging tissue between these two nuclei. Fibers from the paraventricular nucleus proceed through this tissue toward the supraoptic nucleus, joining its axonal outflow to the neurohypophysis, where they terminate around blood vessels in the lower infundibular stem and infundibular process to release oxytocin and vasopressin (Defendini and Zimmerman, 1978; Weindl and Sofroniew, 1985; Zimmerman and Antunes, 1976). Saper (see Chapter 17) presents sections through the human hypothalamus that favorably display the supraoptic and paraventricular nuclei as seen with Nissl staining (Figs. 17.2–17.7). He also presents a comprehensive account of the neuroactive compounds released by the magnocellular and parvocellular neurosecretory nuclei.

The axons of the tuberoinfundibular tract have as their origin parvocellular neurons in a number of brain regions, including the arcuate nucleus (or infundibular nucleus), the paraventricular nucleus, preoptic region, periventricular hypothalamic region, and ventromedial hypothalamus. These fibers terminate in the median eminence and lower infundibular stem in the vicinity of capillary loops to release a number of peptides (releasing hormones) and monoamines, which have been mentioned previously in this chapter and which influence the secretion of hormones from the anterior pituitary gland.

PINEAL GLAND

General Characteristics and Comparative Studies

The modern view of the mammalian pineal that has emerged is that the pinealocytes, the secretory cells of the pineal in mammals, have developed phylogenetically from photoreceptor cells of lower vertebrates but are no longer directly sensitive to light. The pinealocytes, though evolving from neurons, are not true neurons and do not have axonal projections to other brain regions or the periphery but secrete locally synthesized molecules such as melatonin into the circulation. Although not directly photosensitive, pinealocytes in mammals indirectly receive neural signals from the eye conveying information regarding the day–night cycle (Kappers, 1981; Korf *et al.*, 1998).

Stimulation of pineal secretion is dependent on the sympathetic innervation of the gland. This neural input to pinealocytes comes from the superior cervical ganglion. A daily rhythm in melatonin production is observed in many species, with darkness being stimulatory and light inhibitory to melatonin synthesis. It appears that melatonin has a role in the regulation of sleep and reproductive activities, although the precise mechanisms are not yet understood (Tamarkin *et al.*, 1985; Korf *et al.*, 1998).

Human Pineal Gland

Location and Structural Organization

The pineal gland in humans is a solid organ located in the midline roof of the third ventricle and joined by peduncles to the habenular commissure rostrally and posterior commissure caudally (Fig. 19.7A). From a dorsal aspect, it occupies a niche between the lobes of the superior colliculi. This cone-shaped structure of the epithalamus, which increases in size until the age of 2 years, is quite variable in size among individuals (Sumida *et al.*, 1996). It has the following dimensions: length 5–9 mm, width 3–8 mm, and thickness 2–4 mm (Kappers, 1962).

The pineal develops from a thickening of the ependyma around the pineal recess, a diverticulum of the thin roof of the dorsocaudal third ventricle. As it develops, two types of cells can be differentiated. These are small, fibrous cells that are thought to develop into astrocytic glial cells and larger cells with dark-staining nuclei that differentiate into pinealocytes by the eighth month of life (Kappers, 1962). A capsule derived from the pia also develops around the pineal anlage. From this connective tissue sheath there develop intrusions into the parenchyma that form septa breaking the organ into lobules (Tapp, 1979). Blood vessels and nerve fibers distribute within the pineal through these septa (Reyes, 1982). The central part of the human pineal is highly vascularized by sinusoidal capillaries, whereas its periphery is sparsely supplied with small, fine vessels (Duvernoy *et al.*, 2000). Its arterial sources are several pineal arteries branching from the medial posterior choroidal artery, whereas lateral pineal veins drain into the great cerebral vein of Galen (Duvernoy *et al.*, 2000).

Cellular Elements

With the development of the pineal to maturity, the pinealocyte, the cell intrinsic to this organ, becomes the major cell type. These cells, which are innervated and thought to be the major functional unit of the pineal, become arranged in cords or lobules of cells embedded in a matrix of neuroglia surrounded by the septa (Scharenberg and Liss, 1965). Pinealocytes having a large, round to oval nucleus, with a prominent nucleolus and scarcity of heterochromatin, are easily recognized and exhibit a number of cytoplasmic processes (Vollrath, 1984). These processes have been shown to be variable in length, narrow into fine strands, and possess club-shaped endings (del Rio Hortega, 1932; Scharenberg and Liss, 1965). There has been great interest from a functional point of view as to the sites where these club-shaped endings terminate. Vollrath (1984) suggested four terminal regions: the perivascular spaces, in the septa and capsule, between pinealocytes, and near calcified regions.

In regard to the glial cells found in the human pineal, astrocytes form a dense matrix enveloping the pinealocytes, perivascular areas, and septa. These cells are of the fibrous astrocyte type, and their long cytoplasmic processes are in close proximity with pinealocyte processes and fill much of the space between pinealocytes (Reyes, 1982). Ependymal cells of the pineal recess of the third ventricle cover the ventricular surface of the pineal.

Calcification and Cysts

An interesting aspect of pineal morphology is the presence of calcareous concretions (also termed acervuli, corpora arenacea, brain sand, pineal concrements, or psammoma bodies). These mulberry-like concretions, which consist mainly of hydroxyapatite and calcium phosphate, are found in the extracellular space of the parenchyma and septa (Reyes, 1982; Vollrath, 1984). There is great variability between individuals regarding the degree of calcification that occurs; however, concretions can be observed in the pineals of individuals of all age groups (Tapp and Huxley, 1971; von Heidel, 1965). Although this feature may occur in as many as 50% of children (von Heidel, 1965), its incidence increases with age and can be detected radiologically. The cause of pineal calcification is unknown; however, there is no evidence that pineal concretions diminish the secretory function of the pineal. Cysts are also commonly found in the pineal gland. It is considered that cysts with a lumen lined by ciliated ependymal cells are probably cutoff remnants of the original pineal diverticulum. Other cysts lined by neuroglial processes may be caused by degeneration of pineal tissue with a glial plaque surrounding a fluid-filled cyst (Kappers, 1962).

Neural Connectivity

Afferent Connections

The major neural input to the pineal gland comes from the peripheral nervous system. This is a sympathetic input from the superior cervical ganglion (Kappers, 1965). The innervation of the human pineal has been reviewed by Kenny (1985). These sympathetic fibers travel in the nervus conarii, which in humans is bilaterally represented, and enter the pineal at its posterior pole after coursing rostrally beneath the floor of the great cerebral vein of Galen from the dura mater of the tentorium cerebelli. Fibers of the nervus conarii enter the pineal at a number of sites on its posterior pole and extend through the septa and parenchyma of

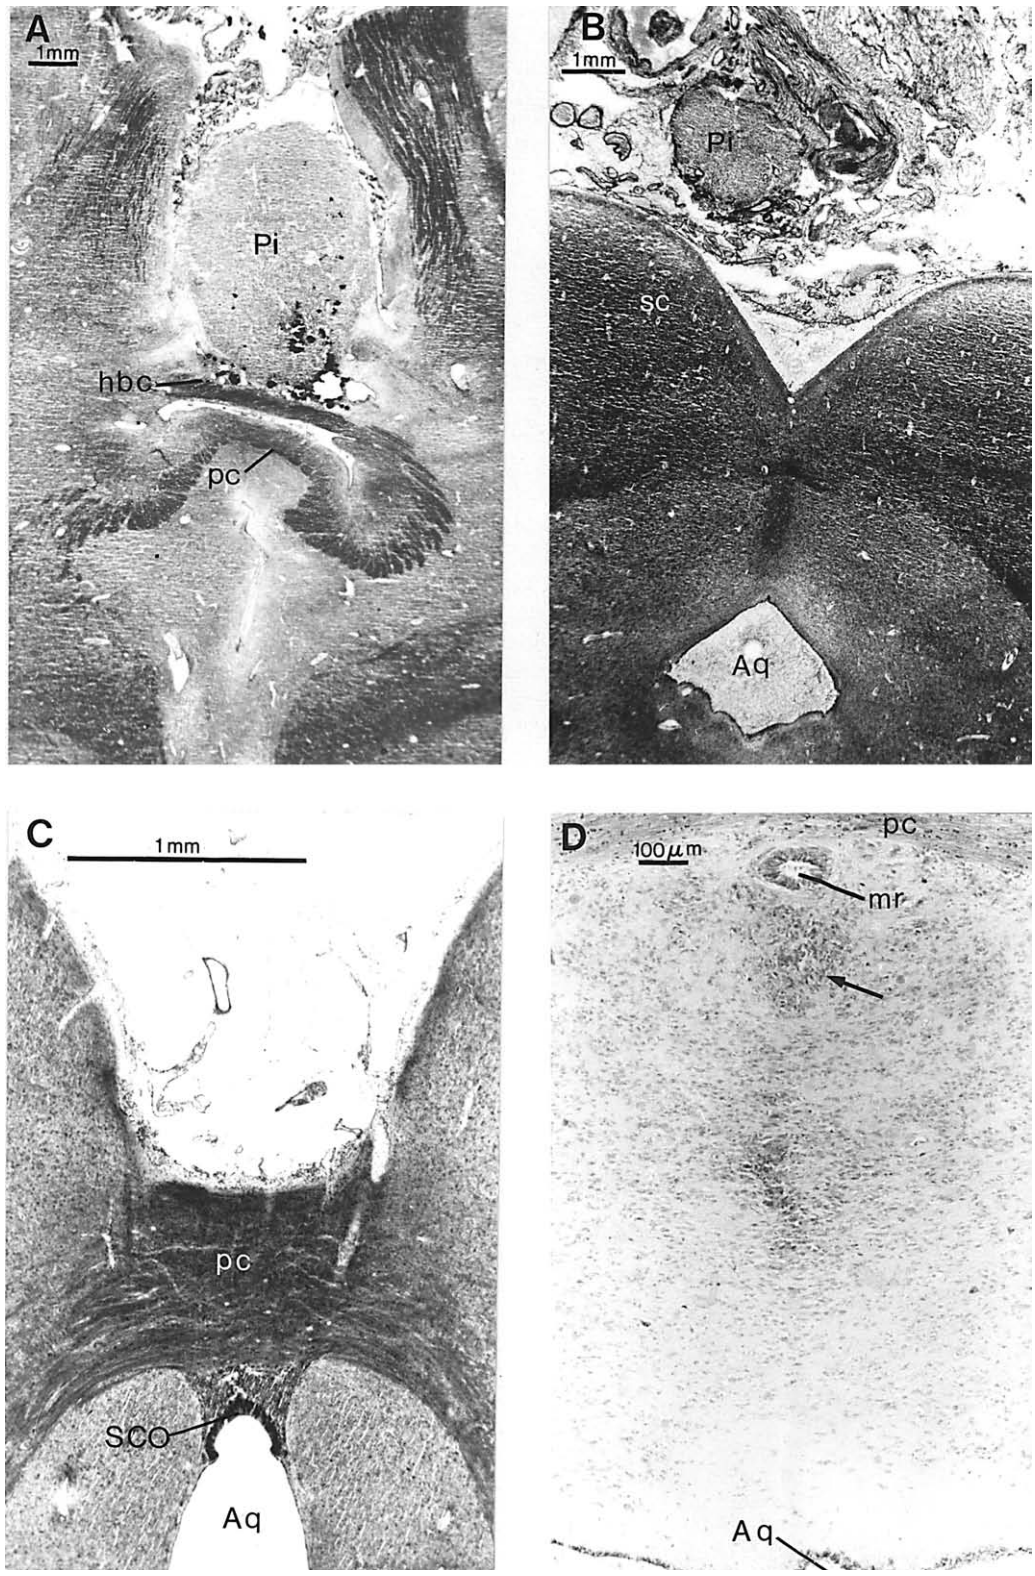

FIGURE 19.7 Coronal sections, stained with luxol fast blue and cresyl violet, through the pineal gland (Pi) of the human brain. **A** shows its attachment to the posterior (pc) and habenular commissures (hbc). **B** is a more caudal section with the superior colliculus (SC) evident. **(C)** Coronal section showing the subcommissural organ (SCO) of the sheep. **(D)** Coronal sections through the enclosed cavity of the mesocelic recess (mr) in an adult human brain. Possible remnants of SCO tissue are indicated by the arrow. Aq, aqueduct of Sylvius.

the gland (Kenny, 1965; Scharenberg and Liss, 1965).

The functional significance of the sympathetic innervation of the pineal and the central pathway linking it to the retina has been described in the rat by several investigators. By means of a series of lesions and knife cuts along the proposed pathway, they obtained evidence that signals from the retina are transmitted via the retinohypothalamic tract to the suprachiasmatic nuclei. From there, information is relayed to the hypothalamic paraventricular nucleus, then to the intermediolateral cell column of the spinal cord, where neurons innervate the superior cervical ganglion, which provides neural input to the pineal gland and its melatonin-secreting cells (Klein *et al.*, 1983; Moore and Klein, 1974; Pickard and Turek, 1983). This pathway has been confirmed and the cell groups involved more precisely defined by recent studies using the transneuronal viral tracer pseudorabies injected into the pineal of rats. The results show that the retinohypothalamic pathway to the suprachiasmatic nucleus is followed by synaptic relays in the dorsal, medial, and lateral parvocellular subdivisions of the hypothalamic paraventricular nucleus, intermediolateral nucleus, and central canal region of the upper thoracic spinal cord and superior cervical ganglion to provide the sympathetic innervation of the pineal (Larsen *et al.*, 1998; Teclamariam-Mesbah *et al.*, 1999). It is by this pathway that information regarding changes in the day–night cycle and seasonal alterations in illumination is transmitted from the eyes to the pineal gland to regulate melatonin secretion (Tamarkin *et al.*, 1985). There is also evidence that information regarding magnetic field changes is also relayed to the pineal from the eye (Olcese, 1990).

Direct input to the pineal originating in the CNS has also been reported from the habenular and posterior commissures (Korf and Moller, 1985). The sources of these fibers have been shown to be the paraventricular hypothalamic nucleus, medial and lateral habenular nuclei, posterior commissural nucleus, superior colliculi, and dorsal nucleus of the lateral geniculate (Guerillot *et al.*, 1982; Korf and Moller, 1985). Nerve fibers coming from the habenular and posterior commissures have also been observed to enter the pineal in humans (del Rio Hortega, 1932; Scharenberg and Liss, 1965).

The tracing studies using the neurotropic virus pseudorabies also produced evidence of a parasympathetic innervation of the pineal. Following infection of the pineal with pseudorabies virus in rats with bilateral superior cervical ganglionectomy, virally labeled neurons were observed in the sphenopalatine ganglion, nucleus of the solitary tract, and salivatory nucleus in the medulla oblongata, suggesting that these latter two medullary regions relayed signals to the pineal via the parasympathetic sphenopalatine ganglion (Larsen *et al.*, 1998). The presence of nerve cells in small (suggesting parasympathetic innervation) ganglia at the periphery of the human pineal has been reported by a number of investigators; neurons that were considered to be the origin of parasympathetic nerve fibers have also been reported in the primate (macaque) brain, the preganglionic parasympathetic fibers having traveled with the nervous conarii. However, such intrapineal neurons are rare in humans (Kenny, 1985).

SUBCOMMISSURAL ORGAN

General Characteristics and Comparative Studies

The term *subcommissural organ* was used by Dendy and Nicholls (1910) to designate a structure that they had observed in a number of mammalian species and that others had previously described in vertebrate classes ranging from cyclostomes to primates. In mammals, the subcommissural organ is situated on the rostral and ventral surfaces of the posterior commissure and forms the initial part of the midline dorsal roof of the aqueduct of Sylvius (Fig. 19.7C). The subcommissural organ is composed of modified ependymal cells that become elongated into a layer(s) of columnar epithelium. In some species, hypendymal cells situated in the subependymal tissue are also classified as part of this organ. Intimately associated with the subcommissural organ is Reissner's fiber, originally described as a threadlike structure that appears to originate as thin strands emanating from subcommissural cells into the cerebrospinal fluid and that aggregate to run caudally the entire length of the central canal of the spinal cord. Reissner's fiber is a noncellular aggregation of glycoproteins continuously secreted by the subcommissural cells (Gobron *et al.*, 1999; Sterba *et al.*, 1981). Although devoid of neuronal somata, ependymocytes of this organ may be neurally innervated (Oksche, 1962; Wiklund *et al.*, 1977). Many investigators have been impressed by the secretory aspect of the subcommissural organ, and such innervation may regulate glandular activity at both apical and basal surfaces of the ependymal cells. While there have been many propositions regarding the function of the subcommissural organ and Reissner's fiber, its function is still the subject of speculation. One of the more widely held views is that the molecules secreted in Reissner's fiber have a role in guiding the development of the brain and spinal cord.

Duvernoy and Koritke (1964, 1969a) studied the vascular arrangement of the subcommissural organ and reported that there is large variability between species. Some animals, including dog, cat, and monkey, have a richly vascularized subcommissural organ whereas others, such as rabbit, have only low vascular density. In the former case, a hypendymal capillary network extending along the organ arises from small arteries branching from the posterior cerebral arteries. These capillaries are extensively linked and may be in contact with the base of the columnar ependymal cells of the organ. Large capillary dilatations and occasionally capillary loops are observed. Venous drainage is mainly by way of a large vein on each side of the lateral wall of the third ventricle which drains other regions such as the habenula nuclei and which may join the great cerebral vein of Galen. A few vascular links with the pineal vessels have also been observed (Duvernoy and Koritke, 1969a).

Human Subcommissural Organ

Location and Structural Organization

Unlike other mammals, the human subcommissural organ is only clearly evident in the fetus and newborn. In the adult it has almost completely disappeared, although remnants of this tissue have been observed by some authors (Gilbert, 1960; Oksche, 1961; Galarza, 2002). There are no reports of Reissner's fiber in the adult human brain and only one report of it in a human fetus (Keene and Hewer, 1935), but there are suggestions that glycoprotein components of Reissner's fiber such as SCO-spondin are conserved in the human genome (Gobron *et al.*, 1999). The subcommissural organ has been discerned in the embryo as early as the second month of gestation in a 27–mm embryo (Castaneyra-Perdomo *et al.*, 1985; Keene and Hewer, 1935). In older fetuses, the subcommissural organ extends from the infrapineal recess caudally along the dorsolateral wall of the roof of the aqueduct of Sylvius to the mesocelic recess. It consists of elongated columnar ependymal cells that are found in the midline roof of the third ventricle around the posterior commissure and extend caudally as far as and including the mesocelic recess, which is a dorsal invagination of the aqueduct of Sylvius with blind-ending pockets in some instances. This recess is found immediately caudal to the posterior commissure in the fetal human brain, and most authors have considered its columnar ependymal cells to be part of the subcommissural organ (Castaneyra-Perdomo *et al.*, 1994; Dendy and Nicholls, 1910; Keene and Hewer, 1935; Rakic, 1965). This point is significant when considering the subcommissural organ in the adult brain because it has been proposed that the only remnant of this organ is the tissue that surrounds a vestige of the mesocelic recess (Dendy and Nicholls, 1910; Galarza, 2002). The mesocelic recess is prominent in the fetus but has virtually disappeared by the second year of life (Rakic, 1965). Dendy and Nicholls (1910) reported finding an irregular midline cavity with no opening to the aqueduct of Sylvius in the tissue over the caudal part of the posterior commissure. They regarded it as the blind termination of the mesocelic recess, the opening to the aqueduct having previously closed. Dendy and Nicholls (1910) reported that columnar ependymal cells of the subcommissural type lined this cavity. Although there are few other similar reports, we have observed such a mesocelic cavity in the adult brain (Fig. 19.7D), and Keene and Hewer (1935) presented evidence that epithelial cells plug the mesocelic recess to variable degrees, possibly leaving cavities in some instances. Rakic (1965) in a study of more than 300 cerebrums remarked on the great variability in size, configuration, and degree of regression of the mesocelic recess over the course of gestation; however, it had all but disappeared 1 year after birth. After this time, the midline ependymal lining of the infrapineal recess and the roof of the aqueduct of Sylvius below the posterior commissure is no longer of the elongated columnar type, and it appears that the subcommissural organ has almost completely regressed.

AREA POSTREMA

General Characteristics and Comparative Studies

The most caudal of the CVOs, the area postrema, is located bilaterally in the medulla oblongata in the walls of the fourth ventricle. In most mammalian species (carnivores, ruminants, and primates), it has the appearance of two convex humps bulging out from the lateral walls of the fourth ventricle. The two wings of the area postrema are positioned over the adjacent nucleus of the solitary tract and converge toward each other as the most posterior part of this CVO is reached at the obex (Fig. 19.8A). Two exceptions to this general description are the areas postrema of the rat and rabbit which, in coronal sections, take the form of a single midline quadrant of spongy tissue over the opening of the central canal. The area postrema is not present in fish or amphibians (Brizzee and Klara, 1984; Wilson, 1906; Wislocki and Putnam, 1920). It has a modified ependyma with few cilia, but some supraependymal cells. Although it was originally suggested that

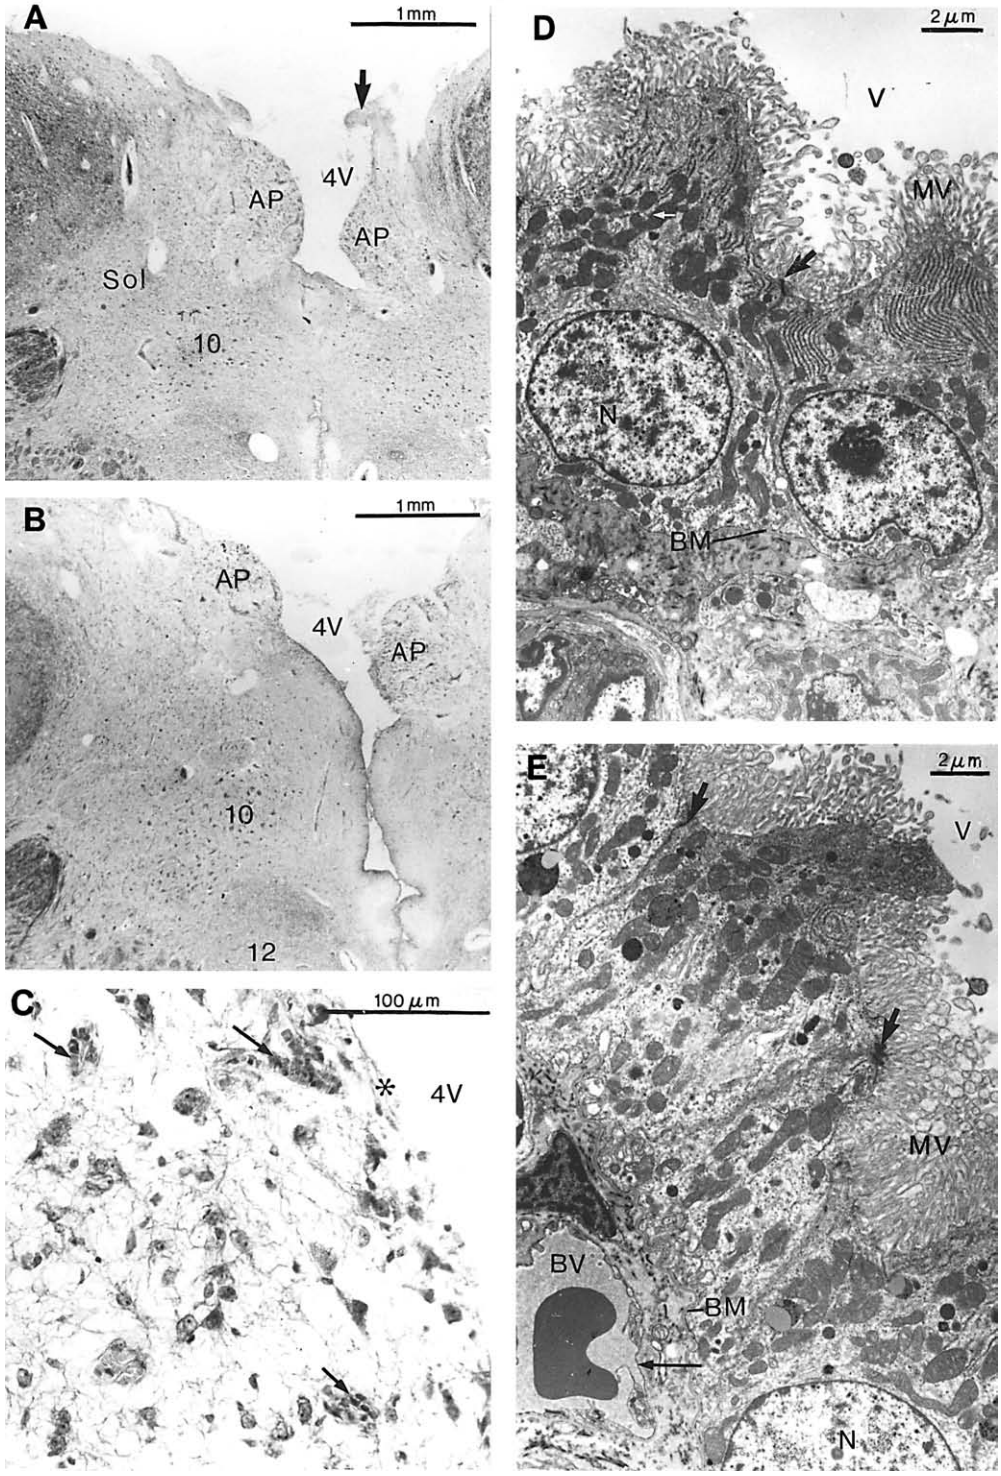

FIGURE 19.8 Low-power photomicrographs of coronal sections, stained with luxol fast blue and cresyl violet, through the human area postrema. The section in **A** is more caudal than that in **B.** AP, area postrema; Sol, nucleus of solitary tract; 10, dorsal motor nucleus of the vagus; 12, hypoglossal nucleus; 4V, fourth ventricle. **(C)** High-power photomicrograph of the human area postrema. Asterisk denotes flattened ependyma, arrows indicate blood vessels. Note the loose network of glial processes and neuronal perikarya. **(D, E)** Transmission electron micrographs of the choroid plexus of a cynomologous monkey. BM, basement membrane; BV, blood vessel; MV, microvilli; N, nucleus; V, ventricle. The thick black arrow in D indicates the zonula occludens, and the thin black arrow in E indicates a fenestrated blood vessel. Note the extensive rough endoplasmic reticulum *(large white arrow)* and mitochondria *(small white arrow)* in D.

neuronal perikarya were lacking in the area postrema of several species (Wislocki and Putnam, 1924), this proposition is no longer tenable. Neurons are situated in a mesh of astroglia, fibers, and numerous blood vessels, the latter exhibiting fenestrations in their endothelium, with two classes of capillaries identified in the rat area postrema (Gross, 1991).

Human Area Postrema

Location and Structural Organization

In humans the area postrema is found in the dorsomedial medulla oblongata and can be observed as two convex prominences bulging into the most caudal part of the fourth ventricle (Fig 19.8A). Longitudinally, the area postrema is a V-shaped structure diverging from an apex at the obex to a separation of 1.5–2 mm in a rostral direction while always overlying the nucleus of the solitary tract. Caudally, the area postrema can be observed bulging out from the lateral walls of the opening of the central canal. Rostrally, the bilateral prominences of the area postrema move dorsally and laterally in relation to the floor of the fourth ventricle (Fig. 19.8B) and at their lateral edges become attached to the pial membranes that form the roof of the ventricle and the tela choroidea. The human area postrema is immediately dorsal to the subpostremal nucleus, which separates the nucleus of the solitary tract proper from the area postrema (Hyde and Miselis, 1992). In the early 20th century, Wilson (1906) noted that there were variations in the human area postrema. In some individuals, the two wings of the area postrema coalesce to form the roof of the central canal, whereas in others there is no fusion of these wings. This latter situation is also observed in a number of animal species, e.g., monkey, sheep, and dog.

Cellular Elements

Morphologically, the area postrema shares many features with the subfornical organ and the OVLT, including rich vascularity, modified ependyma, and a network of neuroglia (Fig. 19.8C). The ependymal surface of the area postrema has been found to differ from the columnar ciliated ependyma of the adjacent ala cinerea in most species. In humans, ependymal cells of the area postrema are flattened to resemble a mesothelium or squamous epithelium, exhibiting few if any cilia (Kuhlenbeck, 1955). The body of this CVO consists of a loose network of neuroglia through which many blood vessels course (Fig. 19.8C). Prominent among the vascular profiles are arterioles with thickened perivascular sheaths of vascular smooth muscle and thin-walled veins or sinusoids (Cammermeyer, 1947b; Wilson, 1906; Wislocki and Putnam, 1920). The ventral boundary of the area postrema with the nucleus of the solitary tract is marked by a prominent array of glial cells, the funiculus separans of Retzius (Wislocki and Putnam, 1920). Fibroblasts and neuroglia occur throughout the area postrema, and Cammermeyer (1947b) reported that mast cells close to the ependyma can be detected with particular staining techniques in the human area postrema.

Although there has been some doubt expressed regarding the presence of neurons in the area postrema (Wislocki and Putnam, 1924), most authors now consider that neuronal profiles occur throughout the region, with their shape and size varying greatly (Cammermeyer, 1947b). Olszewski and Baxter (1982) noted that their appearance altered with age. In children, these cells had little or no cytoplasm around darkly stained, rounded or oval nuclei although a few cells with large clear nuclei were observed with some cytoplasm. In older subjects, more cells with cytoplasm are distinguishable and the ovoid-to-round nuclei tend to be eccentrically placed near the periphery of one side of the cell. In adults, black melanin pigment (in unstained sections) accumulates in the cytoplasm of nearly all neurons, but this is rarely seen in infants or children (Cammermeyer, 1947b).

Vasculature

The area postrema is supplied by a number of thin slender arteries coming from the pyramidal branches of the posterior inferior cerebellar arteries that run along the lateral edge of the area postrema and send arterioles across it to form a rich capillary bed (Wislocki and Putnam, 1920). This capillary bed is extensively linked with capillary loops, tufts, and tendrils and wide sinusoidal vessels. Some of these vessels reach close to the ependymal surface of the ventricle. The capillary bed drains into longitudinally running veins along the mesial edge. It is doubtful whether any vascular connections with the choroid plexus of the fourth ventricle are formed (Cammermeyer, 1947b; Duvernoy and Koritke, 1969b).

Neural Connectivity

Afferent Connections

Details of the neural connections associated with the area postrema come from studies in rats that have examined anterograde and retrograde transport of horseradish peroxidase and its conjugates, and these details are summarized in Table 19.3. The area postrema receives some innervation from the lateral parabrachial nucleus and from the caudal nucleus of the solitary tract (Shapiro and Miselis, 1985; van der Kooy and Koda, 1983). In addition, Hosoya and Matsushita (1981)

TABLE 19.3 Direct Neural Connections of the Area Postrema

produced evidence of diencephalic projections to the area postrema. These projections have been precisely mapped by Shapiro and Miselis (1985), who show that a group of neurons in the lateral parvocellular subnucleus of the paraventricular hypothalamic nucleus as well as in the subadjacent dorsomedial nucleus and perifornical area project to the area postrema. This CVO also receives a small number of direct peripheral inputs from the vagus, glossopharyngeal, and trigeminal nerves (Beckstead and Norgren, 1979; Kalia and Welles, 1980; Miselis *et al.*, 1987).

Efferent Connections

In regard to its efferent pathways, the area postrema has axonal contact with a number of other medullary regions including the neighboring nucleus of the solitary tract, the ambiguus nucleus, the noradrenergic neurons of the caudal ventrolateral medulla, spinal trigeminal nucleus, and paratrigeminal nucleus and midbrain periaqueductal gray. There are other connections to the cerebellar vermis and dorsolateral tegmental nucleus of the pons, and a particularly strong projection to the dorsal lateral parabrachial nucleus (Shapiro and Miselis, 1985).

Function

From a functional viewpoint, there is still considerable speculation as to the precise role of the area postrema. It has long been considered that this CVO may be a chemoreceptor trigger zone for vomiting (Borison and Brizzee, 1951). Ablation of the area postrema in animals also interferes with the taste aversions which become associated with nausea-producing stimuli (Berger *et al.*, 1973; Coil and Norgren, 1981). More recently, evidence has accrued suggesting that 5-HT_3 receptors in the area postrema have a role in vomiting and nausea, and it is blockade of these receptors (by agents such as odansetron) in the area postrema as well as on vagal afferent neurons that is effective in reducing the nausea associated with cancer chemotherapy (Miller and Leslie, 1994; Tyers and Freeman, 1992). Like the OVLT, subfornical organ, and median eminence, there is evidence that the area postrema may be a site of action of blood-borne angiotensin II, particularly with regard to centrally mediated cardiovascular effects of angiotensin II (Joy and Lowe, 1971), which may reset the baroreceptor reflex to a higher level of arterial pressure (Bishop and Sanderford, 2000). Although there are binding sites for angiotensin II in the area postrema of the rat and dog (Mendelsohn *et al.*, 1984; Speth, 1985), in the human area postrema, binding sites for angiotensin II were undetectable (Allen *et al.*, 1988), suggesting that it may not be a receptor zone for angiotensin II in humans. Vasopressin is another peptide hormone that has been shown to bind to the area postrema of the rat (Phillips *et al.*, 1988), and recent experimental evidence suggests

that the area postrema may be the central site at which blood-borne vasopressin acts to cause sympatho-inhibition and facilitate the baroreflex (Undesser *et al.*, 1985; Hasser *et al.*, 2000). Other effects consequential to the production of lesions in the area postrema of rats are loss of body weight, altered appetite, and altered sodium and water intake and excretion (Miselis *et al.*, 1987). Such results have not yet permitted a clear delineation of the exact roles which the area postrema may play in homeostatic mechanisms regulating fluid and electrolyte balance. However, its unique position in the medulla oblongata at the point of entry of visceral sensory information and lack of a blood–brain barrier exposing it to circulating humoral factors give the area postrema the potential to integrate or modulate homeostatic responses (Miselis *et al.*, 1987). In relation to some of the humoral or neurochemical agents which may influence area postrema functions, the rat area postrema displays binding sites for tritiated amino-clonidine, substance P, vasoactive intestinal polypeptide, bradykinin, cholecystokinin, opiates, atrial natriuretic peptide, somatostatin, neuropeptide, pancreatic poly-peptide, calcitonin, and insulin (Chen *et al.*, 2000; Gibson *et al.*, 1986; Helke *et al.*, 1984; Hilton *et al.*, 1995; Martel *et al.*, 1986; Moran *et al.*, 1986; Patel *et al.*, 1986; Shaffer and Moody, 1986; Tranh *et al.*, 1996; Walmsley *et al.*, 1982). In addition, immunohistochemistry has revealed noradrenaline-, enkephalin-, serotonin-, and cholecystokinin-containing neurons and adrenaline-, noradrenaline-, amylin-, and substance P-containing afferent fibers in the rat area postrema (Armstrong *et al.*, 1981; D'Este *et al.*, 2000; Lanca and van der Kooy, 1985; Newton and Maley, 1985). In the human area postrema, galanin, substance P, CGRP, dynorphin B, cholecystokinin, and neurophysin have been immuno-histochemically identified in nerve fibers (Fodor *et al.*, 1994; Unger and Lange, 1991), and serotonin in neuronal cell bodies (Azmitia *et al.*, 1991). In addition, muscarinic cholinergic and 5-HT_3 serotonergic receptor binding sites have been identified in the human area postrema (Hyde *et al.*, 1988; Ohuoha *et al.*, 1994). The 5-HT_3 receptors may be of relevance to the induction of nausea and vomiting (Ohuoha *et al.*, 1994). Finally, neurons sensitive to glucose and sodium have been identified in the area postrema by means of electro-physiological techniques (Adachi and Kobaski, 1985).

CHOROID PLEXUS

The choroid plexus has also been classified as a CVO (Hofer, 1958; Kuhlenbeck, 1970) and will be briefly considered here. Found in the body, collateral trigone, and inferior horn of the lateral ventricle (Fig. 19.2), the roof of the third ventricle (Fig. 19.3A), and also in the fourth ventricle, the choroid plexus has somewhat different features from the other CVOs. In common with the other CVOs, it is made up of elements from the leptomeninges and the ependyma. Highly vascularized tela choroidea of the medial surface of the cerebrum evaginates and acquires an epithelium to form the choroid plexus. The commonly accepted role of the choroid plexus in the formation of a major portion of cerebrospinal fluid (CSF) may be only one of a number of functions of this CVO (Davson, 1967; McComb, 1983).

When the morphological features of the choroid plexus are examined, the enormous surface area that results from the extensively folded surface and microvilli (Fig. 19.8D) of this tissue is consistent with a reabsorptive function as well as a secretory role (McComb, 1983). In addition to the transport of ions and water into the CSF, there is evidence that molecules such as thyroid hormones, leptin, and insulin-like growth factor I are also transported into the CSF from blood (Banks *et al.*, 1996; Schreiber *et al.*, 1990; Walter *et al.*, 1999). The choroid plexus consists of a core of vascularized connective tissue that is interfaced with an epithelium of low columnar or cuboidal cells by a basement membrane at their abluminal surface (Fig. 19.8D). The "capillaries" of this tissue have larger diameters (10–20 μm) than regular capillaries and have been designated as sinusoids (Kuhlenbeck, 1970). At an ultrastructural level, fenestrations can be seen in the vascular endothelium. Large spherical nuclei, microvilli at the luminal surface, abundant mito-chondria, and tight junctions (zonula occludens) between adjacent cells characterize the choroid epithelial cells (Fig. 19.8E).

The choroid plexus of several mammals, including primates, is innervated by cholinergic (from the vagus nerve) and adrenergic (from the superior cervical ganglion) nerves. Some nerve endings are associated with blood vessels whereas others may end at epithelial cells (Edvinsson *et al.*, 1974; Kuhlenbeck, 1970; Lindvall *et al.*, 1977). A number of peptides have been identified by immunohistochemical techniques in these nerve endings. They include substance P and vasoactive intestinal polypeptide (Edvinsson *et al.*, 1983).

In addition to these neurally derived peptides in the choroid plexus, many other peptides may be synthe-sized in the epithelial cells of the choroid plexus. These may be either secreted into the CSF for transport to cerebral targets, or act as local paracrine factors, a function supported by the presence of many peptide receptors within the choroid plexus (Chodobski and Szmydynger-Chodobska, 2001).

Thalamus

GERARD PERCHERON
Institut National de la Santé et de la Recherche Medicale
Paris, France

GENERAL CONSIDERATIONS

Macroscopical Anatomy and Topography

The thalamus is a diencephalic symmetrical oval-shaped mass located between the brainstem below and the telencephalon above, from the posterior commissure to the foramen of Monro (Fig. 20.1A). The medial aspect is observable after a sagittal section through the third ventricle (3V; Fig. 20.1A). The stria medullaris thalami (Fig. 20.1) starting from the ganglion habenulae goes up to the anterior tubercle with the taenia thalami (or habenulae). This is the line of attachment of the tela that forms the roof of the third ventricle. This line, up to cercopithecidae, constitutes the upper corner of the thalamus. Appearing first in chimpanzees, owing to the large dorsal increase of the thalamus, this is no more the case in the human brain. The medial view of the thalamus (Fig. 20.1A) shows two parts in relation to the line of attachment: below (ventricular or periventricular) and above ("extra-ventricular"). In many species, there is in the third ventricle an adhaesio interthalamica (Adh, Fig. 20.1A, or massa intermedia or commissura grisea, see para-median region). This is missing in 30% of the human cases (Rabl, 1958, and own material), not depending on gender or age. When present, the size of the adhesio, generally small, is variable, but the position of its anteroinferior pole is stable (aAd, Fig. 20.1A). The posterior part of the foramen of Monro corresponds to the anterior border of the thalamus (aTh, Fig. 20.1A). Placed between the midline and the internal capsule,

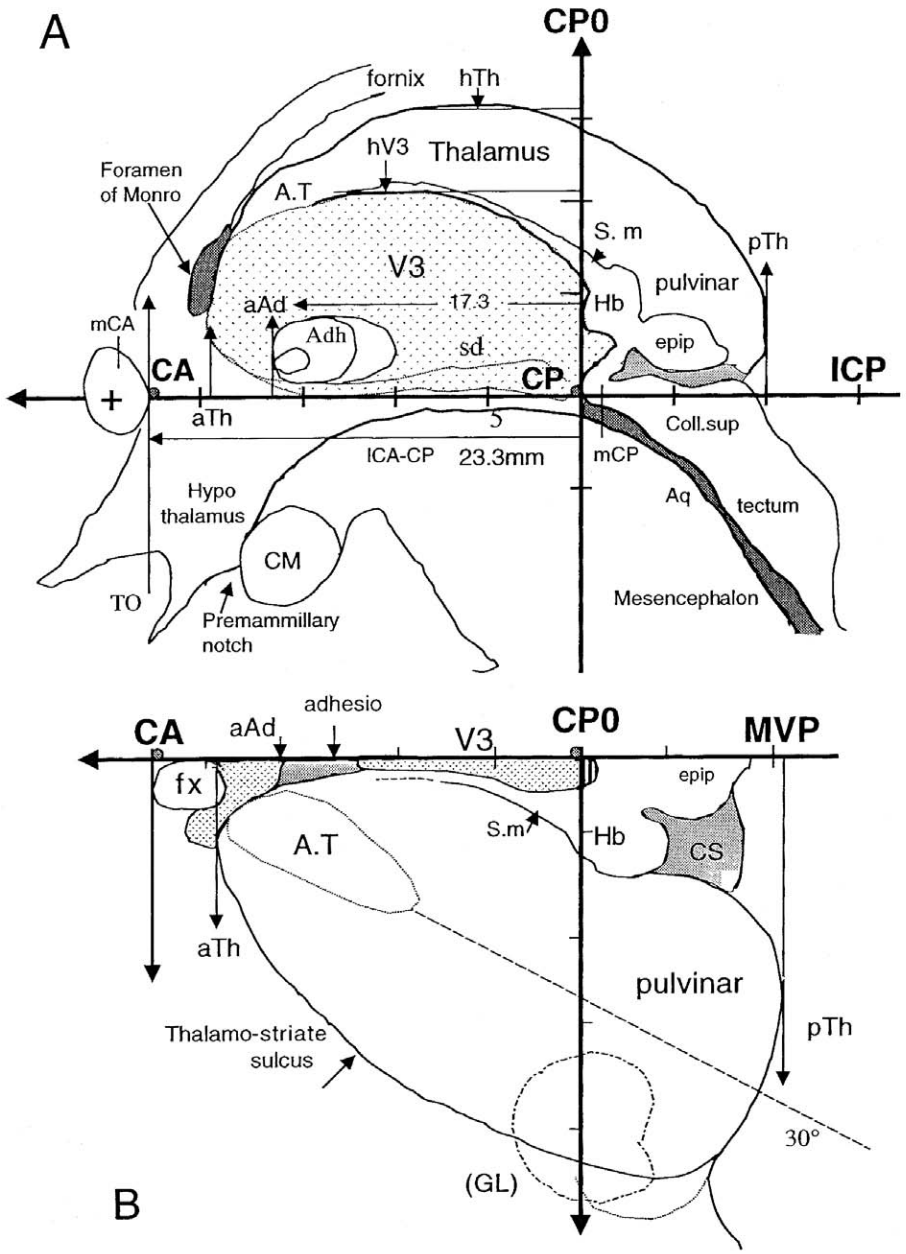

FIGURE 20.1 **(A)** Medial view after a midsagittal section through the third ventricle (V3). Position of the thalamus in relation to other parts of the brain and to the CA-CP, CP0, system of coordinates. This is based on two ventricular points observable on ventriculograms and histological sections, CA and CP located at the maximal protrusion of the border of the commissures where the distance between the two (lCA-CP) is minimum. The intercommissural plane (ICP) is the plane perpendicular to the midsagittal plane (MVP) passing through the two commissural points. CP0 is the plane perpendicular to both MVP and ICP and passing through CP. lCA-CP is the intercommissural length, giving the size of the ventricle allowing individual corrections in the posteroanterior dimension. The dotted area is the ventricular part of the thalamus, delineated dorsally by the stria medullaris medialis (sm) with the taenia habenulae corresponding to the line of attachment of the tela choroidea, the roof of the third ventricle. In man, a great part of the thalamus is extraventricular dorsally and posteriorly. Anteriorly, the anterior pole of the thalamus (aTh) corresponds to the posterior border of the foramen of Monro. Its position is statistically stable and may be used for size measurements. In humans, the adhesio interthalamica (Adh) is missing in 30% of the cases and of limited variable extent in others. The position of the anterior pole of the adhesio (aAd) is rather stable (not the posterior). Ventrally, the border partially follows the sulcus diencephalicus (sd) going from the foramen to the aqueduct of Sylvius (Aq). The posterior pole of the thalamus, pTh is directly observable in ventriculograms. The length of the posterior part of the thalamus CP-pTh is not linked to lCA-CP. The height of the ventricle (hV3) is not linked to its length. The height of the thalamus (hTh) is not linked to that of the ventricle (hV3), thus not offering metrical corrections. Other abbreviations: coll.sup, colliculus superior; CM, corpus mammillare; epip, epiphysis; Hb, ganglion habenulae; TO, tractus opticus. **(B)** Superior view of the thalamus after resection of the corpus callosum, fornix, and choroid plexuses. The thalamostriate sulcus constitutes the lateral border of the superior face. T.A, anterior tubercle. The third ventricle (V3) is shown with an adhesio interthalamica. The midventricular plane MVP passes through the middle of the ventricle. CP and CA are shown. CP0 is the plane of reference for anteriorities in the thalamus. Those of the anterior and posterior thalamic poles are indicated as aTH and pTh and that of the adhesio, as aAd. Back to the ventricle, the habenula (epithalamus)(Hb), the stria medialis or habenulae (s.m) and the epiphysis overhang the superior colliculus (cs). The main axis of the thalamus is not parallel to the midventricular plane and makes an angle of about 30°. Transverse and sagittal sections are thus not orthogonal to the anatomical thalamic axes. GL, lateral geniculate body and the lateral border of the pulvinar.

some faces of the thalamus are "adherent" and others are "free." The lateral face is adherent, to the capsule. The superior, posterior and infero-posterior faces, continuous and smooth, are visible after the removal of the corpus callosum or after pushing the temporal lobe laterally. The dorsomedial side shows the anterior tubercle in front (see superior region) and the dorsal part of the pulvinar in the back (Fig. 20.1B, see posterior region). The inferior side is made up of the superficial faces of the geniculate bodies in front and of the pulvinar posteriorly.

Thalamic Topometry and Cartography

There is general agreement for accepting the orientation and size of the third ventricle as the base for thalamic cartography and stereotaxy. Personal statistical analyses (Meder *et al.*, 1993, unpublished) on ventricular and thalamic average sizes made from 215 ventriculograms (135 from Ohye, 60 from Meder, and 20 from Nguyen) showed that the most practical (since observable in histology and radiography) and reliable CA-CP plane is that of Amador *et al.* (1959, in Schaltenbrand's atlas) (also the most reliable in macaques, Percheron, 1975), not Talairach's. This plane (Fig. 20.1A) links the most anterior point of the posterior commissure (CA) to the most posterior of the anterior (CP) (i.e., the shortest distance between the two) (Percheron, 1975; Meder *et al.*, 1993). Statistical analyses of the individual CA-CP distances (lCA-CP, length of the ventricle) measured on ventriculograms on Japanese and French samples (Meder *et al.*, 1993) led to an average of 23.3 ± 1.3 mm, with no differences between women and men or youngest and oldest. The mean distance from CP to the anterior part of the adhesio (CP-aAd), when present, is also stable (17.33 ± 1.2 mm). This material was compared to anatomical data resulting in about same values. Comparisons with 30 CT (from Ohye, 23.2±1.5) and 200 MRI pictures led to a slightly lower average, around 23 mm. The rule of using the closest commissural point (instead of the abstract middle ventricular plane) improves precision. CPO is the best initial plane for the thalamus (corresponding for instance to the posterior border of the central region, Percheron, 1975, 1997). Thalamic cartography thus relies on a simple cartesian system based on the midventricular plane (MVP), the intercommissural plane (ICP), and the plane perpendicular to the two preceding passing through the CPO point. Most of our figures are maps since following two mandatory rules: they are oriented in relation to a precise, immutable, system of coordinates, and they are scaled. These two properties are necessary for reconstruction in other planes. When the individual value of lCA-CP of the observed brain is less than ± 0.5mm in comparison to the reference, no correction is needed. In the reverse case, as already proposed by Tasker *et al.* (1982), a size correction using the ratio of the CA-CP length of the atlas of reference and of the observed one, improves precision (Percheron, 1975; Meder *et al.*, 1994). Variations of the highest point of the ventricle are not linked to variations in the anteroposterior dimension (as is also the case in macaques, Percheron 1975). Variations in the inferosuperior and in the lateral dimensions cannot be corrected. The CA-CP system of coordinates is not universal as, for instance, another ventricular system is preferable for the amygdala (Percheron, 1997). Some previous atlases of the human thalamus were performed in relation to exactly the same planes and identical CA and CP points: Schaltenbrand and Bailey (1959), Emmers and Tasker (1975) and Schaltenbrand and Wahren (1977). Atlases of Van Buren and Borke (1972), Mai *et al.* (1997); and Morel *et al.* (1997) using the center of the commissures (mCA and mCP, Fig. 20.1A) have the same horizontal plane and can be used with a simple anteroposterior correction (mCA-mCP is about 25 mm). The midsagittal plane, which was not precisely placed in the first Schaltenbrand's atlas (Niemann *et al.*, 1994; Morel *et al.*, 1997), was corrected later. The horizontal plane of section in Schaltenbrand's atlases was oriented at 7° from ICP and the series of horizontal sections cannot be used. The atlases of Talairach and Szickla (1967), Talairach and Tournoux, (1988) using other points of the commissures, or from Brierly and Beck (1959), Andrew and Watkins (1969), and Hassler *et al.* (1979) using the foramen of Monro, cannot be directly compared because they have different reference horizontal planes.

The study of the internal constitution of the human thalamus is made difficult by two geometrical particularities. First, the main axis makes an angle of about 30° (25° to 35°) (Figs. 20.1B and 20.2D) in relation to the midventricular plane (MVP, less than in macaques, 45°). Second, the main axis of the lateral region is strongly curved, its anterior part being almost perpendicular to the midventricular plane (Fig. 20.2D). The effect is such that anterior transverse sections are cut at almost a right angle to posterior (75°, Fig. 20.2D). When looking at histological sections or plates, it is imperious to think in terms of three-dimensional objects having complex forms that have been cut. A single level cannot be used as a proof for a separation or a mixture of elements. The recent progress of cerebral cartography has highly improved the precision of the description and the comparison of data. Sagittal views or slices show the geometrical complexity of the separating elements.

Topological Analysis

Usual concepts used today for the description of the cerebral organization are inherited from the end of the 19th century with their limitations. To understand the thalamic anatomofunctional structure, but also to better interprete experimental results, it is important today to distinguish neuronal sets and neuronal set spaces (Percheron, 1979; Percheron *et al.*, 1991, 1996) (Fig. 20.3A). Neuronal typology uses simple and reliable methods (Yelnik *et al.*, 1991). The founding neuronal set is the neuronal species: the set of neurons whose dendritic arborizations are statistically similar on topological, metrical, and geometrical parameters. Species and their parts are generally located in a given metrical space. There are thus distinct neuronal spaces shown on Fig. 20.3: nucleus, patria, basin, and territory. These spaces were implicitly understood to always coincide with thalamic nuclei, which is often not the case. The recent important changes in the conception of the thalamus come from the application of this rule. Neuronal sets have own internal organization (spatial distribution of items). That of a basin is an output map or outmap (Fig. 20.3); that of a territory is an input map or inmap. The transfer from one to the other forms the connectional map, using various combinatory possibilities. The ones shown on Fig. 20.3. are extreme cases among many intermediary situations. Topological closely linked to the experimental methods. Retrograde labeling disclose basins. Partial injections do not give the same result in the various mappings. Different in- and outmaps do not imply discrepant results.

Phylogenetic Problems

The anatomical description of the human thalamus is limited by the fact that it is still not possible to trace detailed connections in man. The most reliable tracing techniques rely on axonal flows, making necessary the resort to living animals. This had and has serious effects. Many conflicts in the description and nomenclature of the thalamus have come from different standpoints in relation to phylogenesis. The Vogt school (C. Vogt, 1909; Friedemann, 1911; Mussen, 1923; Vogt, 1941, and later Hassler, 1949, 1959; Hopf *et al.*, 1971) essentially worked on the human thalamus, resorting to monkeys for experimental data. Its parcellation and nomenclature were used by most stereotactic atlases, at first that of Hassler (1959, in Schaltenbrand and Bailey's celebrated book). Widely used by neurosurgeons, Hassler's partition was excessively complex with disputable functional attributions. Andrew and Watkins' (1969), van Buren and Borke's (1972), Emmers and Tasker's (1975) atlases are much simpler but, unfortunately, had less success. The "Michigan school" (named so by Walker, 1938) was a school of comparative neurology (Huber and Crosby, 1929), stemming from Le Gros Clark in London and starting with studies on early primate (Le Gros Clark) or nonprimate species (Gurdjian, 1927; Rioch, 1929). The partition and nomenclature were transferred to macaque brains by Le Gros Clark himself, and then by Crouch (1934), Aronson and Papez (1934), and Walker (1937, 1938). This nomenclature was used for the human brain by Sheps (1945), Toncray and Krieg (1946), and Dekaban (1955) and has been recently reintroduced in human brain stereotactic atlases (Talairach and Tournoux, 1988; Morel *et al.*, 1997; Mai *et al.*, 1997), raising problems of equivalence. Keeping the same name for thalamic elements throughout the phylogenesis of the thalamus is a belief in a general mammalian thalamus whose description would suffice for any species including ours. This minimizes evolutionary trends and changes and, as will be seen for the human thalamus, does not always allow the precise description of one species. There are noticeable changes from monkeys to man: thalamic parts have disappeared, others have appeared, and some have considerably developed. Within thalamic parts, the numbers of neurons (particularly of local circuit microneurons) and the complexity of connectivity increase (Kultas-Ilinsky and Ilinsky, 2001). Phylogenetic changes are linked to systemic modifications that must be considered as a whole. The large increase of the cerebral cortex and the differentiation of major afferent systems such as the basal ganglia system have strong thalamic effects that must be taken into account. The recent observation that afferent territories can be indirectly delineated by using immunochemistry has significantly improved the possibility of comparison. The recent understanding of some phylogenetic changes makes it possible to reunite the historic choices of major schools in a new synthesis.

DIENCEPHALON

There remains confusion concerning which cerebral elements really belong to the thalamus. The tradition relied on large ontogenic, embryologic subdivisions. Recent studies, using gene expression, favor the "neuromeric model" (Puelles and Rubinstein, 1993; Mueller and O'Rahilly, 1997, O'Rahilly and Mueller, 1999). In this model, the hypothalamus is no more diencephalic. The embryological lamina limitans of Kuhlenbeck (1920) forms the hin lamina medullaris

FIGURE 20.2 Lamellae and the classical model. **(A)** Transverse section (+12, Hassler *et al.*, 1979, modified) showing separating lamellae. Lamella perithalamica separates dorsal thalamus, or thalamus, from perithalamus (ventral thalamus). Myelinated lamellae separate large thalamic regions: lamella medialis (or interna), surrounding the medial region (regio medialis), and lamella superior, continuous with stratum zonale, surrounding superior region (regio superior, separating it from M and L). Neurons within lamellae form the intralaminar formation (Il) continued medially in the adhesial or commissuralis (Ad co) part, dorsally in cucullaris (cu) making a circle around the nucleus medialis (Grunthal n.circularis, Hassler's involucrum). Medially, regio paramediana or periventricular (dark) is a thin layer covering the ventricular wall. **(B)** Transverse section, more posterior. Perithalamus in continuity with "peripeduncular nucleus" (Ppd) and "nucleus pregeniculatus" (PrG). Appearance of regio centralis (C) and lamella centralis (lc) laterally separating it from the pulvinar and the lower part of the regio lateralis (Varc, nucleus ventralis arcuatus). Intralaminar neurons present in the lamella medialis not in the lamella centralis. **(C)** Slice of horizontal sections (9.7 from Van Buren and Borke's atlas modified). Superior region is surrounded by the lamella superior. Paramedian formation is reduced. The intralamellar lamina includes the intralaminar formation separates regio Medialis from Lateralis. Separation from the pulvinar is incomplete. **(D)** Slice of horizontal sections +2.7 to –0.9 from same (also modified), including the two commissures, the adhesio and the medial continuation of the intralaminar formation, (Adh Co), habenula (Hb) and habenulointerpeduncular bundle (Hbi). Regio centralis (C) strongly modifies the picture. Intralaminar-type groups of neurons are posterior to it: Ilpc, intralamellaris postcentralis and limitans (IlLi). PuO, wedge-shaped forward extension of the pulvinar. The main axis of the lateral region is curved. Its anterior part curves medially almost perpendicular to the midline (75°). **(E)** Transverse slice (Schaltenbrand and Bailey's atlas Fp 13 and 14 modified), close to the posterior commissure (CP) with the habenula (Hb). The lamella medialis still separates central **(C)** from medial region (M). Laterally, lamella centralis is devoid of neurons. Contiguity of intralaminar and limitans ensemble (Li) is made up of similar neurons though not in a lamella. Lm, lemniscus medialis. **(F)** Transverse slice (Fp 14 and 15, modified), posterior to the central region (c, central capsule). The irregular islands are no longer in a lamella with incomplete separation of M and Pu. Continuity of intralaminar elements with the limitans, constituting the intralaminar-limitans formation. Appearance of the regio basalis (B). It is not limited dorsally by a lamina. The presence of the lemniscus medialis (lm) and lateralis (ll) perturbs architecture.

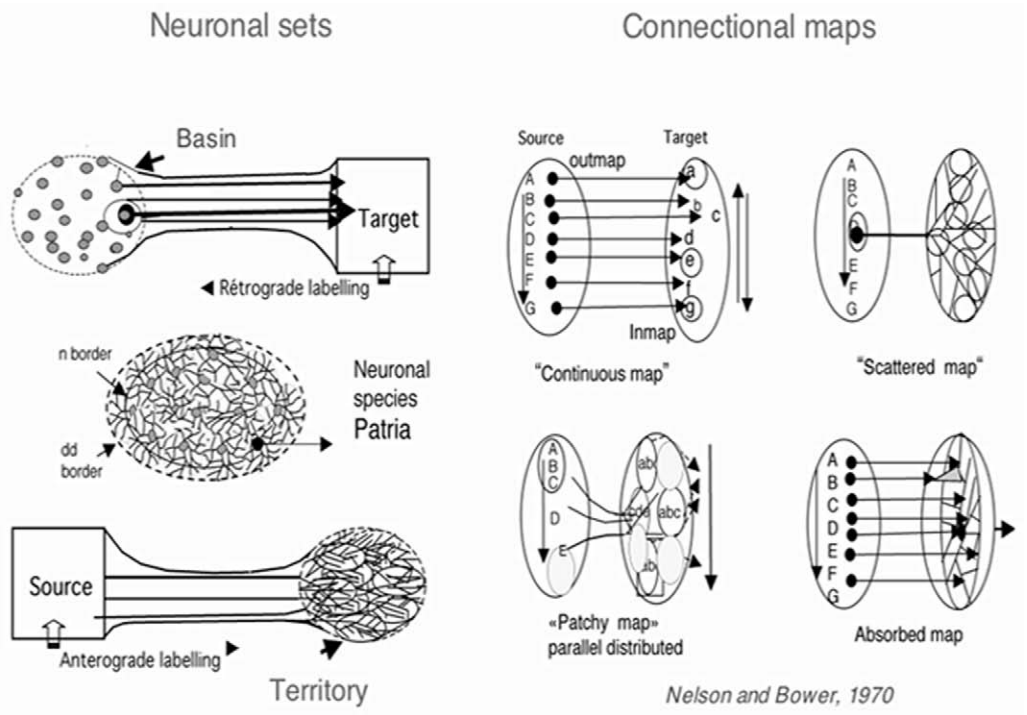

FIGURE 20.3 On the left, neuronal set spaces. The nucleus is the metrical space of all somata of one neuronal species. The patria is that of all dendritic arborizations of one neuronal species. The two borders do not necessarily always coincide. The basin is the metrical spaces containing all origins of neurons sending axons to one target. The territory is the space covered by all axonal arborizations from one source. On the right, connectional maps. Differentiated items may be differentiated in a source (basin). This inner order is an (output map) outmap. Differentiated items may distributed in a target. Their order is an (input map) inmap. The transfer of the outmap to the target may be made in different ways. Nelson and Bower (1990) distinguished three kinds: continuous, scattered, and patchy mappings. The first is the preservation of the discrete order present in the source by an ordered distribution in the target. In the upper left, the order of the source outmap is similar in the target inmap. A reverse order is still the same map. For getting such a distribution, in neuronal set terms, the space covered by one axonal arborization must be small enough (a) in comparison to the whole size of the target to maintain a distinct item of information and an about equal number of differentiated zones. This implies that the receiving dendritic arborizations of the targets is small enough to maintain about the same number of distinct items of information. This is observed in sensory systems. The outmap can be completely lost in the case where every separate element of the source is able to send information to any element of the target (scattered). This is also obtained when every neuron in a target is able to receive information from any distinct items of the source (absorbed). A frequent case in the brain uses islands or subgroups. The outmap is broken in several subparts. Each may give two or several inmaps in the target. This is a possible substrate for parallel distributed processing.

Continued

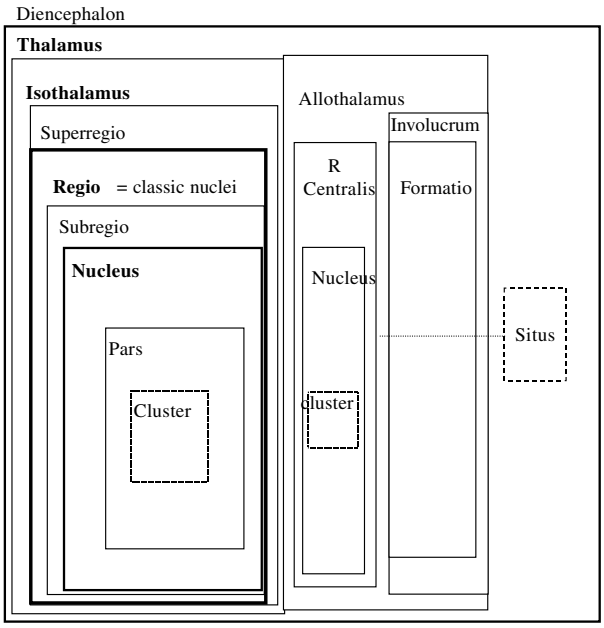

FIGURE 20.3 *Continued* Diagram of the hierarchical subdivision of the thalamus. As for zoological taxonomy, all levels are not filled. A site is not a formal subdivision and simply a distinctive topographic indication.

lateralis or lamella perithalamica (Fig. 20.2A) separating the "ventral thalamus," which is in fact lateral to the "dorsal thalamus" or better perithalamic (Ramon-Moliner, 1962, 1975) from the bulk of the thalamus. The geniculate bodies, ancient "metathalamus," leave early the thalamic mass but are parts of the dorsal thalamus considered here as the thalamus. The main subdivisions of the diencephalon are thus the thalamus and two nonthalamic elements, the epithalamus (habenula) and the perithalamus.

Epithalamus

In Rose and Woolsey's classical concept (1949), the "epithalamus" comprised the "paraventricular complex, habenular complex and the pretectal group of nuclei" not linked to the cortex. Only the habenular complex will be evoked. Habenula (small habena) means belt. This described the stria. The cellular part, commonly designated today as the "habenula" was the "ganglion habenulae" (Sachs, 1909; Hb, Figs. 20.1 and 20.2). This is made up of two nuclei (nuclei habenulae, Nomina anatomica): the nucleus habenulae medialis (HbM) and lateralis (Hbl) with contrasted neuronal types and immunochemical properties. The medial is densely stained by Nissl techniques with small round somata. The main afferent system comes through the stria medullaris (sm, Fig. 20.1). This is a bundle of myelinated axons, a noticeable part of which are pallidohabenular (Nauta and Mehler, 1966; Percheron *et al.*, 1996; Parent *et al.*, 2001). This major connection, in number of axons, is not understood yet. The major efferent bundle is the habenulointerpeduncular tract (fasciculus retroflexus of Meynert, 1872). Arising from the two habenular nuclei, it passes medially and then below the caudal pole of the medial nucleus of the thalamus, and then through the central complex and through the red nucleus to end in the interpeduncular nucleus. Part of this bundle is made up of cholinergic axons. The habenular system offers strong topographical marks for the analysis of the thalamus. The "stria medullaris thalami" (sm, Fig. 20.1 and 20.2) and the taenia thalami form the line of attachment of the tela choroidea and mark the superior roof of the third ventricle.

Perithalamus

As will be seen later, the classical subdivision of the thalamus was done using reference to myelinic lamellae. Arnold's (1838), the first, described a "stratum reticulatum" (reticulate not "reticular"), lateral to the thalamic mass. It was separated from it by the lamella perithalamica or "lamina medullaris externa" pursuing the embryological lamina limitans of Kuhlenbeck that thickens by the addition of various axons. Kuhlenbeck (1948) described a "ventral thalamus" (opposed to the dorsal one) comprising various elements: the reticulate nucleus, the zona incerta of Forel (1877), the pars ventralis of the lateral geniculate body, and the peripeduncular nucleus (ppd, Fig. L14. The ensemble in fact forms a continuous sheet, wrapping the external face of the thalamus (including that of the lateral geniculate body Fig. 20.3E, F). Below the thalamus, it widens and becomes fuzzy medially to form Forel's (1877) "zona incerta," that, as indicated by its name, has no clear border with the upper mesencephalic reticular formation. Posteriorly the so-called GL ventralis (or "ventral part of the lateral geniculate body") is in fact dorsal and lateral and a perithalamic part in primates. Peripeduncular and perigeniculate extensions are observable (Figs. 20.3B and 20.23B). The whole perithalamus is made up of very large neurons with large dendritic arborizations (leptodendritic, Ramon Moliner, 1969, which is a factor of wide convergence) that are flat and intertwined (Fig. 20.25). There are also a few local circuit neurons (about 15%, Dewulf, 1971). The majority of the large neurons contain parvalbumin (Münzle *et al.*, 1999) making a characteristic dark ring around the thalamus (allowing its differentiation from the motor thalamus in its anterior part). Bungarotoxin (alpha BTX) binding is particularly high with islands of higher concentration.

Other islands of cells and axonal endings are rich in calretinin (Ciccheti *et al.*, 1998; Fortin et al., 1998). The meaning of such islands is unknown. The topological position of the perithalamus in relation to the thalamus on one hand and the cortex on the other hand has been well established by the Scheibels (Scheibel and Scheibel, 1966b), (Fig. 20.5). The perithalamus is linked to the thalamus by collaterals from both thalamocortical and corticothalamic axons. One circuit shown by the Scheibels is short. The thalamocortical neuron sends axonal branches to a perithalamic neuron that sends back an axonal branch to the thalamic neuron (Fig. 20.5A). Another, longer, circuit involves the corticothalamic connection. A corticothalamic axon of a cortical pyramidal neuron sends a collateral to the perithalamic neuron that sends its axon to the thalamocortical neuron, which in turn sends a collateral to the perithalamic neuron. This offers the possibility for short circuits that may be the substrate of rhythmic activities. There is a significant literature about perithalamic degeneration in many species. It has been known for long that the perithalamus partially degenerates after cortical lesions together with the adjoining nuclei, at a date later than the thalamocortical neurons (as is also the case for internal circuit microneurons). The perithalamus also receives many cholinergic axonal endings (Heckers *et al.*, 1992). Perithalamic neurons have only one target, the thalamus. The perithalamothalamic axons, usually not much branched, have rather long trajectories through the thalamus, often ignoring the boundaries of nuclei. The anterior pole in macaques gives off more branched axons (Ilinsky *et al.*, 1999). In a comparison of eight species including man, Arcelli *et al.* (1997) showed that the perithalamic formation is a recessive structure (which is evident even between monkeys and human beings). In the human brain, the perithalamus is relatively thin, in some places difficult to delineate, with only few neurons. Arcelli *et al.* (1997) contrast this decline with the large increase in number of local circuit microneurons in the thalamus (Fig. 20.5). Both are GABAergic (inhibitory) and give branches to projection neurons. Perithalamic axons end on thalamocortical or local circuit neurons with long asymmetric synapses. At least 50% of terminal endings from the polar part of the perithalamus end on GABAergic local circuit neurons of the motor thalamus of macaques (Ilinsky *et al.*, 1999). In cats, the perithalamic nucleus is involved in the production of cerebral rhythms. Arcelli *et al.* (1997) made the hypothesis that "with the increase in the number of local circuit neurons in the dorsal thalamus, the Rt role becomes more focused in the regulation of sleep-waking cycle, and/or in acting as a thalamic pacemaker, rather than in direct thalamic inhibition."

THALAMUS

Lamellae and Classic Nuclei. Burdach's Model

The observation of thalamic lamellae was made as early as 1786 by Vicq d'Azyr who noted a "reddish spot" (current medial nucleus) surrounded by a "white circle." Burdach (1822) was the first to use the term "lamina medullaris interna" (lamella medialis, Fig. 20.2A, C) as the reference mark for the topographical distinction of "Kerne" or nuclei, his "innerer Kern" (internus) being medial and his "äusserer" (externus) lateral to it. Two other main subdivisions were the superior (anterior) nucleus and the posterior nucleus or pulvinar. In 1865, Luys added his "centre médian" surrounded by a capsule. A further addition, that of the semilunaris (Dejerine, 1895), cupuliform (von Tschisch, 1896), or arcuatus (Kölliker, 1896) nucleus, to which was linked a middle lamina medullaris, is no longer retained (not being "separating"). Déjerine (1895) insisted on the fact that his "noyau anterieur" was wrapped by a myelinic capsule with two parts: one dorsal, made up of the "stratum zonale," and one ventral, for him a particular thalamic lamella, the "lamina superior or anterior," isolating the anterior (superior) region from the rest (Fig. 20.2A, C). In 1941, the Vogts noted that the term "lamina" (usually designating a set of neurons lying in a row) was misleading and proposed that of lamella (also a recommendation of the Louvain symposium, 1963; Dewulf, 1971), which is followed here. Vogt (1909) and the Vogts (1941) indicated that only the superior part of the capsule surrounding the centre médian (supracentral) was the ventral continuation of the lamella medialis (their La.m., lm, Fig. 20.2B). The lateral part was said to form a distinct entity, their lamella intermedia (La.im, lamella centralis, lc, Fig. 20.2B). This is important for the interpretation of the central region (see regio centralis). Burdach's lamellar system, completed by Luys, forms the "classic model," separating what may be called the "classic nuclei" by the classic lamellae. This model was referred to for decades in works by Forel (1877), Sachs (1909), and Malone (1910). Figure 218 of Foix and Nicolesco (1925) shows the system of laminae that was generally used. At the Louvain meeting, it was recommended that the classic nuclei (separated by lamellae) be denoted "regions" or "formations".

Limiting Elements. Allo- and Isothalamus

The early use of staining techniques following Nissl showed that parts of the lamellae were not simple myelinic entities and contained neurons (Malone,

1910, "nucleus reuniens"). Classical nuclei were thus separated or surrounded by darker elements, particularly making a circle (rather a shell) around the medial nucleus—Foix and Nicolesco's (1925), "formation circulaire hyperchromique," Grünthal's (1934) "nucleus circularis," or Hassler's "involucrum" (or "enveloppe")(see Figs. 20.2 and 20.4). These limiting elements (in the lamellae and elsewhere) have neuronal genera different from those of the bulk of the nucleate thalamus. This is composed of similar neurons organized in the same manner and thus said to form the isothalamus (Percheron *et al.*, 1996; Fig. 20.4). By contrast, the limiting elements are said to constitute the allothalamus. Starting from Louvain's recommendation, it was proposed to reserve the term "regio" for classic nuclei and that of "formatio" for separating elements (Percheron *et al.*, 1996). The central region raises a particular problem because it is both a classical nucleus and allocortical. It is considered here as a region. For practical reasons, the study of the allothalamus is placed at the end of the chapter. To understand the spatial distribution of the limiting elements (particularly intralaminar-limitans), the reader could benefit from looking at Figure 20.24, on which the intralaminar system seems to stem from the adhesio, surrounds the medial nucleus, and ends in a complex way posteriorly to the central region. The lamellar system and the classic model with classical nuclei interpreted from these bases are shown on Fig. 20.2 on transverse sections (A, B, E, F) and two horizontal (C, D). The lamellar system ends at about one half of the length of the thalamus (Figs. 20.2C and 20.7A). There is no complete separation of the medial and posterior regions. All classic nuclei are not delineated by lamellae. For instance, there is no lamella between the posterior part of the lateral and the posterior regions. Anyway, the classic model remains a satisfactory base for the description of the thalamus, allowing to start from major classical works.

The analysis of pathological cases and the use of new techniques, anatomical and physiological, soon showed that some classic nuclei were composed of several anatomofunctional elements. For a long period, these were given the name of "nucleus." The reliance on a single elemental entity, the nucleus, sometimes subdivided in pars, led to a great confusion in the description of the thalamus.

The naming of thalamic parts must take into account the hierarchy of neuronal sets: cerebral part, diencephalon, thalamus. The belonging to either the iso- or the allothalamus leads to different categories. The isothalamus is subdivided into regions, representing the large classical "nuclei." These furnish the first adjective and acronym. The regions may correspond to one nucleus but more often correspond to several subregions. Subregions, are structurofunctional parts of regions. In the case of the lateral region, they are elements of the posteroanterior sequence of territories denoted by the second adjective. As for the zoological system, all levels are not necessarily filled. A regio or subregio may be made of a single nucleus (medialis for instance) and may be simply described as nucleus. Parts (of a nucleus) are designated by the third adjective medial or lateral, inferior or superior. A nucleus can have no pars. Clusters are elements such as rods, lamellae, and islands. Siti (sites) denote topographical places not necessarily positioned in the hierarchy (though often at pars level). They are characterized by their situation, have been often described as nuclei, but may not be a distinct subdivision.

ISOTHALAMUS. CONSTITUTION, ARCHITECTURE, AND FUNCTION

Contrary to its division into smaller masses and to the diversity of the afferent systems, the basic histological constitution of the bulk of the thalamus is made up of the same kinds of elements throughout. The parts of the thalamus built with these elements form the isothalamus (Percheron *et al.*, 1996). This is made up of two neuronal genera: the Golgi type I, "bushy" neuron (Kölliker's Buschzellen, 1898) (Fig. 20.4A) and the Golgi type II (von Monakow's Schaltzellen, 1895; McLardy's microneurons) (Fig. 20.4B). The first is the thalamocortical neuron having a long and robust axon aimed at its outer (cortical) target. The second is devoted to local circuitry. The two are engaged in particular relations. Dendritic arborizations of "tufted." "radiate," "bushy," "principal," thalamocortical, Golgi type I neurons are so peculiar as to be easily recognized in almost all mammalian species and particularly in man. Their graph theoretical analysis (Percheron, 1979, 1982) indicates the abundance of branches, measured by the number of dendritic tips, among the highest in the brain, increasing in evolution (Percheron *et al.*, 1996). There is a rather high number of stems. These stems are the origin of as many radtrees (Percheron, 1979, 1982). Topological parameters are different in individual nuclei and animal species but stable in the same place and animal species, which allows the identification of neuronal species. Metrical features of dendritic arborizations also are noteworthy. While terminal branches, twigs, are long, internodes and stems are usually short. Most nodes are close to the soma. The result is that there are grossly two zones, one proximal (somatic and proximal dendritic) and one distal. Distal inputs run on the longest distance on

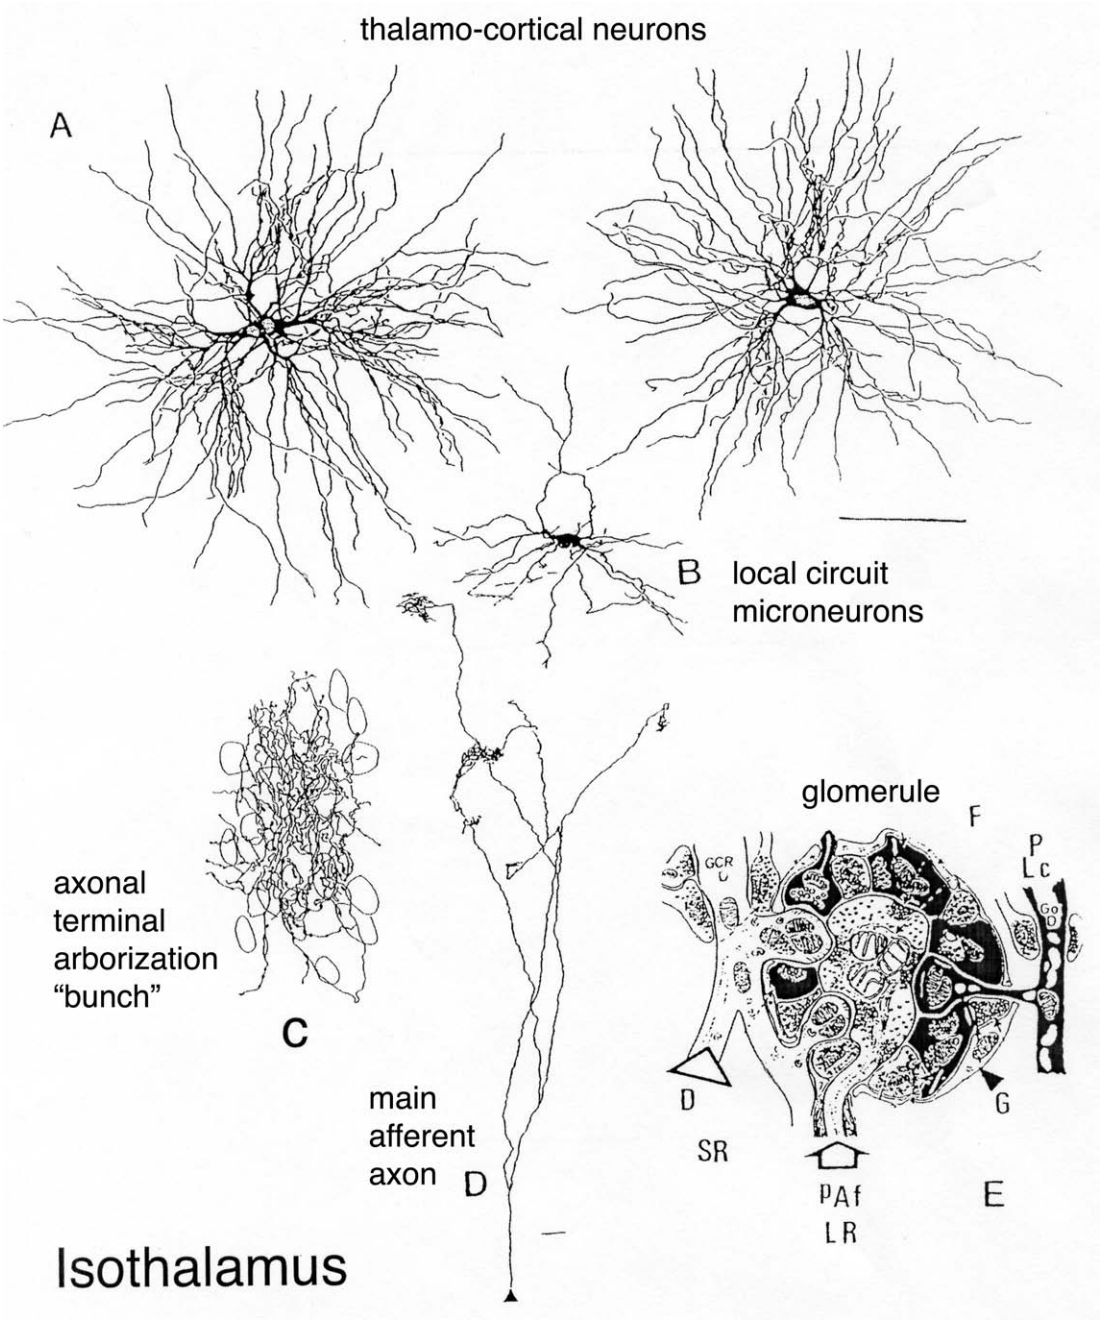

FIGURE 20.4 Elements of the isothalamus. **(A)** Upper row (from Percheron *et al.,* 1996). Two fully reconstructed bushy thalamocortical neurons. Note their high degree of branching. The number of branches and the diameter of arborizations vary with the location in the thalamus and with animal species (growing in evolution). Thick dendritic stems give dendritic subtrees branching close to the soma. Numerous and close branching give these neurons a very recognizable look and specific properties. The presence of such neurons suffices for defining the isothalamus. **(B)** Local circuit microneuron with few short branches and axonlike processes. The percentage of these neurons depends on thalamic parts and animal species (increasing in evolution, maximum in man and "associative" parts). (**C** and **D**) Afferent axon (pallidal) from Arrechi-Bouchhioua *et al.,* 1996). Fully reconstructed pallidal axon from its entrance to its ending in the thalamus. This species of axons gives several long branches and separate terminal axonal arborizations . These "bunches" are dense. The magnification is different from that of A and B. Several of them are thus necessary for covering one dendritic arborization (bringing convergence). One important component, corticothalamic endings, should have been added. **(E)** Early representation by Szentagothai *et al.* (1966) of a thalamic synaptic complex, here a glomerulus (in the GL of a cat), representing an extreme in differentiation of thalamic synaptology. One axonal ending of the principal afference (pAf) gives a large round bouton (LR) synapsing with the dendrite of a bushy thalamocortical neuron (D) and with endings of local circuit neurons (Lc). The glomerulus is closed by a glial capsule (G). The endings of corticothalamic neurons giving SR boutons are usually located more distally on the dendritic arborizations of the thalamocortical neurons. Two other types are F flattened for perithalamic axons (and others) and P from local circuit microneurons.

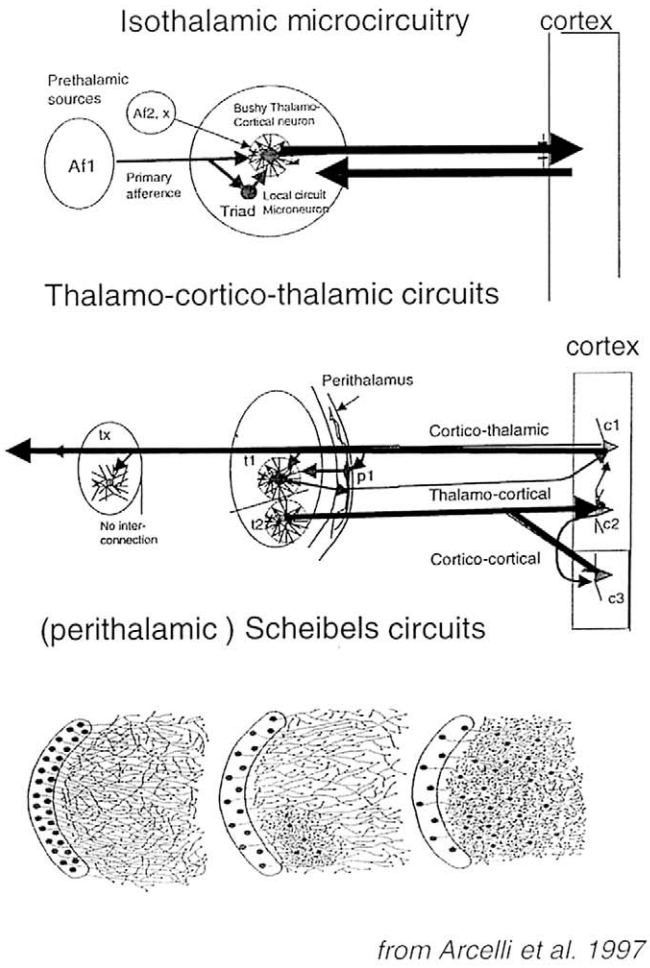

FIGURE 20.5 Topological positions of the perithalamus and local circuit neurons in relation to the cortex and thalamus. The perithalamic neuron with a very large (flat) arborization receives collaterals from the thalamocortical neuron (t1). Perithalamic neurons (p1) have a single target, the thalamus, to which they send an inhibitory message. There is thus a first Scheibels' minicircuit (t1-p1-t1). Another, which is longer, introduces the pyramidal corticothalamic neuron (c1). t1 sends an axon to c1. This, in turn, sends a collateral to the perithalamic neuron (p1), which sends back its axon toward thalamic bushy neurons (t1, thus t1-c1-p1-t1). There is no direct thalamothalamic (t1-t2) but extended corticocortical (c1-c2) interconnections. Thalamocortical neurons generally have several targets (t2 to c2+c3). Corticothalamic axons are generally modestly branched and overpass the nuclear boundaries, usually reaching other thalamic targets (tx). Within the same isothalamic region, a primary afference (Af1) gives synapses to the principal, bushy, thalamocortical neuron and to a local circuit neuron. This sends back synapses to the bushy neuron, forming a triad. The thalamic neuron thus receives two consecutive messages the first (excitatory or inhibitory) from the primary afference and the second, inhibitory, from microneuron. Bottom row. shows the progressive replacement in evolution of perithalamic by local circuit neurons (Arcelli *et al.,* 1997, Fig. 10).

twigs without encountering other afferent branches. Confluence of flows is made only very close to the soma and trigger zone. The three-dimensional geometry of the dendritic arborizations are usually spherical, sometimes modified by local factors and, except for the lateral geniculate body and some arborizations in the lemniscal relay, have no privileged orientation in relation to axonal afferents. The diameter of the arborizations is moderate, around 350 to 500 µm in the "basic" isothalamus, but can be larger in some nuclei. Another remarkable morphological feature of bushy, thalamocortical, neurons in Golgi preparation and in injected neurons is that their long, thick, myelinated axon does not emit initial collaterals (which is not so common) (Fig. 20.5). This means that a given thalamic neuron at one thalamic place does not communicate its leaving information to neighbor neurons (Fig. 20.5). On the contrary, all neurons give *en passant* collaterals

to the perithalamus (Fig. 20.5). Isothalamic neurons do not survive the transsection or serious lesioning of their axon. Their soma degenerates and dies (von Gudden's retrograde degeneration). The terminal axonal arborizations are generally dense in one or several successive bunches ending in layer IV in the eugranular cortex or in the lower part of layer III corresponding to "specific axonal endings." The mediator used by the thalamocortical neurons is glutamate. They stain for CAM II K alpha (Benson *et al.*, 1991; Jones, 1994), evocative of the presence of an exitatory aminoacid (Steriade *et al.*, 1997). They also stain for either calbindin or parvalbumin "and virtually never for both" (Jones and Hendry, 1989); the staining is used to differentiate neuronal groups and nuclei. Jones (1998) elaborated a theory differentiating islands of parvalbumin positive neurons among a "matrix" of calbinding positive neurons, the first projecting to deep layers of the cortex and the other to its superficial layer I. They were presented as constituting two classes of thalamocortical neurons, which is disputable.

The second type of isothalamic neurons is the "local circuit neuron," "interneuron," intrinsic, Golgi type II neuron (Fig. 20.4). They have a small soma (McLardy's, 1963, "microneurons") and short dendritic arborizations, around 250 µm. These arborizations are irregular in topology and three-dimensional geometry, apparently dependant on local conditions. They sometimes have one (or several) distinct axon that branches close to the dendritic arborizations. However, more generally, there are many thin axonal appendages stemming from dendrites, even from their distal part or their tips (the dendrite seems to end as an axon). The thalamic microneurons are GABAergic (inhibitory). Letinik and Rakic (2001) recently found that a part of them is of telencephalic origin in the human, and only in our species, which would serve to increase their number. Microneurons survive longer after cortical lesions but, after several months, do not survive the death of the thalamocortical neurons. The relative percentage between the two isothalamic genera was measured by Dewulf *et al.* (1973), Dom (1976), and Braak and Weindl (1985) in the human and Hunt *et al.* (1991) in the monkey. The ratio increases in evolution (Ilinsky and Ilinsky, 1993) from back to front in the formatio lateralis. The numbers given by Dewulf *et al.* (1973) should be corrected by a supplementary correction of 10–15% for stereological reasons argued by Hunt *et al.* (1991). All studies show that the relative percentage of microneurons is high, about 25% in many nuclei, up to 50 or 60% in the superregio medioposterior of the human brain. This ratio is an index of complexity.

Three kinds of afferent axons are distinguished: the "primary," supplementary, and corticothalamic axons (Fig. 20.4). Primary afferent axons from "prethalamic" sources belong to large afferent bundles and are numerous, usually with abundantly branched terminal arborizations forming dense territories. This is the case for sensory afferences (optic, auditory, gustatory, somesthetic), cerebellar, pallidal, nigral, mamillary, and fornical. The other afferent axons end usually as coafferences within primary territories, often in an insulate manner. They may completely cover or not the territory filled by the axonal arborizations of the primary source. Concerning cortical afferences, a forgotten law is that every isothalamic part receives many more axons from the cortex than it sends thalamocortical axons. This increases noticeably in the phylogenetic scale. Not only does the thalamus inform the cortex, but a strong influence is also exerted upon the thalamus.

The "principle of reciprocity" (Diamond *et al.*, 1969; Jones, 1985), asserting that every part of the cortex that receives axons from one thalamic subdivision sends back its axons to this cortical focus, is generally true but not absolute. The layer receiving thalamic axonal arborizations (IV), being different from that of the corticothalamic neurons (usually in layer VI), Crick and Koch (1998) proposed their "no-strong loops theory" (in fact circuits) made up of "driving" (thalamocortical) and "modulating" connections. Usual corticothalamic axons (Rockland's type 1, Rockland, 1994, 1996) are very sparsely branched and make connections with dendritic arborizations along an almost straight direction (see Yen in Jones 1985; Rockland, 1994), but can go deeply into the thalamus. This leads to feeding information on a long distance with a very low density. Corticocortical connections can transfer the receiving thalamic information to another focus (Fig. 20.5). The ultrastructural study of the isothalamus, started in the sixties (mainly in the lateral geniculate body where degeneration could be easily obtained, Szentagothai, 1960, 1962; Colonnier and Guillery, 1964; Szentagothai *et al.*, 966; Peters and Palay, 1966; Jones and Powell, 1969; Harding, 1971, to select only some), established a peculiar pattern of connectivity that appeared to be also observable in other isothalamic nuclei including the "associative" pulvinar (Mathers, 1972a). Four types of presynaptic terminals are described. The first corresponds to the so-called RL (Guillery, 1969, for round large) or LR (Harding, 1971; Fig. 20.4) terminals, which are electron dense with large mitochondria and round vesicles forming asymmetrical synapses. It is the primary afferent terminal (terminal of the principal prethalamic afferents, pAf, Fig. 20.5E). A frequent type—designated as small round terminals, RS or SR, or small, electron-dense that also forms asymmetrical synapses—is mainly located on the distal part of dendritic arborizations. Many SR

terminals are corticothalamic but not all, for many remain not degenerated after decortication (Mathers, 1972; Harding, 1973). F (for flattened) terminals are relatively electron lucent and form symmetrical synapses. They are GABAergic and end close to the soma. All perithalamothalamic terminals and some local circuit microneurons are of this type. P (Harding, 1972, PSD) terminals are also electron lucent, contain flattened vesicles, are GABAergic, and form symmetric synapses. They are terminals of local circuit neurons. The terminals are organized according to particular patterns. One is the "triad" (Fig. 20.5). It consists of a synaptic connection from the primary afferent (pAf, 5) to dendritic portions of both the thalamocortical and the local circuit microneuron and a synaptic connection from the latter to the former. Triads lead to particular functional properties (Labos *et al.*, 1990). A major pattern is the "glomerulus" (Szentagothai, 1963; Majorossy *et al.*, 1965) (or "archipelago," in case of numerous terminals and combinations), made up of a dense group of synaptic boutons distributed around the large bouton (LR) of the primary afference (Fig. 20.5). It is completely or more often partially ensheathed by glial profiles (G, Fig. 20.5, "ensheating processes"). The main bouton (T1 in sensory systems) ends on a large, central, dendritic segment (D1) of the thalamocortical neuron. The principal afferent terminals (and glomeruli) are often on the soma or on the stems or proximal dendritic segments. Also included in glomeruli are axonal endings of microneurons (P). There are dendrodendritic synapses and synapses between interneurons that may form complex patterns. A particular case is met in the "associative" isothalamus where there is no prethalamic (primary) afference (to be discussed in regio posterior). The extraglomerular part of the isothalamus ("interglomerular neuropil") is made up of the same elements with variously complex arrangements. The most frequent profiles there are the SR boutons. Another indicator of the complexity of isothalamic synaptology is the existence of synapses and minicircuits between local neurons. This characteristic increases in evolution and from back to front in the lateral region (Ilinsky and Kultas-Ilinsky, 1993). The general pattern of isothalamic synaptology is organized in different ways in the nuclei receiving various modalities of information. The glial sheath is more or less closed. The terminal endings of the primary afference are more or less numerous, as well as secondary afferences or local circuit neurons elements. But, to some extent, as already noted by Szentagothai (as early as 1970), the design of the (iso)thalamic machinery may be said to be about the same, depending on the afferent system, only by particular modifications of the general pattern.

The isothalamus works with essentially two mediators. Glutamate, the mediator of the thalamocortical neurons, is also that of the corticothalamic neurons (showing that a binary circuit may be built with the same transmittor) and that of the main afferences—cerebellar and lemniscal. GABA, the mediator of local circuit microneurons is also that of the perithalamothalamic connection and of two main afferences—pallidal and nigral. The "three types of ionotropic glutamate receptors (AMPA, KA and NMDA subtypes) are present and are distributed rather uniformly" but "little is known about metabotropic glutamate receptors" (Kultas-Ilinsky and Ilinsky, 2001). Some other mediators are added by particular afferences, e.g., acetylcholine or enkephalin.

The isothalamus is a fine-grain structure. Thalamic dendritic arborizations of both bushy neurons and microneurons are relatively small, less than 500 μm, making possible the separate distribution of many distinct items of information. Bushy neurons not emitting local collaterals, and microneurons having only short branches, there is no possibility for direct intrathalamic internuclear connections. Specific terminal axonal arborizations are about the same size. There is thus a framework for separate channels for different modalities. Thalamocortical neurons have in common the sending of their axons to the isocortex, with also a general pattern. The isothalamic device probably everywhere does the same basic information processing, giving the access of prethalamic information to the cerebral cortex. The first role of the isothalamus seems to be to filter and format the various kinds of arriving messages in a form "readable" by the cortex. This is helped by the cortex itself, which sends important corticothalamic feedback. The isothalamus would thus be at first a translator. It also distributes and combines in space and time the output to several cortical targets. The second function of the isothalamus would be thus that of a distributor or selector to particular and possibly various areas of the cortex.

REGIO SUPERIOR

This thalamic region links together elements that were united at the beginning and inappropriately separated later, for decades. The nucleus superior of Burdach (1822) or nucleus anterior (Dejerine, 1895; Sachs, 1909; Foix and Nicolesco, 1925) extended posteriorly, as far as there was a lamella superior. Later, the posterior part of this nucleus was removed and misleadingly linked to the lateral (or dorsal) nuclei, as the nucleus "lateralis dorsalis." The knowledge about the constitution and connections of this element led

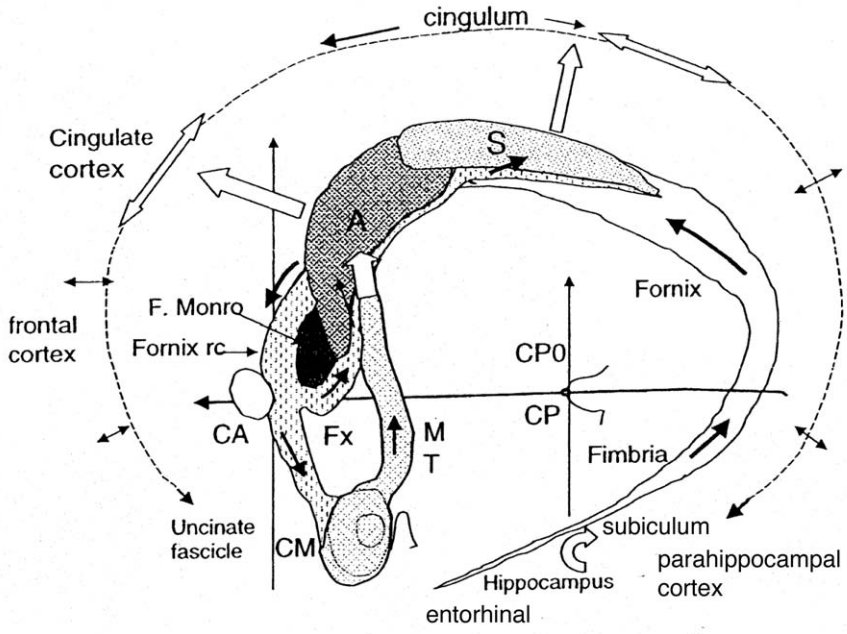

FIGURE 20.6 Regio superior. The two elements of the superior region (A, nucleus anterior; S, nucleus superficialis or superior) are shown in their positions with the complex trajectory of the afferent system from the hippocampus, fimbria, and fornix. After turning around the superior face of the thalamus, the fornix arrives as the anterior pilar close to the anterior commissure. There, a retrocommissural component passes dorsally to the commissure and divides into two parts. The first continues ventrally and reaches the mammillary body (corpus mammillare, CM). From there, a major bundle is emitted, the mammillothalamic tract of Vicq d'Azyr (MT). After a dorsalward sinuous trajectory, this reaches the inferior part of the anterior nucleus where it forms (in part) the lamella superior. The other component of the retrocommissural fornix turns round the inferior border of the foramen of Monro. It also reaches the anterior nucleus but through the superior lamella and essentially runs to the nucleus superficialis. The two nuclei have almost similar connections from the hippocampal system: the nucleus anterior, indirectly through the mamillary body, and the superficial directly. The two nuclei receive axons also from the cortex, at first cingular but not simply. The anterior nucleus has connections with the frontal cortex, and the superficial, with the parietal cortex. Both contribute to a major bundle, the cingulum, which links together many cortical regions and comes back to the parahippocampic cortex.

some to link it again to the anterior nucleus (Yakovlev *et al.*, 1960, 1966; Locke *et al.*, 1961, 1964; Van Buren and Borke, 1972). The regio superior (Percheron, 1969; Percheron *et al.*, 1996) is thus simply the classic anterior or superior nucleus, located above the lamella superior. It is superficial and may be observed on the dorsal surface as the protruding "anterior tubercle" ("tuberculum anterior") (already shown by Vicq d'Azyr, 1786, Fig. 20.1B). The region, larger in this anterior part, is elongated in the anteroposterior dimension. Starting at the anterior part of the thalamus, it ends progressively and merges into the pulvinar. The region constitutes a clearly distinct entity, as it is almost everywhere separated from both the medial and lateral regions by the lamella superior (Fig. 20.2). The "capsule of the anterior nuclei" and the internal lamina differentiate at about 104 mm (Dekaban, 1954). The superior lamella derives from the stratum zonale (Fig. 20.2A) downward with the addition of mamillo- and hippocampothalamic axons. The capsule makes superior elements "closed nuclei" (Mannen, 1960) and more precisely "enclosed nuclei" (Percheron *et al.*, 1996). The presence of a capsule between the nuclei anterior and superficialis separates two "enclosed nuclei" (Fig. 20.6A, 23 L6) one completely, the other only partly. The human "regio superior" is thus divided in two nuclei: anterior and superficialis or superior.

The anterior nucleus (Dejerine's 1906 and Foix and Nicoleco, 1925, "noyau antérieur"; "nucleus anterior" Sachs, 1909; Grünthal, 1934; McLardy, 1950; Russel, 1954; Feremutch and Simma, 1955, 1971; Van Buren and Borke, 1972) is the major ("nucleus anterior principalis", Apr., Vogt and Vogt, 1941), most traditional, nucleus. It has an inverted piriform shape in sagittal sections. In nonhuman species, the nucleus has been often subdvivided into two or three parts: anteroventalis or anterior ventralis (AV), anteromedialis or anterior medialis (AM), and anterodorsalis (AD) said to constitute as many nuclei. The presence and extent of these parts greatly changed in evolution. The subdivision of the anterior nucleus between the antero-

ventral (AV in fact dorsal) and anteromedial (AM) nuclei, already unnecessary in macaques, no longer appears to persist in man (except for coarse SP terminals exclusively observed in AV, Mai *et al.*, 1986). The nucleus anterodorsalis in nonhuman primates is a flat, oblong nucleus lying on the mediodorsal side of the nucleus anterior, from which it is separated by a lamella. In nonhuman primates, the cytoarchitecture of AD has darker cell bodies. It is not certain whether such a nucleus persists in man. Not considered by Toncray and Krieg (1946), the Vogts (1941) gave it the simple status of an accessory nucleus (nucleus anterior accessorius, Aac.). In many individuals, it is indeed made up of the same kind of neurons as the principal part. In macaques, the still obvious anterodorsal nucleus is known to receive afferences from the two (ipsi- and controlateral) mamillary bodies (Veazey *et al.*, 1982). The disappearance of this subdivision means a stricter lateralization of the system. The "anterior nuclear group" of textbooks usually meant AV + AM + AD but did not include the nucleus superficialis.

The nucleus superficialis or superior (S) ("nucleus lateralis dorsalis," LD), is today bound to the anterior group and more appropriately named "Superficiale" (Sf) by the Vogts (1941, II), "nucleus dorsalis superficialis" (D.sf, Hassler, 1959; Van Buren and Borke, 1972) or more simply nucleus superficialis (S. Percheron, 1966; 1996) or superior. It begins anteriorly just before the anterior nucleus ends (Fig. 20.6). It is in the same general topographic position as the anterior nucleus. Posteriorly, it remains superficial, becomes thinner, often makes irregular islands ("nuclei disseminati," Sachs, 1909; Riley, 1960), and moves laterally where it seems to fuse with the pulvinar. It must not be confused with Hassler's Pu.sf, which is more medial and is in fact a part of the pulvinar. The neurons of the two superior nuclei are typically isothalamic, radiate, and "bushy," with rather small dendritic fields. There is a rather large number of microneurons (32% in the anterior and 26% in the nucleus superficialis, Dewulf *et al.*, 1969, 1971, up to 42% GAD-IR neuirons, likely local circuits neurons, (Dixon and Harper, 2001), while they are only very few of them in rats (Dekker, 1976). The anterior nucleus is not covered by the perithalamus anteriorly and dorsolaterally (Fig. 20.2C, 13 L 6). It is rich in cholineric endings (Heckers *et al.*, 1992) in man and heavily stains for acetylcholinesterase (Jones, 1985). One of the characteristic of the region is its staining for calretinin (mainly fibers, Morel *et al.*, 1997; Fortin *et al.*, 1998; Münzle *et al.*, 1999). The (3H) nicotine binding is high, which would represent a significant difference of distribution between rat and monkey (Spurden *et al.*, 1997). There are GABA neurons, mainly local circuit microneurons (Hunt *et al.*, 1991) and a GABAergic innervation, with BZ GABA receptors more frequent in the monkey than in the cat (Bentivoglio *et al.*, 1993). As for other isocortical parts, axonal terminations of mamillary neurons are mainly located on proximal dendrites, while those of the hippocampus and cingulate cortex end on distal dendrites (in the rat, Dekker and Kuypers, 1976; Fig. 20.4 of Bentivoglio *et al.*, 1993).

The main afference to the regio superior is hippocampal, either directly or indirectly, through the fornix and the mamillary body (Fig. 20.6). The axons come from the subiculum ("subiculum proper" Krayniak *et al.*, 1977; Aggleton *et al.*, 1986; Van Hoesen *et al.*, 1993), prosubiculum (Aggleton *et al.*, 1986) and to a lesser extent from CA1 (Van Hoesen *et al.*, 1993) and presubiculum (Krayniak *et al.*, 1979; Aggleton *et al.*, 1986). Subicular axons gather in the fimbria, continue over the thalamus via the fornix, a large bundle increasing in size in evolution. When it arrives close to the foramen of Monro and the surface of the third ventricle, the fornix forms its "anterior pilar" supplying the main part of the "post commissural component" (Figs. 20.1 and 20.2C, D). From there, axons separate into two bundles: one proceeds to the mamillary body—and from there to the superior region—and the other directly to the latter regions in turning around the inferior border of the foramen of Monro (Poletti and Creswell, 1977; Fig. 20.6). The connection from the mamillary body to the anterior nucleus was identified a long time ago. The mammillothalamic tract is so obvious in man that it was dissected and first described in 1786 (Vicq d'Azyr, Pl. XXV; see also Cooper, 1950; Crosby *et al.*, 1962). "Vicq d'Azyr's bundle," as it became named, usually makes a double curve in the sagittal dimension first convex to the rear and then concave (Fig 20.6) and reaches the anterior nucleus at its inferior and lateral border participating in the lamina superior and making the border of the region particularly visible (Veazey *et al.*, 1982; Fig. 20.6). In simians, the main afferent system to the mamillary body is through the fornix (Powell, 1973; Poletti and Creswell, 1977; Aggleton *et al.*, 1986). In man, the mamillary body, the mammillothalamic tract, and the anterior nucleus system make up a major neuronal system that increases in evolution, even in comparison to monkeys (while the lateral mamillary nucleus disappeared in man, Crosby *et al.*, 1962). The system is important in size and in numbers of elements. The ratio between mamillary neurons (411,600) and anterior thalamic neurons (1,069,400) in man is 2.6 (Armstrong, 1986), indicating a limited numeric divergence. While the number of mamillary neurons does not increase from nonhuman anthropoids to human, the number of anterior thalamic neurons does (Armstrong, 1986) (the ratio moving from 1 to 2.6). The anterior nucleus is also furnished by direct hippo-

campal afferents bypassing the mamillary body through fibers of the postcommissural fornix turning round the inferior border of the foramen (Poletti and Creswell, 1977; Mikol *et al.*, 1984, Aggleton *et al.*, 1986). In addition, the anterior nucleus receives afferences from the anterior cingulate cortex through a direct route, round the caudate nucleus (Powell, 1973, Fig. 20.8) and from the posterior cingulate cortex (Vogt *et al.*, 1987). The projection of the anterior nucleus to the anterior cingulate cortex was identified over a century ago, first on human pathological material (Dejerine, 1895), by dissection (Bossy and Lacroix, 1968), and later experimentally (Mufson and Pandya, 1984; Vogt *et al.*, 1987; Bachevalier *et al.*, 1997). The anterior nucleus also sends axons to the posterior cingulate area (Vogt *et al.*, 1987), to the medial cortex dorsal to the gyrus cinguli, to the upper parietal (Niimi, 1962), to the prefrontal, the orbital (Barbas *et al.*, 1991; Carmichael and Price, 1995) and the retrosplenial cortex (Mufson and Pandya, 1984; Vogt *et al.*, 1987).

The nucleus superior does not receive axons from the mamillary body and receives only direct hippocampal afferents through the fornix. This afference was observed in man (van Buren and Borke, 1970; Mikol and Brion, 1975). Axons come essentially from the subiculum (Krayniak *et al.*, 1977; Aggleton *et al.*, 1986) and also, contrary to the anterior nucleus, from the entorhinal cortex (Aggleton *et al.*, 1986). The axons, passing below the foramen of Monro, run in the stratum zonale and reach the anterodorsal part of the nucleus above the anterior nucleus (Poletti and Creswell, 1977; Mikol *et al.*, 1977; Aggleton *et al.*, 1986) (Fig. 20.8). It receives axons from the posterior cingulate cortex (Mikol *et al.*, 1984) and inferior parietal lobule (Asanuma *et al.*, 1985). The nucleus superficialis sends axons to the posterior cingulate cortex (Yakovlev *et al.*, 1960; Locke *et al.*, 1964; Bossy and Lacroix, 1968; Mikol *et al.*, 1977, 1984; Mufson and Pandya, 1984) in continuity with the projection of the anterior nucleus to the anterior cingulate cortex, with some overlap at the junction (Yakovlev *et al.*, 1966). In fact, in man, the nucleus superficialis seems to project strongly also to the anterior cingulate area (Locke *et al.*, 1961). It also sends axons to the retrosplenial cortex, the subiculum (Mikol *et al.*, 1984), the presubiculum (Mufson and Pandya, 1984), the parietal cortex ("area 7"; Niimi and Tutsui, 1962) and the precuneus (7 and 31; Bossy and Lacroix, 1968; Mikol and Brion, 1975; Mikol *et al.*, 1977), which means more than "limbic areas."

The regio superior is an isothalamic region particular by its topography and its links with the historic Broca (1878) "limbic lobe" (cingulate and parahippocampic convolutions). In 1937, Papez described a circuit that started from the hippocampus reaching the mamillary body, the anterior nucleus, and the cingulate cortex and reached through the cingulum, the parahippocampal cortex, coming back to the hippocampus (Fig. 20.6). As already stressed by Shipley (1974), for decades, Papez circuit was not closed (at the hippocampal level). Dagi and Poletti (1983) claimed that "the cingulate cortex is not a prominent link in the Papez circuit." In spite of its success, the Papez circuit is only one among others. The superior region intervenes in these circuits according to complex combinatorics. The shortest are usually thalamocortical two-circuits with the subiculum and the cingulate cortex. One three-circuit is subiculum–mamillary body–anterior nucleus and back to the subiculum. The superficial nucleus receives direct afferences from the entorhinal cortex; another three-circuit is subiculum–superficial nucleus–entorhinal cortex–subiculum. The "Papez circuit" was linked by its author to the "mechanism of emotion". MacLean's included it later in his "visceral brain" (1949), which became his "limbic system" (1952). This led to many ulterior elaborations (see Brodal's, 1981, and Kötter and Meyer's, 1992, critical reviews). Rather than on emotion, the main effects of lesions or stimulation of the superior region provoke memory disturbances. Lesions of the mamillary bodies, Vicq d'Azyr bundle, or anterior and superficial nuclei, bilaterally, cause amnestic deficits such as the "anterograde amnesia" of Korsakoff's syndrome. Lesions of the hippocampal and parahippocampal cortex produce deficit of short-term memory (Penfield and Milner, 1958).

One element of the Papez circuit, the cingulum, is a huge parasagittal bundle of about constant thickness, higher in the posterior cingulate region (Bossy and Lacroix, 1968), that runs above the corpus callosum in the depth of the cingulate gyrus (Yakovlev and Locke, 1961). It links together the two anterior and posterior cingulate areas, the precallosal and retrosplenial regions, and, below the splenium of the corpus callosus, the parahippocampal gyrus. In fact, most axons do not make the whole turn. Most of those from the anterior nucleus do not reach the parahippocampal gyrus, and those from the superficial nucleus do not reach the subgenual or frontal areas (Mufson and Pandya, 1984). The cingulum also contains axons from the oculomotor and inferior parietal cortex (Mufson and Pandya, 1984). The "cingulum related system" is not closed and interconnected with the surrounding frontal (prefrontal and orbital, Vogt and Pandya, 1987; Van Hoesen *et al.*, 1993), parietal and oculomotor (Mufson and Pandya, 1984), and even premotor and motor (Arikuni *et al.*, 1994). The cingulum cannot be reduced to an element of the Papez circuit.

Yakovlev *et al.* (1960, 1966), Locke *et al.* (1961), Vogt and Gabriel (1993), and Bentivoglio *et al.* (1993) defined a "limbic thalamus" as the part of the thalamus that

sends axons to the cingulate, limbic, and cortex. This set, in addition to the superior region, would comprise the medial part of the nucleus medialis, the anterior part of the lateral region (VA), intralaminar, middline nuclei, and even the medial pulvinar (Yakovlev *et al.*, 1966; Vogt *et al.*, 1987; Bentivoglio *et al.* 1993), that is, a heterogeneous anatomical set without known functions. The benefit of such a grouping is not self-evident. The superior region is not so much "limbic" as the thalamic hippocampal territory.

REGIO MEDIALIS

The presence of a round nucleus in the middle part of the thalamus was already noted two centuries ago (Vicq d'Azyr, 1796, for instance). Using the lamella medialis as a landmark, (see "General Considerations"), Burdach (1822) described his "innerer Kern," the "noyau interne" of Dejerine, (1895), Cajal, *et al.* (1925), latinized into nucleus medius (Kölliker, 1895 and 1898) or medialis (Sachs, 1909, Malone, 1910; Nomina anatomica). This has been the term in common use in stereotactic and topographic atlases (Hassler, 1959; Hassler *et al.*, 1979; Andrew and Watkins, 1969; Van Buren and Borke, 1972) and the recommendation of the Louvain symosium (1963). The addition of the adjective "dorsalis" came after the unfortunate consideration, by von Monakow (1895) and C. Vogt (1909), of a "medial part of the thalamus" comprising in addition to the "classical medial nucleus" (C. Vogt, 1909) elements ventral such as the central region, having nothing in common with it. The terms "nucleus medialis dorsalis," "mediodorsal" (MD), "mediale dorsale" (Vogt and Vogt, 1941), and "dorsomedialis" (Sheps, 1945) introduced a persisting confusion that may be avoided by coming back to the initial nucleus medialis. From the beginning, this nucleus was observed to be almost everywhere separated from its surroundings, particularly laterally by the lamella medialis containing intralaminar neurons. Medially, there is a clear border with the formatio paramediana. The main problem is encountered at the posterior pole where there is no continuous frontier with the pulvinar (Fig. 20.2, 13 L9). Dejerine (1895), and many authors since, underlined that they have the same morphological aspect and no clear border. Golgi staining (VanBuren and Borke, 1972, personal material) shows that thalamocortical neurons have similar dendritic arborizations with the same size and shapes. Both regions have the highest number of micro-neurons in the thalamus (36–60.4% in the nucleus medialis, depending on samples or subregions, and 36–50% in the pulvinar, Dewulf *et al.*, 1972), which is considerable. Tracings between the medial nucleus and main pulvinar are carried out by "arbitrarily joining the cell islands of the n. intralamellaris " (Van Buren and Borke, 1972).

The medial nucleus was not divided in man over a long period (Dejerine, 1895; Foix and Nicolesco, 1925; Vogt and Vogt, 1941; Andrew and Watkins, 1969; Van Buren and Borke, 1972; Feremutch and Simma, 0000; Krieg, 1973). A separation was established in lower species (Rioch, 1929; Le Gros Clark, 1932; Crouch, 1934; Walker, 1938a; Olszewski, 1952) into a medial, magnocellular, and lateral parvocellular part. There is a visible "magnocellular" medial part in monkeys. The existence of afferences from the amygdala to this part is well documented in macaques (Nauta, 1961; Porrino *et al.*, 1981; Aggleton and Mishkin, 1984; Russchen *et al.* 1985; personal material). Walker (1938c) found the medial "magnocellular part very reduced in chimpanzees." This subdivision was found missing in more than 50% in human brains (Feremutsch and Simma, 1955). Foix and Nicolesco described a "sensibly unique type" of neurons in man. Cytometric studies made independantly by Dewulf (1971), Van Buren and Borke (1972), and Percheron (1966) did not show significant differences or any mediolateral gradient in somatic size between the medial and lateral parts. These data mean that there is no properly "magnocellular" part in man. This lack of a magnocellular part could cast a doubt on the existence of the amygdalar connection in man. But this connection is likely to persist as Klingler and Gloor (1960) dissected a bundle from the amygdala to the nucleus. However, there is no base yet for tracing the contour of an amygdalar territory in man. Another "lower" connection comes from the ensemble made up of the nucleus basalis, the nucleus of the diagonal band, and the medial septal nucleus (Hreib *et al.*, 1988) sometimes refered to as the "extended amygdala" including Brockhaus' (1938) "supra-amygdala." Vogt (1909), Walker (1938), and Akert (1964), in cercopithecidae described a third, "para-lamellar," subdivision, lateral and close to the lamella medialis—interpreted by some as belonging to the intralaminar formation. For Akert, the three parts—medial magnocellular, lateral parvocellular, and most lateral paralamellar—were three distinct sources of separate thalamocortical connections in macaques (Fig. 20.7). In cercopithecidae, there are in fact two paralamellar parts, not similar in cytoarchitecture: one anterior, in front of the central region, and the other posterior, dorsal to it. They correspond to parts of different territories. The posterior paralamellar site in macaques (pars multiformis of Olszewski, 1952) is a part of the cerebellar territory (Percheron, 1977; Fig. 20.7) with neurons resembling those of the cerebellar

territory in the neighboring lateral region VIm. The anterior paralamellar site, located in front and separate from the preceding, in macaques, receives nigral axons (from the pars reticulata, see subregio rostralis VA) (Ilinsky *et al.*, 1985; Percheron *et al.*, 1996). This part of the nigral territory looks like that located just on the other side of the lamella in VA (see lateral rostral subregion VA). No paralamellar part is described in chimpanzees (Heiner, 1960; Sakamoto, 1964; deLucchi *et al.*, 1965) or (except for a small Mpl for Hassler and pl for Morel *et al.*, 1997) in man. As conceded in the Louvain symposium, most proposed subdivisions in the human nucleus medialis were made on purely myeloarchitectonic differences (more myelinated fascicles being present laterally, Vogt, 1909; Hassler's 1959, 1977, 1979), which was criticized by Krieg, Feremutch, and Simma in Dewulf (1971). Van Buren and Borke (1972) conclude their examination of individual brains at the same level by considering "the n. medialis as a single entity." Immunostaining does not provide a much better tool for subdividing the nucleus. The medial nucleus does not stain for parvalbumin (or weakly, Morel *et al.*, 1997), calbindin or calretinin (Jones and Hendry, 1989; Morel *et al.*, 1977, personal material). Other stainings (e.g., acetylcholinesterase; Hirai and Jones, 1989a; Jones, 1997; Heckers *et al.*, 1992) brings out irregular islands. The topography of such clusters and their relation with cytoarchitectonic differentiation is not established. The lack of visible division in man raises the question whether there are still afferences from the cerebellum, nigra, and tectum in man. The most probable hypothesis today is that the lamella could be not the absolute separator postulated in Burdach's model, allowing territories to straddle it (leading to Feremutsch's heterotopy, 1973). Because of major changes at cortical levels, the two paralamellar sites corresponding to cerebellar and the nigral afferences could have withdrawn to the lateral region. The paralamellar sites and VA of monkeys are reciprocally linked to the frontal eye field (Akert, 1964; Künzle *et al.*, 1976; Akert and Hartman-von Monakow, 1980). The change in cortical oculomotor areas is such that the observed thalamic modifications would not be surprising. The separation between medial and lateral regions being greater in man, connections attributed to the nucleus medialis in macaques, when in its paralamellar part, must not be infered too hastly for humans.

It has been known for a long time that the major afferents to the nucleus medialis are cortical, particularly from the frontal cortex (Nauta, 1964; Akert and Hartman-von Monakow, 1980), according to a reciprocal pattern. This is not exclusive. The anterior cingulate cortex, for instance, projects dorsally, and the precentral motor cortex (Akert and Hartman-von Monakow, 1980), laterally. On the other hand, the medial nucleus is not the simple thalamic target of the medial face of the frontal cortex. Medial frontal cortex also projects to the anterior nucleus and the medial pulvinar.

Most of the knowledge about the efferent connection from the medial nucleus to the cortex came from human pathological material. As is true for other isothalamic elements, the medial nucleus degenerates locally after cortical lesions (von Gudden degeneration). This property was intensively used in the considerable literature devoted to brain examination after leucotomy. After Meyer *et al.* (1947) and Freeman and Watts (1947), McLardy (1950) came to the conclusion that there was a "general circumferential organization such that adjacent regions in the nucleus project to adjacent areas in the cortex." Van Buren and Borke (1972) came to about the same "circumferential" organization (see Fig. 20.7). Contrary to accepted ideas about the medial nucleus, Van Buren and Borke (1972) insisted on projections to cortical regions other than frontal, particularly to the precentral cortex. In macaques, an abundant literature is dealing with the main target of the medial nucleus, the frontal cortex. The intramedial organization of the sources to the various frontal cortical regions was examined by Mettler (1947), Nauta (1962), Leonard (1972), Tobias (1975), Passingham (1975), Goldman-Rakic and Porrino, (1985), Barbas *et al.* (1991), Ray and Price (1993), Bachevalier *et al.* (1997), and Cavada *et al.* (2000). As elsewhere in the isothalamus (see "General Considerations"), mediocortical axons have no local collaterals (Goldman-Rakic and Porrino, 1985). This means that distinct neuronal sources specifically project to distinct targets. In monkeys, the internal distribution was also said to be "circumferential" (Goldman-Rakic and Porrino's, 1985; Fig. 20.7). Kievit and Kuypers (1975) and Kievit (1979) insisted rather on a sagittal organization of the neurons projecting to the frontal cortex. Long stripes of neurons were found to extend not only from the anterior to the posterior pole of the medial nucleus but also anteriorly to the anterior part of the lateral region and posteriorly to the medial pulvinar. These stripes do not contradict the "circumferential" order observed in the medial nucleus since they are also parasagittal. Such stripes are in fact discontinuous (Goldman-Rakic and Porrino, 1985), forming islands with very irregular contours (Rouiller *et al.*, 1999). The frontal cortex had been "defined as the projection area of the mediodorsal nucleus"(Rose and Wolsey, 1948). This is no longer true in both directions. In macaques, the medial nucleus also sends axons to cortical regions other than the frontal: cingulate (Vogt *et al.*, 1979; Baleydier and Mauguière, 1980; Goldman-Rakic and Porrino, 1985; Vogt *et al.*, 1987), insular

FIGURE 20.7 Regio medialis and pulvinar. **(A)** Macaque. *Left,* transverse section of the frontal pole (Fig. 19 of Goldman-Rakic and Porino, 1985; inverted from right to left, midline is on the left). Numbers indicate cortical positions in a circular sequence in relation to cortical faces and main sulci. S.Princ, sulcus principalis. S. cing, sulcus cinguli. *Right*. Part of Section XXX from Olszewski's atlas corresponding to Goldman-Rakic and Porino's level. Position of the sources to different parts of the frontal cortex—"circumferential organization". The cytoarchitectonic borders drawn by Olszewski of the pars magnocellularis medially and pars multiformis laterally are shown. The contours of the nuclei, and subnuclei, not those of the sources placed in relative positions; are topographically mapped. Only the pars magnocellularis could coincide with the source to the orbital cortex. In macaque, the pars paralamellaris receiving tectal and cerebellar afferences projects to the frontal eye field. **(B)** Man. *Left,* transverse sections from Dejerine (Figs. 137 and 138) corresponding to that of the macaque in A. The sulci are indicated according to Bailey and von Bonin (1951). Cing, sulcus cinguli. Sfs, sulcus frontalis superior. Sfm, sulcus frontalis medius. Sfior, sulcus frontalis inferior orbitalis. *Right,* two levels show that the organization remains the same from anterior to posterior and from medial to lateral. The position of the sources are those described by VanBuren and Borke (1972). The spatial organization is also "circumferential," with the source for the orbitofrontal cortex (For) medially. The medial nucleus is not the only thalamic nucleus sending and receiving afferences from the frontal cortex nor the only furnisher of the frontal cortex. It sends axons to the cingular, precentral, and oculomotor cortex. The presence of a pars paralamellaris is not accepted by all in man (see note in the text). **(C)** Organization of the pulvinar in macaques. The position and contours are from Olszewski's (1952) plate XLII. *Left,* the end of the nucleus medialis is continuous with the pulvinar. Four frontal islands f, from Goldman-Rakic and Porino (1985) are radiating from one to the other. The three parietal islands (p) are from Hardy and Lynch (1992). The temporal islands are from Webster *et al.* (1991). The location of collicular islands is from Harting *et al.* (1980), Benevento and Standage (1983). Col-pu indicates the trajectory of tectothalamic axons. The visual pulvinar mainly corresponding to the intergeniculatus (Ig) or inferior part is delineated according to Bender's data. It is retinotopically organized with the limit of the four quadrants indicated by thick lines. The pictures, even not precisely mapped metrically, show that there is no clear mediofrontal border. B is Basal region receiving spinothalamic axons. **(D)** Medial-pulvinar superregion seen from above in man. (thick slice from VanBuren and Borke's 1972 atlas, 2,7 to 13.2). Anterior overlap of the pulvinar oralis dorsalis (PuOD) over lateral formation (L) and cuneiform PuO. Islands of nucleus medialis and pulvinar form a continuous system projecting to the associative cortex. The anteroposterior thickness of pulvinar stripes is not known and likely makes layers in this dimension.

(Roberts and Akert, 1963; Wirth, 1973; Mufson and Mesulam, 1984), parietal (Kasdon and Jacobson, 1978), premotor (Schell and Strick, 1984; Ilinsky *et al.*, 1985; Goldman-Rakic and Porrino, 1985; Matelli and Luppino, 1993; Rouiller *et al.*, 1999), inferior premotor (Matelli and Luppino, 1993), motor accessory (SMA; Goldman-Rakic and Porrino, 1985; Matelli and Luppino, 1993; Rouiller *et al.*, 1999), and preSMA and supplementary eye field, (SEF; Matelli and Luppino, 1993).

REGIO POSTERIOR

The name "pulvinar" comes from Galenus and means pillow or cushion in Latin. Its medial border, medial inferior and superior faces, which may be observed directly after the removal of the corpus callosum, is indeed rounded and smooth (Figs. 20.1 and 20. 7). The pulvinar constitutes the posterior pole of the thalamus. Its posterior border is observable on ventriculograms since they form the posterior curve of the lateral ventricle. As noted in the preceding paragraph, the pulvinar has no complete border with the nucleus medialis. Ventrally, the limit with the limitans is obvious. More laterally, the various tracings of the limit with the basal region (see "Regio Basalis") indicate that this border is not obvious. Two bundles, the tractus corticotectalis (Riley, 1960); (Figs. 20.2F and 20.9C), crossing the pulvinar almost horizontally, and the brachium colliculi superioris are topographic landmarks for the estimation of the anteroposterior position of transverse sections. The pulvinar was undivided in classical studies (Dejerine, 1895; Malone, 1910; Foix and Nicolesco, 1925). Kuhlenbeck (1951) and Dekaban (1953) introduced divisions previously established in lower species (Crouch, 1934; Walker, 1938): a pulvinar medialis (PuM), lateralis (PuL), and inferior (PuI partly equivalent to intergeniculatus). The problem of the subdivision of this large neuronal mass remains difficult and is not yet fixed. As for the medial nucleus, cytoarchitectonics being of no use, the subdivision was made essentially in relation to myeloarchitectonic traits (Vogt, 1909), the lateral part having more myelinated fascicles than the medial. The great variety of tracings exemplifies the difficulty of delineating a border between the "medial pulvinar" and the lateral. For Van Buren and Borke (1972), these "pulvinar divisions are largely areal designations of convenience."

Chemoarchitectonics, except for the particular parts analyzed below, do not lead to precise borders. The level of epinephrin is low (Oke *et al.*, 1997). The irregular concentration of 5-hydroxytryptamin apparently does not fit with subdivisions. On the other hand, some parts have particular topographic characteristics, including some previously described as distinct "nuclei," linked or not to the pulvinar. This was at first the case for the so-called "nucleus lateralis posterior." It was wrongly linked to the lateral region, for which it constituted the emblematic representative of the "dorsal nuclei"

(denoted at that time as "lateral," Aronson and Papez, 1934) as opposed to ventral. The delineation of the "dorsal nuclei", as already explained (Percheron *et al.*, 1996), was based on one effect of the complex three-dimensional shape of the territories of the lateral region, where the preceding ends over its successor. The nucleus lateralis posterior of nonhuman primates—or nucleus dorsalis caudalis (DC ; Vogt and Votg, 1941, and Van Buren and Borke, 1972), in man—is, to a large extent, a creation of transverse sections. Dorsal to the somesthetic nucleus, it contrasted, and still contrasts with it, the posterior lateral subregion VP being parvalbumin–positive, while the pulvinar-LP is not. In sagittal or horizontal sections (Figs. 20.2 and 20.23 L9), the lateral posterior "nucleus" has no border with the pulvinar. All authors already noted that the cyto- and dendroarchitecture of the LP and the pulvinar were similar, not to say the same. This similarity was such that the LP was frequently linked to the pulvinar in the "pulvinar-LP complex" (title of Cooper *et al.*'s 1974 book). Van Buren and Borke (1972) finally wondered "whether [their DC] should not be more simply considered as a division of the pulvinar." Lower mammals do not have a prominent posterior mass (i.e., a pulvinar) and a lateral posterior nucleus. This nucleus "of primitive mammals" was said to be the origin of the pulvinar (Harting *et al.*, 1972). This appears in early primates: bush baby (Galago, Harting *et al.*, 1972), marmoset (Stephan *et al.*, 1980), and cebideae (Emmers and Akert, 1963). The later phylogenetic development of the pulvinar is almost explosive, the number of neurons being said to exceed the total number of neurons of all other nuclei. This increase happens in posterior, dorsal, and anterior directions placing a part of pulvinar over the lateral region (denoted LP). The distribution of afferences and basins in continuous slabs (Asanuma *et al.*, 1985) adds further evidence for consideration of the past LP as a particular topographical site of the pulvinar, the pulvinar oralis dorsalis (PuOD, Percheron et al., 1996). In macaques, chimpanzees, and human beings, a particular cuneiform expansion between the central region medially and the lemniscal nuclei laterally was recognized by the Vogts (1941) as the oral pulvinar (PuO). It is dorsolaterally linked to the pulvinar oralis dorsalis (Figs. 20.2B and 20.21 VVB 1.6) and posteriorly to the bulk of the pulvinar, without any boundary (Fig. 20.23 L14).

Pulvinar Principalis (including lateralis posterior)

The ensemble made up of the "medial pulvinar," the middle, the "pulvinar oral," and the "lateral posterior," which does not receives major lower afferences, constitutes the principal pulvinar (as opposed to the intergeniculatus or inferior and lateral). The lack of major lower afferent territories shaping and separating distinct subdivisions, the general organization of this ensemble is subtle and cannot be analyzed in the same way as other regions. There are no true "nuclei" or even parts. The inner organization is made up of more or less coincident basins to and territories from the cortex. The main pulvinar and nucleus medialis have common connections, in continuous stripes. They constitute together a large isothalamic superregio medio-posterior, which represents some sort of an "associative" thalamus ("association region," Dewulf *et al.*, 1973), involving more than one half of the whole thalamic volume in man. Like the medial nucleus, the pulvinar essentially receives from and sends axons to the cortex. Thalamocortical neurons have rather small dendritic arborizations. Local circuit neurons are particularly abundant, up to 50% in the main part. Large local circuit neurons have complex dendritic endings and clusters of dendritic appendages (Ogren and Hendrickson, 1979). Early observations (Szentagothai, 1970; Mathers, 1972a) noted a remarkable feature. In the absence of lower primary subcortical afferences, special cortical axonal endings take their place as central LR terminals, generalizing in this curious manner the general isothalamic model. Rockland *et al.* (1999) described "pulvinocortical" axons and their endings in the cortex. They emit several branches dividing into several successive subtrees finally innervating rather large cortical surfaces, in layer 3 (and variably layers 4, 5, and 6). Rockland (1996, 1998) has shown two types of corticopulvinar terminal axons. The first ("type 1" "elongate"), emitted by usual pyramidal neurons of layer 5 corresponds to the common corticothalamic pattern. The second ("type 2" "round"), much less numerous, is emitted by giant pyramidal neurons. The first is spread over long distances without respecting ordinary subdivisions. The second is not greatly branched and has a small very dense arborization reaching only few dendritic arborizations.

One reason why the pulvinar cannot be easily subdivided into (medial to lateral) parts is that its internal organization is in fact pseudo-laminated, with horizontal parallel stripes made up of aggregations of islands joined together in parallel stripes, "slab-like" (Grieve *et al.*, 2000) separated by others (Fig. 20.7). The contours of basins and territories often coincide, thus constituting two-circuits, probably obeying Crick and Koch's (1998) "no-strong-loops" rules. At the same time where the nucleus medialis was said to be the single furnisher of the frontal cortex, the main pulvinar was traditionally seen as the main supplier of the parietal and temporal cortex. It is true that the

pulvinar has stong connections with the latter. Hardy and Lynch (1992) showed that the shape and organization of the basins of neurons projecting to the inferior parietal lobule (7a and LIP) in macaques were horizontal and alternate. Such parallel bands (or layers, their anteroposterior extent remaining unknown) already observable in DeVito and Simmons (1976), DeVito's (1978) and Asanuma *et al.*'s (1985) plates, are mainly located in the middle of the pulvinar and extended over about one half of its width (islands p in Fig. 20.7). The source to LIP is sandwiched between two parallel horizontal bands to 7A. The connection to (and from) the temporal cortex is mainly the superior temporal, including auditory areas (Trojanowski and Jacobson, 1975; Burton and Jones, 1976; Mauguière and Baleydier 1978; Yeterian and Pandya, 1988,1991; Kosmal, *et al.,* 1997). They form bands similar to the parietal with an alternation of sources to "TE" and "TEO" (Webster *et al.,* 1993). These could be superposed or, more likely, sandwiched by parietal islands (islands t, Fig. 20.7). In addition to parietal and temporal projections, as well as the medial nucleus, the pulvinar has significant connections with the frontal cortex: orbital (Bos and Benevento, 1975; Trojanowski and Jacobson, 1974; Goldman-Rakic and Porrino, 1985; Yeterian and Pandya, 1988; Romanski *et al.,* 1997; Cavada *et al.,* 2000), frontal polar (Cavada *et al.,* 2000), medial (located ventrally, Barbas *et al.,* 1991; Romanski *et al.,* 1997), principal (Goldman-Rakic and Porrino, 1985), and lateral dorsal (Kievit, 1977 ; Barbas *et al.,* 1991; Romanski *et al.,* 1997). While in the medial nucleus, the frontal layers are parasagittal (Kievit, 1977; Fig. 20.7D), in the pulvinar, they radiate from the most medial part and undergo a rotation (Goldman-Rakic and Porrino, 1985; Kuypers and Kievit, 1977), which places them horizontally (Goldman-Rakic and Porrino, 1985) (Fig. 20.7C). They extend laterally up to the suprageniculate area (B) (Barbas *et al.,* 1991; Romanski *et al.,* 1997). They may coincide with parietal layers (7a, Asanuma *et al.,* 1985). The main pulvinar has various connections with still other parts of the cortex: the anterior, (Vogt *et al.,* 1987) posterior cingulate, retrosplenial (Baleydier and Mauguière, 1985, 1987; Yeterian and Pandya, 1988), parahippocampic (Baleydier and Mauguière,1985; Yeterian and Pandya, 1988), and insular cortex (Burton and Jones, 1976; Wirth, 1970; Mufson and Mesulam, 1984; Romansky *et al.,* 1997). It is important to stress the connection with the oculomotor cortex, in particular with the frontal eye field FEF (Trojanowski and Jacobson, 1974; Bos and Benevento, 1975; Huerta *et al.,* 1986; Stanton *et al.,* 1988; Shook *et al.,* 1991). Oculomotor stripes (Barbas *et al.,* 1991; Romanski *et al.,* 1997) interdigit with or superpose to parietal and parietal with temporal. The set of cortical areas connected with the main part of the pulvinar resembles that projecting to the associative striatum: mixing together classical associative (frontal, parietal, temporal), so-called limbic (cingulate), and oculomotor areas. The dorsal and oral pulvinar (PuOD) has the same connections, in continuity with those of the main mass, with rostral parietal area 5 (DeVito, 1978; Asanuma *et al.,* 1985), the parietal opercule (DeVito, 1978), the "vicinity of the parietal operculum" (Van Buren and Borke, 1972, in humans), the anterior extremity of the first temporal gyrus (Whitlock and Nauta, 1956; Klinger and Gloor, 1960). In the most anterior part of the pulvinar, the cuneiform oral pulvinar (PuO) has also about the same connections. A problem is raised by its proximity with the lateral caudal subregion VP and the basal region, both somatosensory. This could explain the description of connections from and to the somesthetic cortex (DeVito, 1978; Cusick and Gould, 1990). The pulvinar and the medial nucleus form a continuum that could grossly represent the cerebral cortex: frontal medially, then parietal and temporal laterally. Two problems concerning pulvinar-cortical connections remain to be solved. The first is the determination of exactly which neurons from what source are really mixed in islands or separated. The second concerns the distribution in the cortex. A single injection indeed leads to a discontinuous ribbon in the frontal, anterior cingulate, insular, polar, superior temporal (Romanski *et al.,* 1997), posterior cingulate, and parahippocampal cortex (Baleydier and Mauguière, 1985). Stimulations of the left pulvinar (and left deep parietal area) led to anomia showing the role of the thalamocortical circuits in "higher functions."

Nucleus Intergeniculatus and Pulvinar Lateralis

As previously stated, another place generally considered as a part of the pulvinar, the "pulvinar inferior," raises a problem. In fundamental opposition to the main part of the thalamus, it receives lower afferences, namely tectal axons. This creates an important systematic difference that should be reflected in the thalamic division. For instance, it does not belong to the superregio medioposterior defined by not receiving lower afference and having simply corticothalamic afference. It is thus proposed to formally distinguish it from the main pulvinar. The superior colliculus is one major, underesteemed source to the thalamus. Its multiple thalamic targets makes its introduction difficult in a systematic description of the thalamus. In macaques, the terminal arborizations of tectothalamic axons occupy an important territory in

the inferolateral part the classic pulvinar, located anteriorly between the two geniculate bodies. This explains the term nucleus (or pulvinar) intergeniculatus Ig (Vogt and Vogt, 1941). It is also inferior, below the corticotectal tract, hence pulvinar inferior PuI (Crouch, 1934; Partlow *et al.*, 1977; Harting *et al.*, 1980; Benevento and Standage, 1983). The direct retinal projection to the pulvinar, documented in the tree shrew (Tupaia, Somogyi *et al.*, 1982) and old world monkeys (Itaya and Van Hoesen, 1983), no longer exists in macaques (Hendrikson *et al.*, 1970; Trojanowski and Jacobson, 1975) and thus likely no longer in man. The collicular, tectal afference, found in nonhuman primates, is, conversely, likely to persist in the human brain. Collicular axons arise from tectal neurons of superficial layers and follow the lower border of the thalamus parallel to the inferior border of the limitans ("colpu," Fig. 20.7c). The tectal or (superior) collicular afference composes a continuous and dense territory in the inferior part of the pulvinar in the squirrel monkey (Mathers, 1971). This is no more the case in macaques (Benevento and Fallon, 1975; Trojanowski and Jacobson, 1975; Partlow *et al.*, 1977; Harting *et al.*, 1980; Benevento and Standage, 1983) where the territory is made up of several islands. The tectal axonal islandic terminal fields form bands along the lateral border of the pulvinar up to its dorsal border (Harting *et al.*, 1980; Benevento and Standage, 1983; Fig. 20.7). Acetylcholinesterase was found to allow the delimitation of the tectal (collicular) territory in macaques (Lysakowski *et al.*, 1986) not respecting "classically defined thalamic boundaries." Calbindin and Cat 301 brought out variegated pictures that led Gutierrez *et al.* (1995) and Gray *et al.* (1999) to subdivide the inferior pulvinar of squirrel monkeys and macaques into four subparts. Superior collicular axonal endings, as other principal afferents, form central boutons LR (Partlow *et al.*, 1977). They are not numerous in comparison to cortical ones (Ogren and Hendrickson, 1979). Physiological data established the existence of a complete visuotopic map (Bender, 1981, 1982), isolating a clear functional entity. The map does not reach the inferior border of the pulvinar and extends slightly above the corticotectal bundle in macaques. In a further paper, Bender (1983) specified that the visuotopic map was not due to collicular but to cortical, occipital, afferences. The intergeniculate nucleus Ig (pulvinar inferior, PuI) receives cortical axons from the primary visual (Ogren and Hendrickson, 1979), preoccipital (18 and 19, Asanuma *et al.*, 1985), middle temporal and occipitotemporal cortex (Rockland, 1996) and the accessory visual area MT (also projecting to the superior colliculus) specialized in the analysis of visual motion (Ungerleider *et al.*, 1982). The intergeniculate nucleus sends thalamo-cortical axons to the visual and perivisual cortex (17 to 19), to the posterior temporal TEO, area MT (Benevento and Rezak, 1976) and to the inferior temporal cortex (Webster *et al.*, 1993). The morphology of the axonal arborisation of pulvinarocortical neurons, detailed by Rockland *et al.* (1999), showed that projections to MT and V5 are narrower than others.

In addition to the main pulvinar medially and the intergeniculate nucleus inferiorly, there remains a lateral and dorsal part in the pulvinar also receiving (less densely) islandic collicular afferents but not participating in the retinotopic map (Fig. 20.7). Collicular patches are parallel to the lateral border (Benevento and Standage, 1983). The inner organization is almost vertical, with stripes parallel to the lateral border of the thalamus. This part stains more densely for cholinesterase and is sufficiently stained for parvalbumin to allow its delineation (Morel *et al.*, 1997). The lateral pulvinar (PuL) would be restricted to this upper part in man, corresponding to the most laterodorsal part delineated by myelinated bundles in Hassler's and Dewulf's atlases. This part sends to and receives axons from visual areas including the striate cortex (Ogren and Henderson, 1976) and the prestriate area 18 (Curcio and Harding, 1978). It projects to the inferior parietal cortex (Hardy and Lynch, 1992).

Tectal axonal terminations are not restricted to the intergeniculate nucleus and lateral pulvinar. Collicular axonal islands for instance also end in the posterior intralaminar formation (see Formatio intralaminaris-limitans). In old world monkeys, tectal axons end in the posterior paralamellar site (Partlow *et al.*, 1977; Harting *et al.*, 1980), lateral to the nucleus medialis and medial to the lamella medialis (see discussion in regio medialis), along with cerebellar axons. Another place of tectal endings in monkeys is the rostral subregion of the lateral region VA. In macaques, the posterior paralamellar site and VA are both reciprocally linked with the frontal eye field (Akert, 1964; Künzle *et al.*, 1976; Akert and Hartman-von Monakow, 1980). Using transynaptic labeling, Lynch *et al.* (1994) showed that this "frontal eye field" receives confluent afferents from the dentate nucleus, the superior colliculus, and the nigra, indicating at least two tectothalamo-FEF subsystems: one through Vim (mixed with cerebellar axons) and the other through VA (mixed with nigral). See evolutive changes in the lateral region.

REGIO BASALIS

The anatomical demonstration of the ending of spinal axons in the thalamus of man is ancient (Quensel, 1898; Golstein, 1910; see Mehler 1962, 1966; Chapter 30). The classical spinothalamic tracts were

the tractus spinothalamicus anterior and lateralis (Nomina anatomica), both located in the anterolateral quadrant of the spinal cord, the first anteriorly to the second. To these two, forming the ventral spinothalamic tract (VSTT), a dorsal tract has been added, the dorsal spinothalamic tract (DSTT) runing in the dorsal quadrant. The pain and thermal components arise from the lamina I of the cord and ascend, as classically known (Dejerine, 1914), into the anterolateral quadrant. The proprio- and enteroceptice components arise from layer V and deeper parts of the spinal cord. The first experimental approach using an anterograde method in monkeys was Mehler's *et al.*, (1960) celebrated paper. The dorsal extension of the spinothalamic territory is not the same in all accounts in monkeys (Burton and Jones, 1976; Burton and Craig, 1983; Mantyh, 1983; Gingold *et al.*, 1991; Ralston and Ralston, 1992). Later, Mehler (1966) traced the spinothalamic axons in one human case after anterolateral tractotomy (Fig. 20.8). The intrathalamic distribution of spinothalamic afferences is multiple. A first target is the somesthetic lemniscal nucleus (VP). Spinothalamic islands form a "matrix" containing lemniscal "rods." Jones (1998) saw the matrix as a diffuse fundamental system having particular cortical projections (Raussell and Jones, 1991). The matrix is made up of smaller somata. It is calbindin positive (Raussel *et al.*, 1992; Blomqvist *et al.*, 2000) and contains tachykinin and enkephalin (Hirai and Jones, 1989). In front of the lemniscal subregion, spinothalamic islands, probably from lamina V, also reach the cerebellar territory (see subregio Intermedia of the lateral region, VIm-VL). In macaques, spinothalamic axons also end in the posterior paralamellar zone (Burton and Craig, 1983). The affinity of spinothalamic endings for the posterior part of the intralaminar formation (that excludes the central formation) is well known (Mehler *et al.*, 1960; Mehler, 1966): particularly in the supracentral (above the central region) and postcentral (Ilrc Fig. 20.8) sites (Mehler, 1966; Gingold *et al.*, 1991; Greenan and Strick, 1986; Apkarian and Shi, 1994) (see "Formatio Intralaminaris-limitans"). This is also true for the limitans itself, in macaques (Mantyh, 1983) and man (Blomqvist *et al.*, 2000). Some irregular "limitans" islands, visible with acetylcholinesterase staining, may be observed up to the medial corner of the medial geniculate nucleus. The extension of the limitans to more lateral sites in nonhuman primates as in Friedemann's (1911) "pars supragenicula nuclei limitantis" or human as in Hassler's (1959) "Limitans opticus" and "Limitans portae" ("Li.por.") is however not legitimate. The neurons of "Li.por" are indeed of a different neuronal family (isothalamic). There is thus no "limitans-supragenicule complex" or "nucleus."

The description of the thalamic place(s) where spinothalamic axons end elsewhere than in the lateral region (VP, VIm) or the intralaminar-limitans-retrocentral formation (IL) has been a longstanding problem. Two elements, "Vcpor" (Hassler, 1959) and "VPI" (Vcpce), raised the problem of their belonging to the ventral nuclei of the lateral region. Crouch (1934) described Friedemann's (1911) "ventralis parvicellularis" vp as the nucleus ventralis inferior (VPI), but specified that "its scarcity of cells makes one doubtful as to whether it should be called a nucleus." This was also Mehler's (1966) and our opinion (Percheron *et al.*, 1996). Hassler's (1959) Vcpce, Van Buren and Borke's (1972) VCV, Emmers and Akert's (1963), or Lenz (1995) Vci are equivalent to VPI by two characteristics: made up of small neurons and located below VP. The inferior border of VP is fuzzy; some islands or even individual VP larger neurons are located almost in the lemniscus, medially to the medial geniculate nucleus. In contradiction with its name, Hassler's (1959) "ventralis caudalis portae" Vcpor, having a different cytoarchitecture, as already admitted by Van Buren and Borke (1972) and Morel *et al.* (1997), is not a "ventral" element. Vcpor, continuous to VPI (Vcpce), was located posteriorly to the nucleus ventralis posterior medialis (Figs. 20.2 and 20.23 L11 to 14). This explains why it has been attributed by some to its posterior part as VPMpo (Koyoma *et al.*, 1998) or its "cap" ("s", Raussel *et al.*, 1992). The upper border of Vcpor (Hassler's Plate 66) was delineated much too high so that the "nucleus" included some extent of the oral pulvinar (PuO). The participation of the pulvinar oralis, evoked by Jones (1985), may be ruled out since it has not been demonstrated to receive spinothalamic axons and is more dorsal (Fig. 20.9). VPI, Vcpor, VPMO are simple topographical sites of a larger entity not belonging to the nucleus ventralis posterior VP or more largely to the lateral region. Jones' (1985) "posterior complex of nuclei" was composed of two elements: the "supragenicule-limitans nucleus" and the "posterior nucleus." The limitans being removed, two parts remain, "supragenicule" and the "posterior nucleus." The name supragenicule was given by Crouch (1934), in macaques to a place dorsal (in fact medial and posterior) to the medial geniculate nucleus. Its ancestor, the nucleus parageniculatus of Lewandowsky (1904) was linked by Friedemann (1911) to the medial geniculate nucleus. Olszewski's (1952) "supragenicule nucleus" (SG) was said to have no clear border with GM or the pulvinar. Crouch's nucleus, made up of small isothalamic neurons resembling those of the pulvinar, was said to correspond to C.Vogt's "noyau basal." This being said by C.Vogt to correspond to Déjerine's "region du ruban de Reil median" was clearly not a part of the geniculate body. In addition to

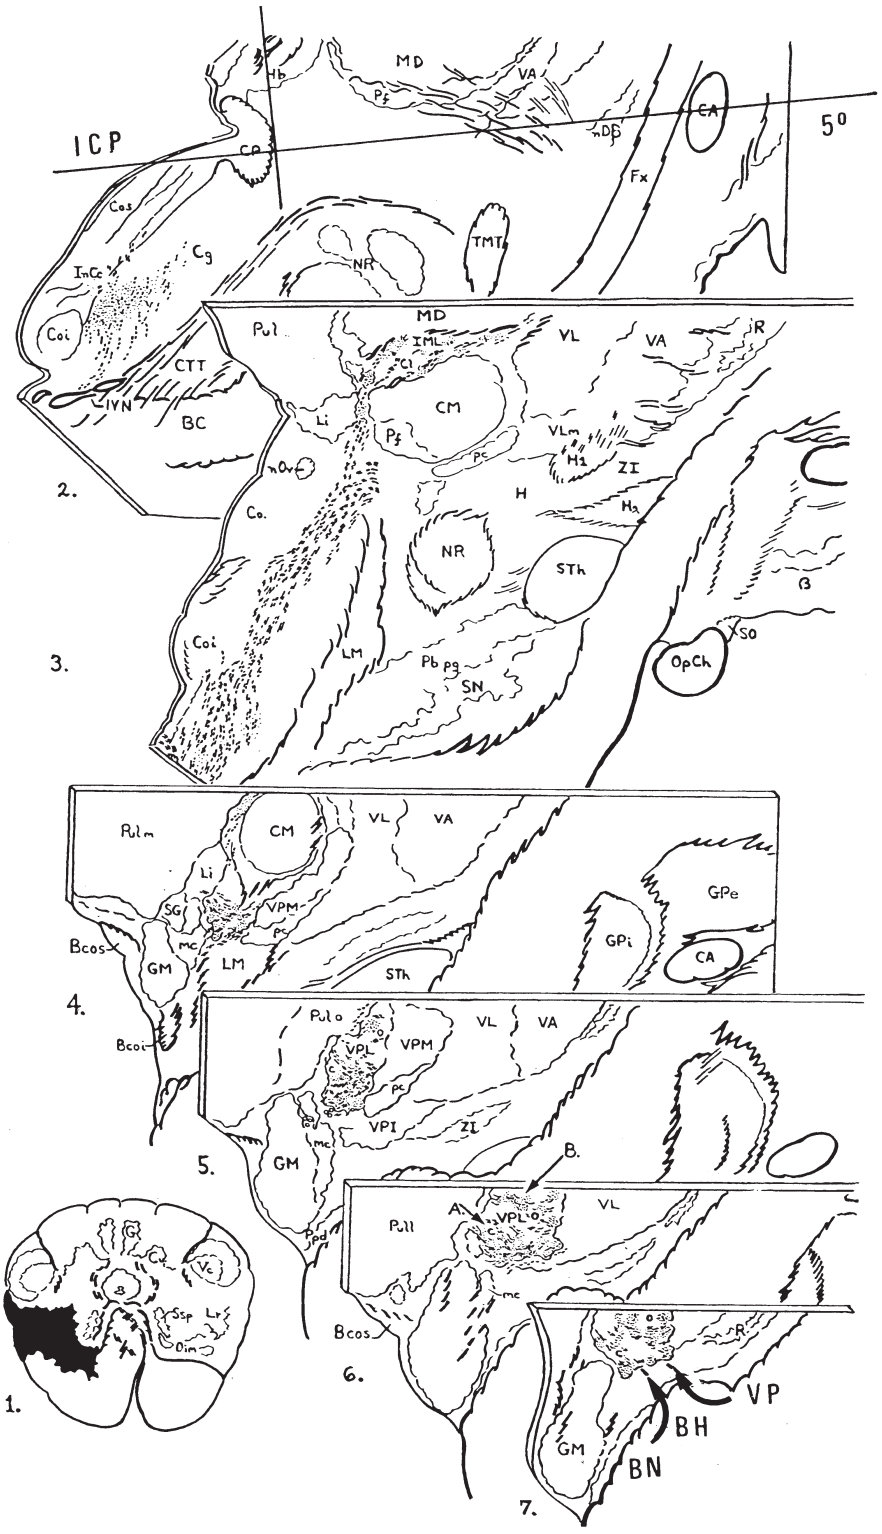

FIGURE 20.8 From Mehler (1966). Trajectory and termination of spinothalamic axons after a medullary lateral tractotomy in man. Sagittal sections. CA-CP line added on the upper section. The central formation (CM and Pf) is devoid of any ending. Intralaminar elements receiving spinothalamic endings are supracentral, dorsal and posterior (3), posterior and ventral (4) and lateral (5 to 7) to the central formation. The place indicated "c" in levels 5 to 7, lateral to CM is distinct from the limitans (Li), suprageniculate (SG) and medial magnocellular part of GM (mc). It corresponds to the nucleus basalis nodalis BN surrounded by a visible halo with few endings (and few neurons) BH. Dorsally to BH, the inferior part of VP.

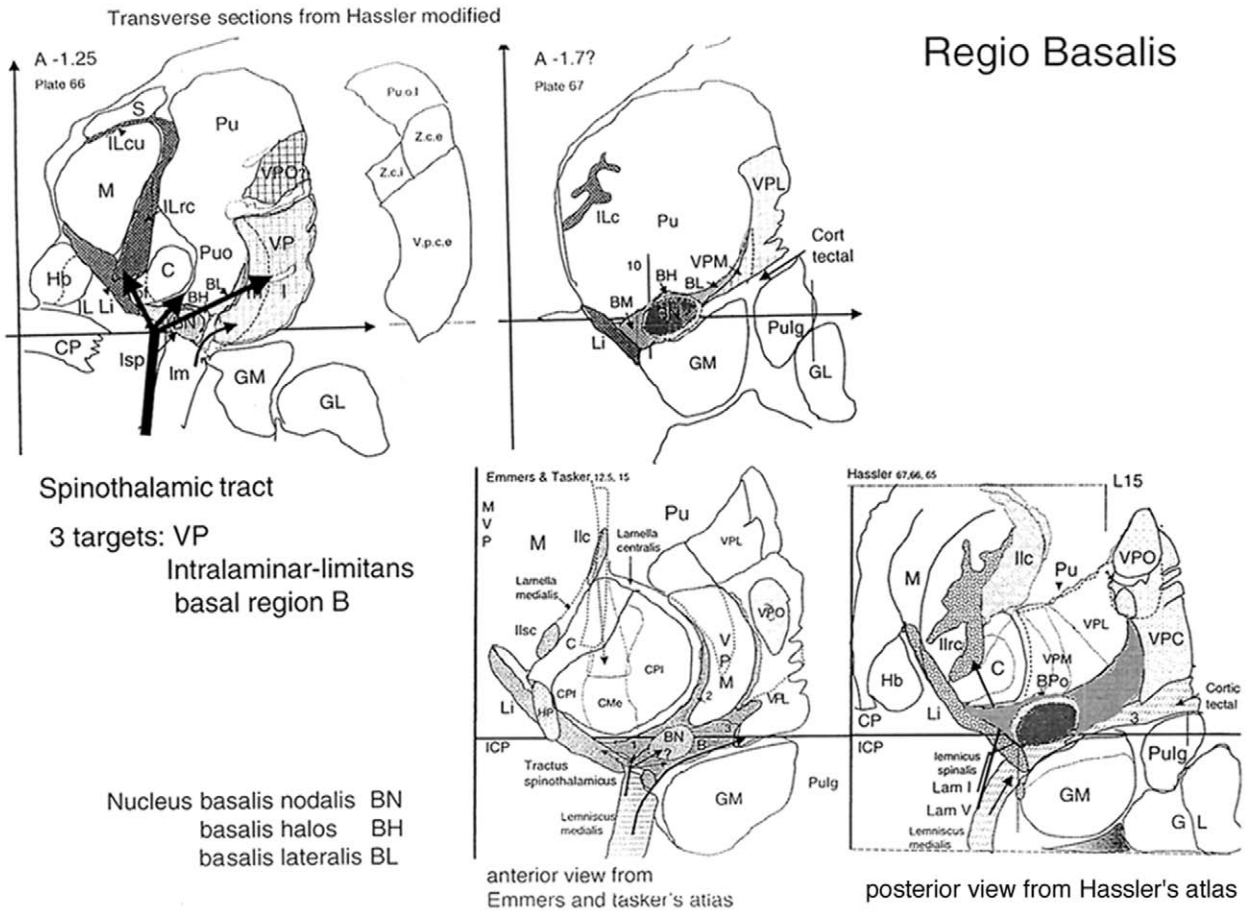

FIGURE 20.9 Regio basalis B. *Upper row.* Two transverse sections from Hassler's atlas. A -1,25 is located at about the posterior pole of the central region, with the medial nucleus surrounded by the intralaminar-limitans formation (limitans clearly visible), the anterior part of the main pulvinar, the posterior part of the lateral region and the appearing basal region. The spinothalamic tract reaches three targets: medially the intralaminar-limitans formation, laterally the somesthetic nucleus VP, and the basal region. At the more posterior -1,7 section, at the bottom of the pulvinar, one may observe a denser element (nucleus basalis) surrounded by a clearer halo (nucleus basalis halos). The ensemble is located in a region extended from the limitans to the VP with a part medial to BN (nucleus basalis medialis) and another one lateral (basalis lateralis) equivalent to VPI. The region is just posterior to the inferior part of the somesthetic cutaneous VP. *Inferior row.* Slice made by superposing several transverse sections from Emmers and Akert's atlas showing the basal part of the thalamus, seen from front. The central region is surrounded medially and ventrally by elements of the intralaminar-limitans formation: caudal Ilc (located dorsally to the central formation), supracentral Ilsc (dorsal to it, in the ventral part of the lamella medialis or interna), and retrocentral (posterior to the central formation). There is no intralaminar elements (and no spinothalamic endings) in the lamina centralis forming the lateral wall of the central formation. The slice made by superposing several transverse sections from Hassler's atlas is, this time, seen from the back in order to unveil the retroventral part C is the posterior pole of the formatio centralis.

the suprageniculate "nucleus," the "posterior complex of nuclei" of Jones (1985) or "posterior region" of Burton and Jones's (1976), comprised a more lateral "posterior nucleus". The physiological literature in macaques mentions a "Po" (DeVito and Simmons, 1976; Applebaum *et al.*, 1979; Asanuma *et al.*, 1983; Burton and Craig, 1983) or "posterior complex," "posterior nucleus" (Apkarian and Shi, 1994) or "posterior group PO/SG" (for suprageniculate posterior, Ralston *et al.*, 1995). The adjective "posterior" is confusing since "regio posterior" designates the pulvinar (e.g., Crouch, 1934) and the term ventralis posterior (VP), the lemniscal territory. Contrary to what might have been expected from a system presented as assuming an "archaic" function, the ensemble is highly evolutive. Burton and Jones' (1976) posterior region was said to exist in early mammals, for instance in marsupials (Rockell *et al.*, 1972) but "best appreciated in sections of higher primates" (Jones, 1985). In the cat, "Po" was divided into two parts—Pom and PoL (Jones, 1985). PoL, said to receive tectal afferents, could have given the intergeniculate, inferior pulvinar of primates (indeed

receiving tectal axons, see "Pulvinar Principalis"). The primate site receiving spinothalamic axons could be a derivative from the single Pom.

Because of its position, shape and unclear inhomogeneous cytoarchitecture, the analysis of the suprageniculate-posterior ensemble is made difficult by the presence of the numerous thick afferent axons of the medial lemniscus (as stressed by Dejerine's name: "region du ruban de Reil median," 1895, or Hassler's "portae," 1959) and of the spinothalamic fascicle (see Fig. 20.9). In addition, small ascending vessels disturb the pictures. The spinothalamic territory not included in the intralaminar-limitans or the lateral regions forms an irregular but continuous ensemble extended from the limitans (excluded) medially to the corner of the medial geniculate body laterally (excluded), passing posteriorly to the VPM to which its sends anterior fringes up to posteriorly and inferiorly to the VPL. This covers several sites, previously described as nuclei, shown in Fig. 20.9, "suprageniculate" (1), retroventral posterior (2) and "VPI" (3). This ensemble is not a part of the ventralis posterior (VP) defined as the lemniscal territory (parvalbumin-positive). Not limited by lamellae, it is thus not a classical region. Refering to the "noyau basal" of C. Vogt (1909), it is said to form the Regio Basalis (B).

The situation has changed recently. In macaques, the pain component of the spinothalamic tract arising from lamina I has been claimed to end in a particular thalamic place separated from others modalities (Zhang and Craig, 1997), Spinothalamic axons arising from layer I of the spinal cord can be selectively stained by calbindin immunochemistry, in rat, monkey, and man (Craig *et al.*, 1994; Blomqvist *et al.*, 2000). Using this tool, Blomqvist *et al.* (2000) found a new nucleus with a particular cytoarchitecture, composed of a dense core and a halo, or shell. This ensemble was already observable in Mehler's (1966) drawings (levels 4 to 7, reproduced in Fig. 20.9), unfortunately named "pars caudalis of the ventralis posterior lateralis" (VPLc) (in a caption a "nucleus basalis" B). The nucleus and the halo are clearly observable in the monkey (e.g., in Friedemann's (1911) Fig. 5, Burton and Jones' (1976) Figs. 18, 19 and 23, and Jones' (1985) Fig. 11.2). In man, the two are easily traced on Hassler's large magnification pictures, in transverse as well as in sagittal plates (drawn in Fig. 20.9), where, partly but indisputably, they correspond to "Li.por." In both planes, one nucleus is round or ovoid and is surrounded by a clearer ring. This contains few neurons and is partly made by neighboring bundles or fascicles (medial lemniscus, corticotectal and spinothalamic tracts) that are exploited for a nuclear closure. For reasons analyzed later, the denotation by Craig *et al.* (1994) and Blomqvist *et al.* (2000) of the nucleus as "VMpo" ("posterior division of ventromedial nucleus," Giesler, 1995), is not tenable. The regio being named basalis, it is proposed to denote "Vmpo" the nucleus Basalis Nodalis (BN; expressing its central position and its look), and its schell ("Po" of Blomqvist *et al.*, 2000) the nucleus Basalis Halos (BH, not conjugated in Greek). As observable in successive transverse plates of Fig. 20.9, the nodalis complex is at the same time in a suprageniculate position and posterior to the medial part of VP (VPM). The stereotactic coordinates given by Craig *et al.* 1994; (A –0.5 to +2, L 12 to 16, H-1 to +1) are about those found in our tracings on Hassler's plates, except for the lateral dimension (not firm in Hassler's atlas). The neurons of the nucleus basalis nodalis are calbindin-positive and form clusters, some of them substance P-positive. The neurons respond to painful heat (Lenz *et al.*, 1993). Their stimulations induce pain (Dostrowski *et al.*, 1992; Lenz, 1995). The surrounding is calbindin negative and CGRP-positive (calcitonin gene-related peptide)(deLacalle and Saper, 2000). Its afferent axons come from the vagal-solitary-parabrachial ensemble, which brings a different, enteroceptive, visceral information (Blomqvist *et al.*, 2000). The assessement that lamina I axon end only in the nucleus basalis nodalis BN is contested by Willis and colleagues (2001) and Ralston (2003). The injection of a retrograde marker into VP indeed shows numerous labeled neurons in lamina I in the macaque. It is clearly too soon for attributing to the BN/BH ensemble the exclusive processing of pain messages. This does not call into question its anatomical observation and topographical description. The ensemble is evolutive. In cats and rats, only "a primordial homologous region may exist" (Blomqvist *et al.*, 2000). Observed in cebideae (Blomqvist *et al.*, 1996) or cercopithecideae, it is nowhere as clear as in man (Blomqvist *et al.*, 2000). As could be also the case for the tectal intergeniculate nucleus, this could be made by a late differentiation of the ventral part of the pulvinar. An argument could be that some pulvinar neurons are furnished in primates (Rakic and Sidman, 1969) and some local circuit neurons only in man (Letinik and Rakic, 2001) by the telencephalic "ganglionic," or ventricular eminence.

In L11 sagittal section, the BN/BH ensemble in the mediolateral dimension, is in a central, intermediate, position in the basal region. This has thus one medial (BM, medial to BH) and one lateral (BL) additional parts not exactly corresponding to previous subdivisions. The nucleus basalis lateralis, BM, posterior to the taste relay, could be furnished by quintothalamic axons. The nucleus basalis lateralis BL (including "VPI") is likely

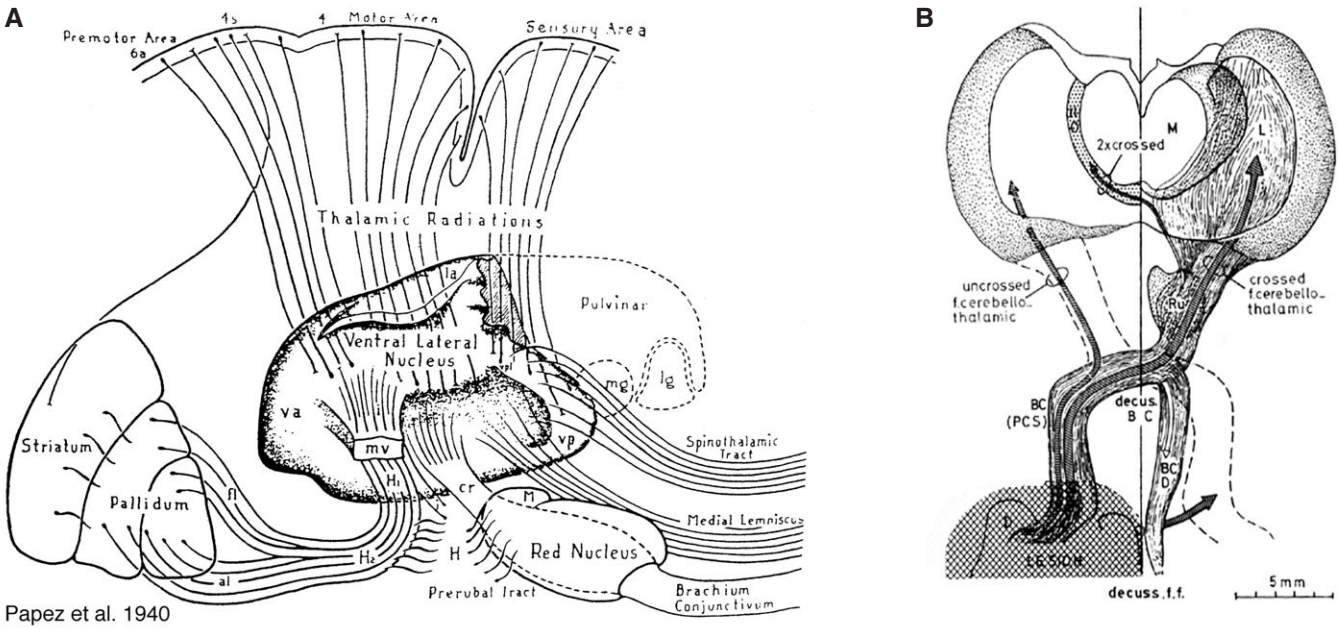

FIGURE 20.10 **(A)** Figure from Papez *et al.* (1940), sketching the thalamic organization in relation to the main afferent systems. The pulvinar and geniculate bodies are shown. The sequence matches C. Vogt's scheme (with three "radiations") and the spinothalamic tract posterior to the medial lemniscus. The latter formed Vogt's "lemniscal radiation." In front of it, Vogt's "prelemniscal radiation" is furnished by the brachium conjunctivum. It ends in a part of the ventral lateral nucleus. In front is the "thalamic fascicle" H1 field of Forel (Vogt's "lenticular radiation"). In front of the last, "va" is not shown to receive lower afferences, today the nigral territory. To the prethalamothalamic organization corresponds a thalamocortical distributed over the two sides of the central sulcus. **(B)** Figure from Percheron (1977). The brachium conjunctivum is reconstructed from series of sections in a macaque. The brachium arises from the cerebellar nuclei, mainly from the dentate nucleus. It ascends in the superior cerebellar peduncle PCS. Then it crosses at the decussatio brachiorum conjunctivorum (decus BC) and divides. The brachium conjunctivum descendens BCD goes down in the brainstem. The brachium conjunctivum ascendens is the cerebellothalamic tract. Ascending in the superior cerebellar peduncle (BCA), it crosses and is lateral to the red nucleus (Ru) before ending in the lateral intermediate subregion of the thalamus. Some axons do not cross the midline.

supplied by axons from lamina V of the spinal cord conveying other modalities that pain and thermaestesia. What was said about VPI may be transferred to BL: own somatotopic map and possibly modulatory (Chapter 28). The thalamocortical connections of the regio would comprise efferents to the superior temporal cortex (Kosmal *et al.*, 1997), frontal cortex and above all the anterior insula (Craig, 1995) or in an area of the granular insula (Ig) located between the the secondary somatosensory SII above and the primary auditory area AI (Burton and Jones, 1976; Jones and Burton, 1976).

REGIO GENICULATA

The two "geniculate bodies" once thought to form the metathalamus are in fact isothalamic elements detached from the thalamic mass early in embryonic life that later get a strong morphofunctional differentiation. The two nuclei are ventral, posterior, and lateral (Figs. 20.1B and 20.2E, F), located below the pulvinar.

Nucleus Geniculatus Lateralis

The nucleus geniculatus lateralis (GL), usually named lateral geniculate nucleus, is inferior in the thalamus, inferolateral to the lateral region. It has a superficial face that may be observed by dissection. Its anterior border is round. The nucleus geniculatus lateralis, everywhere except medially, is surrounded by thick myelinated bundles (thus forming an enclosed nucleus). The separation is complete. It is covered by the nucleus pregeniculatus Pr in Fig. 20.2. This thin element (the "ventral geniculate") is in fact an extension of the perithalamus. Ventral in nonprimates—even in lemurians—it is dorsal in higher primates. Part of the perithalamus, the pregeniculate does not belong to the regio geniculata. The lateral geniculate nucleus in primates is made up several cellular layers separated by axonal layers (the lamination, still not observable with the unaided eye in lemurians, appears after enucleation). There are six layers, numbered from the inferior surface, often subdivided into magno-

cellular layers I and II and mediocellular from III to VI. The first two contain a low percentage of local circuit neurons (14%; Dewulf, 1973), yet higher than in the other layers (4.5%). Layers II, III, and V are furnished by axons from the ipsilateral eye, and layers I, IV and VI, by the controlateral hemifield of the retina. The dendritic arborizations of the thalamocortical neurons are flattened or elongated in axes perpendicular to the layers. They do not cross their border. They however belong to the general bushy thalamocortical genus. The fine structure of the geniculate body has been the subject of extensive research for several decades as a kind of prototype of thalamic structure. It constitutes the extreme in nuclear separation and differentiation. The lateral geniculate nucleus has a particularly rich innervation in cholinergic afferents. It is particularly dark in cholinesterase staining. It is important to point out that the lamination observed in the geniculate body is different from that of the stratolaminate histotype (observed for instance in the cortex) since it is not underbased and covered. The lateral geniculate is the primary visual relay receiving axons from the retina through the optic nerves and tracts, thus the retinal territory. It contains a retinotopic map. Its voluminous efferent system is the optic radiation in direction to the primary visual cortex.

Nucleus Geniculatus Medialis

The nucleus geniculatus medialis GM (medial geniculate nucleus) is more medial and more anterior than the lateral. It is also superficial. Contrary to the lateral it still adheres to the thalamic mass and that fact creates problems of delineation and inclusion particularly dorsomedially. Posteriorly it is separated from the lateral geniculate body by the intergeniculate part of the pulvinar (Figs. 20.10B and 20.17). The main problem is raised by the so-called magnocellular part neighboring the formatio basalis. This is located just medial to the entrance of the medial lemniscus. Some large neurons appear to be neurons from the VPL located ventrally. The medial geniculate nucleus is parvalbumin positive with some calbindin positive islands (Jones, 1998) and poorly stained in acetylcholinesterase. More medially and posteriorly the "magnocellular part" with larger calbindin positive neurons (Molinari *et al.*, 1995) is contiguous to the part receiving spinothalamic axons (B, see VIII). The medial geniculate nucleus receives its afferents from the lateral lemniscus. It is made up of cellular "laminae." It contains a cochleotopic-tonotopic map. It is analyzed with the auditory system (see Chapter 34). The medial geniculate sends most of its axons to the primary auditory area (AI, AA1) (Mesulam and Pandya, 1973) and fewer to the second (AA1) and third (AA3; Kosmal *et al.*, 1997) auditory cortex. AI is located in the posterior part of the superior temporal gyrus, Bailey and von Bonin's (1952) "regio supratemporalis," more precisely in the transverse gyrus or gyri of Hesch. The auditory cortex, alike others primary sensory cortex, is a koniocortex surrounded by a perikoniocortex (area 41, TC or Kam and Kalt).

REGIO LATERALIS

Generalities

The regio lateralis (Louvain, 1963) corresponds to the classic lateral nucleus ("äusserer Kern" of Burdach, 1822, "noyau externe" of Dejerine, 1901, "nucleus lateralis thalami" of Riley, 1960), that is, the thalamic region topographically lateral to the lamella medialis, medial to the lamella perithalamica, and anterior to the posterior region (pulvinar). It extends up to and forms the anterior pole of the thalamus. The main recipient of major "prethalamic" afferences and the place of thalamic stereotaxy, it has been the subject of an important literature.

For a long time, there has been a lack of data on the precise topography of afferent territories. This has led to an excessive reliance on cytoarchitectural signs. Cytoarchitectonic "nuclei" with no precise definition have been drawn in an excessive number with various boundaries and names. The opposition made by Meynert (1872) between "ventral" versus "dorsal" nuclei introduced a longstanding misinterpretation. Techniques at hand for tracing connections were not able to show axonal endings. Only ventral elements were observed to receive "lower afferences." "Ventral nuclei" were thus declared to be "relay nuclei" as opposed to "dorsal" "associative nuclei" of the same group as the pulvinar. The use of the von Gudden technique (retrograde degeneration) for studying thalamocortical connections, extensively used in Walker's celebrated work (1938), did not result in clear subdivisions.

Territories Rather Than "Nuclei"

The major change in the understanding of the lateral region occurred with the consideration of territories. The subdivision of the lateral region using the separation of territories of identified afferences was effected as early as 1909 by C. Vogt. Her postero-anterior sequence of three "radiations" was lemniscal (caudal VC), "prelemniscal," cerebellar (intermediate VI, Vim in 1941), and "lenticular" pallidal (oral VO). The presence of a nigrothalamic connection was not known, only demonstrated in the 1960s. After its confirmation by Shuster (1936) and Kornyey (1926) in newborns and partly by Le Gros Clark (1936) experi-

mentally in the macaque, this scheme was supported by Papez *et al.* (1940) who added the more posterior "spinobulbothalamic tract" (Fig. 20.10). While mentioning the overlap of spinothalamic and medial lemniscal endings, they insisted on the separation of the other, somesthetic, cerebellar, and pallidal places of termination. This was illustrated by their Fig 4B (reproduced in Fig. 20.10). Bailey and von Bonin (1951) accepted this sequence. "The three systems i.e., the somesthetic tracts, the cerebellothalamic and the pallidothalamic systems, appear to end in different parts of the 'ventral nucleus.' " Bailey and von Bonin (1951) added that "the distinction into three systems that we recognized remains valid for the thalamocortical radiation", (i.e., the prethalamothalamic order had a corticothalamic correspondent). Sheps (1945) adopting Walker's scheme in man admitted that this and the one of the Vogts "agree in general." A curious scientific turn occurred in the 1950s. Thalamic subdivisions were no longer asked to correspond to particular afferent territories. A cytoarchitectonicist era rose up. Following Nissl and Jacobsohn's tradition, Olszewski and Baxter (1954) claimed that "the criteria used for cytoarchitectonic subdivisions are of biological importance." Olszewski's atlas (1952), during decades the common document of reference for experimenters on macaques, was not founded on precise afferences. This atlas, histologically and topographically careful, has been the tool used for establishing faulty attributions. It is now admitted that Olszewski's VPLo was not a part of VPL but, along with "Area X" (telling its uncertain belonging), a major part of the cerebellar territory. Olszewski's most unfortunate choice has been the attribution of what is known to be the pallidal territory to VL. This nucleus includes only a small part of the cerebellar territory (post VLc and ps) and the major part of the pallidal territory (his Vlo, VLm and the anterior part of VLc) and excludes important parts (VPLo and "area X"). VA was considered to receive no lower afferences. The identification and proof of the separation of the main territories has been arduous. The separation between the lemniscal and cerebellar territories was demonstrated by C.Vogt (1909) and then by Van Buren and Borke (1971) and Asanuma *et al.* (1983); that between the cerebellar and the two basal ganglia territories, by Percheron (1977), Asanuma *et al.* (1983), and Ilinsky and Kultas-Ilinsky (1987); and that of the pallidal and nigral, by Carpenter and Strominger (1967), Ilinsky *et al.* (1985), and Percheron *et al.* (1993, 1996). Finally, by tracing and using cartographic methods, it was shown that a restricted number of main afferent territories, often covering several cytoarchitectonic nuclei, separate one from the others, making a simple, functional, parcellation possible. The main territories have four geometrical properties (Figs. 20.17 and 20.18). First, they are continuous. Second, they have complex three-dimensional shapes. Third, their caudal part overhangs dorsally the next more caudal element (Percheron *et al.*, 1996; Fig. 20.17) explaining the classical (improper) separation between ventral and dorsal elements essentially made on transverse sections. Fourth, their borders are strongly irregular in some places with long fringes (already noted by Asanuma *et al.*, 1983, and the Ilinskys, 1987, 1993; Fig. 20.18). The now general agreement that territories are everywhere separate has been challenged by some recent studies insisting on a possible peripheral overlap (Rouiller *et al.*, 1994, or Sakai *et al.*, 1999, 2000). Some are the result of phylogenetic reasons (cebideae lacking complete separation), others to plane, bidimensional, sections of the interdigitation of fringes that, in the absence of three-dimensional reconstruction, may give the impression of a mixture. To our knowledge, no study has ever proven at the ultrastructural level the innervation of a single thalamic neuron by two distinct main sources. A major, recent advance has come from the observation that certain territories have particular immunocytochemical properties (particularly in calcium-binding and acetylcholinesterase histochemistry). This led to the possibility of tracing presumably similar entities in other species like the *Macaca*, particularly for man, in the absence of direct experimental data.

Lateral Rather Than Ventral and Dorsal

As already explained ("General Considerations"), two rival systems were used to name the parts of the lateral region. Both accepted Meynert's (1872) opposition between dorsal and ventral elements. The Vogt school (Vogt, 1909; Friedemann, 1911; Mussen, 1923; Vogt and Vogt, 1941) named the dorsal elements "dorsalis," but the so-called Michigan school (Walker, 1938), "lateralis." A major result of performing tracing methods has been that (at least for three of them) the main territories are not simply ventral but also dorsal, reaching the dorsal border of the lateral region. Thus, as already criticized at Louvain's symposium, "to indicate the formatio lateralis, the term ventralis is no longer desirable" (Drooglever Fortuyn 1963, in Dewulf, 1971). At the end of our studies on the topography of the main territories (Percheron *et al.*, 1996), we proposed to give to all elements of the lateral region the first adjective Lateralis (L). This remains the more rational and less confusing. However, a strong reluctance appeared to abandon the term "ventral." Ventralis is thus accepted as the first adjective, with one condition. The equivalence of ventral and lateral elements is possible if and only if there is no other "ventral" and "lateral" nuclei (e.g., no longer lateralis

dorsalis and lateralis posterior), which can be done on other arguments.

Evolutive Changes in the Lateral Region

The disputes in conception and nomenclature, perceived as cultural, as already mentioned in "General Considerations," were to a large extent linked to different standpoints toward phylogenesis. The so-called Michigan school was at first a school of comparative anatomy with no particular consideration for the human brain. The Vogt school, after works on nonhuman primates intensively worked on the human thalamus (1941). Hassler's atlas (1959) was used for decades by stereotacticians. Phylogenetic changes at the thalamic level must be interpreted in the larger frame of the evolution of neuronal systems, where relative numbers of constituents, volume, and internal organization vary. In the lemniscal territory, the separation of cutaneous and kinaesthetic afferents led to the differentiation of a particular thalamic area. In the cerebellar territory, the differentiation of the motor cortex developed a specialized lateral subpart. The changes in the basal ganglia system had even heavier effects. In sauropsids, the "pallidum" (pale, in the topographic position of the lateral pallidum of upper primates) sends most of its axons to the tectum (Reiner *et al.*, 1984). In nonprimate genera, the sequence is restricted to the few intracapsular neurons forming the "entopeduncular nucleus" (not an equivalent yet of the medial pallidum) and the substantia nigra. In catarhineae (from cercopithecideae to man), the full lateromedial sequence of the striatal targets is lateral pallidum, medial pallidum, nigra lateralis, and nigra reticulata (including dendrites of the compacta) (Percheron *et al.*, 1994). The first and the third have no thalamic outputs, the lateral pallidum projecting, among other targets, to the subthalamic nucleus and the nigra lateralis to the tectum. The second and fourth elements are the origins of two separate prethalamothalamic subsystems. The development, differentiation, and separation of the medial pallidum go with that of the pallidothalamic bundle and the selective projection to the supplementary motor area (SMA) (see Fig. 20.19 and VO pallidal subregion). This chain adds to the lemniscal, cerebellar, nigral, and pallidal territory, VO, a fourth thalamic territory. The complete separation with the nigral territory has led to the disappearance of "VM." No VM existed in the founding literature on monkeys (Vogt, 1909; Mussen, 1923; Crouch, 1934; Walker, 1938). Aronson and Papez (1934), in a brain cut very obliquely, described a VM said to be similar to that described by Rioch (1929) in dogs. In the cat, VM (along with VL) is known to receive both cerebellar (e.g., Hendry *et al.*, 1979; Kultas-Ilinsky *et al.*, 1980) and nigral afferences (Hendry *et al.*, 1979). A ventral and medial thalamic part, located just in front of the central formation, called VMp by Jones (1985, 1995), is actually a topographical part of the nigral territory; thus included in VA (see "Subregio Lateralis Rostralis. Nigral Territory"). Since the convergence of cerebellar and nigral afferences in the VM no longer exists, it may be said that there is no longer a VM in upper primates. Jones's VMb (Asanuma *et al.*, 1983; Jones, 1985, 1995) and followers (Craig *et al.*, 1994; Morel *et al.*, 1997; Blomqvist *et al.*, 2000) was a totally different thalamic entity, the taste relay, belonging to the lateral region ("Subregio Arcuata"). Still another part, the relay of the spinothalamic system conveying pain (Craig *et al.*, 1994; Blomqvist *et al.*, 2001) has been recently labeled Vmpo. It does not belong to the lateral region but to the spinothalamic receiving basal region (see "Regio Basalis."). Other major thalamic changes came with the evolution of the oculomotor systems (see Chapter 33). In macaques, one important thalamic source to the oculomotor cortex is located in the paralamellar site of the medial region receiving tectal and cerebellar axons. This is likely to have disappeared in apes and man and to have moved to the lateral region. In macaques, the frontal eye field (FEF, area 8) is anatomically defined as dysgranular and linked to the arcuate sulcus. This no longer true in chimpanzees. The arcuate sulcus has disappeared and the frontal eye field has moved far anteriorly (Grunbaum and Sherrington, 1901; Leyton and Sherrington, 1917; Hines, 1940) and FDT of Bailey *et al.* (1950) is isocortical. In man, the delineation of area 8 led to a great discrepancy between Brodman (1909), Vogt and Vogt (1926), and von Economo and Koskinas (FC, 1925). Stimulations by Foerster (1939), Penfield and Brodley (1937), Rasmussen and Penfield (1948), Penfield and Rasmussen (1957) led to a more posterior position than in the chimpanzee, close to the precentral sulcus. There would be in fact at least two oculomotor areas (Tehovnik *et al.*, 2000). FEF would be located at the posterior part of the middle frontal gyrus. This is more inferior than for Paus (1996). The varying positions of FEF must not be seen as the mere displacement of one cortical spot but as a sign of deep and fast evolutive changes. With such cortical changes, thalamic interspecific differences are not surprising.

Subdvision and Nomenclature

The discovery and description of main afferent territories brought out the necessity of having to name four of them: from back to front at first the lemniscal territory (with posterior, cutaneous, and anterior kinaesthetic parts), the cerebellar territory (with lateral and a mediodorsal parts), the pallidal, and, finally, the most anterior, nigral territory. For the second topo-

graphic adjective (after ventral or dorsal), the Vogts' school used caudal, intermediate, and oral. The Michigan system used posterior and anterior (both acceptable by the Nomina Anatomica). Kievit (1979) and Stanton (1980) accepted the "VL-Vim" equivalence for naming the cerebellar territory. The late discovery of the nigral territory opened a problem. In Cecile Vogt's account, a subdivision ("fasciculaire") was located in front of the pallidal territory (Vo). In Papez' *et al.*'s drawing (1940; Fig. 20.10), va was in front of the pallidal afferences, making possible an attribution to a rostral (nigral) territory. The VL-VA system of the Michigan school had only two adjectives for three subdivisions (cerebellar, pallidal, nigral) in primates. This could have two possible interpretations. That of Jones (1985; Hirai and Jones, 1989; Morel *et al.*, 1997), continuing Olszewski's choice, had two VL (VLp, cerebellar and VLa, pallidal) and one VA-VM. The attribution of the same label (VL) to two obviously distinct anatomofunctional territories, having different properties, one excitatory (cerebellar) and the other inhibitory (pallidal), is hardly defensible. The other system, that of Ilinsky and Kultas-Ilinsky (1987, 1993, 2001) has one VL (cerebellar), two VA, one pallidal (Vadc, a new naming), and one nigral (Vamc). The two distinct (pallidal and nigral) territories have some features in common: their belonging to the basal ganglia system, and their receiving GABAergic, inhibitory messages. They have, however, different sources and different staining properties. The pallidal territory is acetylcholinesterase positive. Only somata in the nigral territory are calbindin positive with a different ultrastructure. Above all, the separation of the nigral and pallidal territories in upper primates expresses the separation at the thalamic level of two thalamocortical subsystems: one rather "motor" (MI, SMA) and the other rather "associative" (frontal and cingulate) and "oculomotor" (FEF, SEF) (Fig. 20.20). The placement of the pallidal territory into a single VA perpetuates the continuous neglect of the nigral territory. The two territories must be distinguished with two different names.

In the last decades, some attempts have been made to homogenize the thalamic nomenclature for monkeys to human beings (Louvain symposium, 1963; Percheron, 1969, 1977; Jones, 1985; Ilinsky and Kultas-Ilinsky, 1987; Hirai and Jones, 1989; Percheron *et al.*, 1994, 1996; Macchi and Jones, 1997). During the writing of this chapter, competent colleagues were asked for their opinion about the nomenclature for thalamic subdivisions of the human thalamus (and more generally to the catharinian thalamus). After the acceptance of ventralis for lateralis for denoting elements of the lateral region, the basis for an agreement for the second adjective was mainly the anterior-posterior system ("Michigan" choice, with VO added). In catarhinians primates (and man), from back to front, the sequence of territories is as follows (Fig. 20.18). The lemniscal territory is the nucleus ventralis posterior VP (Kaas *et al.*, 1984), with two parts. The most caudal, cutaneous, is the nucleus ventralis posterior caudalis (VPC). The, more oral, kinaesthetic, is the nucleus ventralis posterior oralis VPO with its own map. Taking into account the rejection by some of any reference to VL for the cerebellar territory in man, it is proposed that the choice be between VL (in the Ilinsky's conception) or ventralis intermedius, either VI (Crouch, 1934; Kusama and Mabuchi, 1970; Percheron, 1977, in macaques) or VIm (Vogt and Vogt, 1941; Hassler 1959 in man). The problem of the pallidal territory (Fig. 20.18) may be simply solved by accepting that it requires its own name. Part of the ventral oral nucleus of C. Vogt and the anterior part of VO (Voa) for Hassler (1959) were retained together with VA at the Louvain symposium. The pallidal territory may thus be the nucleus ventralis oralis VO. The sequence is continued by the nigral territory, which, in spite of deep phylogenetic changes, could be the nucleus ventralis anterior VA. The third adjectives, in thalamic nomenclature, usually denote parts (of nuclei). The Vogt school used externus and internus (that also meaning inside and outside are not adequate, Louvain, Dewulf 1971). Parts are thus medial or lateral or inferior or superior. VPC has two subparts VPL and VPM (ventralis posterior lateralis and medialis), with a single map. The cerebellar territory is subdivided into two parts: one lateral Vim L or VLL and one medial VimM or VLM. The sequence (VP-Vim-VO-VA) may bring a common language to both stereotacticians and neuropathologists on the one hand and neuroanatomists and physiologists working on the primate thalamus (starting from cercopithecideae) on the other.

SUBREGIO LATERALIS ARCUATA. NUCLEUS VENTRALIS ARCUATUS. VArc

The posterior part of the lateral region has a clear-cut boundary with the pulvinar. This is true in cytoarchtectonics and in Golgi impregnation where dendritic arborizations bend, forming a dendritic wall. In immunocytochemistry, the border is observable using parvalbumin immunoreactivity, the lemniscal territory, not the pulvinar, being parvalbumin positive. The most posterior part of the lateral region is not entirely simple. Medial to the caudal nucleus (vc), a crescent-shaped part surrounding the central formation of Luys was described: the nucleus "semilunaris" (Dejerine, 1895), cupuliform (von Tschisch 1896), or

arcuatus (Kölliker, 1896). Its macroscopic contrast with the lateral caudal nucleus, particularly in myelin stains, was such that it was considered only as "accessory" to the lateral region (Dejerine, 1895). A lateral lamella was described, but it was not a true one because it was not separating (see "Lamellae and Classic Nuclei. Burdach's Model"), but rather was made by a sheet of lemniscal axons. Another problem is due to the fact that only the dorsal part of the arcuate nucleus is somesthetic with one common map with the more lateral ventral posterior. The ventral part of the classical "arcuate nucleus" is the thalamic part receiving and processing gustatory information.

The most inferior and medial part of the classic nucleus arcuatus or semilunaris ventral and anterior to the central formation that it surrounds usually considered as a part of VPM (Vci) has particular cytoarchitectonic traits: small pale and round neurons (VPMpc parvocellularis; see Mai *et al.*, 1986; Chapter 31). Because it does not receive lemniscal axons, it is not a part of the lemniscal territory that defines VP. It prolongs the representation of the tongue in the adjoining ventralis posterior but does not belong to the somatotopic map of the lemniscal nuclei. A particular nucleus that is so strongly stained for calbindin makes its observation and differentiation easy. It is proposed to denote it nucleus ventralis arcuatus Varc (Aronson and Papez, 1934; Papez *et al.*, 1940, "arc"). Bowman and Combs (1969) found a projection of hypoglossal afferents to VPM without precision about the parvocellular part but likely in Varc. Becksteadt *et al.* (1980) showed a selective afference from the nucleus of the solitary tract, which receives axons from the vagus (X). In macaques, Roberts and Akert (1963) and Wirth (1973) showed a projection to the insula. Concerning the thalamocortical connections, see Chapter 31. The primary gustatory area is known to be located below the primary somesthetic area, in the opercule up to the insular cortex (Sanides, 1968).

SUBREGIO LATERALIS CAUDALIS. LEMNISCAL TERRITORY

This subregion is analyzed in Chapter 28, which is devoted to the somatosensory system. Its general shape is rather simple (Fig. 20.15). The posterior curvature corresponds to the anterior border of the central region. One problem is raised by the presence of a subpart devoted to "deep" afferents. As established in macaques by Mountcastle and Henneman (1952) and Poggio and Mountcastle (1963), it is agreed today that the cutaneous and kinaesthetic representations of the body are separate in the primate thalamus, the second being more dorsal and more anterior. The physiological separation is sharp. The anatomical delimitation on cytoarchitectural criteria is difficult. In any case, it is necessary to distinguish two nuclei VPC and VPO.

Nucleus Ventralis Posterior Caudalis. VPC

The traditional (cutaneous) part VP is usually subdivided in two formal parts being given the status of nuclei, one medial (VPM) and one lateral (VPL). In opposition to their histological contrast, the lateral part VPL and the superior part of the arcuate nucleus VPM constitute a single nucleus with a single cutaneous somatotopic map: the nucleus ventralis posterior caudalis (VPC; Hassler's Vcp). This is made up of two subparts: the lateral corresponding to the classical VPL and the medial to the upper part of the arcuate ensemble VPM. This is composed of CO-rich rods in a CO-weak "matrix" (Raussel and Jones, 1991a, b). VPL has less obvious but similar elements (Raussel *et al.*, 1992). Only the parvalbumin positive CO-rich rods would receive lemniscal afferent. The CO-weak matrix would receive spinothalamic axons. The reception of lamina I spinothalamic axons, in the VP has recently been reassessed by Willis *et al.* (2001). This input is said to act in "the sensory-discriminative processing of nociceptive information." The source toward the somatic sensory cortex is "onion-like" with "lamellae" for small cortical fields (Jones *et al.*, 1979). The cortical projection asks for a short presentation of the perirolandic cortex. This is a zone of strong morphological (and functional) differentiation, myelinating early in ontogenesis (Flechsig). This led Bailey and von Bonin (1951) to distinguish it as the "sector" or "regio centralis." Because the presence of scissurae, sulci, and gyri, cortical points have three topological positions: gyral on the surface, sulcal on the ridge, and fundic in the bottom of the sulcus (Von Economo, 1927; Krieg, 1963). The central sulcus is the origin of two, pre- and postrolandic, opposed morphogenetic gradients (Sanides, 1966, 1968). In the depth of the central sulcus (fundic) is the "transitory" area 3a (Vogt and Vogt, 1919; Jones and Porter, 1980) or intermediate sensorimotor area (Ism; Sanides 1967). The posterior bank of the central sulcus is sensory. Most primary sensory areas (somesthetic, visual, auditory, and gustatory) are sulcal, on the ridge of a gyrus, often not visible on the surface in man. Primary sensory afferences are strong morphogenetic agents of cortical differentiation. They form koniocortical (Von Economo, 1927; from *konios*) dust, linked to the presence of many "granular neurons" in layers IV and III or hypergranular gradients. The koniocortex (area 3b of Brodmann, somatic koniocortical area, Ks, Sanides, 1967) is surrounded by the perikoniocortical area 1 (Brodmann's order does not follow the arithmetic order). The "area 3b" (PB1,

Von Economo) and "area 1" (PC) constitute the primary somesthetic cortex SI. It is followed by the gyral area 2. The eugranular parietal cortex starts with area 5. The cutaneous VPC (VPL + VPM) projects somatotopically to the postcentral, sulcal, composed of "area 3b" (PB1) and and "area 1" (PC)(Jones and Powell, 1970; Jones *et al.*, 1979; Jones and Friedman, 1982). The CO-rich lemniscal rods would project to the deep layers of SI. The CO-poor matrix would project to its superficial layer.

Nucleus Ventralis Posterior Oralis. VPO

The segregation of thalamic neurons responsive to different somesthetic modalities (cutaneous, tactile versus deep, kinaesthetic) was observed first in macaques by Mountcastle and Henneman (1952). The individuality and precise intrathalamic location of the kinaesthetic group has been the subjects of debates for several decades. In macaques, Maendly *et al.* (1981) observed a "narrow zone with a maximal longitudinal extent of 3mm" in the "rostral cap" of the VPL with "short-latency field potentials evoked by group I muscle afferents," Jones and Friedeman's (1982) opposed a kinesthetic "shell" (anterosuperior) to a cutaneous "core" in the nucleus ventralis posterior. The aspect and topography of the kinaesthetic zone were not easily established. Walker (1938) yet had made an exact description of an "anterior part of the nucleus ventralis posterior" forming "a quite narrow, almost vertical, sheet of cells which are distinguished by their large size and deep staining. It extends posteriorly tail-like over the dorsal part of the nucleus ventralis posterior pars lateralis for some distance" (p. 46). This concerned a "nucleus ventralis intermedius," evidently different from that of C. Vogt (cerebellar), which Walker no longer mentioned and was forgotten by its followers. The situation in sane monkeys was however relatively clear: the kinaesthetic group was located in the lemniscal nucleus ventralis posterior. The problem was more complex in man because of the lack of distinction between sane and pathological conditions. On cyto- and myeloarchitectonic differences, Hassler's (1959, followed by Emmers and Tasker, 1975) distinguished two parts in the nucleus ventralis caudalis (Vc equivalent to ventralis posterior): V.c.a. and V.c.p (each with medial and lateral subparts) surmounted by Zc (zonalis caudalis). In 1966, Albe-Fessard *et al.* showed the location of a zone in the human thalamus receiving information "from deep tissue, joints and we believe from Group I muscle afferents." illustrated on a modified Hassler's map (their Fig. 1 reproduced in Fig. 20.27). This zone, crescent-shaped over the cutaneous VPM, involved V.im and a region dorsal to the somesthetic nucleus (Z.c, Fig. 20.27). The selected reference L15 plane was unfortunately too medial. The transfer of the data to planes L16 of the same atlas, L16 of Van Buren and Borke (1972) or L16.7 of Morel *et al.* (1997) shows that the kinesthetic zone likely was in Hassler's Vc.a.e and Zce. The two elements, not seen in continuity, actually form a sort of comma in front and above the cutaneous VP (Fig. 20.28 from L14 to 18.5). The kinaesthetic zone was not described earlier because of its misleading cytoarchitecture, appearing even more "cerebellar" than the cerebellar territory itself, with particularly large neurons, distant one from the other. In horizontal sections, Hirai and Jones (1989) delineated a subdivision having cell-sparse large neurons looking like the cerebellar territory but staining for cholinesterase (like the lemniscal). This part, equated to the Vcae of Hassler (1959), was said to form an anterior part of the lemniscal territory, renamed VPLa (in opposition to the cutaneous VPLp). Hassler's Zc was not considered. In the squirrel monkey, Kaas *et al.* (1984) and Kaas (1988) later described two subnuclei: one nucleus ventralis posterior oralis (VPO) located in front of the cutaneous VP (thus potential equivalent to V.c.a.e) "relaying muscle spindle information" and projecting to area 3a and one nucleus ventralis posterior superior (VPS), superior to it (thus potential equivalent to Zc), relaying "deep receptor" (articulation, tendon) input to area 2. This separation is now said to be "inconclusive in primates" (Chapter 28), leading to a single subdivision (VPS, Kaas). VPS privileged a ventrodorsal sequence (VPI-VP-VPS) when the kinesthetic part is located in a general caudooral sequence (VPC-VPO-Vim-VO-VA) previously acknowledged in Hassler's Vca or Jones VPLa. VPO is thus preferable. This anterior part of the lemniscal territory is embedded between the cutaneous and the cerebellar territories (horizontal sections, Fig. 20.16; transverse, Fig. 20.17 A 4.2 to –1.25; sagittal, Fig. 20.23, L14 and Fig. 20.15 L15 and 16). It does not mix with the cerebellar territory or the cutaneous, from which it is separated by an irregular spacing strip. The kinesthetic nucleus has been the subject of many physiological studies in man (Albe-Fessard *et al.*, 1966; Jasper and Bertrand 1966; Bertrand *et al.*, 1967; Ohye *et al.*, 1972, 1990; Tasker *et al.*, 1982; Lenz *et al.*, 1988, and 1990; Seike, 1993). Lenz *et al.* (1988) insisted on the fact that "kinaesthetic" axons had lemniscal physiological characteristics. The kinaesthetic part has its own complete somatotopic map, thus forming a separate complete nucleus. The kinesthetic nucleus VPO projects to the fundic, intermediate sensorimotor (Ism; Sanides, 1967), area 3a (Jones and Friedman, 1982; Darian-Smith *et al.*, 1990; Darian-Smith and Darian-Smith, 1993; Kaas *et al.*, 1984) and to "area 2."

SUBREGIO LATERALIS INTERMEDIA. CEREBELLAR TERRITORY

Nucleus Ventralis Intermedius Lateralis. VimL or VLL, and Nucleus Ventralis Intermedius Medialis. VimM or VLM

The ending of cerebellar axons in the lateral part of the thalamus is known for long. C. Vogt (1909), after the destruction of the dentate nucleus in a monkey, showed cerebellothalamic axons forming her "prelemniscal radiation." This was located in front of the medial lemniscus and posterior to her lenticular radiation, thus in an intermediate position explaining the term "n. intermédiaire," latinized as nucleus intermedius (Crouch, 1934)(V.im for the Vogt and Vogts, 1941). The radiation was also observed during myelinization (Vogt, 1909; Kornyey, 1926). Crouch and Thomson (1938) and Walker (1938), in macaques, experimentally confirmed the location of the cerebellar territory, Walker adding that it is not simply ventral but also dorsal caudally. Van Buren and Borke (1971) found the same position in chimpanzees and Larson *et al.* (1982) in man. A series of experimental studies in macaques using anterograde degeneration extended the distribution of the territory (Mehler, 1971; Kusama *et al.*, 1971; Kievit and Kuypers, 1972) but thought that it overlapped with the more anterior pallidal territory. Our first topographic studies (Percheron, 1975, 1977) showed the high density, continuous, and complex three-dimensional shape of the territory. The comparison with previously published maps indicated that the cerebellar territory was separate from the pallidal and nigral territories, which was not accepted at that time. Further works (Chan-Palay, 1977; Berkley, 1980; Stanton, 1980; Kalil, 1981; Asanuma *et al.*, 1983; Ilinsky and Kultas-Ilinsky, 1987) confirmed the thalamic extent of the territory and its spatial separation from the lemniscal territory. Three-dimensional studies, rotations, and reslicing (Ilinsky *et al.*, 1993; Percheron *et al.*, 1996) showed the complex three-dimensional shape of the territory and its fundamental position for the analysis of motor thalamus (Fig. 20.17).

The cerebellar source to the thalamus is in all cerebellar nuclei (dentate, emboliform, globose and fastigial) (see Chapter 11). Transynaptic studies (Wiesendanger and Wiesendanger, 1985; Orioli and Strick, 1989; Hoover and Strick, 1999), however, specified that the main component of nucleocerebellar-thalamic connection was from the dentate nucleus (75–90%; Hoover and Strick, 1999), only 15–20% from the interposed nucleus and very few from the fastigial nucleus. Asanuma *et al.* (1983) put forward a somatotopic organization of the cerebellar nuclei with the face caudally and the leg anteriorly. Hoover and Strick (1999) showed instead a gross somatotopical organization only in the dorsal third of the dentate nucleus in monkeys having transynaptic links with the motor cortex M1. This part of the dentate nucleus would contain multiple somatic maps. Other, more ventral, parts of the dentate nucleus transynaptically project to other cortical areas. The two parts of the interpositus nucleus (nucleus interpositus anterior or emboliformis-emboliform nucleus and nucleus interpositus posterior or nucleus globosus-globose nucleus) together would contain another single complete somatotopic map.

The trajectory of cerebellothalamic axons is well known (Percheron 1977; Fig. 20.12A; Percheron *et al.*, 1996), through the superior cerebellar peduncle, decussating in the decussatio brachium conjunctivum and the brachium conjunctivum ascendens (Fig. 20.10B). This crosses the lateral part of the red nucleus and reaches the inferior border of the lateral region of the thalamus from which it spans to form the thalamic territory.

The cerebellar territory is intercalated between the nigral and pallidal territories anteriorly and the lemniscal territory posteriorly, thus intermediate: "nucleus ventralis intermedius" or "V.im". The description of its topography is made difficult by its complex geometry (Fig. 20.18). It is strongly curved sagittally (Figs. 20.17 and 20.18, 20.23). The anterior border with the pallidal territory is sinuous with long fringes, even peninsulae (Fig. 20.23 L11 and 12). Sections, may lead to misinterpretations about mixture, only avoided by three-dimensional reconstruction. The territory ends dorsally over the lemniscal territory (Fig. 20.23, L14). In horizontal sections (Fig. 20.21), the territory, oblique, is located medially to the pallidal, which is a noticeable difference with the monkey. The cerebellar territory expands ventrally and dorsally (Fig. 20.23 L8). Posteriorly, the border with the lemniscal subregion is rather smooth (Fig. 20.21 H1 0,9 to 7 and Fig. 20.23 L11 to 14). The intermediate subregion makes a clear contrast with the smaller cells of the posterior region and the dense islands of the pallidal subregion (also Hirai *et al.*, 1982). There are difficulties for delineating the cerebellar from the more anterior "magnocellular" neurons of the nigral subregion and the more caudal lemniscal subregion that also have large cells. The last, however, has more densely packed neurons mixed with small and middle-sized neurons (see "Subregio Caudalis. Lemniscal Territory"). The cerebellar territory stains for parvalbumin, which allows its delineation from the more anterior calbindin positive pallidal (also acetylcholinesterase positive) and nigral territories and from the poorly stained posterior region (pulvinar),

FIGURE 20.11 Cerebellar territory. Twenty transverse levels from Percheron *et al.* (1996), from among 32, placed in CA-CP coordinates and regularly spaced, *Macaca fascicularis*. The brachium conjunctivum is visible from 3.9 to 2.65. At first frontal levels, the territory starts as two—one medial and one lateral—islands. The two join posteriorly, and the territory becomes ventral. Starting from CP 3,65, pushed by the VP, it goes up dorsally and ends posteriorly in the upper lateral corner as the postremus site Lips. Note the dorsal place left for the pallidal territory. The territory does not respect the posterior part of the lamella medialis end and includes the paralamellar site that looks like a medial extension of the lateral region (l)I. LC, lateral caudal, lemniscal territory (LCL = VPL, LCM = VPM); LI, lateral intermediate, cerebellar subregion (of the lateral region), with two parts LIL (VImL or VLL) and LIM (VimM or VLM); LO, lateral oral subregion pallidal (VO) pallidal; LR, lateral rostral subregion nigral (VA); Larc, lateralis arcuatus, taste relay; Lu n, subthalamicus of Luys; C, regio centralis; M , nucleus medialis; Pu, pulvinar with PuO pulvinar oralis and PuOd pulvinar oralis dorsalis (ex LP).

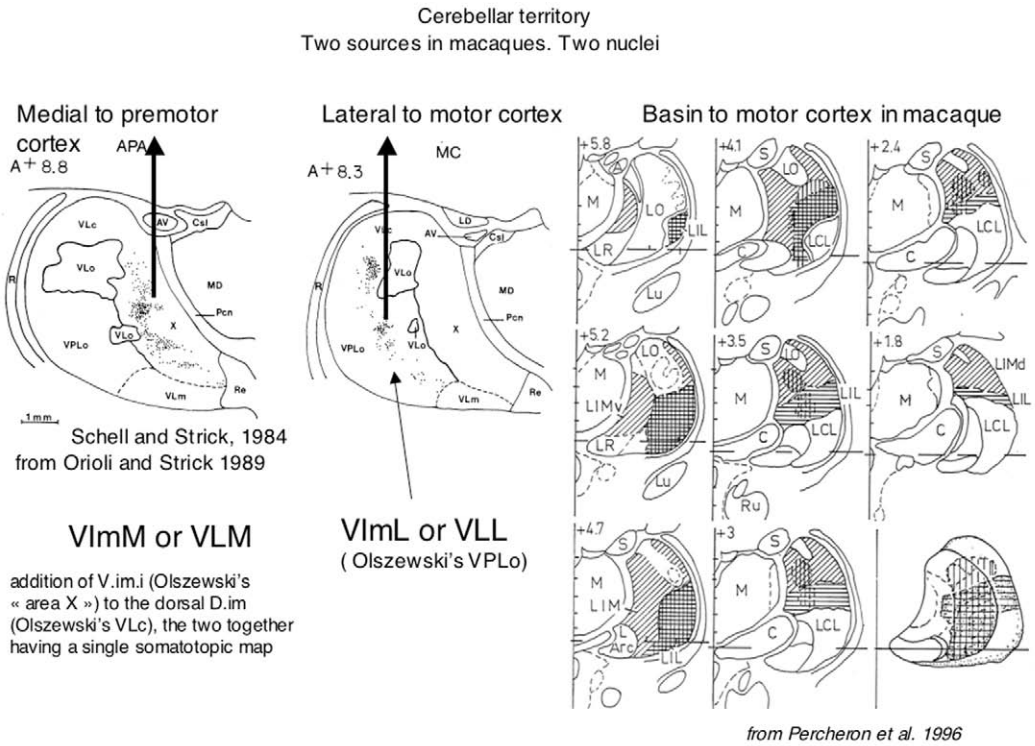

FIGURE 20.12 Subdivision of the cerebellar territory. *Left:* Picture from Orioli and Strick (1989) showing that there are distinct basins for the motor and premotor cortex. There are two parts generally separated ventrally in the macaque (VPLo and areaX) and man (Vim;e and V.im.i). The dorsal site is a continuation of the medial with a single somatotopic map. There are thus two nuclei: V.Im.L (o VLL) projecting to the motor cortex and V.Im.M (or VLM) projecting to the premotor. V.Im.L is strongly magnocellular with sparse neurons. *Right:* Picture from Percheron *et al.* (1996). This character is plotted using horizontal hatching on eight transverse sections of one monkey. The extent of the basin to the motor cortex (in vertical hatching) is traced on data from several works from literature. The two coincide essentially anteriorly where the separation of the two parts is visible.

but not simply from the lemniscal territory also parvalbumin+. The cerebellar region is, however, less dark with curved fascicles in sagittal sections.

The, intermediate, cerebellar subregion is not homogeneous, having some cytoarchitectonic diversity more or less coinciding with several previously delineated "nuclei." It has been known for a long time that the lateroventral part is made up of particularly large neurons, confirmed by cytometric studies (Dewulf, 1971; Van Buren and Borke, 1972; Hirai *et al.*, 1982, 1989). In Golgi staining, the dendritic arborizations of these neurons are larger than in the rest of the thalamus; about 500 to 600 µm in diameter (Hirai *et al.*, 1989; Percheron *et al.*, 1996). This part (VImL-VLL) also has a particularly low density of neurons giving a quite distinguishable aspect. The mediodorsal ensemble (VImM-VLM) contains smaller neurons. It is denser than the lateroventral part but still relatively poor in neurons; the whole cerebellar-receiving territory forming Asanuma *et al.*'s (1983) "cell sparse zone." As will be seen later, the distinction of two subparts in the cerebellar territory is not primarily based on cyto- or myeloarchitectonic criteria. The fine structure of the cerebellar territory has been analyzed by Kultas-Ilinsky and Ilinsky (1991) who found interspecific differences with few or no glomeruli and only few triads in macaques.

Contribution of the Different Cerebellar Nuclei and Distribution of Cerebellonuclear Axons

The cerebellar territory is at first the controlateral dentate territory, alone covering all its extent (Chan-Palay, 1977; Stanton, 1980; Asanuma *et al.*, 1983) and acting as the main territory with cerebellar and other coterritories. The distribution within the dentate territory is composed of onion-like layered curved laminae (Thach and Jones, 1979). Individual dentate axons emit one or only a few bunches of terminal twigs, ovoid or conical in shape, whose length and width is about 200 µm (Percheron, 1977). This points to rather focused input information and the possibility for the distribution of many separate items. But one point of the dentate nucleus may project to many laminae (Thach and Jones, 1979). The territories from others cerebellar sources such as the ipsilateral dentate or interposed territories are included within the main territory, often as spread islands. So does the fastigial

territory (Kievit and Kuypers, 1972; Asanuma *et al.*, 1983). The distribution of the axons from various cerebellar sources within the cerebellar territory must be analyzed according to neuronal paths starting from precerebellar afferents, cerebellar zones, and ("deep") cerebellar nuclei (Chapter 11). The zonation also involves the accessory vestibular nucleus of Deiters, the "nucleus X," and the interstitial nuclei. The interposed nuclei through the cerebellar cortex receive spinal afferences from spinocerebellar tracts conveying "deep" information from muscle (Allen *et al.*, 1977, 1978), articulations, tendons, and skin pressure.

Coterritories. Vestibulothalamic Coterritory

For a long time, the topography of the vestibular afference was not fixed. It is extended over the whole extent of the cerebellar territory and more abundantly posteriorly in macaques (Büttner-Ennever and Büttner, 1978; Lange *et al.*, 1979; Asanuma *et al.*, 1980, 1983), and man (Havrylyshyn *et al.*, 1978); (see Chapter 33).

Spinothalamic Coterritory

The spinothalamic coterritory also has a predilection for the posterior part of the nucleus (Mehler, 1969, 1971; Mehler and Nauta, 1974; Applebaum *et al.*, 1979; Boivie, 1979; Burton and Craig, 1983; Asanuma *et al.*, 1983; Berkley, 1980, 1983; Jones, 1983; Mantyh, 1983; Greenan and Strick, 1986; Apkarian and Hodge, 1989; Apkarian ans Shi, 1994). Spinothalamic axons end in other thalamic places (see "Regio Basalis."), but their presence among cerebellar afferents raises important problems that, in spite of their pathophysiological importance, have not been solved yet. The intervention of the spinothalamic system in the emission of messages to the motor cortex has been ruled out by Greenan and Strick (1986) based on the lack of register between islands of spinothalamic axons and of motor cortex-projecting neurons. There are strong indications that, in addition to the interposed contribution, the spinothalamic afferents bring deep information from articulations, muscles, and tendons that are recorded in the motor cortex (Goto *et al.*, 1968). For Mackel (2001), the sensory imput to VImVL could be important in the recovery from cerebellar motor deficits.

Tectothalamic Connection

The tectothalamic coterritory of the cerebellar territory also raises unanswered questions. In macaques, collicular endings are observed in the paralamellar part of the medial region (see discussion on paralamellar site in "Regio Medialis"), a part of the cerebellar territory with larger somata. This part is no longer observable on cyto- or immunoarchitectural signs in man. Morel *et al.* (1997) delineated a "VLpl" (nucleus ventralis lateralis paralamellaris), on unspecified criteria but indicated that it was a part of Olsewski's "area X" in macaques (i.e., a ventromedial part of the cerebellar territory, corresponding to Hassler's V.im.i in man—and not V.o.i).

The neurons in the cerebellar territory in macaques are sensible to passive limb manipulation or torque perturbation (Vitek, *et al.*, 1994) with no difference for fast or low movements (Strick, 1976; Goto *et al.*, 1968, in man). The internal organization of the cerebellar receiving zone of the lateral region is at least dual. Microstimulations in the ventrolateral part (Olszewski's "VPLo," VImL-LIL) in macaques (Anner-Baratti *et al.*, 1986; Buford *et al.*, 1986; Vitek *et al.*, 1996; Miall *et al.*, 1998) evoke movements of all parts of the body including orofacial ("lips, tongue, jaw, eyebrows and, occasionally, the eyes," Miall *et al.*, 1998) with a predilection for the production of proximal arm (shoulder and elbow) and face movements. The evoked movements are complex, multijoint (more complex than in the motor cortex and close to what is observed in SMA, Miall *et al.*, 1998). Considered separately, the medial (Olszewski's "area X" or Hassler's V.im.i) and dorsal elements (Vlc or DI) have incomplete maps (the first without leg, the second without face or eye representation). Together they make another map with about same topological organization (favoring their grouping together as VimM or VLM). The map in this ensemble is much less organized than in the lateral nucleus, the slabs being not well segregated, with some overlap for instance between arm and eye or face (Anderson and Turner, 1991; Vitek *et al.*, 1994). The cerebellothalamic system brings the necessary information for the coordination of movements in relation to the body ensemble and in space. There are task-specific differences in the macaques between the lateral VImL (VLL) and the medial VImM (VLM) in relation to internally triggered or visually guided movements (Miall *et al.*, 1998). One is preferentially driven by inner and the other by spatial environmental requests. Data in human are unfortunately not completely reliable in the absence of anatomical verification of trajectories but the functional organization of macaques is likely to be similar.

Efferences to the (sensorimotor) striatum have been shown only recently in macaques (McFarland and Haber, 2000). Conversely, it was known for a long time that the main target of the cerebellar receiving thalamic region was the primary motor cortex (Walker, 1938a, b; Strick, 1975; Jones, 1978; Myita and Sasaki, 1983; Gosh *et al.*, 1987). The anterior ridge of the central sulcus (of Rolando), then precentral or prerolandic, is shaped by an agranular gradient. The

motor cortex or primary motor cortex (MI, Mot., "area 4", Gig) is agranular and gigantopyramidal. In front of it are other agranular areas (past area 6). One is medial, the supplementary motor area (SMA), with a "preSMA" (Matzuzaka *et al.*, 1992). The other is lateral, the premotor cortex (Premot)(Wise, 1985a, b), often subdivided in macaques in dorsal PMd and ventral PMv parts. In macaques, in front of the premotor cortex is the dysgranular oculomotor cortex (frontal eye field, FEF, area 8) and an SEF (supplementary eye field) (Schlag and Schlag-Rey, 1987). These are histologically not obvious in chimpanzees and humans and not precisely located yet. Schell and Strick (1984) and Orioli and Strick (1989) found that the primary motor cortex is not furnished by the neurons of the whole cerebellar-receiving subregion (VIm/VL), and essentially by those of its lateroventral part (with larger neurons, i.e., Olszewski's "VPLo" or V.im.e; Fig. 20.12). Schell and Strick (1984) added that the medial part of the cerebellar subregion, in contrast, in macaques, sends its axons to the ventral premotor cortex ("postarcuate cortex," "APA"). This founded the proposed separation of the cerebellar subregion into one ventrolateral (VImL-VLL) and one dorsomedial (VImM-VLM) subparts (Percheron *et al.*, 1996). This differentiation, proper to upper primates, could be linked to the higher differentiation of the primary motor cortex (and of the pyramidal tract) and to the development and diversification of the premotor cortex. In a recent study, Dum and Strick (2003) found that a different part of the macaque dentate nucleus transynaptically project to different cortical areas. The thalamic lateral nucleus (VimL) projects essentially to the motor cortex while the ventral premotor cortex, the parietal 7b and the frontal (46 and 9) areas are furnished by the medial nucleus (VimM). This indicates that the differentiation into two subsystems starts from the dentate, the thalamic separation being secondary, and adds a further weight to the formal anatomical separation. As noted by stereotacticians, VImL (V.im.e) is organized according to a clear, complete, somatotopic map. Vertically oriented slabs ("shell-like") correspond to the leg laterally and the arm and face medially (i.e., grossly the same map as that of the lemniscal territory). Microstimulations, however, show multiple points for digits and face together (Miall *et al.*, 1998). Shindo *et al.*, (1995) found adjacent but separate, insulate basins to distal or proximal representation in the motor cortex, indicating a highly complex system. In the motor cortex, the inmap privileges proximal over distal parts of the body (Vitek *et al.*, 1994). The distribution to the motor cortex is inhomogeneous, not point to point and patchy (Hoover and Strick, 1999). The output map from the cerebellar subregion was carefully analyzed by Matelli and Luppino (1993) after retrograde tracer injections into subdivisions delineated by Matelli *et al.* (1991). Recent works using multiple labeling in macaques showed that the selectivity for cortical targets is not absolute and that the connections are subtle and weighted. The ventrolateral subpart (VImL-VLL), main furnisher of the primary motor cortex, also sends some axons to the ventral and dorsal premotor cortex (PMv, Pmd, Rouiller *et al.*, 1999; Sakai *et al.*, 1999) and to the supplementary motor area (SMA proper, whose main afferentation is from the pallidal territory, Hoover and Strick, 1999; Sakai *et al.*, 1999; Rouiller *et al.*, 1999). The mediodorsal part (VImM-VLM), which receives neurons from the ventral premotor cortex, the main furnisher of the premotor cortex, ventral (PMv, PMvr and PMvc) and dorsal (PMd, rostral and caudal, Pmdr and Pmdc) also sends axons to the preSMA (Rouiller *et al.*, 1999) and to SMA itself (Shindo *et al.*, 1995; Rouiller *et al.*, 1999; Sakai *et al.*, 1999). The sources to the primary and the supplementary motor cortex are separate with little overlap. The dorsal part of the mediodorsal part (VImM-VLM) sends axons also to the parietal cortex (Miyata and Sasaki, 1983; Schmahmann and Pandya, 1990). The cerebellar- and tectal-receiving paralamellar region (see above) sends axons to the oculomotor cortex (frontal eye field, FEF and SEF, Scollo-Lavizzari and Akert, 1963; Akert, 1964; Huerta *et al.*, 1986). The paralamellar subpart of the cerebellar territory has the same projections as other VImM-VLM parts (i.e., to the premotor Pmv, Schell and Strick, 1984, and motor cortex, Gosh *et al.*, 1987). This is an argument for not separating a VLpl or VImpl from VimM.

In conclusion, on histological, hodological, and physiological arguments, there are likely (at least) two cerebellar thalamic nuclei in man: VImL-VLL, corresponding to the Vogts' V.im.e, (famous V.im), and VImM-VLM (V.im.i + DI). These cannot be delimited with certainty in man in the absence of a reliable way of delineating the source to the motor cortex. Only the magnocellular character of the somata could be used, allowing some differentiation anteriorly. Tracings on Figures 20.21 to 20.23, are just the most likely. In addition, motor thalamocortical connections having different weights and simian cortical subdivisions having neither clear equivalent nor firm assessment may be made about the situation in man.

SUBREGIO LATERALIS ORALIS. PALLIDAL TERRITORY

Nucleus Ventralis Oralis. VO

The history of the pallidothalamic connection is long, since the connection was first described by C. Vogt in 1909 and was still being discussed relatively

recently, starting with the pioneering experimental work by Nauta and Mehler (1966) in macaques. C. Vogt established the continuity of the pallidothalamic axons in the right sense. The works of the Ransons (1939, 1941), furnishing sufficient data, had been unjustly forgotten (see Percheron *et al.,* 1996). The pallidal territory corresponded to C. Vogt's "lenticular radiation" located in front of her "prelemniscal" (cerebellar) radiation. As previously explained ("Lateral Region. Generalities") the sequence, accepted by Papez *et al.* (1940; Fig. 20.10) and Bailey and von Bonin (1951), was no longer taken into account in the formal subdivision of the thalamus effected by Olszewski (1952) and further authors. This had long-lasting detrimental effects on the whole thalamic parcellation. After the works of Carpenter and colleagues (Kuo and Carpenter 1973; Kim *et al.,* 1976), DeVito and Anderson (1982) and from Ilinsky and Kultas-Ilinsky (1987), in macaques, our study (Percheron *et al.,* 1994, 1996) delineated the territory on 52 transverse levels (20 in Fig. 20.13) followed by three-dimensional reconstruction. This led to the consideration of the pallidal as one of the major territories of the primate motor thalamus. It cannot be analyzed without placing it into a larger system, a three-path (with three consecutive connections), which are nonexistent in nonprimate orders, composed of the medial pallidum, the thalamic pallidal territory, and the cortical supplementary motor area (SMA; Fig. 20.19). This ensemble appears in simians, increases in size and number of neurons and progressively segregates from other systems. The process is not achieved in cebideae since, in the squirrel monkey for instance (Sidibé *et al.,* 1997), a part of the pallidal territory is located in front of the central region (Fig. 20.19 L6) shown in macaques to receive only nigral afferences (Percheron *et al.,* 1996). The catarhinian pallidal territory cannot be named using nomenclatures devised for lower animal species. The initial name given by C. Vogt to the recipient of her "lenticular radiation" was the "ventral oral" nucleus (more precisely her "noyau ventral oral lateral" Vogt, 1909, later V.O.e, Vogt and Vogt, 1941). Hassler (1949, 1982) constantly mislocated the thalamic place where cerebellar afferents are ending, wrongly placing them in the posterior part of the Vogts' V.o.e to which he described two parts: one anterior V.o.a, pallidal, and one posterior V.o.p, cerebellar. This misinterpretation, illustrated in Fig. 20.23 L8 to L14, had heavy effects in stereotactical culture. The other part of the Vogts' Vo, V.o.i, medial, was within what is known to be the nigral territory (VA). There was and is only one pallidal nucleus ventralis oralis VO; a term retained together with VA by the Louvain committee.

The source of the pallidal territory is the medial pallidal nucleus alone (Parent and de Bellefeuille, 1982; Fénelon *et al.,* 1990). The main afference of the medial pallidum is the striatum through the striatopallidonigral fascicle (the striatum, the bundle and the direct targets, pallidum and nigra, constituting the "core of the basal ganglia," Percheron *et al.,* 1994). The striatum is subdivided into associative and sensorimotor striatum (Percheron *et al.,* 1984). The latter receives axonal intertwined islands from the somatosensory, motor, premotor cortex and accessory motor, SMA. The greatest part of the macaque medial pallidum (63%, François *et al.,* 1994) receives axons from the sensorimotor component. This must be tempered by the fact that the geometry of the communication between striatal and pallidal axons (Yelnik *et al.,* 1984; Percheron *et al.,* 1984) realizes a drastic compression of information. The dendritic arborizations of the pallidum are flat, discoid, very large, and perpendicular to the emitting striatal axons. One pallidal (or nigral) neuron is in the position to receive pieces of information from numerous upstream striatal axons and is able to combine them. The map of the striatum is thus greatly impoverished in the pallidum. Transynaptic studies using viruses have shown that the outmap of the medial pallidum is still subdivided into a main, ventral, sensorimotor part and a dorsomedial associative part. Projections through the thalamus to SMA, motor, and premotor cortex arise from the sensorimotor part, while the transynaptic connection to the frontal cortex does it from the associative part (Middleton and Strick (2000). In the sensorimotor part, there could be a crude somatotopic outmap, the neurons transynaptically projecting to the part of the motor cortex devoted to the leg being more dorsal than those projecting to the face (Hoover and Strick, 1993, 1999). In the sensorimotor part, pallidal neurons are activated by passive movements of the controlateral part of the body. They intervene before the initiation of movement with elective directions of movements and kinematics (Turner and Anderson, 1997).

Medial pallidal neurons have several other targets; the most remote one being the pedunculopontine complex (PPN, Parent *et al.,* 2001). On their way, they successively emit collaterals to the oral lateral subregion, the central complex, the "nucleus of the field of Forel" and finally the pedunculopontine complex PPN. Some axons reach all four targets. The majority of the neurons of the medial pallidum project to the lateral region of the thalamus (Fénelon *et al.,* 1991; Parent *et al.,* 2001). Axons ending in VO are all collaterals of pallidoperipeduncular axons in macaques. About one half of these axons give a collateral to the central complex (see Arrechi-Bouchiouia *et al.,* 1997), the other not (Fig. 20.14). In the pallidum, pallidal axons run anteriorly, medially, and ventrally. They arrive at the anteroinferior part of the medial pallidum

FIGURE 20.13 Pallidal territory. Twenty of the 52 levels from Percheron *et al*. (1996). Intrapallidal injection of H3 in a *Macaca fascicularis* at CP+6.75. The massive pallidothalamic bundle makes successively the three Forel's H2-H and H1 fields (the last is the classic "fasciculus thalamicus"). Lateral position of the territory in the initial sections with oblique oblong islands. Separation from nigral VA (shown as LR) and cerebellar V.Im (shown as LI) territories. Posteriorly, pushed by the cerebellar territory inferiorly, the territory ends dorsally far posteriorly.

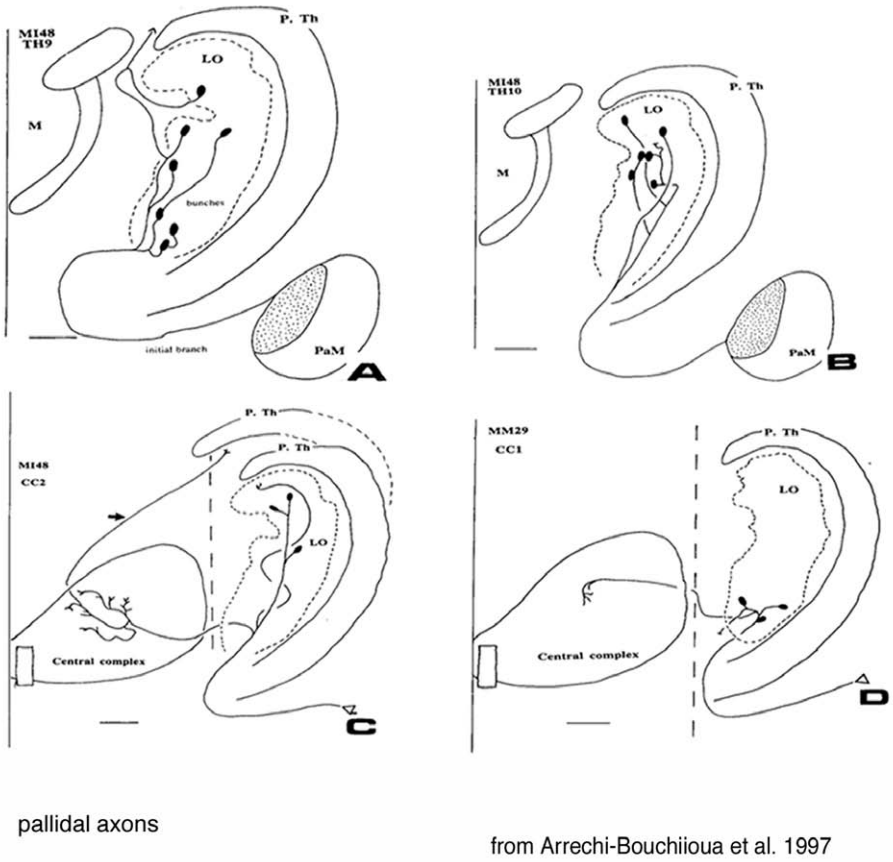

FIGURE 20.14 From Arrechi-Bouchhioua *et al.* (1997), showing the distribution of single pallidal axons labelled by biocytin. All of them reach the pallidal territory (here Lo). Long branches distribute widely rather small very dense glomerules of terminal endings ("bunches"). This spatial distribution makes unlikely the possibility for a somatotopic organisation. Two of the neurons emit a collateral to the central complex. Note that the mode of arborization is different in the two targets.

that they cover as a cap. The separation between the ansa lenticularis, inferior, and the fasciculus lenticularis, superior, argued at length by Nauta and Mehler (1966) is likely not necessary as they appear as mere aspects due to the section of an unique major bundle. Parent *et al.* (2001) showed that pallidal axons may give two branches, one horizontal and one ventral, that would have been said to run to the ansa or to the fasciculs. When pallidal axons arrive at the internal capsule, they cross it in separate elongated bundles forming Edinger's (1904) "Kamm-system" or "comb" (also containing cells). At the other side of the capsule, they gather together to reach the dorsal border of the subthalamic nucleus where they constitute the first part, H2, of the Forel's fields (1877). The pallido-thalamic bundle has a very peculiar three-dimensional trajectory that perturbed interpretations. Pallidal axons indeed go down in the hypothalamus. The so-sudden and so-sharp curve (about 350°) of the axons at "H," unusual in the brain, made unlikely that the two parts could belong to a single axonal system. Wilson (1914), for instance, believed that the descending branch corresponded to a lenticulorubral bundle (not existing but the main element of his "extrapyramidal system"). The continuity with the ascending "fasciculus thalamicus" (H1) and the direction were yet recognized by C. Vogt (1909) in the brain of a newborn (later confirmed by Kornyey, 1926, and Verhardt, 1938). The general shape of pallidal territory, relatively simple in horizontal sections (Fig. 20.19) is complex in three-dimension (Figs. 20.17 and 20.18). It is extended from the lower to the upper borders of the lateral region, thus neither ventral or dorsal and "lateral" (i.e., belonging to the lateral region). It is curved following the lateral border of the lateral region in the mediolateral dimension in frontal sections (Fig. 20.22, A 16.8 to 13). It is crescent-like in sagittal sections (Fig. 20.23 L9 to 12,), its dorsal and posterior part ending over the cerebellar territory. The medial and posterior border is highly sinuous with long

peninsulae (Percheron *et al.*, 1996; Kultas-Ilinsky *et al.*, 1997, Fig. 20.23 L8 and L11). This creates problems of interpretations on single sections without three-dimensional reconstruction. The irregularity of the contour must be considered along with the opposite nigral fringes. In transverse sections in macaques, there are oblique oblong islands densely containing small neurons. Bands in between have few neurons. Such bands are still visible in the most anterior transverse sections of the human brain (Fig. 20.22 A 16.8, 14.5) but are more evident in sagittal sections (Fig. 20.23 L9 to 12). They are interdigitated with similar ones of the nigral territory anteriorly and of the cerebellar territory posteriorly, mainly dorsally. The pallidal territory selectively stains for calbindin (Percheron *et al.*, 1996; Parent *et al.*, 2001), which is already the case at 23 weeks (Forutan *et al.*, 2001), where it is stained alone in the lateral region. Both neurons and "neuropil" are stained, allowing the delineation from the nigral territory in the absence of experimental methods. In addition, the pallidal territory stains for acetylcholinesterase. In man, the calbindin-positive territory is still anterior to the cerebellar. An internal change occurred in comparison with monkeys, as the nigral and the medial cerebellar territories seem to have moved anteriorly. What is medial to the pallidal territory in macaques is the nigral territory while in man it is the anteromedial part of the cerebellar territory (Fig. 20.21, H 3.9, Fig. 20.22, A 12 5 and 8.4). The pallidal axons arrive in great number at the inferior border of the lateral region (Fig. 20.23 L8 and 9). Their density leaves little room for neurons that led to the unnecessary isolation of a ventral subdivision (Vlm) (see "Lateral Region. Generalities"). In the pallidal territory, pallidal axons (Fig. 20.14) spread over large extents up to the dorsal border (Yelnik *et al.*, 1996; Arrechi-Bouchiouia *et al.*, 1997; Parent *et al.*, 2001). They emit several long distributing branches covering loosely the extent of the territory with no discernible order. At their extremity, they give off dense "bunches" (Arrechi-Bouchouaia *et al.*, 1996, 1997; Ilinsky and Kultas-Ilinsky, 1997; Parent *et al.*, 2001) or plexuses or baskets made by numerous axonal terminals (Fig. 20.7). Smaller than the receiving dendritic arborizations, such bunches bring a convergence and impoverishment of the thalamic map. Bunches are emitted in the inferior and dorsal part as well. This pattern offers little possibility for a somatotopic distribution if any. Thalamocortical neurons, which belong to a single neuronal species, are smaller than those of the more posterior intermediate neurons (Hirai *et al.*, 1982, 1985, 1989) and have medium-sized dendritic arborizations (VanBuren and Borke, 1972; Percheron *et al.*, 1996). Pallidal-receiving VO has the usual amount of local circuit neurons for the lateral region (24.5%, Dewulf, 1971). The pallidal boutons are mainly located on the somata and proximal dendrites (Kayahara and Nakano, 1996; Kultas-Ilinsky *et al.*, 1997; Ilinsky and Kultas-Ilinsky, 2001; Kultas-Ilinsky and Ilinsky, 2001). The mediator of the pallidothalamic connection is GABA (Aizawa *et al.*, 1999). Pallidal boutons contain pleimorphic vesicles and display synaptic contacts. Also ending on local circuit microneurons, they constitute triads (Ilinsky and Kultas-Ilinsky, 2001; see "Isothalamus. Constitution, Architecture, and Function") that are peculiar by the fact that they involve only inhibitory GABAergic neurons.

Pedunculopontine Coterritory

As already mentioned, the pallidal territory contains acetylcholinesterase-positive axons. These are likely of pedunculopontine origin. Since the medial pallidum directly sends axons to the pedunculopontine complex (Nauta and Mehler, 1966; Percheron *et al.*, 1996, Shink *et al.*, 1997, Parent *et al.*, 2001), the medial pallidum exerts a double influence on VO: one direct pallidothalamic, inhibitory, and the other indirect, medial pallidum- PPN-pallidal territory VO, excitatory.

The pallidal-receiving VO sends axons to the sensorimotor striatum in macaques (Nakano *et al.*, 1990; MacFarland and Haber, 2000; personal material) contributing to an important basal ganglia subsystem. The main cortical target of the pallidal receiving VO is the supplementary motor area (SMA; Strick, 1976; Jinnai *et al.*, 1983; Schell and Strick, 1984; Miyata and Sasaki, 1984; Wiesendanger and Wiesendanger, 1985, 1987; Wiesendanger *et al.*, 1987; Tokuno *et al.*, 1992; Hoover and Stick, 1993; Jinnai *et al.*, 1993; Matelli and Luppino, 1993; Nakano *et al.*, 1993; Shindo *et al.*, 1995; Sakai *et al.*, 1999). The pallidal three-path medial pallidum-pallidal territory-SMA very likely is still an important ensemble in man. SMA has been the subject of many works and reviews (see Goldberg, 1985; Tanji, 1994; Sakai *et al.*, 1999). SMA has numerous "functions" including motor preparation and sequential movement. Lesions there have major clinical effects (Laplane *et al.*, 1977). Some data have to be reconsidered after the discovery of the pre-SMA (Matuzaka *et al.*, 1992). It is today certain that VO also projects to the anterior part of the motor cortex M1 (Matelli and Luppino 1989; Shindo *et al.*, 1995; Kayahara and Nakano, 1996; Hoover and Strick 1999; Middleton and Stick, 2000). It also sends axons to the premotor cortex, dorsal (Pmd)(Kievit, 1968; Jinnai *et al.*, 1989, 1993; Nakano *et al.*, 1992, 1993) and ventral (Matelli *et al.*, 1986; Matelli and Luppino 1993; Hoover and Strick, 1993; Nakano *et al.*, 1993; Middleton and Stick, 2000). A

projection to the frontal cortex (principalis) has been observed by Middleton and Strick (1994, 2000). The pallidal territory has been postulated to be somatotopically organized, continuing orally the somatotopic order of the lateral cerebellar territory with three slabs, that of the leg laterally and that of the face more medially (Matelli and Luppino, 1993). In human patients, Hassler *et al.* (1979) drew a homunculus, which does not fit with Schaltenbrandt *et al.*'s (1971) observations and the axonal distribution described previously. One major difference with the efferences of the nigral subregion is the absence of projection to the orbital cortex (Cavada *et al.*, 2000).

The physiological analysis of the lateral oral subregion is made difficult by its indentation with the more posterior cerebellar territory (VIm-VL). Recent studies in the "pallidal receiving area" (found to be such after pallidal stimulation) are bringing rapid progress. In humans, neurons were said to be only weakly sensitive to passive movements (Vitek *et al.*, 1996) or do not respond to sensory stimulation at all (Jasper and Bertrand, 1966). VO neurons are sensitive to active movements (Vitek *et al.*, 1996). In human patients, some neurons have multiunit activity associated with arousal (e.g., sudden noise, unexpected taps, or sudden verbal instructions). But the most characteristic are "voluntary units" (or "voluntary motor cells," Jasper and Bertrand, 1966) firing only when voluntary movements are executed. This was discussed by Ohye (1990). Raeva (1986) found neurons whose activity was not rhythmic at rest but could become rhythmic during the initiation of movement and during the phase that follows motor tasks. The same author described the "triggered verbal command unit" increasing their activity after verbal commands for active movements, before the movement. The effects of microstimulation are disputed. Anner-Baratti *et al.* (1986), Bufford *et al.* (1996), and Vitek *et al.* (1996) found that it occasionally caused complex movements organized according to a somatotopic map. The reappraisal of their data led Miall *et al.* (1998) to the conclusion that microstimulations of pallidal-receiving neurons cannot produce movement (which would remain the property of the cerebellar-receiving neurons). The striatopallidal and the pallidothalamic connections being both inhibitory form an unusual path with a desinhibition well known by physiologists. The transient inhibition of the pallidum by injection of muscimol leads to an increase in the firing rate of thalamic neurons (Anderson *et al.*, 2001). The tonic inhibitory output of the medial pallidum would be of main importance for the maintenance of postural stability (Inase *et al.*, 1996). The medial pallidal system would contribute to the holding of the general and limb posture making the pyramidal system able to effect fine distal movements.

SUBREGIO LATERALIS ROSTRALIS. NIGRAL TERRITORY

Nucleus Ventralis Anterior. VA

The interpretation of the anterior part of the lateral region has raised many questions for a long time (discussed in Percheron *et al.*, 1992, 1993). In the beginning, the most anterior part of the lateral region has been separated from the rest on several assessed properties: (1) lack of projection to the cortex, as it did not degenerate (or degenerated incompletely) after hemidecortication (in macaques, Walker, 1935, 1938; Peacock and Combs, 1965); in chimpanzee, Walker, 1938; and in man, Powell, 1952; (2) lack of lower afferences (Jones, 1985 among others); (3) projection to the striatum (Walker, 1938); and (4) linkage to a diffuse system extending the reticular formation (Carmel, 1970) or to the limbic system (Angevine *et al.*, 1962a, b; Bentivoglio *et al.*, 1993). The long-standing interrogation concerning the polar part of the lateral region was partly linked to its unclear borders. This is caused by the strong curvature of the main axis of the lateral region, its anterior part ending not anteriorly but medially, almost perpendicular to the ventricle (Figs. 20.2D, 20.16). Another element of difficulty is the crossing of many fascicles breaking borders and cytoarchitecture. The neglect of the nigral territory for years, particularly at the time where the lateral region was being subdivided, had a detrimental effect on the whole structurofunctional subdivision of the thalamus that is still noticeable today. Cécile Vogt (1909) ignored the nigral territory as later did Crouch (1934), Walker (1938), and Olszewski (1952) among others. Hassler (1959, 1979, 1982) constantly rejected the existence of this afference, leading to its omission by stereotacticians. The acceptance of a nigrothalamic connection in primates appeared only after the work of Cole *et al.* (1964) using Nauta's method, followed by a series of works by Carpenter and colleagues (Carpenter and McMasters, 1964; Carpenter and Strominger, 1967; Carpenter and Peter, 1972; Carpenter *et al.*, 1976). These studies showed only the ventral part of the territory. The cartographic delineation of the whole extent of the territory was done only later (Ilinsky *et al.*, 1985; Ilinsky and Kultas-Ilinsky, 1987; Percheron *et al.*, 1993, 1996). These studies not only confirmed the connection but, as previously assessed by Carpenter and Strominger (1967), its separation from the pallidal territory, making it (with the cerebellar and the

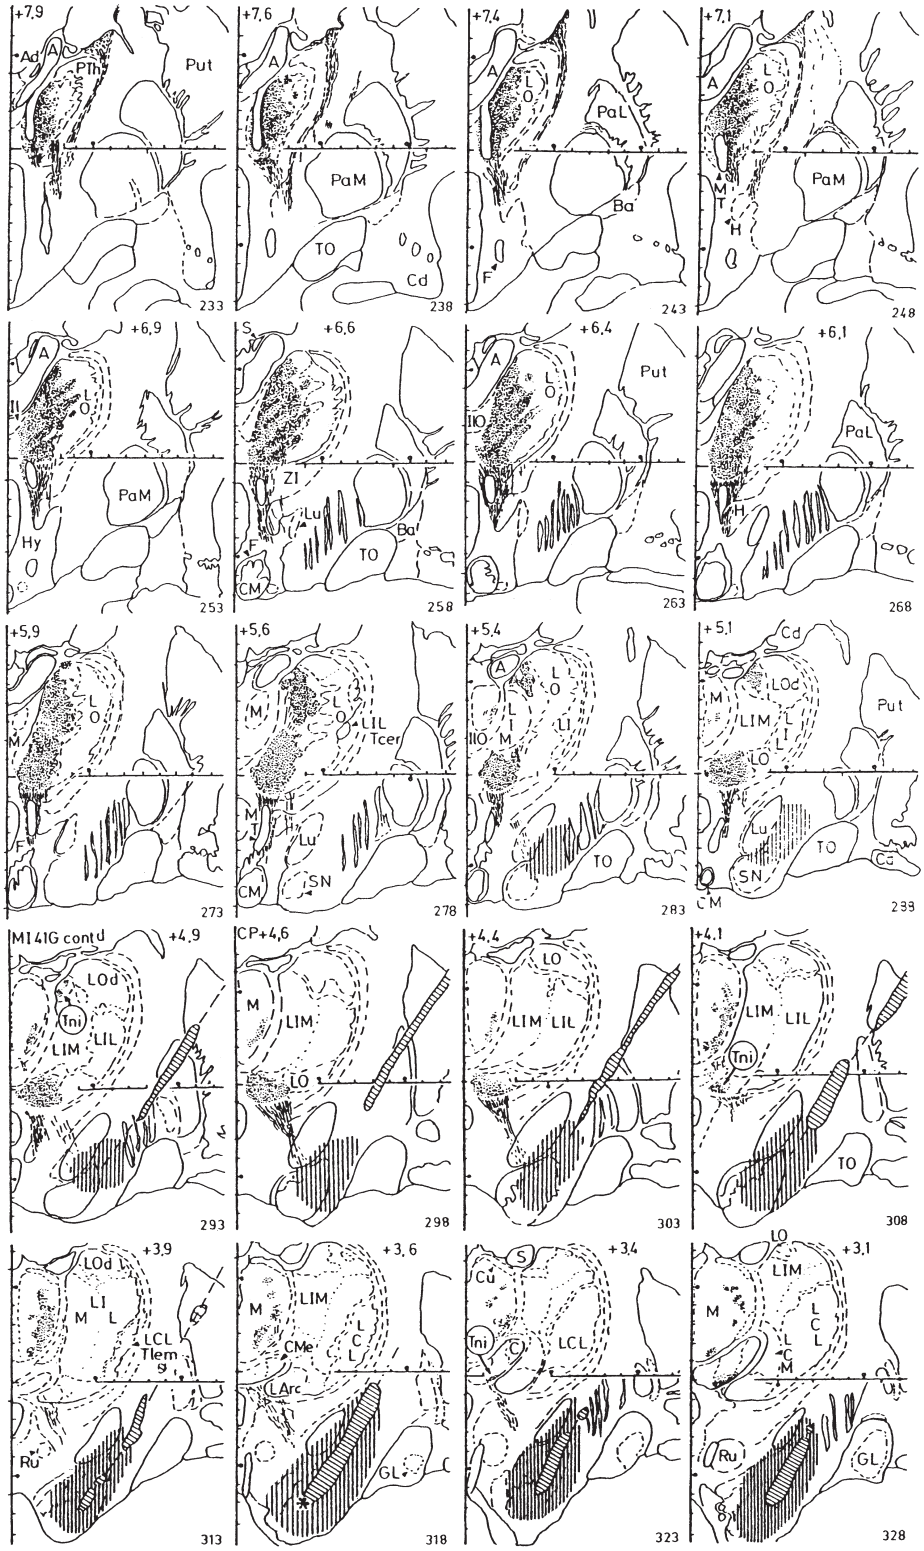

FIGURE 20.15 Nigral territory. Twenty levels on 41 from Percheron *et al.* (1996). The tip of the nigral injection with H3 is at CP+3.6 (star), with nigra almost entirely injected. The nigral territory, traversed by the mamillothalamic fascicle of Vicq d'Azyr, is medial and fills the anterior part of the lateral region not occupied by the pallidal territory LO (VO). The long indentations of the lateral border fit with sinuosities of the medial border of the pallidal territory. Posteriorly, the nigral territory is broken in its middle into ventral and dorsal parts by cerebellar territory. The ventral part continues far posteriorly up to the anterior pole of the central formation (CP+4.9 and 5.1) in a position sometimes separated as VM.

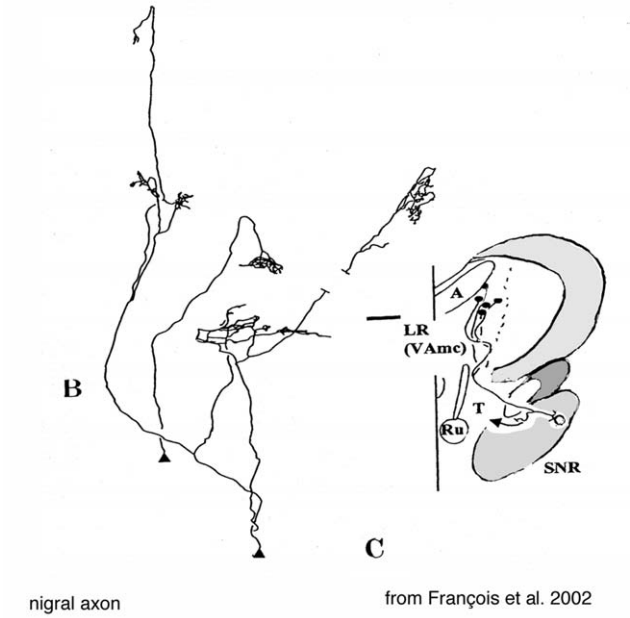

FIGURE 20.16 From François *et al.* (2002) modified showing the distribution of a single nigral axon in the nigral territory or rostral lateral subregion (LR) or VA. In B, one loose and widespread nigral arborization emits bunches similar to the pallidal, but they are less complex and less dense.

pallidal) the third major "motor" territory. Our study in macaques (Percheron *et al.*, 1996), where 41 successive maps were presented (20 in Fig. 20.15), brought out its three-dimensional extent, much larger than previously thought. The nigral territory also includes a place located just in front of the central region (Fig. 20.15, VA, Fig. 20.23, and Fig. 20.22, A12.5 and 13, L6), often isolated as a distinct lateral nucleus, the so-called "nucleus ventralis medialis." This, in higher primates, is the mere posterior continuation of the nigral territory (see "Lateral Region. Generalities"). The nigral territory contains patchy coterritories but has no other territory in front of it. It constitutes the anterior pole of the lateral region, being thus "polar" as for Hassler's nucleus lateralis polaris.

The source of nigral axons is located in the pars reticulata, lateralis, and mixta (above the compacta) (François *et al.*, 1984, 2002; Middleton and Strick, 1996). Nigral axons do not form a massive bundle; rather they form a continuous sagittal curtain through the hypothalamus, close and surrounding the mammillothalamic tract and avoiding the pallido-thalamic (H-H1 Forels fields) tract laterally (Percheron *et al.*, 1996; Fig. 20.17). Anteriorly and laterally it is surrounded by

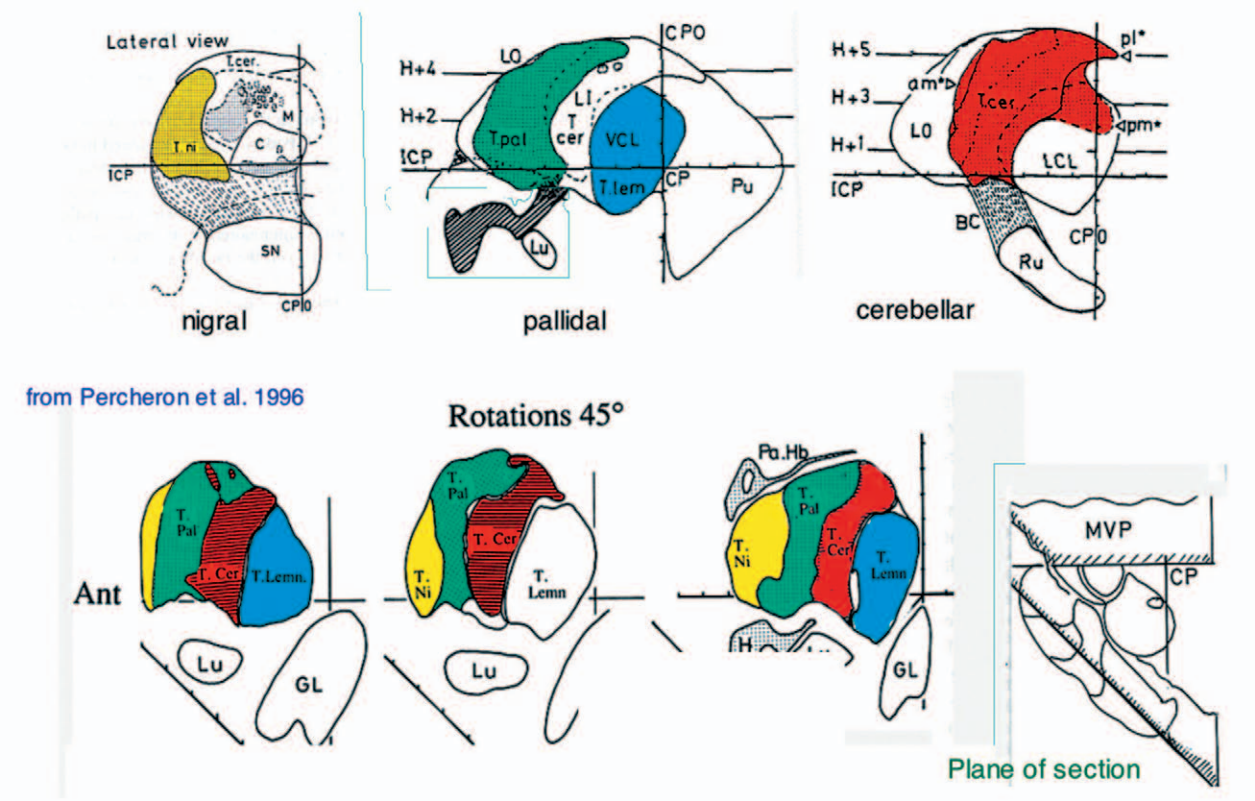

FIGURE 20.17 *Upper row.* From Percheron *et al.* (1996), colored. Sagittal reconstruction of the territories shown in Figures 20.15 (nigral), 20.13 (pallidal), and 20.11 (cerebellar) in *Macaca fascicularis*. The stong curvature of the territories may be observed convex to the front. The posterior part of the more anterior territory ends over the anterior part of the next territory. The three-dimensional geometry is complex. *Lower row.* "false sections" at 45° from the midventricular plane show a posteroanterior succession of territories: (retinal) lemniscal, cerebellar, pallidal, and nigral, still in macaques. This kind of section strongly reduces the curvature of territories.

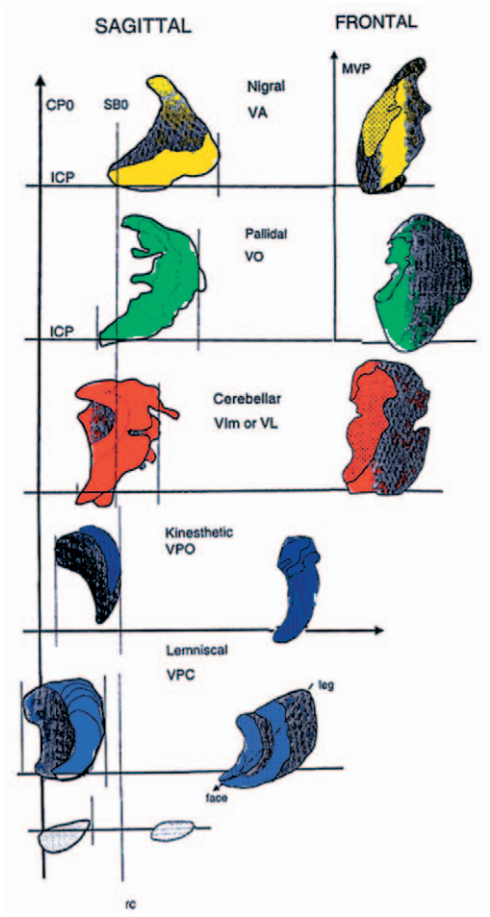

FIGURE 20.18 Sagittal reconstructions of the nigral, pallidal, cerebellar, kinaesthetic, cutaneous, and gustatory territories in human. The same curvature is observed as in the monkey. The relative position or sequence of territories is the same. Some borders are smooth but others, such as the pallidal and cerebellar, are strongly fringed, meaning sinuous borders whose section may create difficult interpretation.

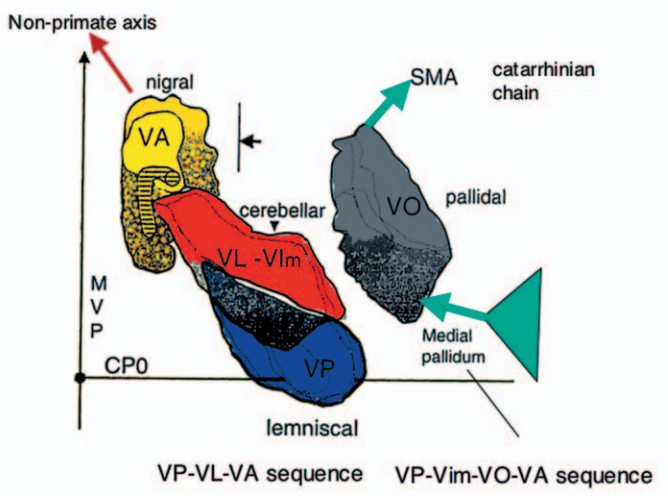

FIGURE 20.19 Three-dimensional reconstruction of subregions from horizontal sections in man. The sequence of the three, most medial subregions, is left in its position in relation to the CP0 system of coordinates. The pallidal subregion is moved apart laterally. The lemniscal, cerebellar, and nigral territories constitute a sequence observable in nonprimate species translated as the VPL-VL-VA sequence. The addition of the pallidal territory, which remains lateral, is particular to primates. It is linked to the development of a three-path: medial pallidum-pallidal territory-SMA. The pallidal territory deserves a particular name and acronym: VO. The nigral territory, crossed by the mammillothalamic tract, develops anteriorly. The cerebellar territory is pushed medially and reaches the posterior border of the nigral territory. The lemniscal territory has the same obliquity.

the perithalamus, which is particularly thick there. It is broken by the heavy myelinated fascicles that form oralwards the anterior thalamic peduncle. The territory is crossed through its whole ventrodorsal extent by the mammillothalamic tract of Vicq d'Azyr (Fig. 20.22 A14.5 and Fig. 20.23 L6). The posteromedial border of the nigral territory with the cerebellar territory is difficult to trace on cytoarchitectonic pictures in man since they both have large cells. This may be solved by using calcium-binding immunostaining, the nigral territory being not parvalbumin-positive. The border with the pallidal territory is sinuous with interdigitation in both frontal and sagittal sections (Fig. 20.23 L9). The nucleus ventralis anterior was said to be made up of several cytoarchitectonic nuclei: magnocellularis around the mammillothalamic tract, parvocellularis or principalis (or unspecified VA for Olszewski, 1952). The structure of the magnocellular part, proper to primates, has been analyzed by Ilinsky and Kultas-Ilinsky (1990) and Kultas-Ilinsky and Ilinsky (1990). The thalamocortical neurons are of various sizes and packed in subparts with no clear borders. The magnocellular differentiation, which is mainly medial, fades out laterally, dorsally, and ventrally in the less differentiated part. In humans, there is an obvious extension of this magnocellular differentiation, making its distinction from the large sparse-celled part of the cerebellar subregion more difficult than in macaques. Dekaban's (1953) VA, Andrew and Watkins' (1969) LOI, and VanBuren and Borke's (1972) Lpo did not contain any magnocellular subpart in man. At the reverse, a parvocellular differentiation is generally not taken into consideration. This part is more visible in man than in monkeys, which could expresses a further differentiation. It is made up of smaller somata and smaller dendritic arborizations (Van Buren and Borke, 1972). Ventromedial, it probably corresponds to the nucleus fasciculosus ("fasciculaire", Vogt, 1909) proposed by Van Buren and Borke (1972) to belong to the ensemble. For Ilinsky and Kultas-Ilinsky (1990), the magnocellular part Vamc would be the essential (or the only)

recipient of the nigral afferences. In fact, the parvocellular part also receives nigral afferences in macaques (Percheron *et al.,* 1996; Fig. 20.15; François *et al.,* 2002). The nigral territory in this genus covers different cytoarchitectural parts with apparently no care about cytoarchitectonics, giving no argument for making subdivisions on cytoarchitectonic criteria. The nigral territory does not stain for parvalbumin. Some of its neurons stain for calbindin, but much less than in the pallidal subregion from which it can be differentiated and which has no axons. The nigral territory is sagittally curved with a posterior and ventral part located just in front of the pole of the central region (Fig. 20.23 L6). At this level, it expands anterolaterally. The percentage of local circuit neurons is said to be only 10% in macaques (Ilinsky and Kultas-Ilinsky, 1990) but is 25% in the human thalamus (Dewulf *et al.,* 1973), the usual percentage in the lateral region. This indicates that VA is an evolutive part of the lateral mass. The nigral axonal endings within the nigral territory enter ventrally. From there, they climb on long distances, up to the superior border (Fig. 20.16). In their course, they irregularly emit long branches (Ilinsky *et al.,* 1993; François *et al.,* 1998, 2002; Fig. 20.14) that cover a great part of the territory. Many synapses are emitted *en passant,* all along the way of the axon (Ilinsky and Kultas-Ilinsky, 1990). There are, however, dense terminal axonal arborizations (François *et al.,* 2002) to some extent resembling the pallidal "bunches." Their average dimensions are 157 × 156 × 131 µm (François *et al.,* 2002); that is smaller than the average size of dendritic arborizations (about 400 µm). These sizes lead to the convergence of various axons on a single thalamocortical neuron not a simple transmission. The nigral boutons are similar to the pallidal and their distribution mainly on somata and proximal dendritic stems; however, they are less marked than in the pallidal territory (Ilinsky and Kultas-Ilinsky, 1990). Probably due to the low number of local circuit neurons in macaques, few triads and no glomeruli were observed (Ilinsky and Kultas-Ilinsky, 1990), which could be different in man with much more microneurons. The distribution of the axonal bunches is made in large extents of the nucleus, which does not offer a spatial substrate for a somatotopic organization. The physiological study of Vitek *et al.* (1994) did not find "a clear somatotopic picture" either. Studies in the posterior part of the nigral subregion in humans ("VOi") found either a partial (face and tongue, Hassler, 1968) or no somatotopy (Schaltenbrand *et al.,* 1971). The substantia nigra itself does not have a clear somatotopic organization. For DeLong *et al.* (1983, 1985) and Hoover and Strick (1999), the lateral part of the nigra would continue the outmap observed in the medial pallidum (orofacial). There is, however, no known somatotopic map in the nondopaminergic substantia nigra.

Amygdalar Coterritory

The anterior and medial part of the ventral anterior nucleus also receives axons from the basal nucleus of the amygdala in macaques (Percheron *et al.,* 1996). Amygdalar axons arrive anteriorly and branch without forming dense arborizations. Both the rostral part of the thalamic lateral subregion VA and amygdala have reciprocal connections with the cortex. The addition of the amygdalothalamic connection would create a link between the two. There is, however, no direct argument for the presence of this afference in human brains.

Tectal Coterritory

As already said in "Regio Basalis." and lateral intermediate subregion, terminal axons of the superior colliculus also end in the rostral subregion (Künzle and Akert, 1977; Harting *et al.,* 1980). They form islands within the nigral territory, not particularly in its magnocellular patch.

The three, nigral, collicular, and amygdalar sources make a peculiar set of afferences. All three have links or are parts of oculomotor systems. All three are sending axons in the nucleus medialis in macaques. But, as already mentioned, paralamellar subdivisions likely no longer exist in apes and humans. The topographically medial extensions of the tectal, nigral, and perhaps amygdalar territory of cercopithecidae could have moved partially or even completely in the lateral region namely in VA in man. The nigral subregion also receives abundant cortical afferences, from the frontal cortex in particular. Efferences from the nigral subregion VA to the striatum have been observed in macaques (Walker, 1938; Nakano *et al.,* 1990; Druga *et al.,* 1991; Fénelon *et al.,* 1991; McFarland and Haber, 2001), essentially to the associative striatum, thus participating in a subsidiary basal ganglia circuit. This connection was said to explain the lack of complete degeneration after cortical lesions. There is no argument for its persistence in the human brain where the polar region more clearly degenerates after cortical lesions (VanBuren and Borke, 1972). There would be projections to the anterior intralaminar complex (explaining the postulated link to the "non specific thalamic system," Carmel, 1970). Contrary to the initial claim, the efferences to the cortex are abundant. In contrast with the cerebellar and pallidal subregions, there is no projection to the motor cortex (Ilinsky *et al.,* 1985). The major projection of the nigral-

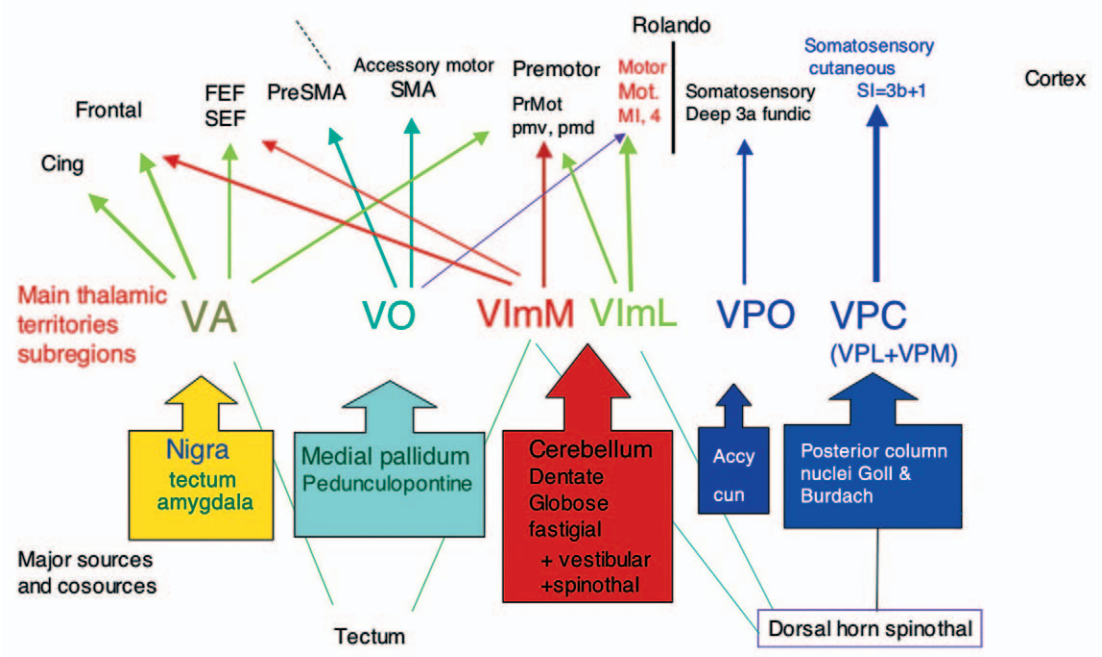

FIGURE 20.20 Flow chart of inputs to and outputs from the thalamus. In front of the central sulcus (Rolando) the number of cortical targets and the combinatorics increases. The separation of the pallidal and nigral territories leads to differentiated cortical targets and systems.

receiving VA, in partial continuity (on the other side of the lamella) with the anterior paralamellar part of the medial region is to the eugranular frontal cortex. Frontal targets are the superior, supraprincipalis (Rouiller *et al.*, 1999) and above all the inferior part from the principalis sulcus, infraprincipalis, and orbital (Carmel, 1970; Ilinsky *et al.*, 1985; Barbas *et al.*, 1991; Dermon and Barbas, 1994; Rouiller *et al.*, 1999; Middleton and Strick, 2000). Level 1 of Figure 4 of Cavada *et al.* (2000) shows that the source of projection to the orbital cortex exactly corresponds to the extent of the nigral territory (including fringes) and not the pallidal. There is a projection to the anterior cingulate area (Vogt *et al.*, 1987). In human brains a projection to the insula, considered as a major one, has been described by Angevine *et al.* (1962) and Van Buren and Borke (1972), not documented in macaques (Wirth, 1973). Another target is the inferior temporal cortex (TE; Middleton and Strick, 1996), known to be "critically involved in the recognition and discrimination of visual objects." There are projections to the premotor cortex (Ilinsky *et al.*, 1985; Nakano *et al.*, 1992, 1993), essentially in its dorsal part Pmd (Inase and Tanji, 1994; Pmdr and Pmdc, Rouiller *et al.*, 1999). Matelli and Luppino (1993) showed that there is no somatotopic outmap. There is also a projection to the supplementary motor cortex, SMA proper (Nakano *et al.*, 1992; Shindo *et al.*, 1995; Rouiller *et al.*, 1999) and preSMA (Rouiller *et al.*, 1999), which could concern essentially the last. VA thalamic axons also end in the temporal TE (Midleton and Strick, 2000). A particular discussion must deal with the projection to the oculomotor cortex. The neurons projecting to the frontal eye field (Huerta *et al.*, 1986; Lynch *et al.*, 1994; Middleton and Strick, 2000) and the supplementary motor eye field (Shook *et al.*, 1991) in macaques are located in the medial part of the nucleus. In this position, they can receive nigral, tectal, and perhaps amygdalar information. As already discussed, the evolution of the oculomotor cortex, from macaques, chimpanzees, to humans is such that it would have been surprising if the rostral lateral subregion (VA) had not changed. Very little is known concerning its physiology and physiopathology. There are almost no recordings of neurons in the nucleus. There are few data concerning microstimulations. One problem is linked to the abundance of crossing thalamocortical (thalamofrontal from the medial nucleus) fascicles, leaving little chance to avoid their excitation during the stimulation. Knowing the afferences (nigral, amygdalar, collicular) and the efferences to frontal, premotor, inferior temporal, and oculomotor cortex, the rostral subregion (VA) would be at first visuomotor likely more than that. This is one more argument for formally separating the two topographically distinct territories from basal ganglia sources and for giving the nigral territory its own space and identity.

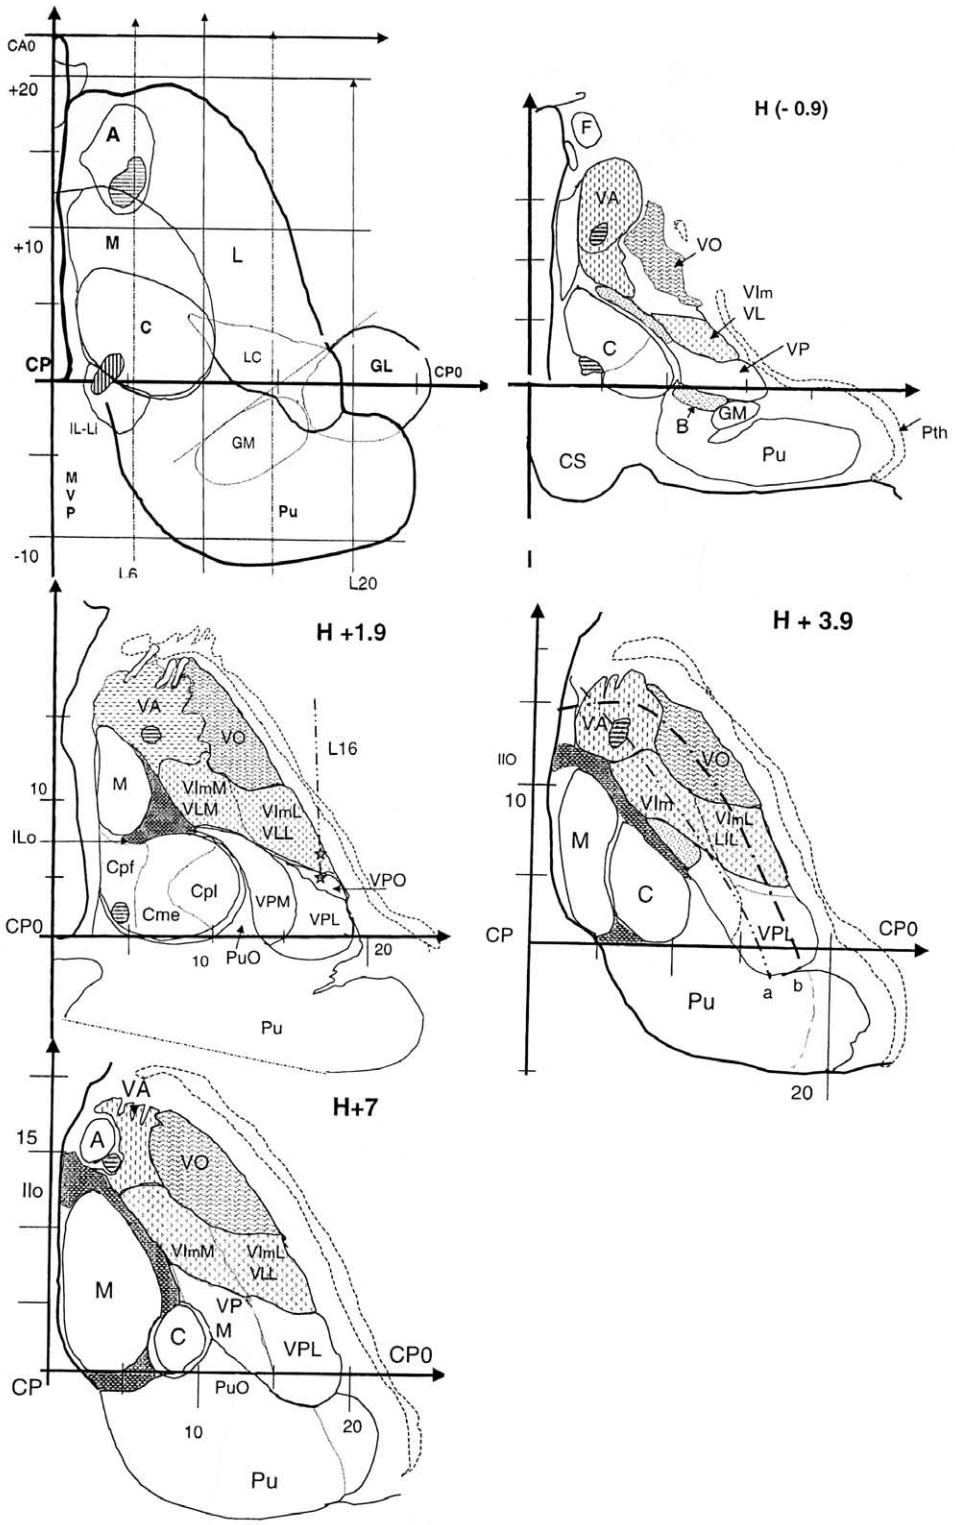

FIGURE 20.21 Horizontal sections and slices. *Upper left*. Horizontal projection (not an upper view) of the maximal contours plotted from the whole series of horizontal sections of Van Buren and Borke (1972) atlas. Contours do not correspond to any level but to their addition. C, central region; L, lateralis; M, medialis. The projection of the central region is included within that of the medialis. Projection of anterior nucleus overlaps with the anteromedial part of the lateral region. The projection of the two geniculate bodies (GL and GM) is shown. Horizontal sections from Van Buren and Borke atlas with reference to equivalent levels of Morel *et al.*'s atlas (1997)(Hassler's material was cut because of an improper angle). *H(–0.9), (V0.9 of Morel)* with the five elements of the lateral region, including Varc (arcuatus), gustatory nucleus. *H + 1.9 (D 1.8 Morel)*. Maximal extent of the central region. VA (lateral rostral subregion) is traversed by the mamillothalamic tract. The line at 16.5 corresponds to the frequent trajectory of stereotacticians for tremor alleviation. It visualizes a major problem of interpretation since the electrode crosses through VIm and/or anterior part of the VP receiving kinesthetic afferences (VPO). *H+ 3.9 (D3.6 Morel)* middle ventral level. Two lines are traced. The first (a) most medial, follows the main axis of the lateral region (here about 30°). From the posterior border of the lateral region, the sequence includes first VP (including face representation), then the cerebellar VL, and finally VA. This is the organization of nonprimate species where VA receives convergent afferences from both the nigra and entopeduncular nucleus. The second curve (b) follows the border of the lateral region at about equal distance and passes through an nucleus proper to primates, the pallidal territory VO over a long distance and ends in the nigral territory afferences VA (Lateral Rostral subregion). *H + 7 (D6.3 Morel)* transition plane. Appearance of the superior (A) and disappearance of the central (C) region.

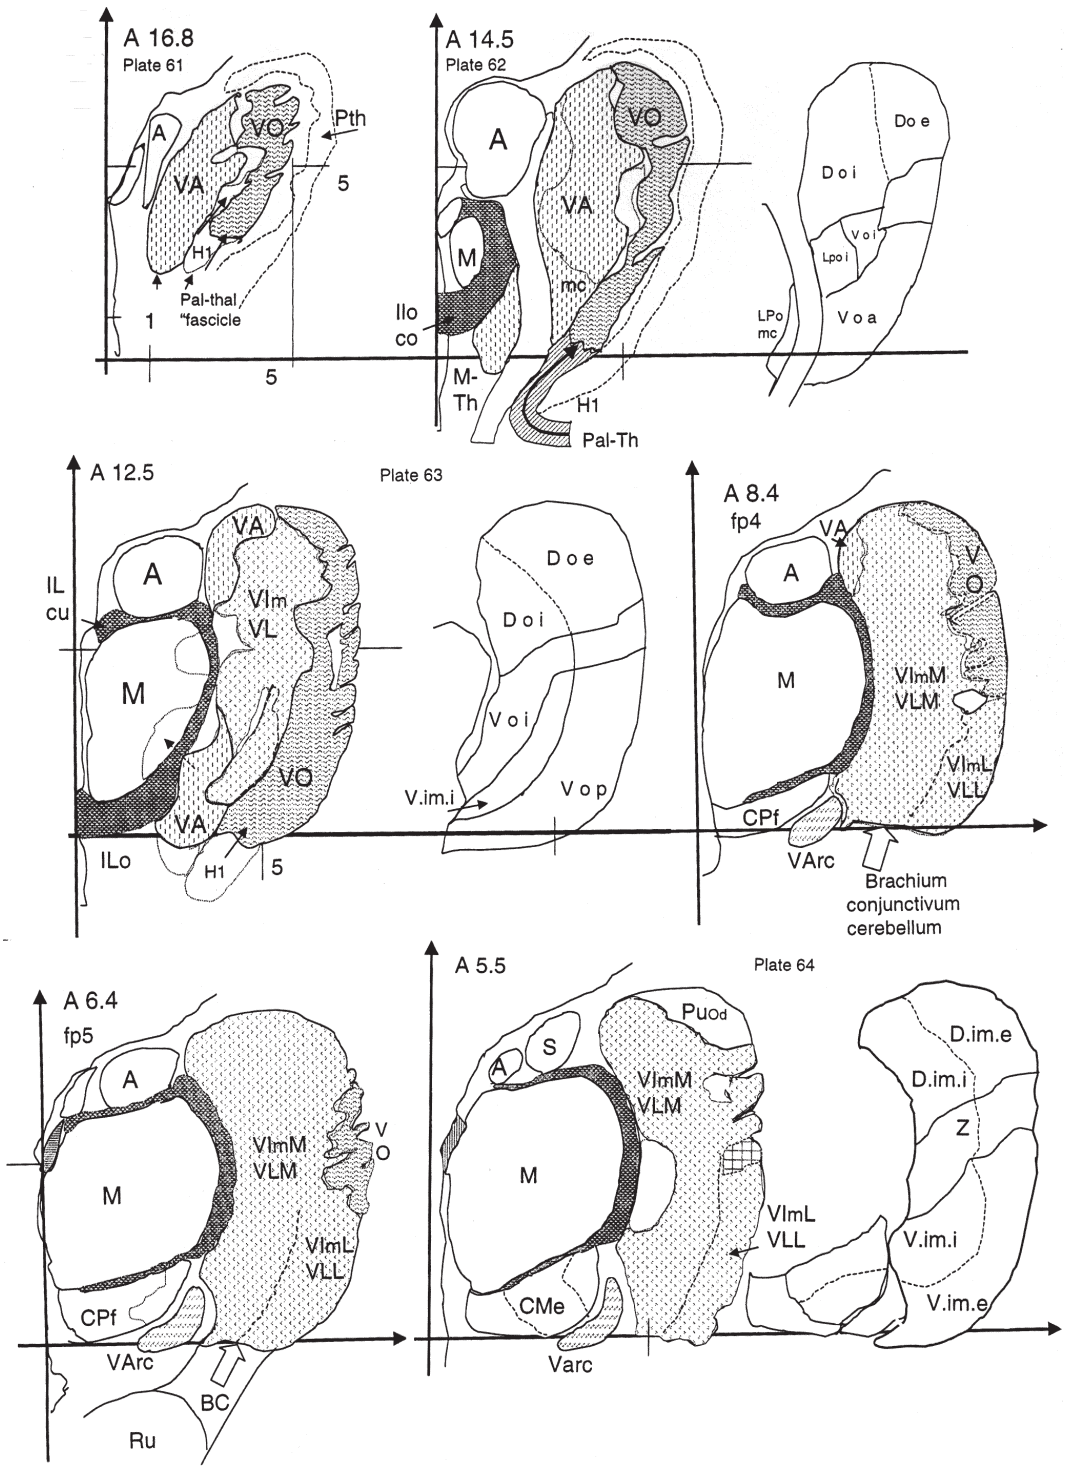

FIGURE 20.22 Series of transverse sections from Schaltenbrand and Bailey's atlas (from plate 61 to 67). The anterior position of each level from CP was calculated from its placement in relation to CP0. This series is unfortunately irregular with lacks at levels of transitions. Additional levels of the same and from Van Buren and Borke were used. Correspondance with Van Buren and Borke's and Mai *et al.*'s atlases are given. *A 16.8* (plate 61, corresp Van Buren and Borke's, 20.3, Mai +6.7 – 27). Border between nigral, on the left, and pallidal subregions, on the right, highly sinuous with interrupted spacing strips (myelinic or acellular). The perithalamus cut obliquely appears thick. *A 14.5* (plate 62) (Van Buren and Borke, 17.2, Mai +12 –31) passing through the mammillothalamic tract with the appearance of the medial nucleus. The nigral (VA) lateral rostral subregion has a maximal extent from the ventral to the dorsal border of the lateral mass and medially in front of the medial nucleus. The border with the pallidal (VO) lateral oral subregion is sinuous. This is broken laterally by oblique fascicles *A 12.5* (plate 63, corresp Van Buren and Borke's, 10.9, Mai+14.6 or 16 –33 or 34) Opening of the nigral territory VA (lateral rostral subregion) with two subparts—dorsal and ventral. The presumed cerebellar territory (VIm-VL, lateral intermediate subregion) is already well developed, with a differentiated subpart denoted V.im.i by Hassler. Parasagittal organization, with from medial to lateral, the nigral, cerebellar and pallidal subregions. *A 8.4.* (fpa, plate 38, corresp VanBuren and Borke 7.8, Mai +19.9 –37). Intermediary section the nigral territory disappearing and the cerebellar expanding. This covers the majority of the lateral region except for a pallidal border. The cerebellar territory is differentiated into a mediodorsal part, VImM-VLM, and a lateral, VImL-VLL, magnocellular that, in macaques, projects to the motor cortex. *A 6.4* (fp5, plate 39, corresp. Mai +21.2 38). The lateral region is almost entirely covered by the VL-VIm, cerebellar (lateral intermediate subregion). *A 5.5* (plate 64, M, corresp. Mai 22.6 –39) disappearance of the pallidal territory and appearance of the pulvinar dorsally. Hassler's "zonalis" (Z) corresponded to an almost acellular area.

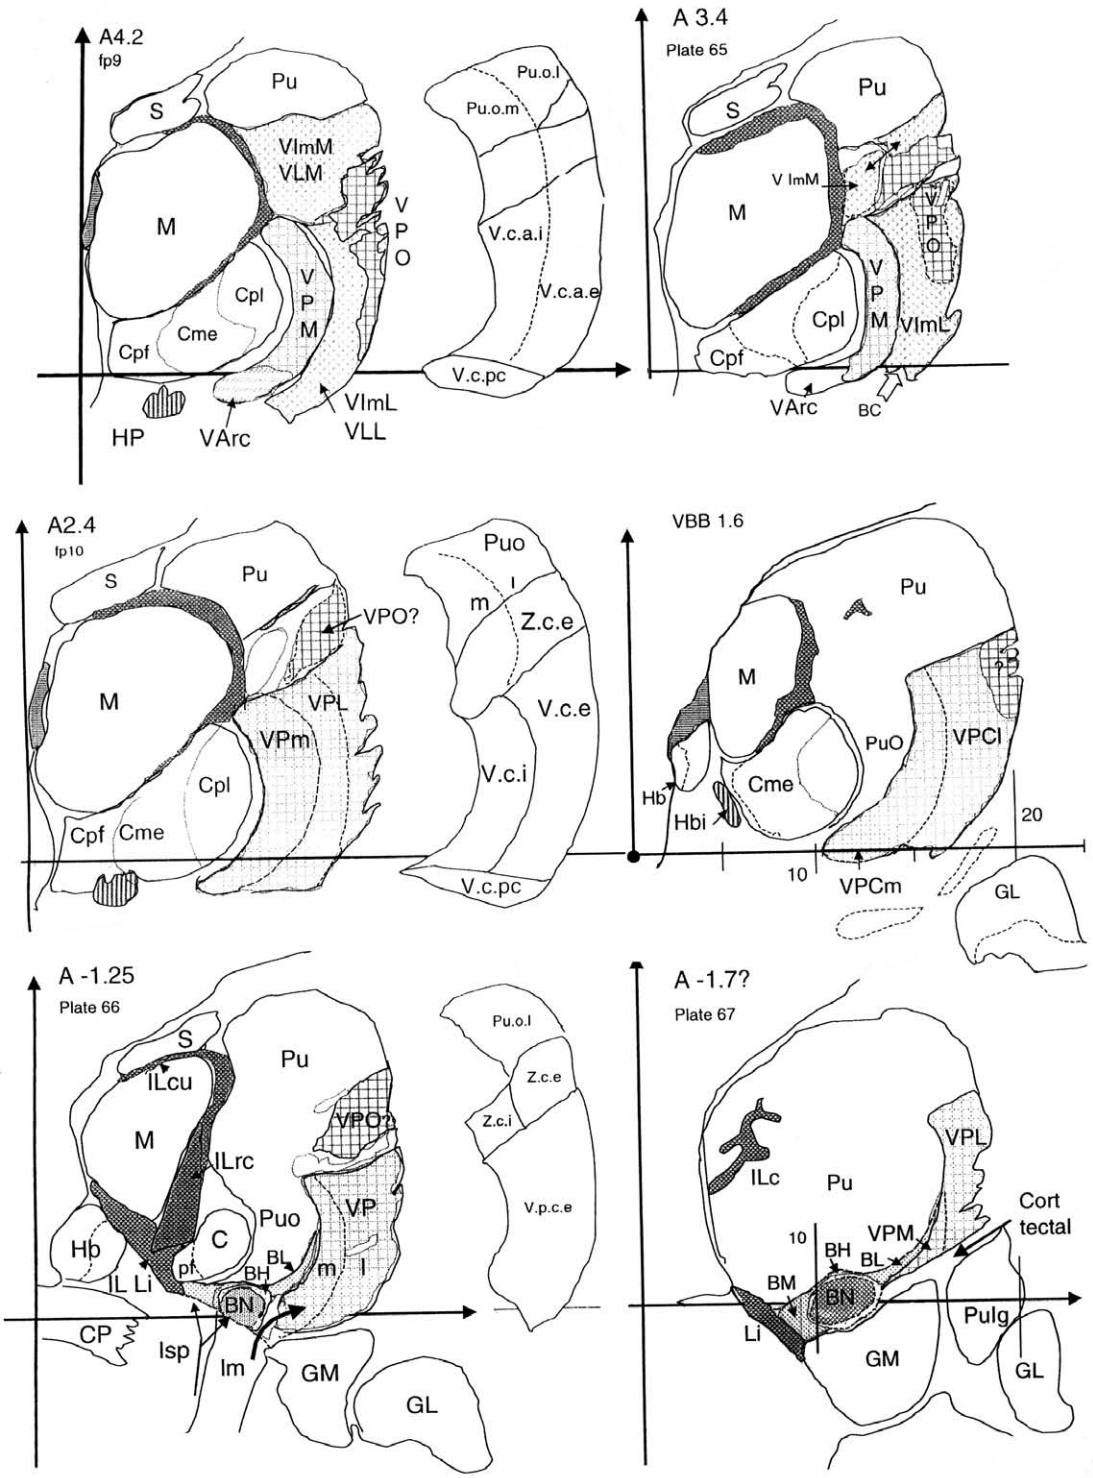

FIGURE 20.22 *Continued* Transverse series, posterior levels (with somesthetic nuclei). *A 4.2.* (fp9, plate 39, corresp Mai 23.9 –40). The sagittal pattern, still visible in the lower part is reinforced by the appearance of the lemniscal territory. The horizontal organization appears with the cerebellar subregion in the middle, the somesthetic ensemble below, and the pulvinar (oral dorsal) dorsally. Maximal extent of the classical arcuate nucleus whose upper part is VPM and lower, Varc. Laterally, magnocellular subdivision are likely attributable to the anterior part of the lemniscal kinesthetic "VPO". *A 3.4.* (Plate 65 corresp, Mai 25.2 –41, VanBuren and Borke 3.4– 25). Posterior end of the cerebellar subregion ventrally (VImL) and dorsally (VImM). The transition with the lemniscal (caudal subregion) is not topographically similar to that observed in the monkey. VimL appears relatively smaller. VPO is raising up. Dorsally, lowering of the pulvinar. *A 2.4.* (fp10, plate 39, corresp Mai 26.5). The dorsal magnocellular field is likely VPO. It goes up in a dorsal position in relation to VPL. Medially to VPO is an almost acellular field, a separating strip with the pulvinar. *VBB 1.6.* Additional map from Van Buren and Borke (corresp. Mai 27.8 –43) to fill the lack of a level showing the wedge-shaped oral pulvinar separating the central from the lateral region. This map brings out the imprecision in the laterality of transverse series of Schaltenbrand and Bailey's atlas, due to problems in the placement of the midventricular plane, MVP. *A-1.25.* (Plate 66). Posterior pole of the central formation C. The pulvinar is reaching the lower border. A patch of large neurons is still present over the VP, possibly the VPO. Appearance of the limitans. Retrocentral part of the intralaminar formation Ilrc. Appearance of regio basalis B with centrally located nucleus (N) and basalis nodalis (BN) receiving axons from spinothalamic tract forming the lemniscus spinalis (lsp). *A-1.7* (Plate 67). Section placed too posterior in the atlas. Corresponds to Van Buren and Borke 1.6–27, Morel *et al.* 1.8, Mai 29.2–44). End of VP, and of the lateral region, laterally. In the basal region, the n. basalis nodalis is surrounded by the n.basalis halos (BH). BL, n. basalis lateralis.

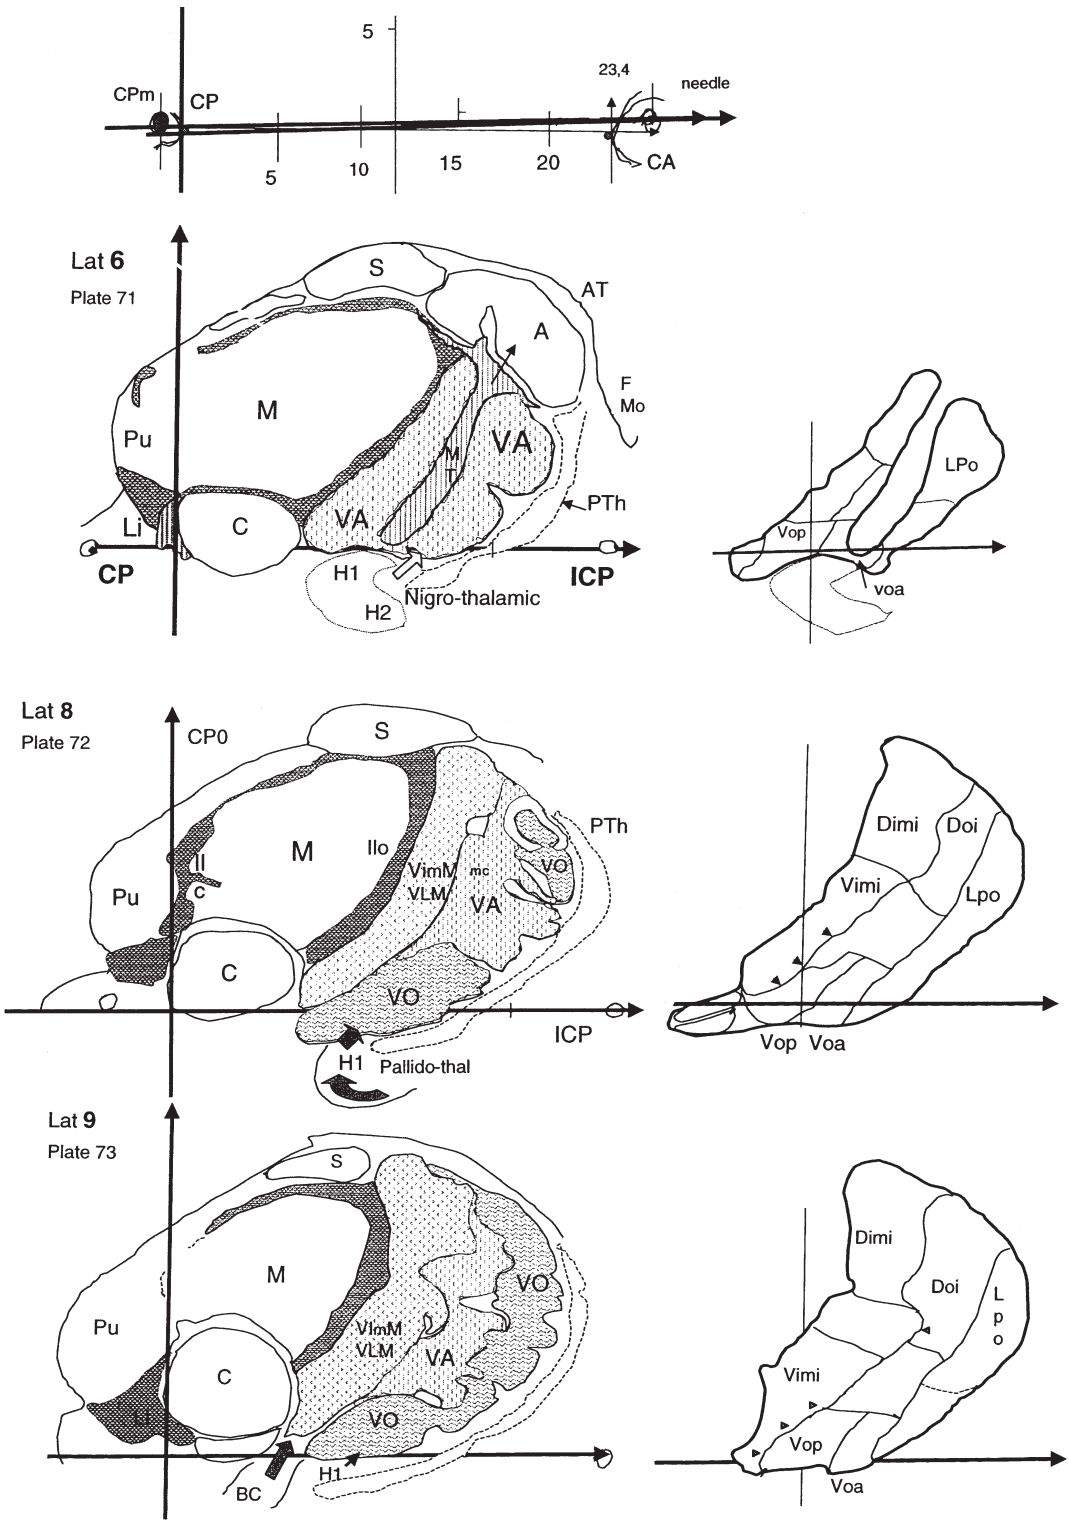

FIGURE 20.23 Sagittal sections. Series of sagittal sections redrawn on high magnification photos (plates 70 to 76) from Schaltenbrand and Bailey's atlas, on transparent sheets and reduced. *Upper drawing*, commissural landmarks and system of coordinates from plate 70 (L3). The two marks made by needles do not exactly correspond to CA and CP points. The two lines are traced. The only cartographic modification in this series is the use of CP as the 0 for anteroposterior positions (instead of Hassler's midcommissural point of poor topometric value). Successive plates may be compared to same levels of plates 44 to 47 from same authors. *L6* (plate 71). Medial section cutting the superior region with anterior nucleus and superficialis fragmented in nuclei disseminati, the medial nucleus and the central region. The lateral region is crossed all the way by the mammillo-thalamic tract (MT). The anterior part of the lateral region is similar to VA of macaques, presumed to correspond to the nigral territory and goes back up to the anterior pole of the central region. On the right, Hassler's tracings with the unjustified separation between ventral and dorsal elements. *L8* (plate 72). Anterior nucleus disappeared and replaced by the lateral region. Nigral territory also disappearing. Its lateral border and the medial border of the pallidal territory being curved, the section leaves still some VA at midheight. The pallidal territory appears ventrally and dorsally to it VO. Hassler's tracings coincide only at the border between the cerebellar (sparse large cells) and the pallidal territory (dense small cells; indicated by small arrows). *L9* (plate 73) complete filling by the lateral region replacing the anterior nucleus. Curved banana-shaped succession of three territories and lack of separation between ventral and dorsal elements. Hassler's Voa and Vop were one single thing belonging to the pallidal territory.

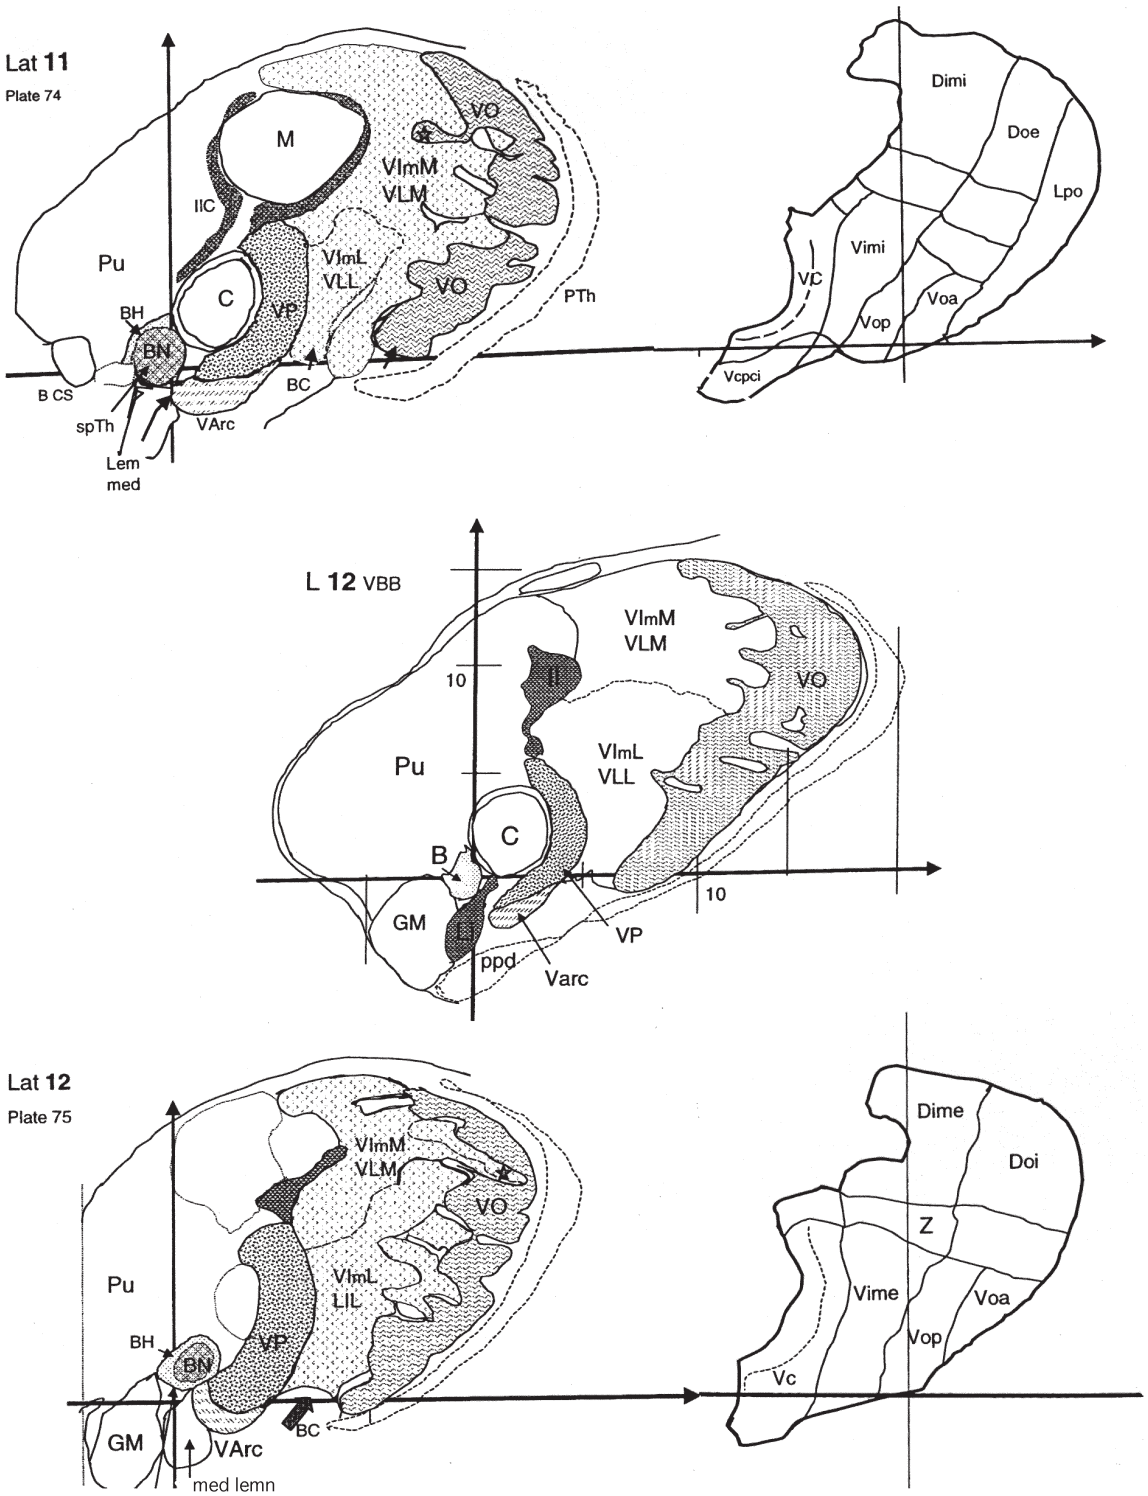

FIGURE 20.23 *Continued* Sagittal sections L11 and 12. *L11* (plate 74). Strong curvature of territories, dorsal parts of subregions passing over the more posteriorly located territory. Irregularity of territorial borders with long peninsulae (one shown by a star—pallidal within cerebellar). Two apparently ventral elements appear, one most posterior, lemniscal (also arcuate in this plane). On the right, Hassler's Vop was likely cerebellar. VImL-VLL distinguished by the presence of large cells, not necessarily corresponding to the place projecting to the motor cortex. Varc, gustatory nucleus made up of small neurons. The roundel of the basalis ensemble with BN and its halo BH is well observed. *L12 VBB* level 12 of Van Buren and Borke atlas giving metrics from CP illustrating individual variations in shape but a stable pattern. *L12* (plate 75). Section passing at the lateral borders of both the medial and central regions disturbing pictures dorsally. In lateral region, Hassler's Vop was very likely pallidal. The border between pallidal and cerebellar subregions is extremely sinuous. Long islands (such as the one with a star) correspond to section of fringres. Some are bordered by spacing strips (white places with no neurons separating territories). In Hassler's tracings, Z is zonalis (between ventralis and dorsalis, not founded). The roundel of BN-BH still observable. *Continued*

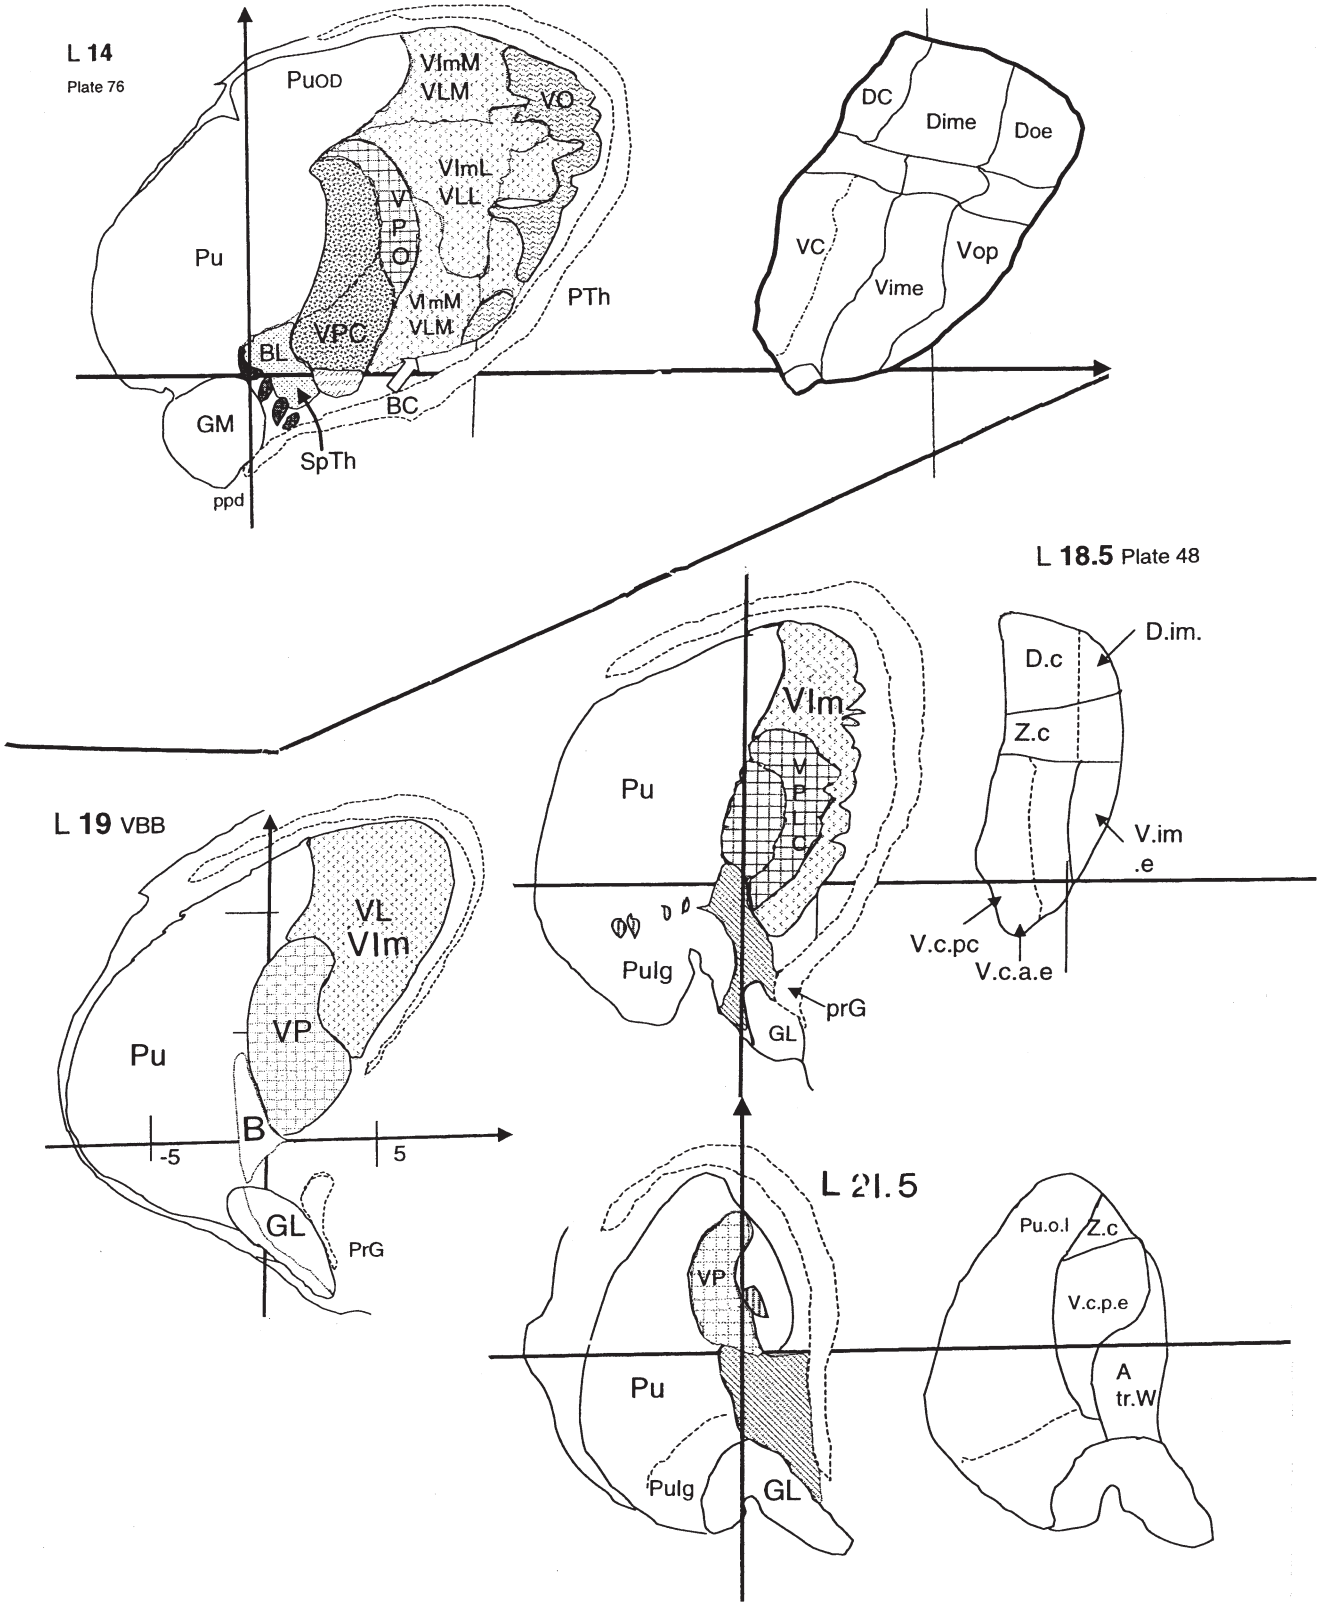

FIGURE 20.23 *Continued* L14 and most lateral sections, L18 to L21.5. Intermediary levels of the sagittal series showed in Figures 20.19 and 20.20. *L14* (plate 76). Pallidal subregion disappearing lemniscal expanding. Compared to Figure 20.2C stained for parvalbumin by Morel *et al.* (1997). The differentiation between what is designated as VLL-LIL or VLM-LIM, theoretically founded by different sources to the cortex, is based on magnocellular or less magnocellular parts. Appearance of a particular subdivision, also "magnocellular," adjacent to and more anterior than VLL-LIL, presumably VPO, the kinaesthetic part of the lemniscal subregion. The lateral region in most lateral sections, *L18,5 of Hassler and L19 of VanBuren and Borke,* with only the cerebellar (Vim or VL) and the lemniscal (VPL) territories. *L 21.5.* The lateral region is represented by the most lateral part of VPL.

ALLOTHALAMUS. INVOLUCRUM

As already discussed at the start of the chapter, some thalamic components surrounding the medial region have projection neurons morphologically different from those of the bulk of the thalamus and defined by contrast, which are said to constitute the allothalamus (Percheron *et al.*, 1996). This ensemble is not homogeneous. It may be divided in two different entities: the ensemble made up of the paramedian and intralaminar formations (involucrum or enveloppe) and the central region. Textbooks still frequently group the two in "the intralaminar nuclei," subdivided into an anterior (grossly intralaminar) and a posterior group (the central complex). This was detrimental for the understanding of the central region (Percheron *et al.*, 1991) and that of the intralaminar ensemble. The intralaminar elements were said to be a part of a system for the unspecific excitation of the cortex (see Steriade *et al*.). The central complex of primates has no known role in such function. Topographic analyses (Fig. 20.24) show a spatial separation of the intralaminar and central ensembles, the first wrapping around the second without any mixture. Today, many arguments, from neuronal types to connections are in favor of separating the two ensembles in man and upper primates.

The two first allothalamic components—the paramedian and intralaminar formations—have a common ontophylogenetic origin (Rose and Woolsey, 1949). Rose (1937), in the rabbit, grouped them into a "centrocommissural system." In the macaque, Olszewski (1952), described together "the midline and intralaminar nuclei." The two formations are continuous (or mixed) medially. They form a ring around the medial region, corresponding to Foix and Nicolesco's (1925), "formation circulaire hyperchromique", Grünthal's (1934) "nucleus circularis," or Hassler's "involucrum" (or "enveloppe"). The involucrum is commonly said to be made up of distinct (small) "nuclei". The existence of such nuclei (that imply some degree of closure) is highly disputable. The ensemble stain in the same way for Nissl, acetylcholinesterase, calbindin, and calretinin. It contains tachykinin- and enkephalin immunoreactive fibers (Hirai and Jones, 1989b). In addition to the two traditional paramedian and intralaminar formations, two other neuronal sets must be considered together. One is the "nucleus limitans" usually considered separately. The other, well visible in man posteriorly to the central formation, "retrocentral," can be linked to the intralaminar formation in the formatio intralaminaris-limitans IL.

Formatio Paramediana

The formatio paramediana is the ensemble of thalamic elements located close to the midline. It may be seen as the thalamic part of a much more extended neuronal ensemble starting from the periependymal gray of the spinal cord up to the periventricular gray of the third ventricle ending at the foramen of Monro and continued by the hypothalamus. Highly regressive, the thalamic paramedian formation is difficult to describe in the human brain. The adhaesio interthalamica or massa intermedia, present in all other species, still conspicuous in macaques, even in chimpanzees, has disappeared in 30% of human brains or is present just as a remnant. A certain number of afferent systems that cross the midline through the adhaesio in macaques can no more do it in man, implying a higher hemispheric lateralization. In the human brain, the paramedian formation is reduced to a rather thin layer forming the wall of the third ventricle, separating it from the rest of the thalamus, mainly the medial nucleus. The neuronal genus of the paramedian formation is known only in young rats (Scheibel and Scheibel, 1971), where it is not very different from the intralaminar and parafascicular types in this species (i.e., short leptodendritic). There are only a few local circuits, GABAergic, neurons (Hunt *et al.*, 1991), and none in lower species. Multiple cytoarchitectonic subdivisions have been proposed in the literature. Several levels may be distinguished, at first in relation to the taenia: ventricular, inferior to it, or supraventricular, superior to it (Fig. 20.1). In the ventricular part, the level of the adhaesio made by the junction of the two medial lamellae gives a reliable reference for distinguishing an interlamellar level (Ad co, Fig. 20.2A) corresponding to Rabl's (1958) nucleus reuniens or to Hassler's (1959) and Van Buren and Borke's (1972) nucleus commisuralis. The term situs commissuralis (co, Figs. 20.2 and 20.4 or adhesialis, or reuniens) of the intralaminar ensemble should be preferred to that of "nucleus centralis medialis" (CeM), leading to a confusion with the central region (centre médian, CM). The junction of elements of the two oral intralaminar nuclei is the only element (with glia) constituting the human adhaesio (Rabl, 1958). Inferior to the interlaminar level, Rabl (1958) distinguished a paramedianus inferior (nucleus endymalis, VanBuren and Borke, 1972), and superior to it, a nucleus paramedianus superior (paramedianus anterior, Van Buren and Borke 1972). Above the level of the stria (or taenia), a nucleus paratenialis or parataenialis is often described. A part located superior to the taenia and covering the dorsomedial corner of the medial region

joins the paramedian and intralaminar formations. Specific to primates (Macchi and Bentivoglio, 1988), its neuronal species being still unknown, the pars superior or Hassler's nucleus cucullaris (Cu, hat-shaped, Fig. 20.2A, B), could belong to one or the other formation. Immunochemistry does not allow much more precision. Some paramedian neurons are calretinin positive neurons (Ciccheti *et al.*, 1998), cholecystokinin CCK, SRIF, and substance P positive neurons (Molinari *et al.*, 1987). The paramedian formation receives afferences of the reticular type: serotoninergic from the raphe and norepinephrinergic from the locus coeruleus (Oke *et al.*, 1997). Paramedian neurons give axons to the striatum (Fénelon *et al.*, 1991; MacFarland and Haber, 2000). It is traditionally admitted that the paramedian region does not project to the cortex, since it does not degenerate after cortical lesions (Walker, 1935; Peacock and Combs, 1965). Van Buren and Borke (1972), however, described a complete degeneration four years after a large infarct. Kievit (1977) described a connection to the orbital cortex, and Bachevalier *et al.* (1997), to the frontal and anterior cingulate cortex. It is proposed that, except when there is an adhaesio with a visible adhesial bridge between the two lamellae or in the case of an evident particular afferent or efferent distribution, the paramedian formation be left undivided. Its real role is not known.

Formatio Intralaminaris-Limitans

For reasons developed later, this formation does not include the central complex (see "Regio Centralis"). The presence of neuronal groups within the medial lamina was observed in the human thalamus very early, for instance by Malone (1910, in his "nucleus reunions") and Foix and Nicolesco (1925). As already said, following the Vogts (1941), the Louvain symposium recommended that the term "lamella" be employed rather than the term "lamina". The term "lamella" is used for the fibrous components but, in order to come closer to common use (and in accordance with the Nomina anatomica), the adjective "intralaminar" is used for neuronal groups. The appearance of the lamella medialis, though considered as a major topographic key is relatively late in fetal life (Gilbert, 1934; Yakovlev, 1969). There is also no complete coincidence between the topography of the lamella and the topographic distribution of the neurons of the intralaminar neuronal genus. Not all parts of the lamellae contain intralaminar neurons. Not all neuronal groups of the intralaminar genus are within lamellae. This is particularly true posteriorly, back to the central region (Fig. 20.24). The evolution of the neuronal ensemble is only scarcely documented. Its constitution in the anterior part is rather stable as its topography in relation to the medial region remains similar. The presence of calretinin (and acetylcholinesterase activity), documented in rats and primates, makes equivalence possible. The purely intralaminar part is phylogenetically regressive in number and density of neurons. Moreover, the neuronal types change in primates. Equivalencies are particularly difficult posteriorly. The posterior elements, usually not considered among the intralaminar ensemble, show an evolutionary increase, suggesting that there could be a phylogenetic move of neurons of the anterior intralaminar set toward a position posterior to the central complex (see Fig. 20.24). The "nucleus limitans" (Friedemann, 1911; previously shown in man by Malone, 1910, as a part of his reuniens) was given this name because it separates the thalamus from the pretectum. In the rat, the parafascicularis nucleus has a lateral extension, the ethmoid nucleus (Eth, Paxinos and Watson, 1986), with a topography similar to that of the limitans but containing the parafascicular type of neurons (Deschênes *et al.*, 1996). Not described in the cat or in the tree-shrew, the limitans apparently appears with lemurians (Stephan *et al.*, 1980) and is obvious in simians. In human brains, cytoarchitectural similitude already led Malone (1910) and Feremutsch and Simma (1954) to classify this neuronal group among intralaminar elements. Some neurons observed in Golgi-impregnated specimen were seen to be of the intralaminar genus. Recently found properties make it reasonable to concur with the conclusion of the Louvain symposium (Dewulf, 1971), Jones (1997) and Steriade *et al.* (1997) and to link these elements to the continuous and extended intralaminar-limitans formation. Neuronal islands are generally described as nuclei. Steriade *et al.*, (1997) insist on a "compartmental organization" of different kinds of neurons and on the patchy distribution of afferent axons. From the little known about it, the ensemble with relatively short dendritic arborizations in fact constitutes a continuous layer (Fig. 20.24) with no delimited nuclei. The subparts may be described at most as parts or sites (see Fig. 20.3). The continuous intralaminar-limitans formation is extended from the adhaesio interthalamica medially, from which it seem to emanate, to the limitans site behind the central complex (Figs. 20.2 and 20.24). The formation is made up of two neuronal families. One is the local circuit neuron, close to that of the isothalamus but with a lesser percentage. In the human brain, Dewulf (1971) found numbers from 11 to 16% (paracentral, 11%, limitans 11, 3, centralis lateralis 14, 5, 15, 5), which are significantly less than those in

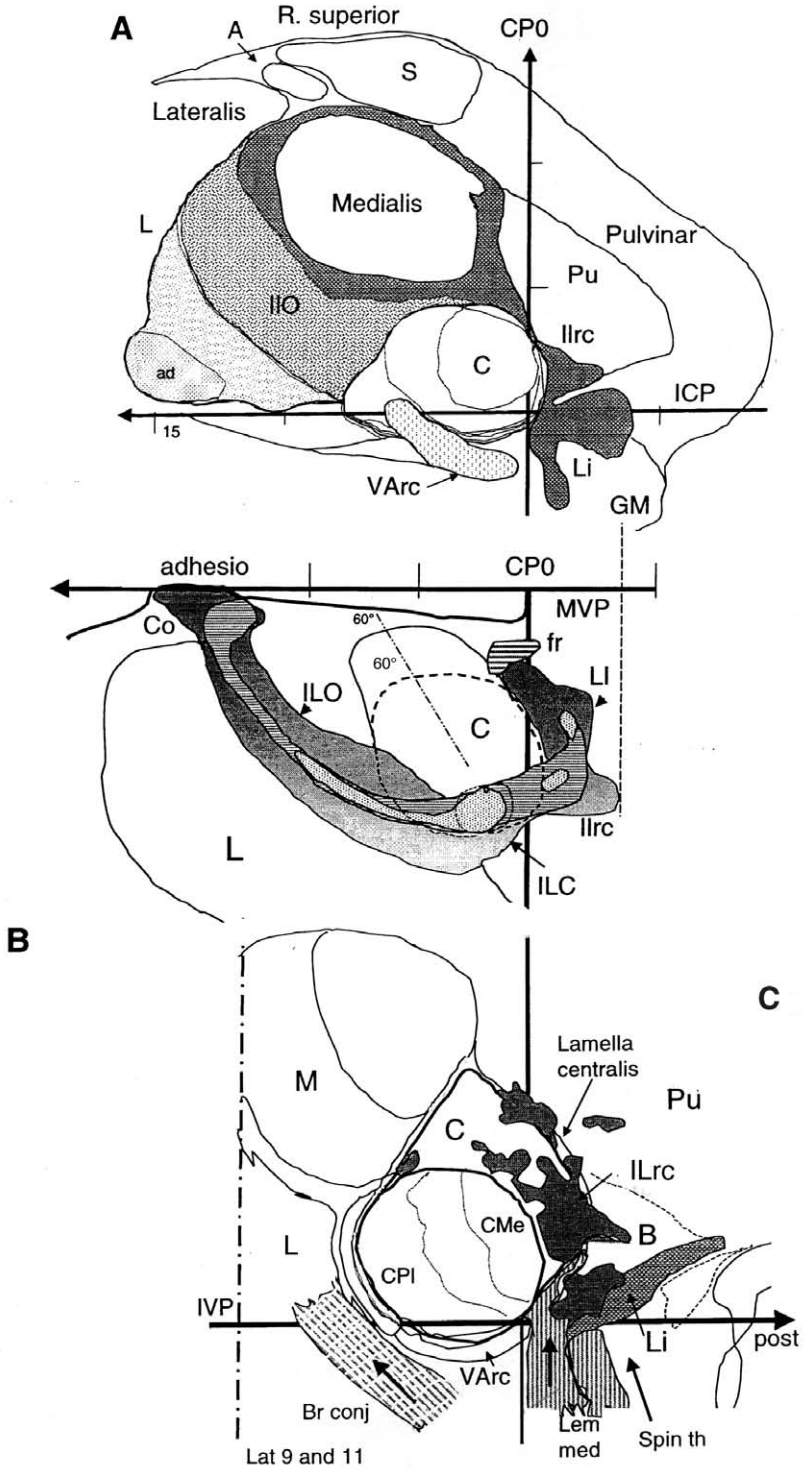

FIGURE 20.24 Separating elements. Formatio intralaminaris-limitans. Allothalamus. **(A)** Sagittal slice from VanBuren and Borke's atlas (up to L9 and 12). Lateral view showing the lamella medialis and intralaminar elements surrounding the medial nucleus in successive slice. A noticeable portion, generally not considered, is located posteriorly to the central region (C). The retrocentral intralaminar subnucleus (Ilrc) is continuous with the limitans (Li). These elements cover posteriorly the central region without penetrating it. Varc, part of the lateral region, the taste nucleus. **(B)** Slice of horizontal sections from the same atlas (not same brain). The continuous intralaminar-limitans formation seems to arise from the adhesio. The oral site (IlO, "paracentralis") turns around the medial nucleus. The supracentral, intralaminar caudal ILC ("centralis lateralis") surrounds the lateral part of the central complex. Fr is the retroflexus tract (habenulo-interpeduncular) of Meynert. The comparison of A and B shows that the rather thin band in B is in fact a continuous layer, with no obvious subdivisions other than topographical, extended from the adhesial or commissural place anteriorly (co, commissuralis crossing the midline when there is an adhesio) to the limitans posteriorly. C is the slice of sagittal sections from Emmers and Tasker's atlas. Medial view. Intralaminar elements surround (not penetrate) the central formation **(C)**, showing that this is not intralaminar. Dorsal islands of the traditional "nucleus centralis lateralis" are continuous with posterior retrocentral elements and the "nucleus limitans" not included in any lamina.

the central region. In macaques, Hunt *et al.* (1991), however, found a higher number of GABAergic neurons (25.4 and 27.9%), close to those of the lateral region. The projection neurons are different from those of the isothalamus (with fewer branched dendritic arborizations), and this difference explains their attribution to the allothalamus. These neurons hardly stain in Golgi variants, and no statistical neuronal typology is available. It is worthwhile stressing that the neuronal type found in the primate intralaminar ensemble (Fig. 20.25) differs from those described in rats and cats. In these orders, neurons are indeed leptodendritic (i.e., with scarcely branched arborizations, to some extent resembling those of the reticular formation; Scheibel and Scheibel, 1972; Ramon-Moliner, 1975; Tömböl *et al.*, 1990). In our material (Fig. 20.25), primate intralaminar dendritic arborizations appear shorter than those of cats and different from those of surrounding isothalamic neurons. These arborizations are often bitufted (Percheron *et al.*, 1978), with few stems (about four), often simply large extensions of the soma emitting several branches (Fig. 20.25). They are generally oriented in the direction of the lamella or obliquely in the direction of thalamocortical fascicles. In the anterior intralaminar site at least, their arborizations seldom, if ever, cross the border of the lamella. This fact would indicate that they could be partly closed nuclei (opposed to the reticulate histotype). Dorsally to the centralis complex there are no clear dendroarchitectonic boundaries. Along with intralaminar neurons, typical isothalamic bushy neurons are also found. When incompletely cut, these may lead to confusing pictures. Intralaminar neurons are dark in Nissl stains, heavily stained for calbindin (Jones and Hendry, 1989; personal material), calretinin (Ciccheti *et al.*, 1998; which is the reverse of the regio centralis, with a dense calretinin positive neuropil (Fortin *et al.*, 1998), and acetylcholinesterase (Poirier *et al.*, 1977; Heckers *et al.*, 1992). Some neurons contain cholecystokinin (CCK; Burgunder and Young, 1992).

The formation has been subdivided into many small entities, often with no precise criteria, according to animal species and the traditions of different schools. The central region being excluded, one may subdivide the intralaminar-limitans formation into several, not separate, topographical parts or sites: one oral, inside the well differentiated anterior part of the lamella medialis; a second more caudal, dorsal to the central complex; a third one corresponding to the limitans site; and a last one caudal to the central complex. The simplest situation is observed in the anterior lamellar subregion. The lamella is obvious and the intralaminar neuronal sets, well differentiated from their surrounding are located inside it. The situs intralaminaris oralis Ilo (i.la or "nucleus" paracentralis, or alaris) is sheet-shaped and wraps around the anterior part of the nucleus medialis (Figs. 20.2A, C, and 20.24). This intralaminaris oralis situs is continuous, ventrally and medially, with the pars or situs commissuralis (Ilco) (Figs. 20.2A and 20.24) linking in the adhaesio the left and right formations. Another element usually linked to the oral intralaminar site (already mentioned in "Formation Paramediana") is its dorsomedial continuation, in the superior lamina, over the upper border of the nucleus medialis, corresponding to Olszewski's centralis superior lateralis or to Hassler's cucullaris (as a hat; Figs. 20.2 and 20.3). This site cannot be attributed (as frequently labeled) to the nucleus centralis lateralis, which is more posterior. One reason for the complexity of the posterior part of the intralaminar formation comes from the important development of the regio centralis modifying topographical positions and from the fact that the posterior part of the lamella itself is fuzzy. The intermediate intralaminar site comprises at first an element located in the lamella medialis above the regio centralis, at the superolateral border of the regio medialis (ncl. intralaminaris caudalis Ilc. or "centralis lateralis"; Fig. 20.24). Traced in Nissl sections only with difficulty, it may be observed using calbindin, calretinin, and cholinesterase immunochemistry. It appears then significantly thinner than in Nissl or myelin stains. In man, it is irregular with interspersed islands. Another, more regular site is observed in the lower part of the lamella medialis located between the central and medial regions, the supracentral site (Fig. 20.24, Ilsc), with elongated islands intensly stained for calretinin. The most caudal elements of the formation are located behind the central region. Some elements are still in lamellae (such as the intralaminaris retrocentralis, Ilrc, Fig. 20.2D and 20.24). But the existence of neuronal groups not topographically intralaminar makes the description difficult. This generally neglected part of the formation is continuous with the intralamellar sheath wrapping around the posterior pole of the medial region. The so-called limitans nucleus (Fig. 20.2C) forms an oblique thin band starting from below the central region to the medial geniculate nucleus. After Friedemann's (1911) "pars supragenicula nuclei limitantis," Hassler (1959) described an excessively extended limitans comprising parts ("Li opt" and "Li.por") that are known today to belong to the basal region (see "Regio Basalis."). The situs limitans of the intralaminar-limitans formation having an intense staining for calretinin (Ciccheti *et al.*, 1998) is restricted to a thin discontinuous band extending from the medial border of the thalamus to islands

close to the medial corner of medial geniculate body (Fig. 20.2).

The intralaminar-limitans formation receives afferences of the reticular kind. This is particularly the case for very dense cholinergic afferences (Heckers *et al.*, 1992) contrasting with the surrounding isothalamus. The oral intralaminar site ("paracentral") and the limitans receive dense projections from brainstem cholinergic reticular sources (Olivier *et al.*, 1970; Paxinos *et al.*, 2000), the pedunculopontine complex (PPT) and the laterodorsal tegmental nucleus (LDT; Wainer and Mesulam, 1990) forming a single complex PPT/LDT (Steriade *et al.*, 1997). The formation also receives from this complex noncholinergic, glutamatergic axons with a colocalization of cholinesterase and glutamate (Lavoie and Parent, 1994). There are also tachykinin and enkephalin axons (Hirai and Jones 1989b). The intralaminar formation, in addition, receives other glutamatergic axons from the medulla, caudal pons, and midbrain and from the magnocellular bulbar reticular fields. Mainly in its posterior subregion, it still receives afferences from "lower" large afferences—at first spinothalamic. Axons from the spinothalamic tract end in the caudal part surrounding the central region (the pars caudalis, ILc, CL, supracentral and retrocentral, parts and limitans; Mehler, 1966a; Burton and Craig, 1983; Mantyh, 1983; Fig. 20.9). Another lower afference is cerebellar. Endings are observed essentially in the intralaminaris caudalis (ILc, CL) not in the supra or retrocentral nor in the limitans parts (Percheron, 1977; Percheron *et al.*, 1996). Yet another afference comes from the superior colliculus (Benevento and Fallon, 1975). This set of afference, spinothalamic, cerebellar, and collicular, is peculiar. Only the last also projects to the parafascicular part of the central region. The two others, in the cat, already do not completely coincide, and they form a less diffuse organization than ordinarily claimed (Bentivoglio *et al.*, 1988).

For a long time, the intralaminar ensemble was said to have no cortical connection, since it was observed to remain intact after cortical lesions. This was explained by its strong connection to the striatum (Nakano *et al.*, 1990; Fénelon *et al.*, 1991; MacFarland and Haber, 2000). Axons to the striatum come from the whole intralaminar-limitans formation including its limitans part (Nakano *et al.*, 1990), in continuity with the parafascicular part (CPf) of the central region. The destination of efferent axons to the striatum was considered by Jones (1997) and Steriade *et al.* (1997) as necessary for isolating "intralaminar" elements. In fact, other thalamic regions, even the lateral, also project to the striatum. Even incomplete degeneration is observed in macaques after hemidecortication (Peacock and Combs, 1960; Jones and Leavitt, 1974). Intralaminar-limitans neurons actually project to the cortex. The oral intralaminar neurons project abundantly to the frontal cortex according to the same spatial plane as that of the medial region (Van Buren and Borke, 1972) and to the supplementary motor area but not to the motor cortex (Shindo *et al.*, 1995). The limitans degenerates after large lesions, essentially parietooccipital (Powell and Cowan, 1967) or with additional deep lesions (VanBuren and Borke, 1972), rather densely to the insular cortex and to a lesser extent to the superior temporal cortex including the primary auditory area (Kosmal *et al.*, 1997). The axons of the intralaminar axons, presumably, as drawn by Lorente de No (1938), end primarily in layer I and VI and reach rather widespread cortical surface. But this remains a disputed point. Studies and experiments on "intralaminar nuclei" have been the subject of a considerable literature that (in spite of the claimed nucleation) finally led to the concept of diffuse or unspecific systems. The evolutionary decrease of intralaminar groups in primates and particularly in man is not easily compatible with their role in the unspecific excitation of the cortex, as their volume does not increase in proportion to the cortical surface. Considering the major anatomical changes in this part of the thalamus, it is very difficult today to assign functions to the intralaminar-limitans formation in human beings. It is proposed to consider the intralaminar-limitans ensemble IL or IlLi as a whole with mere topographical parts or sites, including purely intralaminar elements, the commissural, superior or cucullaris part (these two being thus excluded from the paramedian formation), the retrocentral part, the limitans and extralaminar islands.

REGIO CENTRALIS

Luys (1865) discriminated his "centre médian" on its whitish aspect on unstained human brain sections. The anatomical situation, the link with the fasciculus retroflexus or Meynert's bundle (Meynert, 1872) or habenulo-interpeduncular fascicle and the presence of a capsule were already observed at that time. The twin nucleus, medial to the habenulointerpeduncular fascicle was described later, in a cercopitheque, as the "champ parafasciculaire" (C. Vogt, 1909) or nucleus parafascicularis (Friedemann, 1911). Over time, the two nuclei were united into what has been named the "centre médian-parafascicular complex." Recent studies in cercopithecidae and human brains (Fénelon *et al.*, 1991, 1994, Percheron *et al.*, 1991) have stressed the necessity for replacing the

traditional binary opposition by a ternary partition of a "central complex," forming the central region or regio centralis. This stands out clearly from its surrounding. Its medial frontier with the periventricular gray is traced without much difficulty, on cytoarchitectonic differences. Above all, in man and upper primates, it is clearly separated by a myelin capsule, making it an almost enclosed nucleus (closed by a wall, Percheron *et al.*, 1991)(Figs. 20.24 and 20.25). This capsule first appears as C-shaped at about 9 (Cooper, 1950), 13–15, (Yakovlev, 1969), or 16 weeks (Forutan *et al.*, 2001), that is, much earlier than the intralaminar formation. The nature and components of this capsule have been already discussed (see mention of lamellae in "General Considerations"). It is made up of two parts (Fig. 20.2B). Only the dorsal, supracentral, separating it from the regio medialis is the ventral continuation of the lamina medialis or interna, alone containing intralaminar elements (see "Formatio Intralaminaris-limitans" and Fig. 20.24). The lateral part is the lamina centralis separating it laterally from the lateral region (its caudal somesthetic subregion) and caudally from the pulvinar (Fig. 20.2B). The myelinization of this lateral part (lc; Fig. 20.1B, 20.6A) is late, 30th week, 170 mm; Niimi *et al.*, 1960) and only complete at about 8 months postnatal (Yakovlev and Lecours, 1967) at the same time as the myelinization of the medial lemniscal axons.

The central region is hanging at the inferior part of the thalamus, overhanging the mesencephalic reticular formation, not covered by the perithalamic lamina and perithalamus (Fig. 20.2B). Its posterior pole, in macaques and humans, almost corresponds to the CP0 plane and its inferior border to the ICP plane. Its general shape is piriform with the largest part located caudally. Its main axis is oblique in relation to the midsagittal plane and curved (60° in Fig. 20.24). The complex is crossed in its medial third by the habenulointerpeduncular, or retroflexus, fascicle of Meynert. Oriented obliquely from back to front, its position in relation to the complex is a reliable landmark for the determination of anteroposterior positions. The primate regio centralis is also obvious with particular stains. It is strikingly unstained for calbindin, calretinin (Fortin *et al.*, 1996; Ciccheti *et al.*, 1998), or cytochrome-oxydase (Jones, 1997) and irregularly stained for parvalbumin (Jones and Hendry, 1989), with parvalbumin-stained somata (Munkle *et al.*, 1999), which is the reverse of truly intralaminar elements. The problem of the subdivision of the region is an old one. In 1941, the Vogts introduced a subdivision of the human centre médian into a dorsomedial pars magnocellularis (CeMc) and a ventrolateral pars parvocellularis (Cepc), endorsed by many successive authors working on the human brain (see Fénelon *et al.*, 1994, for a review). From phylogenetic arguments, Niimi *et al.* (1960, 1973) also retained a tripartition of the complex but interpreted the Vogts' magnocellular part as the lateral part of the parafascicular nucleus (Pfl), the parvicellular part only forming the centre médian "in a narrow sense." Braak (1971), though designating more subparts, showed that the lateral and the parafascicular parts are regular, one darker and the other lighter, when the intermediate is irregular with oblique stripes (also observable in the chimpanzee, Sakamoto, 1964). The phylogenesis of the region leads to conflicting conclusions concerning its subdivision. Today, following Nauta's opinion (1966), it is agreed that there is no centre médian in rodents, only a parafascicular nucleus. According to Mehler's interpretation (1966; concurred by Royce, 1987) a small centre médian would appear in carnivora, limited to the small lateral part receiving confluent afferences from the entopeduncular nucleus and the motor cortex. But this could be as well, in Niimi's conception, the lateral part of the parafascicular nucleus. In the prosimian Galago, a "centre médian," whose neuronal type is that of the macaque pars media, has increased and sends axons to the sensorimotor cortex (Pearson *et al.*, 1984). In cebideae, in the owl monkey (Aotus) there is apparently no sign of a lateral subdivision (Stepniewska *et al.*, 1994). In the squirrel monkey (Saimiri), while only two parts, including a dorsolateral part of the parafascicular nucleus receiving pallidal afferences, are described (Sadikot *et al.*, 1992; Sidibé *et al.*, 1997, 2002) there is in fact a curved slim, located at the most lateral part of the complex, not receiving pallidal axons, not projecting to the striatum and sending axons to the cortex, likely prefigurating the pars paralateralis. The development of the pars media (either lateral parafascicular or medial centre médian) is more than likely due to that of the medial pallidum (appearing in platyrhinians) from which its receives its main afferences. The appearance of the pars paralateralis becomes obvious only in cercopithecideae (that include macaques). Its tracing may be made on the fact that contrary to the two other parts it does not stain for acetylcholinesterase. In man, the paralateral part is voluminous, almost one half of the complex, which represents a massive increase. Having a particular neuronal type, particular staining properties and connections, and a huge development, it could be considered as the "centre médian" proper (Percheron, 1966). In such a case, it would be an old-world primate creation linked to modifications of corticosubcortical connections whose meaning is not known yet. For the traditional binary description of the region leading to dead ends for cercopithecidae

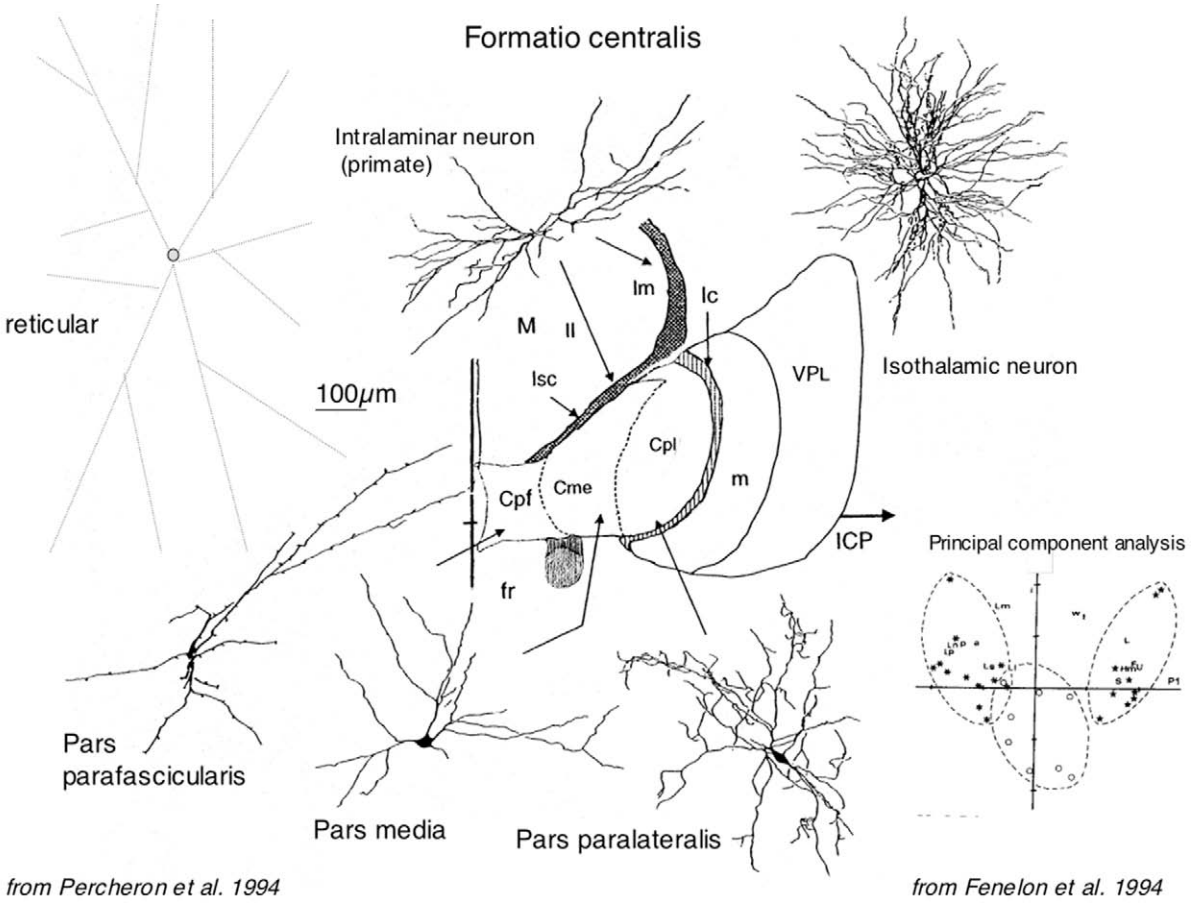

FIGURE 20.25 Regio centralis. Central region or central complex shown at is maximal extent on a slice made up Fp 7 to 10 from Schaltenbrand and Bailey's atlas. It is surrounded by a capsule composed of the supracentral part (lsc) of the lamella medialis (lm) dorsomedially (single continuation of the lamina medialis, containing intralaminar neurons) and the lamella centralis (lc) laterally. The complex is crossed by the habenulointerpeduncular (Meynert's) bundle (or retroflexus, fr). The central complex is made up of three parts, each with a particular neuronal species (lowere part of A). The pars parafascicularis (Cpf) has leptodendritic neurons (long and scarcely branched). Laterally, the pars paralateralis (Cpl, present only in upper primates) is made up of neurons with thinner and more branched arborizations with axonlike processes. The bar represents 100 μm. The intermediary pars media (Cme) is also intermediary in neuronal morphology (complete variations in Fénelon *et al.*, 1994). The principal component analysis shows that there is no gradient and a separation into three neuronal species. These species are clearly different from those of the isothalamus. The neuron on the upper right is a typical small bushy or tufted neuron much more branched with short stems. The region is thus allothalamic. Central neurons are not of the intralaminar neuronal genus shown dorsally, made up of bitufted elongated arborizations in primates (different from those of rat and cat). The complex is distinct from the intralaminar-limitans formation almost everywhere.

and human brains, a tripartition was proposed (Fénelon *et al.*, 1991, 1994; Percheron *et al.*, 1991) that is detailed now.

The regio centralis is made up of two distinct neuronal families: projection neurons and local circuit neurons. These are similar to the ones found in the isothalamus (i.e., microneurons with small somata, short dendritic arborizations, and axon-like appendages). Their proportion—19% in the parafascicular part and 25% in the lateral half (Dewulf *et al.*, 1969, 1971) in man and 28% and 27.4 of GABAergic neurons in macaques (Hunt *et al.*, 1991)—are higher than that in the intralaminar formation and close to numbers in the lateral region. In contrast, the cellular types of the projection neurons are clearly different from those of the isothalamus (Fig. 20.25), explaining their attribution to the allothalamus, and from those of the intralaminar formation (Fig. 20.25), explaining the removal from the so-called intralaminar group. Quantitative typology (on topological and metrical parameters) of dendritic arborizations of centralis neurons in macaques and humans (Fénelon *et al.*, 1994) showed that there are in fact three neuronal species, each for one of three subparts (Fig. 20.25): the medial pars parafascicularis (Cpf), with a lateral expansion below the next, the pars media (Cme), approximately

equivalent to the Vogts' Ce magnocellularis, Ce.mc or to Niimi's Pfl and the lateral pars paralateralis Cpl, (Niimi's, 1960, center median proper). CPf is made up of leptodendritic neurons (with scarcely branched dendritic arborizations, Fig. 20.25) similar to the neurons of the rat parafascicular nucleus (Scheibel and Scheibel, 1972; Deschênes *et al.*, 1996) of which 20% were seen to give initial collaterals. Cme, topographically intermediate, has neurons with intermediate dendritic characteristics (Fig. 20.25). Cpl, pars paralateralis, has richly ramified neurons bearing many axon-like processes. This differentiation is accentuated in human brains with larger and even more branched dendritic arborizations. In the two most lateral parts, electron microscopic studies (Harding, 1974; Balercia *et al.*, 1996) observed serial synapses and triads, but only a few glomeruli were not considered as typical elements. Immunohistochemistry brought new arguments. The two medial, Cpf and Cme, subparts are heavily stained for acetylcholinesterase (Olivier *et al.*, 1970) and for GABAa 1 (Huntsman *et al.*, 1996), while Cpl is weakly stained or unstained in human thalamus (Hirai and Jones, 1989; Heckers *et al.*, 1992; Jones, 1997; personal material) and stained for acetyltransferase (Heckers *et al.*, 1996) and GABAα5 and β3 (Huntsman *et al.*, 1996).

The connections of the complex point out its specificity. In opposition to surrounding intralaminar elements, there are no afferences from the spinothalamic tract or the brachium conjunctivum, just crossing through the complex for a more dorsal destination (Mehler, 1966; Percheron, 1977). Again in contrast with the surrounding intralaminar elements, the main subcortical afference comes from the system of the basal ganglia, at first the medial pallidum (Nauta and Mehler, 1966; confirmed by further works, François *et al.*, 1988; Percheron *et al.*, 1996). The intrapallidal distribution of the neurons that project to the complex overlaps with that of the neurons projecting to the lateral region (Parent and de Bellefeuille, 1983; Fénelon *et al.*, 1990). They are in fact collaterals of the axons targeted to this region (Arrechi-Bouchiouia *et al.*, 1997, Fig. 20.14). Branching is *effected* within the lateral region. Pallidocentral axons then go in a posterior direction, passing the central capsule. There are intraorder differences between macaques and cebideae (the last having endings in the parafascicularis and a particular dorsolateral PF, Sidibé *et al.*, 1997). In macaques, the intracentral territory of pallidal endings is mainly the pars media (François *et al.*, 1988; Percheron *et al.*, 1996; Fig. 20.6B). These endings are only sparsely ramified, with no dense arborizations (Arrechi-Bouchiouia *et al.*, 1997). Electron microscopic studies (Harding 1974; Balercia *et al.*, 1996) showed that the boutons of pallidal origin, calcium-binding protein negative, are not of LR (large round) type but of a subpopulation of F1 type boutons with symmetric, GABAergic synapses. They are often located on the dendritic stems, in any case close from the soma. LR boutons are different from those found in the isothalamus (Balercia *et al.*, 1996). Another afference from the basal ganglia system comes from the nigra lateralis and reticulata (Ilinsky *et al.*, 1985; Percheron *et al.*, 1996; François *et al.*, 2002; Fig. 20.26). Nigral axons selectively projecting to the pars parafascicularis including its ventrolateral extension below the pars media (François *et al.*, 2002; Sidibé *et al.*, 2002). The same parafascicular part also receives axons from the superior colliculus (Harting *et al.*, 1980). The parafascicular part of the complex, at least, is innervated by the brainstem reticular formation. The complex receives cholinergic axons from the pedunculopontine complex (Ch5; Lavoie and Parent, 1994) and lateral dorsal tegmental nucleus (Mesulam *et al.*, 1989), more intensively in the medial part, which likely explains the intense staining for acetylcholinesterase of the pars parafascicularis and media. It receives also glutamate afferents from the same pedunculopontine complex and from other reticular sources. The complex receives axons from extended portions of the perithalamus (Parent and de Bellefeuille, 1983). In addition to subcortical, the regio centralis receives cortical afferences. The afferences from the motor cortex to both paralateral (Cpl) and intermediate (Cme) parts are well documented (DeVito, 1969; Künzle, 1976, 1978; Jones *et al.*, 1979; Miyata and Sasaki, 1983; Leichneitz, 1986) and confirmed by Kuypers and Pandya (1966) in the chimpanzee. The topography of the endings of the axons from the premotor cortex, dorsal and ventral, is more medial since also involving the parafascicular part (Künzle, 1978; Miyata and Sasaki, 1983; Wiesendanger and Wiesendanger, 1985). There could be an evolutionary change as only the pars media receives premotor axons in chimpanzee (Kuypers and Pandya, 1966). The topography of the territory of the motor supplementary cortex (SMA) is even more extended as it comprises the three parts of the complex (DeVito and Smith, 1959; Wiesendanger and Wiesendanger, 1985). In addition, the pars parafascicularis selectively receives axons from the frontal eye field (Astruc 1971; Künzle and Akert, 1977; Akert and Harmann-von Monakow, 1980; Huerta *et al.*, 1986, Stanton *et al.*, 1988), from the supplementary frontal eye field (Huerta and Kaas, 1990) and from the associative frontal cortex (DeVito, 1969; supra and infraprincipalis, Künzle, 1978; Preuss and Goldmann-Rakic, 1987) and from the cingulate cortex (Van Hoesen *et al.*, 1993).

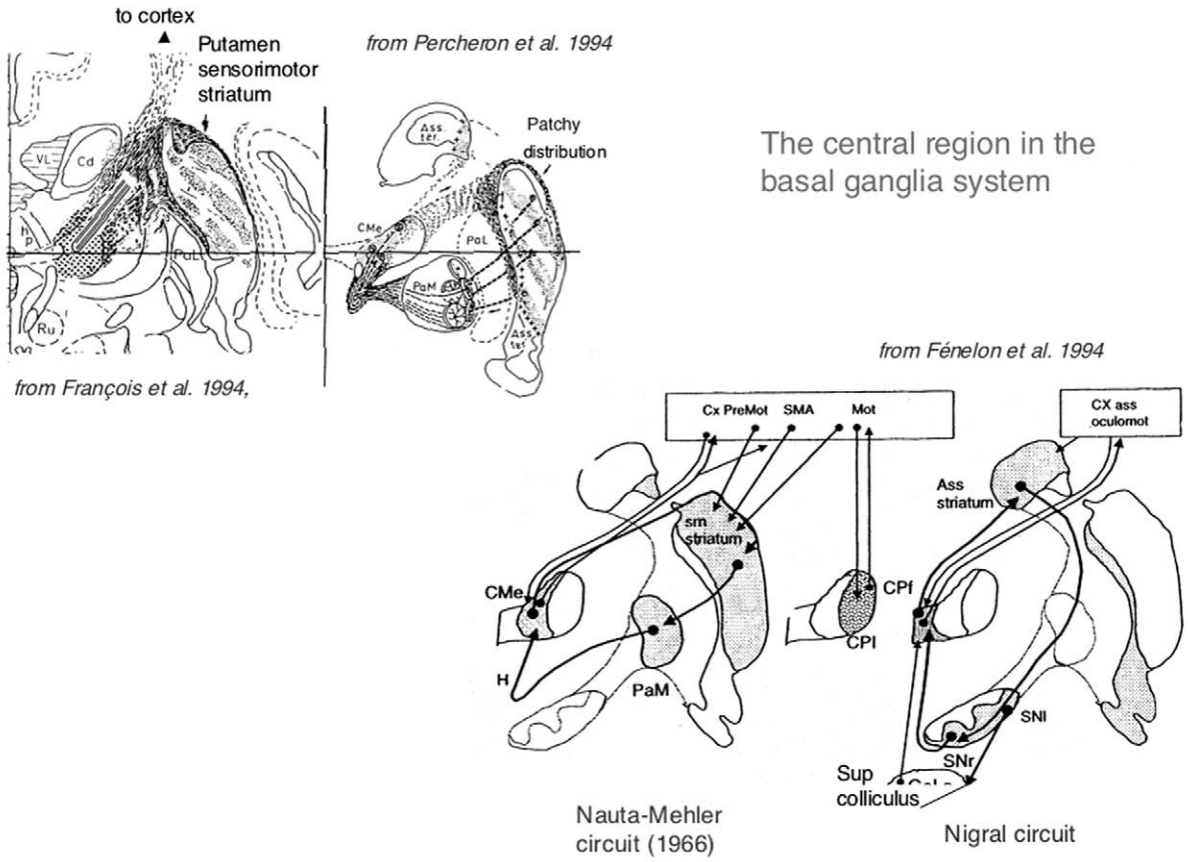

FIGURE 20.26 *Upper part* from François *et al*. (1994). Showing the connection from the central region to the striatum. The injection of tritiated amino acids shows that the tract is massive, reaching the upper border of the putamen. Central axons form separate oblique layers in the putamen. This constitutes the first part of the Nauta-Mehler circuit: striatum-medial pallidum-central region-striatum. Essentially sensorimotor. The striato-pallidal connection, due to the large dendritic arborizations of the pallidum represents a step of strong convergence (Percheron *et al.*, 1994). *Lower part*. The central region as a part of the system of the basal ganglia. Modified from Fenelon *et al.*'s (1994). The striatum of a macaque with its sensorimotor, mainly putaminal, and associative part, caudate and lower putamen. On the left, the pars media (Cme) receives afferences from the medial nucleus of the pallidum (PaM) through Forel's fields (H). CMe sends most of its axons to the sensorimotor striatum (Nauta-Mehler's circuit). Cpf receives afferences from the substantia nigra pars reticulata (SNr, in addition to superior colliculus, col s) and send its axons to the associative striatum, forming another subcortical circuit, the nigral circuit. Cpl receives some pallidal axons in macaques, does not send axons to the striatum and is mainly involved in reciprocal cortical connection, in particular with the primary motor cortex (mot).

Cortical endings form SR boutons making asymmetric synapses located distally on the dendrites of the centralis neurons (Balercia *et al.*, 1996).

The complex does not degenerate after cortical lesions in man and macaques (Peacock and Combs, 1960) and was thus said to receive no cortical efferences. The main efference, probably explaining this resistance, the striatum, was discovered on pathological material (Le Gros Clark and Russel, 1939; Vogt and Vogt, 1941). This projection was found to be ordered: the nucleus parafascicularis to the fundus, the dorsomedial Ce.mc., to the caudate nucleus and the inferolateral Ce.pc. to the putamen (Simma, 1951). The degeneration technique was also used experimentally in monkeys (Powell and Cowan, 1956). A lesion by Mehler (1966) and injections (François *et al.*, 1991; Sadikot *et al.*, 1990, 1992) in the middle and lateral part of the complex allowed to observe that the centralo-striatal connection is a major one, in terms of number of axons and density. Centralis axons cross obliquely through the lateral region and then the internal capsule and arrive at the superior border of the lateral pallidum where they either enter the lateral pallidal lamina or follow the lateral border of the putamen (François *et al.*, 1991)(Fig. 20.26). The pars media is the part that sends most axons to the sensorimotor striatum (Nakano *et al.*, 1990; Fénelon *et al.*, 1991; MacFarland and Haber, 2000), exclusively in the matrix. The axonal distribution is inhomogeneous (as already the case in rats, Deschênes *et al.*, 1996; cats,

Royce, 1987; squirrel monkeys, Sadikot *et al.*, 1992) in the form of dense irregular islands. In macaques, these make long oblique streaks following the direction of the somatotopic bands and forming long parasagittal bands (François *et al.*, 1991). The centralis complex is one element of the Nauta-Mehler's circuit (1966; striatum-medial pallidum-striatum; Fig. 20.26). This, mainly sensorimotor, circuit is doubled by another one, associative. The neurons of the pars parafascicularis indeed send axons to the associative striatum (Nakano *et al.*, 1990; Sadikot *et al.*, 1990, 1992; Druga *et al.*, 1991) comprising the caudate nucleus, the fundus and the ventral part of the putamen (Fig. 20.26) The complex finally covers irregularly (not including the spaces between streaks) the whole extent of the striatum. The centralostriatal connection is glutamatergic, excitatory. The presence of cholecystokinin in neurons of the three parts of the complex (Burgunder and Young, 1992) could be one source of CCK axons in the striatum. Centralis terminals form asymmetric synapses on dendrites (66%) and spines of the spiny neurons. In addition to the striatum, the central complex sends axons to the oral intralaminar nucleus (ILo including the IL cucullaris, see "Formatio intralaminaris-limitans") and to the formatio paramediana (Sadikot, 1992). Furthermore, it sends axons to other elements of the basal ganglia, lateral pallidum and subthalamic nucleus (Sadikot *et al.*, 1992, verified in macaques), and likely to the medial pallidum and nigra. The connection to the substantia nigra pars compacta appears selectively dense. The projection to the pedunculopontine complex would come from the pars Pf or from the adjacent reticular formation (Sadikot *et al.*, 1992). In the rat, the efferent connection from the pars parafascicularis to the different targets is effected by an arborescent connection distributing branches first to the perithalamus, the lateral pallidum, the striatum, and then the cortex (Deschênes *et al.*, 1996, 20% reaching all targets, others reaching only the pallidum). The projection to the cortex is constantly a collateral of the centro-striatal. In the cat (Macchi and Bentivoglio, 1985; Steriade *et al.*, 1997), the projection neurons were reported as either "striatally" or "cortically projecting," with some bifurcated axons (Jinnai and Matsuda, 1981). However, the bifurcated pattern could be in macaques the same as in rats (François, personal communication). Contrary to the classical assessment, the complex also projects to the cortex. The parafascicular part sends axons to the associative frontal orbital (Ilinsky *et al.*, 1985), "prefrontal" (Sadikot *et al.*, 1992; Rouiller *et al.*, 1999), oculomotor (frontal eye field), and anterior cingulate cortex (Vogt *et al.*, 1987). The efferences from the two lateral parts, CMe and CPl, are not different in macaques. They send axons to the motor cortex (Wiesendanger and Wiesendanger, 1985; Sadikot *et al.*, 1992; Rouiller *et al.*, 1999), the postarcuate premotor area (Shell and Strick, 1984), and the accessory motor cortex SMA (Wiesendanger and Wiesendanger, 1985; Shindo *et al.*, 1995; Rouiller *et al.*, 1999). The centralis axons end both in layers I and IV (Steriade *et al.*, 1997).

The functional meaning of the regio has varied in history. Luys' conception was sensory. As previously stated, the spinothalamic tract ends outside of it, dorsally and laterally (Mehler, 1966, Fig. 20.11), in the posterior intralaminar formation. Nociceptive responses in the parafascicular part observed after strong visceral stimulations (Berkley *et al.*, 1995) were attributed to a serotoninergic afference from the dorsal raphe (Reyes-Vazques *et al.*, 1989). This is documented in rats, not in primates. In the 1960s, the complex was a stereotactic target for the relief of central pain. Localized lesions there were rapidly shown to have no real effect, and this procedure was therefore abandoned. As assessed by Blomqvist *et al.* (2000), the postulated role in nociception was in fact very likely linked to the concomitant stimulation or lesion of the neighboring regio basalis (see "Regio Basalis."). The generally held interpretation of the function of the region, coming from LeGros Clark (1932, see above), is its belonging to the so-called intralaminar group, of which it was said to constitute the posterior or caudal part. The arguments in favor of such an ensemble was that both, intralaminar and central elements, are rich in cholinesterase (linked to an afference) and project to the striatum. The two criteria do not apply to the more lateral, paralateral, part. Furthermore, even if the bulk of the thalamic axons to the striatum in primates comes from the central or intralaminar formations, this is not their exclusivity since, in macaque at least, the paramedian and the motor isothalamus also send axons to the striatum (Nakano *et al.*, 1990; Fénelon *et al.*, 1991; McFarland and Haber, 2001). The central complex has more localized selective cortical connections than the intralaminar elements. Above all, the complex has its specific neuronal types and stains in a contrary way for calcium-binding proteins. On the other hand, in common with the isothalamus, the complex sends and receives axons to and from the perithalamic formation and has interneurons in about the same quantity and a nonidentical but close synaptic pattern. The intervention of the central region in nonspecific activation (sleep-wakening cycle or polysensory projection to the cortex, Jones, 1985; Steriade *et al.*, 1997) is unlikely. Lesions in the central complex in human brains do not lead to modification of consciousness or sleep. Thus, in spite of its persisting attribution to the intralaminar group, no argument is solid enough in comparison to its belonging to the

basal ganglia system as proposed in upper primates (see Percheron *et al.,* 1991). One reason, probably explaining the resistance to this attribution is that experimental and pathological lesions have no obvious motor effect. But anatomical data and systemic analyses are all concordant. The two Nauta-Mehler's and nigral circuits are major elements of the system of the basal ganglia. The second involves not only the usual associative elements but also the cingulate and oculomotor elements. The nigra lateralis projects to the superior colliculus. Considering the direct tectal afference to the pars parafascicularis and its cortical connections to FEF and SEF, this part was attributed a role in oculomotor control (Fénelon *et al.,* 1991; Sadikot *et al.,* 1992). The mixing with associative frontal, parietal, and temporal cortex indicates that its function would be more general. The most intriguing question remains, what is the functional role of the most lateral part (Cpl) receiving axons from the motor cortex?

The conclusion is that the central formation is not an element of the intralaminar formation and a major constituent of the basal ganglia system, which deserves to be studied as such.

THALAMIC STEREOTAXY

The principles and bases (at least cartographic) of stereotaxy have been explained in "Thalamic Topometry and Cartography". The resort to stereotaxy, a neurosurgical method allowing to reach deep structures with minimal cerebral damage, was introduced first in animals by Horsley and Clarke (1908; Clarke 1920) using bony landmarks. Because of large individual skull-brain variations, these were soon found to be unreliable in human. The resort to pineal calcifications (Spiegel and Wycis, 1952) was a step toward ventricular landmarks. A few years later, the reliance on the protrusion of the posterior commissure was durably exploited using ventriculography (Talairach and Szickla, 1967; Talairach *et al.*, 1957). The CA-CP system (see "General Considerations") became the usual reference. The most frequently used atlas in operation rooms was that of Hassler (1959, illustrated in Figs. 20.22, 20.23, 20.27 and 20.28 and later Hassler, 1967), on which observations and results were generally plotted, most often on sagittal sections. Among stereotactical techniques and apparatuses over at least 30 years, Leskell's ones became the most popular.

The main indications for thalamic lesions were intractable pain, tremor, and parkinsonian symptoms. Concerning the first, in the 1960s, many lesions were done in or around the central formation. The reappraisal of their inconstant effects led to the abandonment of this approach. As suggested by Craig *et al.* (1994) and Blomqvist *et al.* (2000), the lesions that had some positive effect probably included the nucleus basalis nodalis (see "Regio Basalis."), indeed close to the central region. The more precise topographic knowledge acquired during the last years could lead to a reappraisal of stereotactic possibilities in this domain. It is worthy to note that lesions of the central region never had observable motor consequence. The recent data from Henderson *et al.* (2000) showing primary degeneration in the central region of parkinsonian patients could lead to reconsider stereotactic possibilities.

The stereotaxy for the improvement of motor disorders has been preceded by neurosurgical hesitations. A vascular lesion of the capsule was already known by Charcot to improve parkinsonian symptoms. Later, the infarction of the territory of the anterior choroid artery, including the medial pallidum and its efferent bundles, had been observed to improve parkinsonian symptoms. The medial pallidum thus became the first neurosurgical target for parkinsonian-invalidating manifestations. Various surgical interventions targeted at the pallidum were proposed at that time, exposed in Cooper's treatise (1950). Later, the lesion of the internal capsule was thought to give better results than that of the pallidum. Continuing medially, finally the thalamus for some time became the usual selective target (Hassler *et al.,* 1979). A previous review (Percheron *et al.,* 1996) extensively analyzed the data on the location of thalamic sites whose stimulation or lesion were efficient in improving neurological motor symptoms and the possible mechanisms of their intervention (also a question, among others, for Marsden and Obeso, 1994). The best effects of lesioning were on tremor. Neurosurgical teams agree that the most efficient thalamic sites of lesion for alleviating or improving tremor, either "essential," cerebellar, or parkinsonian was always the same. They accepted that the "best target" was located at the lower part of the celebrate V.im, (Vogts 1941, Hassler's, V.im.e; Fig. 20.27; L 16), recipient of cerebellar afferences (see lateral intermediate subregion) where the axons of the brachium cunjunctivum are concentrated. This was understandable for the cases of cerebellar lesions or dysfunction (such as multiple sclerosis) but not in parkinsonian syndrome where the cerebellar system is anatomically intact. New interrogations had been raised by the discovery of "tremorosynchronous" neurons, whose firing rate was the same as that of the tremor, about 7–10 Hz (Albe-Fessard *et al.,* 1961). Tremor synchronicity became a major criterion for the selection of the target in parkinsonian tremor. The distribution of tremorosynchronous neurons was plotted by Albe-Fessard *et al.* (1961, 1966), Jasper and Bertand (1962), and

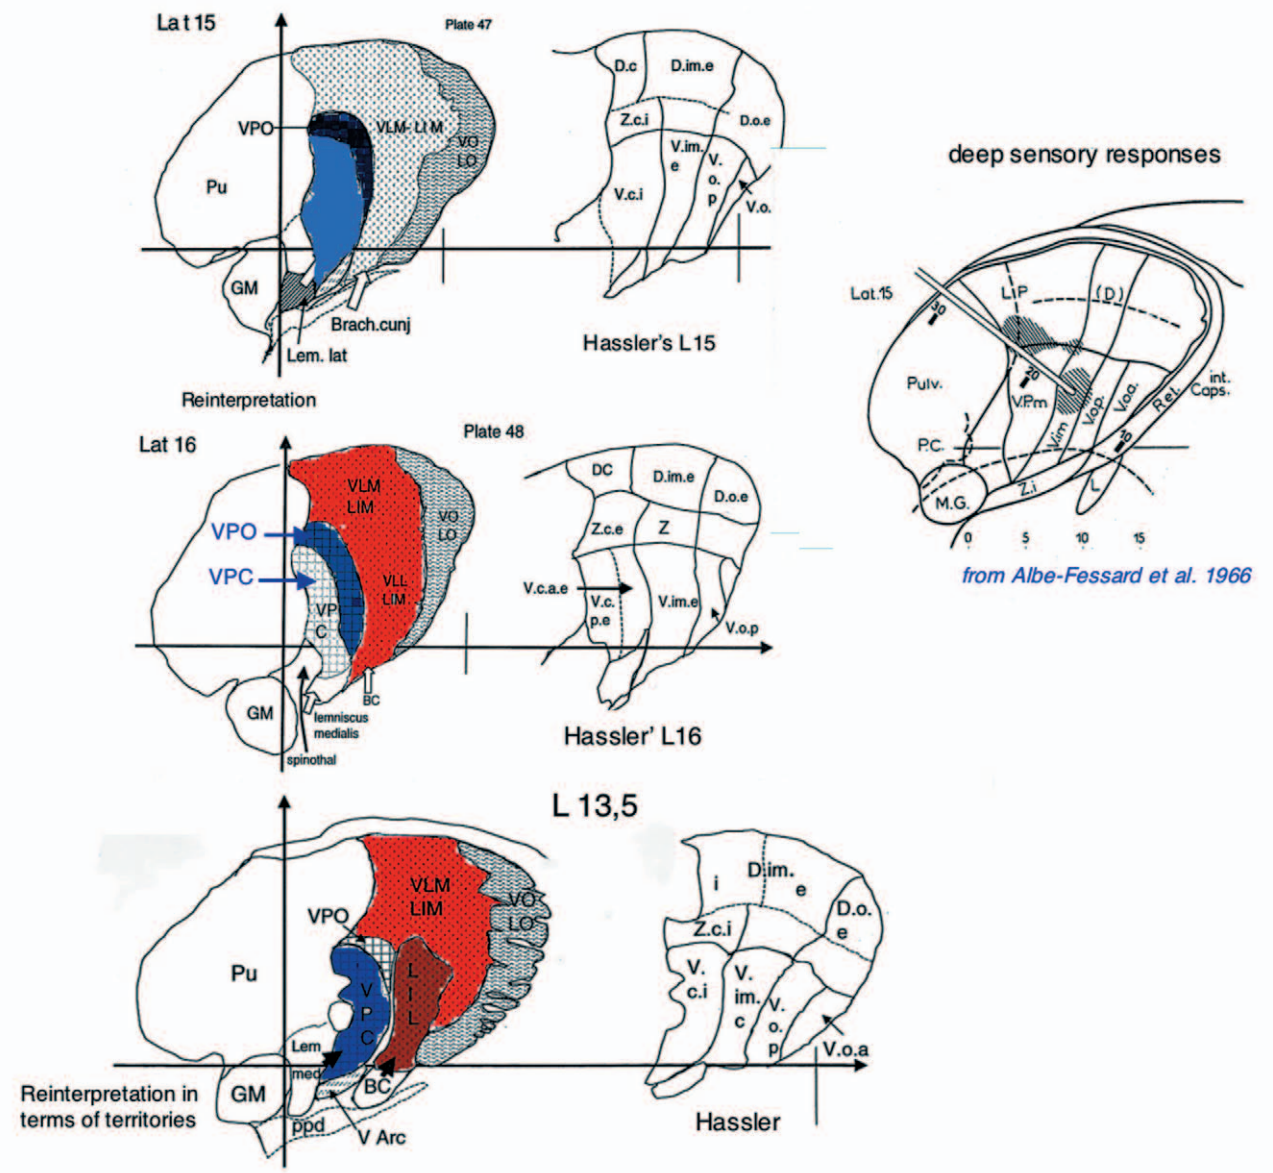

FIGURE 20.27 Stereotaxic data and additional sagittal sections. L15 and 16 from Schaltenbrand and Bailey's atlas—VPO. Drawing from Albe-Fessard *et al.* (1966) plotting points responding to deep stimuli (pressure, passive movement). One part is located dorsally in Hassler's Z.c.; the other, in his V.im.e. The comparison with the maps located above (L15) and below (L16) shows that the two could correspond to the curved VPO. *L-15.* Tracings from Hassler. The dorsal part of VPO is located in his Z.c.i (Hassler's interpretation). VPO is his anterior part of the lemniscal territory Vc (Vc a.e) and comprises also a part of Zc. Hassler's V.o.p at this level is part of the pallidal territory VO. The separation into zonal Z or dorsal D elements was artificial. DC was cerebellar like D.im. *L15.* Personal tracings. Appearance of VPO, the kinaesthetic part of the lemniscal territory (Kaas, VPS). Succession of three curved territories: pallidal VO, cerebellar VIm (or VL) and lemniscal (VP) with no ventrodorsal limits. The first two territories reach the dorsal border of lateral region.

Tasker *et al.* (1982; Fig. 20.19), essentially in Hassler's Vim. The nucleus ventralis intermedius (V.Im) has been the subject of much work particularly by Ohye (Ohye, 1978, 1982; Ohye and Albe-Fessard, 1978; Ohye and Narabayashi, 1979; Ohye *et al.*, 1972, 1976/77, 1977, 1989, 1990) including histological studies (Hirai *et al.*, 1982, 1989). The physiological characteristics of Vim were an intense activity with very large spikes (the highest in the thalamus, Fig. 20.28). The tremorosynchronous neurons were soon found to be sensitive to deep stimuli ("responses to passive and active movements of joint or muscle on the controlateral extremity but never to light stimuli," Ohye and Narabayashi, 1979). This led to a long-lasting confusion between pathologically tremorosynchronous and normal kinaesthetic neurons of sane monkeys and

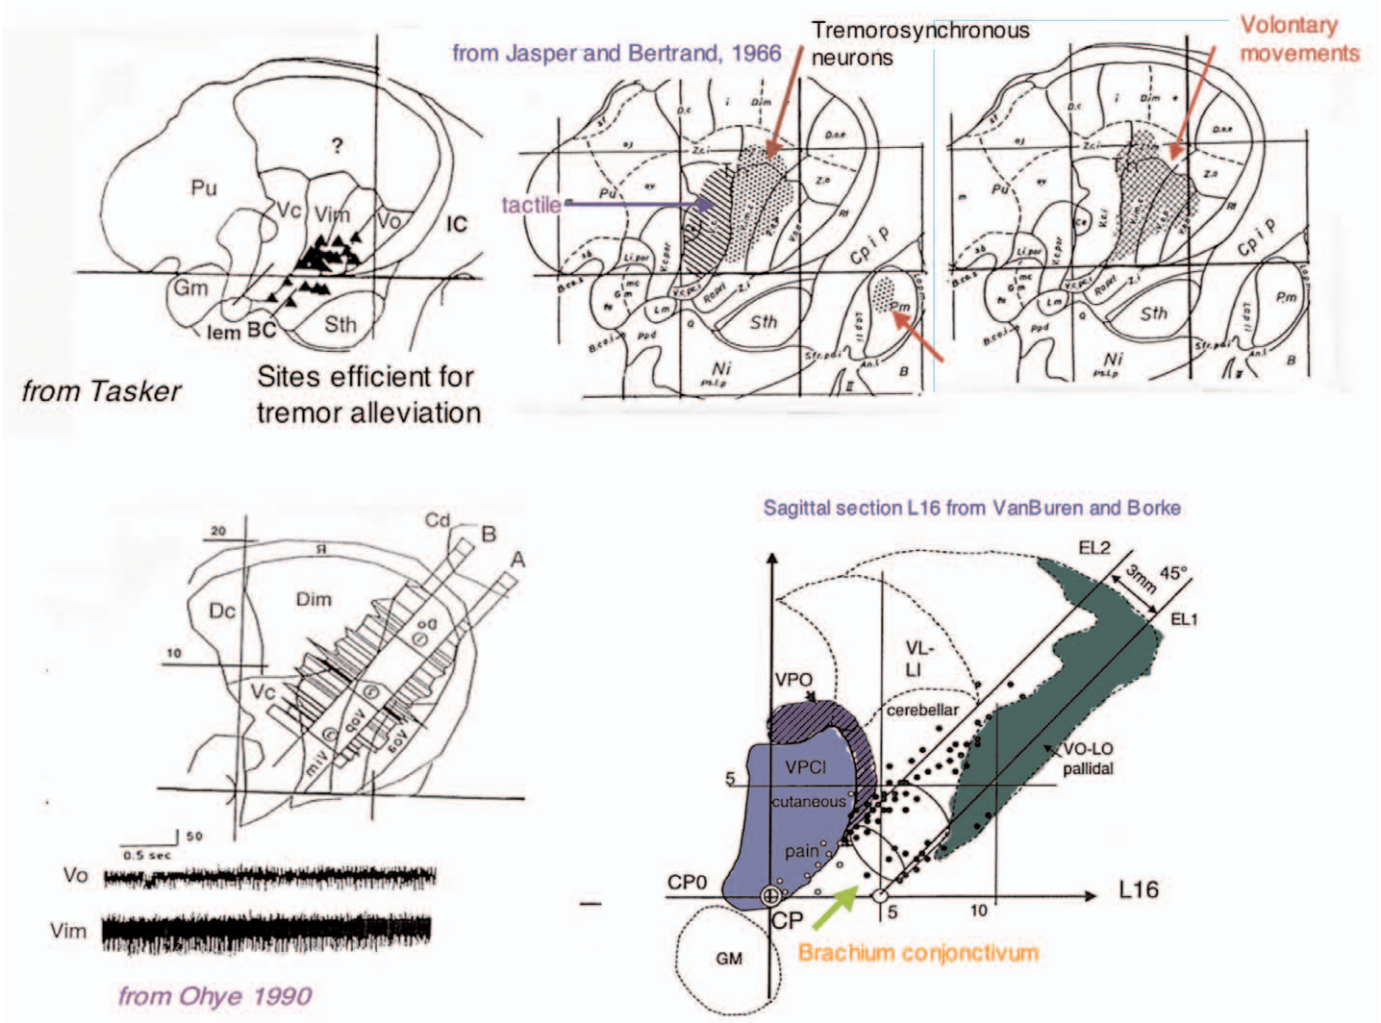

FIGURE 20.28 Stereotaxic data on tremorosynchronicity and the cure of tremor. *First row* from Tasker *et al.* (1982) and Jasper and Bertrand (1966). *Lower left* from Ohye *et al.* (1990). The surgical protocol is always the same. Two parallel electrodes 3 mm apart enter simultaneously at 45° from the intercommissural plane ICP. The lowest is targeted at the point located 5 mm in front of the posterior commissure on ICP. The activity on the upper electrode traversing Vim is much higher with larger spikes. That of the inferior electrode is that of the pallidal-receiving neurons. *Lower right.* Original drawing plotting of data from Ohye (Maebashi, Gunma) on level L16 of VanBuren and Borke's atlas (inverted and intentionally given larger magnification). The tracing of VPO is personal and made outside their VC. The points correspond to positions in 30 patients with parkinsonian tremor. Their anteroposterior position, as in Tasker *et al.* (1982), was corrected in relation to their individual CA-CP lengths. The open points, were those where stimulation evoked paraesthesia or pain. Neurons there are irresponsive to either active or passive movements. The black points are the positions of tremorosynchronous neurons also responding to deep information. Some are in the lower part of VPO. Still others are in the pallidal territory. The majority is located in the inferior part of the cerebellar territory. The cylinder shows the usual place of therapeutic lesions for alleviating parkinsonian tremor. It is located in the lower part of the cerebellar territory VIm, here VimL, projecting to the (primary) motor cortex, or at the entrance of cerebellar afferences (brachium conjunctivum, Brach. Cunj. in 15 and B.C in 16). The efficacy of lesions or stimulations is not linked to destruction or lesion of the set of neurons receiving deep information VPO but to another cause (see text).

men. From the beginning, it was admitted that there is no overlap between the somesthetic lemniscal and the cerebellar territory. The location of kinaesthetic neurons plotted in man by Albe-Fessard *et al.* (1966, 1967 on level 15, reproduced in Fig. 20.27), Jasper and Bertrand (1966), and Bertrand *et al.* (1967, Fig. 20.19) was considered to be outside the classic somesthetic nucleus (V.c), in the cerebellar territory (V.im) and dorsally to it (Z.c)(Figs. 20.19 and 20.20). In the "Albe-Fessard-Jasper-Ohye hypothesis" (see Percheron *et al.*, 1996), the intervention of the lemniscal system was ruled out because the denervation of limbs (rhizotomies) did not suppress thalamic rhythmic activity. The pathways conveying kinaesthetic information to Vim were

thought to be possibly the interposed component of the cerebellar input and the spinothalamic coafference, both forming islands interspersed in the dentate (cerebellar) territory (see "Subregio Lateralis Intermedia. Cerebellar Territory"). Starting from physiological data in sane monkeys and based on the fact that the afferents to the Vim have the characteristics of lemniscal axons, this was contested by the "Jones-Lenz hypothesis" according to which the tremorosynchronous neurons were simple kinaesthetic neurons passively driven by tremor. Recent topographic studies have added a nucleus between the cutaneous VP and the cerebellar Vim, receiving lemniscal kinaesthetic information, VPO (Kaas' VPS) (see "Subregio Caudalis. Lemniscal Territory") leading to other interpretations. This subdivision existed in Hassler's maps as the ventralis caudalis anterior externus Vcae at lateral levels 16 (Fig. 20.27) to 18.5 (Fig. 20.23), that is, in more lateral planes than the ones generally selected by neurosurgeons for plotting their points. A simple transfer to more lateral maps modifies the possible interpretation (see Fig. 20.27). Today it may be accepted that neurosurgeons looking for the most characteristic neurons could have preferentially selected VPO kinaesthetic neurons for their presentations. But the lesion of these neurons cannot explain alone the improvement of tremor. In Figure 20.27, data from 30 patients of Dr. Ohye at Maebashi were plotted on VanBuren and Borke L16 map on which a VPO was added. Tremor synchronous neurons are located anteriorly to the border of the cutaneous representation, VPC. The superior electrode skims the inferior border of VPO, likely lemniscal and kinaesthetic. However, the majority of tremorosynchronous neurons is more anterior, within the cerebellar (Vim-VL) and, to a lesser degree, the pallidal subregion (VO; Fig. 20.27). The location of lesions (Fig. 20.20, L16, cylinder) shows that the efficient places of lesions or stimulation for alleviation of parkinsonian tremor was not the kinaesthetic zone but V.im.e (VImL-VLL), known to project to the motor cortex. In the intermediate subregion (VIm), this receives massive "reciprocal" corticothalamic afferences from the motor cortex. The activity of the motor cortex is perturbed in the parkinsonian condition, overexcited and less selective. An explanation could be that cerebellar-receiving Vim neurons, normally not responding to deep stimuli, could do it in pathological conditions. Successive dynamic changes in neuronal systems also involving the basal ganglia and cortex might render thalamic neurons overexcited by lower afferents. The explanation for the improvement of tremor by thalamic lesions could be the interruption of perturbed messages. Another could be the suppression (lesion) or modification (stimulation) of perturbing messages to the motor cortex.

The presence of tremorosynchronous neurons in the medial pallidum was already known by Jasper and Bertrand (1966; Fig. 20.27). An abundant stereotactic literature underlines the fact that, if lesions in the VIm (cerebellar) improve parkinsonian tremor, more anterior lesions (in VO, pallidal territory) improve akinesia and rigidity. The pathophysiology of MPTP-induced parkinsonian syndromes, nowadays take into account that pallidal neurons are tremorosynchronous and perhaps tremorogenous (Raz *et al.*, 2000). These data open up a different view of the role of the thalamus in parkinsonian symptomatology and physiopathology. Surgical interventions in parkinsonism today include instead pallidal and subthalamic stimulation.

The basal ganglia work in concert with cortex to orchestrate and execute planned, motivated behaviors requiring motor, cognitive, and limbic circuits. Their main driving force is cortex, as indicated by both a massive projection from cortex and the functional relationships associated with this input. Historically, the basal ganglia are best known for their motor functions. This functional association was established in large part by the neuropathology in the neurodegenerative disorders affecting the control of movement, such as that found in Parkinson's disease (PD) and Huntington's chorea. In addition, while receiving input from wide areas of cortex, basal ganglia pathways were thought to return primarily to motor cortex (Nauta and Mehler, 1966). In further support of the role of the basal ganglia in the control of movement, animal studies demonstrated several roles in motor control, including (but not limited to) regulation of posture or postural reflexes, as a center for automatic movements and as a source of inborn motor programs. Furthermore, the basal ganglia are involved in generating the necessary timing (ramp signals) for smooth guided movements (Denny-Brown, 1962; Kornhuber, 1974; MacLean, 1978). Later studies demonstrated basal ganglia involvement not only in motor execution but also in motor planning and in sensory-motor integration (Marshall *et al.*, 1971; Teuber, 1976; Marsden, 1984; Evarts *et al.*, 1985; Lidsky *et al.*, 1985; Marsden, 1985).

While a role for the basal ganglia in the control of movement is now clear, our concept of basal ganglia function has dramatically changed in the last 20 years, from a purely motor or sensory-motor one to a more complex and complicated set of functions that mediate the full range of goal-directed behaviors. Thus, in addition to their involvement in the expression of goal-directed behaviors through movement, the basal ganglia are also involved in the processes that lead to movement—in other words, the elements that drive actions, including emotions, motivation, and cognition. Indeed, regions within each of the basal ganglia nuclei

have been identified as serving not only a sensory-motor function but also limbic and cognitive ones. Ventral regions of the basal ganglia play a key role in reward and reinforcement (Heath *et al.*, 1968; Fibiger and Phillips, 1986; Everitt *et al.*, 1989; Robbins *et al.*, 1989; Wise, 1996; Schultz, 1997; Rolls, 2000) and are important in the development of addictive behaviors and habit formation (Kalivas *et al.*, 1993; Nestler *et al.*, 1993; Koob, 1999). More central basal ganglia areas are involved in cognitive functions such as procedural learning and working memory tasks (Mishkin *et al.*, 1984; Phillips and Carr, 1987; Jueptner *et al.*, 1997; Levy *et al.*, 1997; Jog *et al.*, 1999). Diseases affecting mental health, including schizophrenia, drug addiction, and obsessive compulsive disorder, are linked to pathology in the basal ganglia, albeit the ventral basal ganglia (Stevens, 1973; Kalivas *et al.*, 1993; Mogenson *et al.*, 1993; Swerdlow *et al.*, 1993; McGuire *et al.*, 1994; Breiter *et al.*, 1996; Koob and Nestler, 1997; Pantelis *et al.*, 1997). This is in contrast to diseases that interfere with motor control and primarily affect the dorsal basal ganglia. Thus, the role of the basal ganglia in cognitive and emotional behaviors is now as well accepted as is the role in motor control. Although several new theories of general function have emerged from the enormous progress in understanding the anatomy, physiology, and behaviors associated with the basal ganglia (Penney and Young, 1983; Nauta, 1986; Marsden, 1987; Hikosaka and Wurtz, 1989; DeLong and Georgopoulos, 1991; Kimura and Graybiel, 1995; Mink, 1996; Wise *et al.*, 1996; Wickens, 1997; Bergman *et al.*, 1998; Graybiel, 1998; Parent and Cicchetti, 1998; Schultz *et al.*, 1998; Boraud *et al.*, 2002), the actual role of the basal ganglia in executing goal-directed behaviors remains elusive. What is clear from the recent progress is that this set of subcortical nuclei work in tandem with cortex (particularly frontal cortex) via a complex corticobasal ganglia network to develop and carry out complex behaviors. The present review describes the organization of the primate basal ganglia from the perspective of cortical function in carrying out goal-directed actions. In some situations, when necessary, data are also presented from rodent work. We have attempted, whenever possible, to integrate the anatomical data with physiological and behavioral findings.

TOPOGRAPHY, CYTOARCHITECTURE, AND BASIC CIRCUITRY

Overview of Terminology and Basic Pathways

The basal ganglia (BG) refer to the large subcortical nuclear masses, the caudate nucleus, putamen, and the globus pallidus. In addition, two closely related structures, the substantia nigra (SN) and subthalamic nucleus (STh), are generally included as components of the basal ganglia. The caudate nucleus and the putamen form the neostriatum. The term "striatum" was assigned to these structures because of their striated appearance owing to the penetration by fascicles of dispersed corticofugal, striatofugal, and corticopetal axons. This region is also referred to as the dorsal striatum to distinguish it from the more recently identified ventral striatum (Fig. 21.1). The concept of the ventral striatum was introduced as the ventral extension of the striatum that included the nucleus accumbens, the medial and ventral portions of the caudate and putamen, and the striatal cells of the olfactory tubercle and anterior perforated substance. While the concept of a ventral extension of the striatum into the anterior perforated substance of the human was suggested some time ago (von Economo and Horn, 1930; Brockhaus, 1942; Macchi, 1951), it has been accepted relatively recently based on its connections, cell morphology, and histochemistry (Heimer, 1978; Heimer *et al.*, 1994).

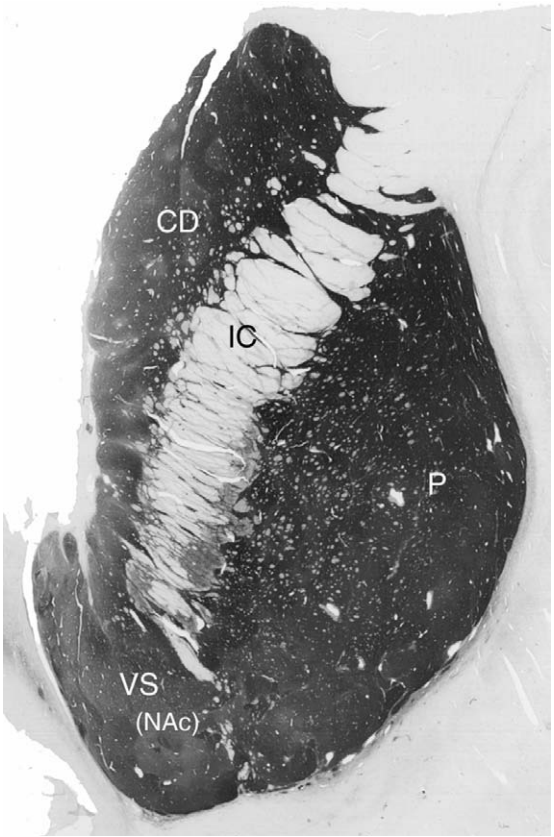

FIGURE 21.1 Photomicrograph of a acetylcholinesterase-stained coronal section through the rostral, human striatum. NAc. Accumbens; CD, caudate nucleus; IC, internal capsule; P, putamen; VS, ventral striatum.

The pallidal complex is comprised of the external (GPe) and internal segments (GPi) of the globus pallidus and the ventral pallidum. While the external and internal segments (together referred to as the dorsal pallidum) receive inputs from the caudate and putamen, their connections differ in important ways and are discussed in detail in a later section. They are separated by the internal medullary lamina. These two pallidal structures, along with the putamen, form the lentiform nucleus (Figs. 21.2 and 21.3). The ventral pallidum is located ventral to the anterior commissure and extends rostrally invading the parts of the ventral striatum (Fig. 21.2). Caudally it occupies the ventral and medial extremes of the external and internal pallidal segments (Parent, 1986; Haber *et al.*, 1993; Heimer *et al.*, 1999). The ventral pallidum receives its input from the ventral striatum and exhibits a combination of features of both the external and internal segments of the dorsal pallidum (Haber and Elde, 1981; Haber *et al.*, 1985, 1993). The STh nucleus can be considered an intrinsic nucleus of the basal ganglia (Fig. 21.4). It receives its input from the external pallidal segment and projects to both the internal and external pallidal segments. The connections and function of the STh are, of course, much more complicated, and its role in mediating basal ganglia function is central to some of the therapeutic treatment strategies for PD. These issues are addressed in detail in "The Subthalamic Nucleus." Finally, the substantia nigra and the adjacent ventral tegmental area (VTA) can also be considered intrinsic nuclei. The substantia nigra is divided into two parts, the pars compacta (SNC) and the pars reticulata (SNR) (Fig. 21.5). Dopamine neurons from both the pars compacta and VTA project to the striatum and the striatal output is directed toward both the dopamine neurons and the pars reticulata.

The striatum is the main input structure of the basal ganglia. It's afferent projections are derived from three major sources: (1) it receives a massive and topographic input from all of cerebral cortex; (2) the second

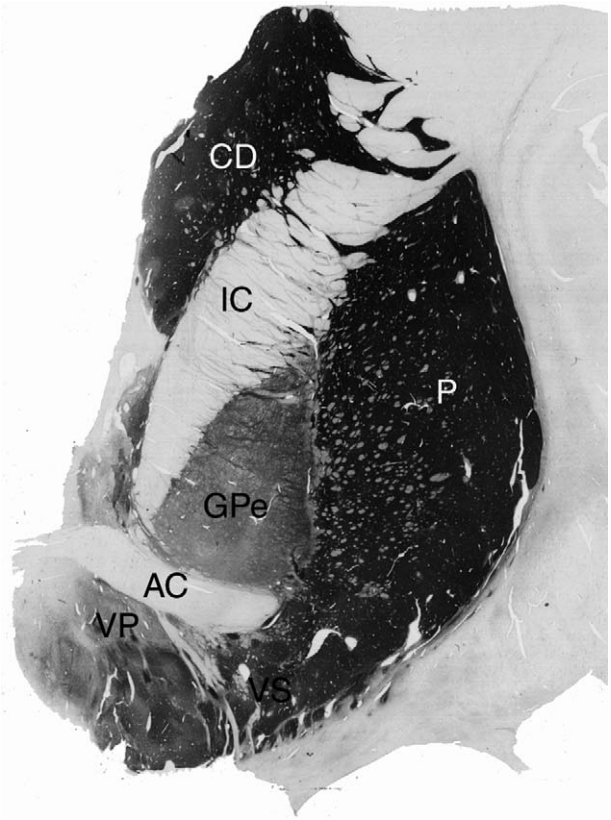

FIGURE 21.2 Photomicrograph of an acetylcholinesterase-stained coronal section through the human striatum at the level of the anterior commissure. Note the ventral extension of the striatum beneath the anterior commissure. AC, anterior commissure; CD, caudate nucleus; GPe, globus pallidus external segment; IC, internal capsule; P, putamen; VP, ventral pallidum; VS, ventral striatum.

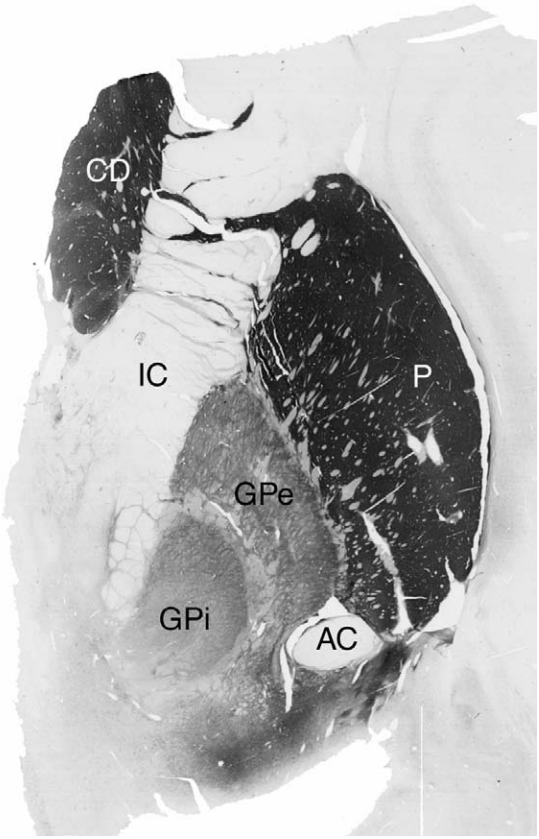

FIGURE 21.3 Photomicrograph of a acetylcholinesterase-stained coronal section through the central, human striatum. This level includes both the internal and external segments of the globus pallidus. AC, anterior commissure; CD, caudate nucleus; GPe, globus pallidus external segment; GPi, globus pallidus internal segment; IC, internal capsule; P, putamen.

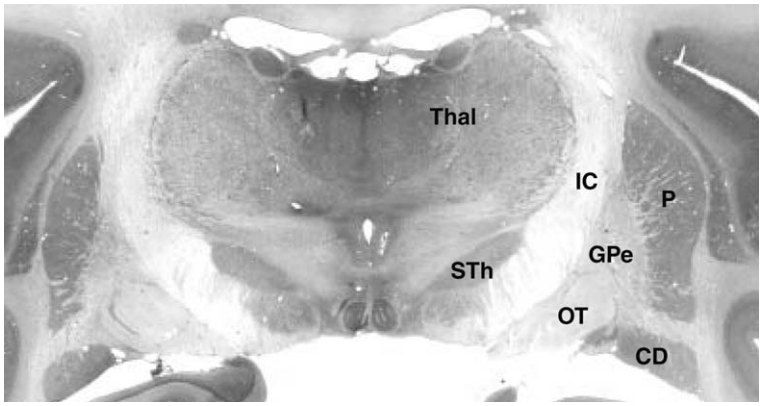

FIGURE 21.4 Photomicrograph of a Nissl-stained coronal section through the nonhuman primate brain at the level of the subthalamic nucleus. CD, caudate; GPe, globus pallidus internal segment; IC, internal capsule; P, putamen; OT, optic tract; STh, subthalamic nucleus; Thal, thalamus.

largest input is derived from the thalamus; and (3) the third main input is from the brainstem, primarily from both the dopaminergic cells of the midbrain and the serotonergic cells of the dorsal raphe nucleus. Afferent projections terminate in a functional topographic manner (Alexander *et al.*, 1986; Parent, 1986; Haber and McFarland, 1999a), such that the dorsolateral striatum receives cortical input from sensory-motor areas, central striatum receives input from associative cortical areas, and the ventromedial striatum receives input from limbic areas. Within this organization, afferent projections terminate in a patchy and interdigitated manner (Künzle, 1975, 1976; Goldman and Nauta, 1977; Künzle, 1977, 1978; Yeterian and Van Hoesen, 1978; Selemon and Goldman-Rakic, 1985; Kunishio and Haber, 1994; Chikama and Haber, 1995; Haber *et al.*, 1995b; Yeterian and Pandya, 1998; McFarland and Haber, 2001). The striatum, in turn, projects topographically to the pallidal complex and the substantia nigra, pars reticulata (Fig. 21.6) (Szabo, 1962, 1967, 1970; Parent *et al.*, 1984; Smith and Parent, 1986; Haber *et al.*, 1990b; Hazrati and Parent, 1992b; Parent and Hazrati, 1993; Lynd-Balta and Haber, 1994c; Parent and Hazrati, 1995; Smith *et al.*, 1998a). The outputs from the GPi and SNR are to the thalamus, which then projects back to the cortex, completing the basic corticobasal ganglia circuit. This is referred to as the "direct" pathway (Fig. 21.7A). Several investigators have successfully exploited the topographic corticostriatal organization of the several functionally distinct and separate BG circuits, demonstrating parallel corticosubcortical channels through the basal ganglia (see "The Direct and Indirect Basal Ganglia Pathways") (Alexander and Crutcher, 1990; Groenewegen *et al.*, 1990; Dum and Strick, 1991b; Middleton and Strick, 1997; O'Donnell *et al.*, 1997; Smith *et al.*, 1998b; Sidibe *et al.*, 2002). Other studies suggest a more complicated pattern of basal ganglia connections that indicate potential complex interactions between these channels (Percheron *et al.*, 1984b; Percheron and Filion, 1991; Joel and Weiner, 1994; Bevan *et al.*, 1996; Yelnik *et al.*, 1996; Joel and Weiner, 1997; Haber *et al.*, 2000; McFarland and Haber, 2002a). In reality, these two organizational schemes likely work together, rather than in conflict, allowing the coordinated behaviors to be maintained, and focused, but also to be modified and changed according the appropiate external and internal stimuli. Indeed, both the inability to maintain and to focus in the execution of specific behaviors, as well as the inability to adapt appropriately to external

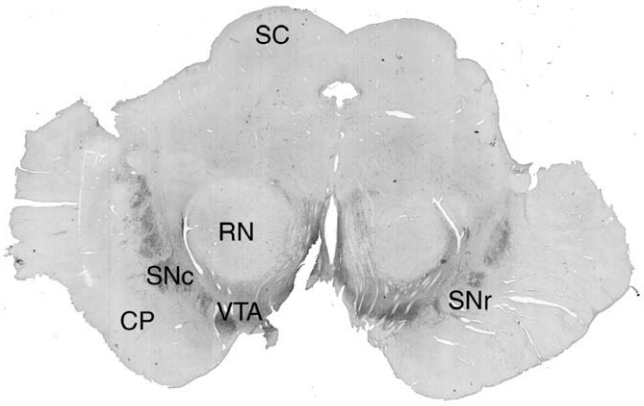

FIGURE 21.5 Photomicrograph of a tyrosine hydroxylase-stained coronal section through the midbrain of a human brain, illustrating the distribution of the dopamine cells in the substantia nigra and adjacent ventral tegmental area. CP, cerebral peduncle; RN, red nucleus; SC, superior colliculus; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; VTA, ventral tegmental area.

and internal cues, are key deficits in basal ganglia diseases that affect these aspects of motor control, cognition, and motivation. We will return to this topic in "Functional Basal Ganglia Connections."

The GPe is part of the BG intrinsic circuitry and is reciprocally connected to the STh. The STh in turn projects to the GPi. This is referred to as the indirect pathway in contrast to the direct pathway described earlier (Fig. 21.7B). These two striatal output systems are associated with different transmitters and receptors, which are described in more detail later. The main extrinsic afferent projections to the BG are excitatory, using glutamate as the excitatory transmitter. Intrinsic connections (with the exception of the STh) are typically inhibitory, using gamma-amino-butyric acid (GABA) as the primary transmitter. Because of the

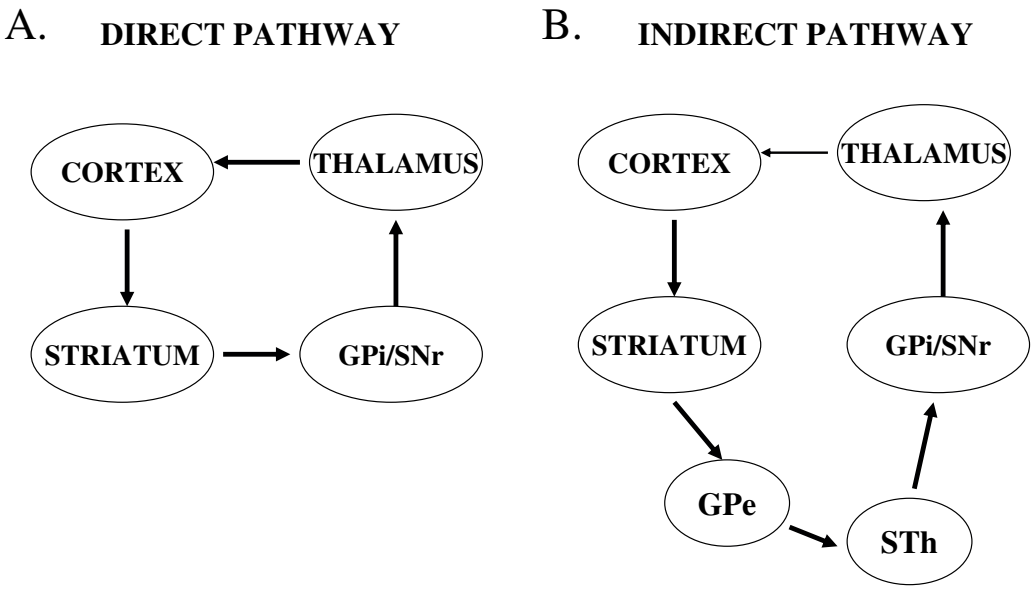

FIGURE 21.7 Diagram demonstrating the two corticobasal ganglia circuits: the direct and indirect pathways. **(A)** Direct pathway. **(B)** Indirect pathway involves a side loop, which includes the globus pallidus external segment and subthalamic nucleus. GPe, globus pallidus external segment; GPi, globus pallidus internal segment; SNr, substantia nigra pars reticulata; STh, subthalamic nucleus.

complex internal circuitry of the BG, the net effect of cortical and thalamic input to the striatum is to increase firing of striatal cells, which, in turn, inhibits (through the direct pathway) the relatively high rates of tonic activity in the pallidum and SN. This, in turn, serves to disinhibit thalamic firing and, consequently, increase thalamic stimulation of cortical activity. In contrast, through the indirect pathway, inhibition of the GPe disinhibits STh firing, which effectively stimulates GPi firing, thereby inhibiting thalamic stimulation of cortex. In this way, these two pathways have opposing actions on the thalamocortical activity: the direct pathway serves to reinforce cortico-BG activity, and the indirect pathway serves to inhibit cortico-BG activity (see Fig. 21.8). As with the parallel processing scheme mentioned earlier, the concept of direct and indirect pathways and associated transmitter-related molecules has stimulated a very productive area of research leading to important insights in basal ganglia function and therapies, particularly for PD. However, we also now recognize that the concept of direct and indirect pathways is likely to be far too simplistic, as a more complex organization emerges (Kawaguchi *et al.*, 1990; Parent *et al.*, 1995; Surmeier *et al.*, 1996; Smith *et al.*, 1998b; Reiner *et al.*, 1999). Finally, the dopamine cells of the midbrain (the SNC and VTA) also represent an intrinsic set of pathways. These cells project to the striatum and also receive striatal output. The control of dopamine on the striatal output cells is an area of intense research as the importance of this transmitter system is recognized for the normal (and abnormal) functioning of the BG (see Fig. 21.6).

The Striatum

In mammals with a more developed cortex, and especially in the human, the striatum is separated into the caudate nucleus and the putamen by the internal capsule. However, the separation is incomplete. This is particularly evident at rostral levels where the head of the caudate is joined to the putamen by the "striatal cell bridges," interspersed between the fibers of the internal capsule. The caudate nucleus forms an elongated nuclear mass, which is closely related to the

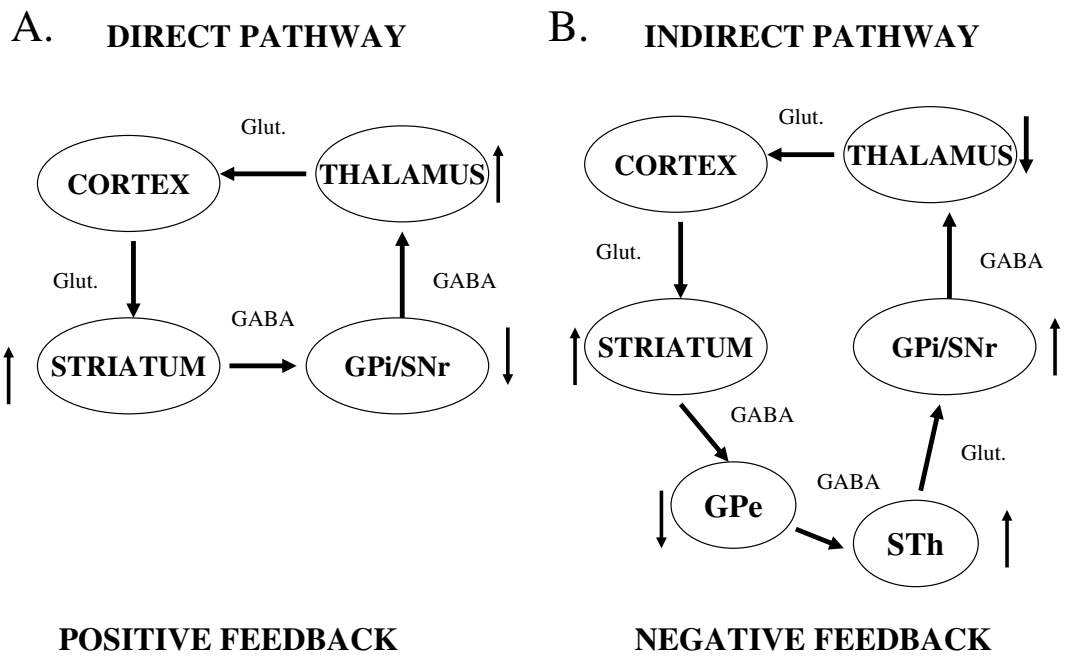

FIGURE 21.8 Diagram demonstrating the consequences of cortical activation of the direct and indirect pathways. Arrows indicate the direction of activation following an increase in cortical activity. Transmitters for each pathway are indicated in parenthesis. Glutamatergic (Glut.) excitation of the striatum via cortical inputs increases striatal activity in both pathways. **(A)** Increased striatal GABAergic activity reduces the output of GPi and/or SNr in the direct pathway. This reduction reduces the inhibition of thalamic neurons, resulting in an increase of glutamatergic thalamic activation of cortical neurons. This is then referred to as positive feedback to cortex via the direct pathway. **(B)** The consequences of cortical activation of the indirect pathway have the opposite effect on the indirect pathway. Increased striatal GABAergic activity reduces the output of GPe activity. This reduction reduces the inhibition of subthalamic neurons, resulting in an increase of glutamatergic subthalamic activation of the GPi/SNr. Activation of this inhibitory pathway reduces thalamic activation of cortical neurons. This is then referred to as negative feedback to cortex via the indirect pathway. GPe, globus pallidus external segment; GPi, globus pallidus internal segment; SNr, substantia nigra pars reticulata; STh, subthalamic nucleus.

lateral ventricle throughout its extent. Its thick anterior portion is referred to as the head of the caudate, which gradually narrows into the body of the caudate. The body is located in the floor of the central part of the lateral ventricle on the dorsolateral side of the thalamus. The body of the caudate gradually tapers off and becomes the tail of the caudate, as it curves along with ventricular system entering the temporal lobe caudal to the thalamus. The putamen, the largest part of the striatum in humans, forms the large lateral part of the lentiform nucleus and is separated from the globus pallidus by the external medullary lamina. The ventral border of the putamen cannot always be easily delineated in gross-anatomical preparations. Rostrally, it is continuous with the accumbens underneath the anterior limb of the internal capsule (see Fig. 21.1). At the level of the crossing of the anterior commissure, the putamen reaches towards the ventral surface of the brain. Caudally, the putamen merges in varying degrees with the tail of the caudate (Figs. 21.1–21.5).

The nucleus accumbens and the rostroventral most aspects of the caudate and putamen form the ventral striatum. In the human brain, the broad continuity between the caudate nucleus and putamen underneath the rostroventral aspect of the internal capsule is generally referred to as the fundus striati and includes the nucleus accumbens. At a slightly more caudal level underneath the lateral extension of the anterior commissure, the ventral striatum includes the ventral extension of the putamen, which reaches the surface of the brain in the region of the anterior perforated space. This ventral region, which had been included in the term, the "substantia innominata," has now been histochemically identified as a ventral extension of the striatum. In addition, the olfactory tubercle and the rostrolateral portion of the anterior perforated space adjacent to the lateral olfactory tract in primates are also included in the ventral striatum (Heimer *et al.*, 1999). The remainder of the anterior perforated space appears to be a mixed area with elements of the putamen, extended amygdala, the corticopetal cell complex, and the ventral extension of the pallidum.

Cell Types and Intrinsic Organization of the Striatum

The striatum (both dorsal and ventral) contains several cell types that are generally divided into two general groups: projection neurons and interneurons.

Projection Neurons Projection neurons are the most common cell type and are referred to as medium spiny neurons (MSN) or the principal neurons (also referred to as spiny I neurons) of the striatum: in nonprimate species they account for over 90% of the cells, and about 70% in primates (Fox *et al.*, 1971a; Kemp and Powell, 1971b; DiFiglia *et al.*, 1976, Difiglia *et al.*, 1982; Graveland and DiFiglia, 1985; Graveland *et al.*, 1985; DiFiglia and Carey, 1986). These are medium size, ovoid cells (14–20 μm) with four to seven radiating dendrites that are heavily covered with spines (Fig. 21.9). The axon emerges from the soma or the proximal part of a primary dendrite and gives rise to a dense collateral network (Wilson and Groves, 1980). Human striatal cells have a larger soma and dendritic radius compared with the monkey, but fewer spines (Graveland and DiFiglia, 1985). In addition, there is a second spiny neuron (type II spiny neuron which is relatively infrequent, (about 1%) and varies considerably in size (Graveland and DiFiglia, 1985; Graveland *et al.*, 1985; DiFiglia and Carey, 1986). The medium spiny neurons are the main efferent cells of the striatum, projecting to the globus pallidus, ventral pallidum, and substantia nigra (Szabo, 1962; Kemp and Powell, 1971a; Szabo, 1972; Grofova, 1975; Somogyi and Smith, 1979; Preston *et al.*, 1980; Bolam *et al.*, 1981; Chang, 1981; Parent *et al.*, 1984; Haber *et al.*, 1990b; Selemon and Goldman-Rakic, 1990; Lynd-Balta and Haber, 1994c). Axon collaterals also terminate within the striatum, onto both interneurons and other medium spiny cells (Somogyi *et al.*, 1981a; Bolam *et al.*, 1986; Pickel and Chan, 1990). Terminals of the medium spiny neurons are small to medium in size, densely packed with vesicles, and have few mitochondria. They form symmetrical synaptic contacts and contain GABA (Bolam *et al.*, 1985; Kita, 1993; Smith *et al.*, 1998b). These data, along with electophysiological data, indicate that the projection cells of the striatum are inhibitory (Wickens and Oorshcot, 2000). Based on histochemical localization of neuropeptides, there are two general types of medium spiny cells: one that co-contains substance P (SP) and GABA; and one that co-contains enkephalin (enk) and GABA. Substance P-containing medium spiny neurons project primarily to the internal segment of the GP and sustantia nigra, while the enkephalin-containing cells project primarily to the extenal segment of the GP (Pickel *et al.*, 1980; Haber and Elde, 1981; Bolam and Izzo, 1988; Bolam and Smith, 1990; Pioro *et al.*, 1990; Reiner *et al.*, 1999). In addition to these transmitter molecules, smaller subpopulations of the principal neurons also co-contain other neuropeptides (Haber, 1986; Graybiel, 1990; Reiner and Anderson, 1990). For a review of the histochemistry of the striatum, see Graybiel and Ragsdale (1983) and Holt *et al.* (1997).

The main extrinsic inputs to the medium spiny cells are derived from the cortex, thalamus, and brainstem. Cortical fibers primarily project to the dendritic spines, form asymmetric terminals, are glutamatergic

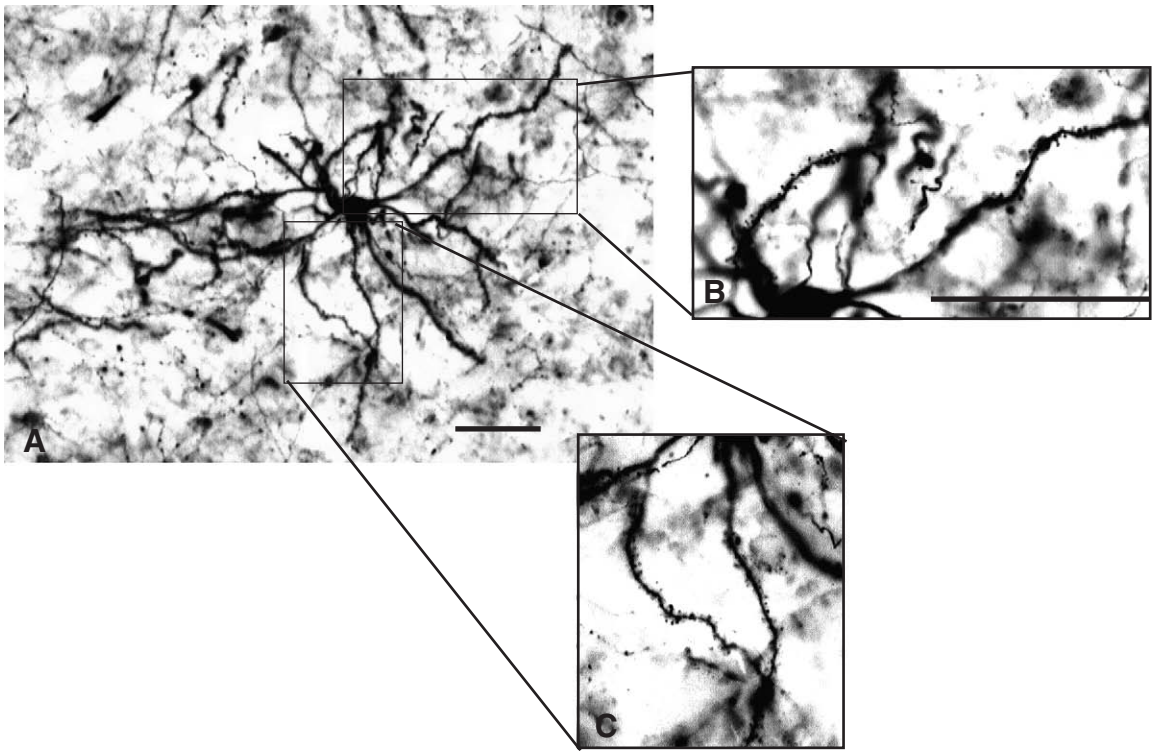

FIGURE 21.9 Photomicrograph of a medium spiny neuron (MSN) filled with Lucifer Yellow. Boxes in panel A are enlarged in panels B and C to reveal prominent spines on the dendritic processes. Scale bars = 50 μm.

and are excitatory (Kemp and Powell, 1971c; Somogyi *et al.*, 1981a; Smith and Bolam, 1990). Thalamic projections terminate primarily onto dendrites, are excitatory, and probably also are glutamatergic (Kemp and Powell, 1971c; Dubé *et al.*, 1988; Sadikot *et al.*, 1992b; Sidibe and Smith, 1996). In the striatum, as in other brain regions, glutamate binds to three receptor types, AMPA (AMPARs), NMDA (NMDARs), and metabotrophic glutamate receptors (mGluTRs). AMPA and NMDA receptors are ionotrophic receptors, mediating fast transmission. These receptors, particularly the NMDA receptors, are thought to be involved in the pathophysiology that leads to cell death during neurodegenerative diseases such as Huntington's disease (Beal *et al.*, 1991; Ferrante *et al.*, 1993; Young, 1993). AMPA and NMDA receptors are asssembled from several subunits, encoded by different genes. The combination of the different subunits determines specific membrane properties such as gating, permeability to Ca^{2+}, and Mg^{2+} sensitivity (Gotz *et al.*, 1997). The distribution, expression, and function of these subunits in the striatum demonstrate that the principal neurons express AMPA receptors that exhibit slow gating and moderate Ca^{2+} permeability. While the NMDA subunit expression differs between the principal neurons and interneurons, there is little functional variation between subunit configurations in the striatum (Landwehrmeyer *et al.*, 1995; Gotz *et al.*, 1997). The mGluRs couple to G proteins to modulate ion channels and intracellular signaling. The distribution of five cloned mGluRs demonstrates a differential distribution of these receptor subtypes throughout basal ganglia structures (Testa *et al.*, 1994; Tallaksen-Greene *et al.*, 1998; Testa *et al.*, 1998; Calabresi *et al.*, 2000b). The three glutamate receptor groups are involved in various aspects of longterm potentiation (LTP) and long-term depression (LTD), two forms of synaptic plasticity associated with learning and memory. Indeed, the striatum plays a central role in learning, and both LTP and LTD have been demonstrated at corticostriatal synapses (Calabresi *et al.*, 1992; Kombian and Malenka, 1994; Mori *et al.*, 1994; Gotz *et al.*, 1997; Calabresi *et al.*, 1999; Calabresi *et al.*, 2000b; Kerr and Wickens, 2001; Reynolds *et al.*, 2001).

Extracellular physiological recordings in awake, behaving monkeys show that the medium spiny neurons are phasically active neurons (PANs). Phasically active neurons have a very low spontaneous discharge rate (0.5–1 spike/s), but a relatively high firing rate associated with behavioral tasks. Phasically active

neurons are activated antidromically from either GPe or GPi, thus identifying them as the projection neurons. These cells exhibit phasic discharges that are time-locked to specific behaviors including movement, preparation for movement, and the performance of learned tasks (Crutcher and DeLong, 1984b; Kimura, 1990; Kimura *et al.*, 1996). Medium spiny neurons are bistable, shifting between two membrane states: an upstate and a downstate (Wilson and Kawaguchi, 1996; Plenz and Kitai, 1998). In the downstate, the membranes are hyperpolarized and cannot generate action potentials. In the upstate, the membranes are relatively depolarized and close to threshold for spike generation. Movement from a downstate to the upstate occurs in response to the combined effects of temporally coherent and convergent excitatory input from cortex and/or thalamus (Wilson, 1993; O'Donnell and Grace, 1995; Calabresi *et al.*, 2000b). Neurons in the upstate are primed to fire in reponse to further depolarization. However, in the absence of the coherent excitatory input, the membrane returns to the downstate. While the medium spiny neuron membrane is not intrinsicaly bistable, the successful transfer between states does depend on intrinsic membrane channels that mediate ion conductances (Wilson and Kawaguchi, 1996; Hernandez-Lopez *et al.*, 1997; Stern *et al.*, 1997; Kerr and Plenz, 2002). The distribution and function of the glutatmate receptor groups and their constituent subunit composition along the spiny dendrite have direct impact on complex regulation of the firing state of the principal neuron. Recently the bistable membrane properties of the MSN have also been demonstrated to exist in awake monkeys, further establishing that this important phenonmenon is likely to be relevant to most mammalian striatal cells including human. We will return to this topic later as we examine the role of the interneuron and dopamine in contributing to the regulation of MSN firing pattern.

Brainstem projections from the substantia nigra, pars compacta, and the VTA terminate onto the spines as well as the dendritic shafts of the medium spiny neurons (Bouyer *et al.*, 1984a, b; Freund *et al.*, 1984; Smith *et al.*, 1994b; Hanley and Bolam, 1997; Kung *et al.*, 1998). These projections are primarily dopaminergic. The distribution of dopamine terminals onto dendrites, soma, and spines has been studied by many investigators. The general conclusion of all these studies is that, for the dorsal striatum, there are few terminals onto the soma, but they are relatively evenly split between the spine and dendrite. In contrast, for the ventral striatum, particularly the shell of the nuc. accumbens, dopamine terminals are more commonly found on the dendrite than on the spine (Zahm, 1992). Early studies using fluorescence staining, and later studies using TH immunhistochemistry to mark the dopaminergic terminals, clearly demonstrated the dense distribution of dopamine fibers throughout the striatum (Felten and Sladek, 1983; Lavoie *et al.*, 1989). The topography of this projection from the midbrain is well documented by lesion studies, tracing studies, and the pathological material from Parkinson's disease patients (Szabo, 1979; Gerlach *et al.*, 1991; Pifl *et al.*, 1991; Lynd-Balta and Haber, 1994a, b). Five different dopamine receptor genes have been cloned, (D_1–D_5), which are divided into two distinct families, D1 and D2, based on pharmacological and molecular criteria (Civelli *et al.*, 1993; Sokoloff and Schwartz, 1995). Although within each family the receptor subtypes may involve different G-proteins and intracellular responses, their effect on cAMP is relatively consistent (for review see Sokoloff and Schwartz, 1995). D_1, D_2, and D3 are expressed in MSN and found in dendrites and spines (Gerfen *et al.*, 1990; Hersch *et al.*, 1995; Caille *et al.*, 1996). The D_3 receptor is primarily expressed in the ventral striatum, while the D_1 and D_2 receptors are expressed throughout the striatum. The D_2 receptor is also expressed in axons. The D1 family of receptors (including D_1 and D_5 receptor subtypes) activate G-proteins that stimulate cAMP. Medium spiny neurons that contain high mRNA expression levels for the D_1 receptors also co-contain mRNA for substance P. The D2 group (D_2, D_3, and D_4), acting through different G-proteins, inhibits cAMP. Cells that contain high mRNA expression levels for the D_2 receptor subtype also co-contain mRNA for enkephalin. The separation of receptor subtypes within different pathways, along with their different pharmacological actions and co-localized neuropeptides, has been particularly important in forming the functional framework of the direct and indirect pathways (Emson *et al.*, 1980; Haber and Elde, 1981; Inagaki and Parent, 1984; Albin *et al.*, 1989; Bolam and Smith, 1990; Gerfen *et al.*, 1990; Le Moine *et al.*, 1991; Harrington *et al.*, 1995; Lu *et al.*, 1998) (Fig. 21.10). Cells of the direct pathway contain mRNA for the D_1 receptor preprotachykinin and project to the internal pallidal segment and to the substantia nigra, pars reticulata. Cells of the indirect pathway contain mRNA for the D_2 receptor preproenkephalin and project to the external pallidal segment (see Fig. 21.11). However, the discovery of the $D_{3\text{-}5}$ dopamine receptor subtypes has complicated this notion. Recent studies have demonstrated subpopulations of medium spiny projection neurons that coexpress different complements of dopamine receptor subtypes, including the D_4 and D_5 receptors, as well as cells that colocalize substance P and enkephalin. Of particular interest here is the D_3 receptor subtype (part of the D2 family) which is often colocalized with

Pharmacologically-defined DA receptors:

D1-like receptors: **Activates G-proteins resulting in stimulation of cAMP.**

- **D_1 receptors: striatum, neocortex**
- **D_5 receptors: hippocampus, hypothalamus**

- **D2-like receptors:** **Activates G-proteins resulting in inhibition of cAMP.**
- **D_2 receptors: striatum, SN/VTA, pituitary**
- **D_3 receptors: NAc, olfactory tubercle, hypothalamus**
- **D_4 receptors: frontal cortex, medulla, midbrain**

the D_1 receptors in the ventral striatum (Surmeier *et al.*, 1996; Aizman *et al.*, 2000; Nicola *et al.*, 2000).

The other main brainstem input arises from the dorsal and median raphe nuclei. This pathway uses serotonin as a transmitter. Unlike the distribution of dopaminergic terminals in the striatum, serotonergic terminals are not densely distributed throughout the striatum. Rather, they are more abundant in the ventral striatum (Lavoie and Parent, 1990). There are several serotonergic receptor subtypes, and their localization has been identified primarily in rats (Patel *et al.*, 1995; Ward and Dorsa, 1996). Inputs to the striatum also

5 Cell Types	Classical Name	Size	Transmitter	Dendrites	Axons	Inputs	Outputs
1	Aspiny I	Medium	GABA/PV	Arborize within 300um of the cell body	Collaterals are relatively local	Main input: Cortex; also from GPe.	Main target: MSN Terminals on proximal dendrites and cell bodies, forming pericellular baskets around MSN GAP Junctions
2		Medium to large	GABA/NPY/SOM +NOS			Cortex	MSN
3		Small to Medium	GABA/Calretinin				
4	Aspiny II	Large	Acetylcholine	Long dendrites, 400 um from cell extensive arborization	extensive	Thalamus, also from MSN, dopamine, (cortex)	MSN, other aspiny II cells
5	Aspiny III (infrequent)			Moderate branching	Few branches

include projections from other components of the basal ganglia including the external globus pallidus (and comparable region of the ventral pallidum), and the STh (Spooren *et al.*, 1996; Smith *et al.*, 1998b; Sato *et al.*, 2000b).

In addition to the extrinsic inputs, the projection neurons also receive input from interneurons and from local collaterals of other medium spiny cells. These terminate onto the spines, dendritic shafts, and soma of the medium spiny cells (Bishop *et al.*, 1982; DiFiglia and Aronin, 1982; Takagi *et al.*, 1983; Bolam *et al.*, 1985; Phelps *et al.*, 1985; Aronin *et al.*, 1986; DiFiglia, 1987; Izzo and Bolam, 1988; Kawaguchi *et al.*, 1990; Kita *et al.*, 1990; Pickel and Chan, 1990; Bennett and Bolam, 1994; Yung, 1996). The cholinergic interneurons terminate onto dendritic spines of the MSNs, which contain an enriched complement of muscarinic receptors. The m_1 and m_4 are the principal muscarinic receptors on the these neurons and play an important role in modulation of cortical effects on MSN spiking activity (Hersch *et al.*, 1994; Calabresi *et al.*, 1998, 2000a; Yan *et al.*, 2001). In addition, other interneurons also project to the MSN affecting their activity as well (Kawaguchi *et al.*, 1995; Kawaguchi, 1997; Calabresi *et al.*, 2000b). The relationships among these chemically identified cells and terminals reveal an intricate local network that forms the basis for the complex neuronal processing within the striatum (see section on microcircuitry).

Interneurons In addition to the spiny projection neurons, there are at least five distinct types of aspiny neurons, which are considered to be interneurons (Fox *et al.*, 1971b; Pasik *et al.*, 1976; Graveland and DiFiglia, 1985; Graveland *et al.*, 1985; Kawaguchi *et al.*, 1995) (Fig. 21.12). All are relatively less abundant compared to the medium spiny projection neurons and possess a relatively short axon, which is highly arborized into a rich local network. Aspiny type I cells are medium sized, round, and contain GABA. These are relatively frequent in the human striatum and constitute as many as 23% of the medium-sized cell population in the primate compared with less than 5% in the rat and mouse. The medium-sized interneurons give off two to five primary dendrites that branch profusely while remaining rather close to the soma. The axons of these cells also collateralize extensively relatively close to the parent cell, adding evidence that they are interneurons. These neurons have recently been further classified on the basis of histochemical markers and physiological properties (for review, see Kawaguchi

et al., 1995). One population co-contains GABA and the calcium-binding protein, parvalbumin (Gerfen *et al.,* 1985; Cowan *et al.,* 1990; Kita, 1993). These cells are slightly larger than the medium spiny projection neurons. Their dendrites arborize within 300 µm, and their axon collatoral arborization is relatively local. The parvalbumin-positive, GABA interneurons receive a powerful input from cortex (Lapper *et al.,* 1992; Kita, 1993). At least some of this cortical input is funneled to the substantia nigra via the MSN projection cells. Of particular interest is that these cells have gap junctions, indicating that they are coupled in a continuous network. Thus, while relatively few in number, their inhibition on medium spiny projection neurons is likely to be particularly effective (Kita, 1993; Jaeger *et al.,* 1994). The second type of aspiny, GABA-containing interneuron stains positively for the neuropeptides somatostatin, and neuropeptide Y, and co-contains nitric oxide synthase (NOS) (DiFiglia and Aronin, 1982; Takagi *et al.,* 1983; Vincent and Johansson, 1983; Vuillet *et al.,* 1989). These cells also receive cortical input (Kawaguchi *et al.,* 1995). Similar to the parvalbumin-immunoreactive cells, they synapse onto the soma and dendrites of the medium spiny projection neurons. The parvalbumin- and neuropeptide-containing interneurons differ in their intrinsic electophysiological properties (Kawaguchi *et al.,* 1995). The third type of GABA-containing medium-sized interneuron co-contains calretinin, a calcium-binding protein. Less is known about this group of medium aspiny interneurons.

Aspiny type II neurons are the largest of the striatal cells (30–40 µm) and represent approximately 1% of the population. These are the cholinergic interneurons. Compared to aspiny type I cells they have longer dendrites with extensive dendrite trees. They have 3–14 primary dendrites that branch frequently and extend to as much as 400 µm from the soma. Furthermore, their axonal fields are also more elaborate than other striatal cells (Braak and Braak, 1982; Graveland *et al.,* 1985; Yelnik *et al.,* 1993). These features have led to the hypothesis that the cholinergic interneurons play an important role in integrating inputs between functional or compartmental regions of the striatum (Kawaguchi *et al.,* 1995). Anatomical studies demonstrate that excitatory input is derived primarily from the thalamus (Meredith and Wouterlood, 1990; Lapper and Bolam, 1992) and is mediated in part by NMDA, AMPA, and mGluR receptors (Testa *et al.,* 1994; Landwehrmeyer *et al.,* 1995; Gotz *et al.,* 1997; Testa *et al.,* 1998; Pisani *et al.,* 2002). However, physiological examination of these cells also shows a cortical influence (Wilson *et al.,* 1990). The cholinergic interneurons have a complex relationship with the medium spiny projection cells, both receiving input from and projecting to them. Synaptic inputs from the medium spiny cells to the cholinergic cells terminate primarily onto the dendritic shafts and spines (Bolam *et al.,* 1986). Although synaptic inputs to the medium spiny cells from the cholinergic cells terminate onto cell bodies, they primarily target the dendritic shafts and spines (Izzo and Bolam, 1988). The cholinergic cells also receive dopaminergic input and have high expression levels of both the D_2 and D_5 receptor subtypes (Surmeier *et al.,* 1996). The central role for the functional balance between dopaminergic/cholinergic populations is well documented in both Parkinson's disease and in experimental animal models. Indeed, it had been assumed for some time that the cholinergic interneurons received direct input from the dopamine-containing fibers. However, more recently it has been demonstrated that while there is a direct input to the cholinergic cells, mostly mediated via D_2 receptors, much of the dopamine and cholinergic interaction likely takes place via converging inputs onto MSN (Lehmann and Langer, 1983; Kubota *et al.,* 1987; Chang, 1988b; Izzo and Bolam, 1988; Kawaguchi *et al.,* 1995).

The cholingergic interneurons are marked by their characteristic, spontaneous firing pattern and are referred to as tonically active neurons (TANs; Wilson *et al.,* 1990; Aosaki *et al.,* 1995). This firing pattern was observed in awake behaving primates in which pauses in the spontaneous cell firing occurred in conjunction with rewarded visuomotor behavioral tasks (Crutcher and DeLong, 1984a; Kimura *et al.,* 1984; Liles, 1985; Apicella *et al.,* 1991a). Tonically active neurons are thought to be involved in the detection of stimuli that have inherent motivational significance. These neurons respond to stimuli that have been conditioned, through behavioral training, to be associated with the delivery of primary rewards (Kimura *et al.,* 1984; Aosaki *et al.,* 1994b; Apicella *et al.,* 1997; Ravel *et al.,* 2001). In contrast to the membrane properties responsible for the physiological (up and down) states of the MSN, which are controlled in large part by extrinsic connections, the tonically active neurons' spontaneous firing patterns are by and large a function of the intrinsic membrane properties of the cholinergic cells (Bennett and Wilson, 1999; Bennett *et al.,* 2000). These properties are modified by synaptic inputs, which are influential in the temporal regulation of spikes sequences (Aosaki *et al.,* 1994b; Raz *et al.,* 1996). Unlike the MSN, tonically active neurons require relatively few extrinsic synaptic inputs to directly influence their spiking pattern (Wilson *et al.,* 1990).

The fifth class of interneurons includes small neurons with variable dendritic morphology that have only rarely been described. Nonetheless these may be

more prevalent in the human striatum than in other species (Graveland *et al.*, 1985). They have an average equivalent diameter of 10 µm, with aspiny to sparsely spiny moderate branching dendrites, which extend up to 130 µm from the soma. Axons are very fine and have few branches, which remain close to the parent soma. These cells in humans appear somewhat different from their closest counterpart in the monkey (Aspiny type III; DiFiglia *et al.*, 1976). The latter neurons have a more elaborate arborization, while in the human, axons for small cells were often absent, although failure to impregnate the axon could not be excluded. In this context it should be mentioned that in the primate, but not in the rat, significant numbers of small (8–12 µm) dopaminergic neurons have been reported at the dorsal, lateral, and ventral borders of the caudate and putamen (De la Torre, 1972; Felten and Sladek, 1983; Kohler *et al.*, 1983; Dubach *et al.*, 1987; Pearson, 1990).

Finally, Braak and Braak (1982) identified an additional large aspiny cell type (their type III), having long thick radiating dendrites and few branches. These cells are most probably not striatal, but rather are pallidal neurons that invade striatal territory (Haber, 1987; Heimer *et al.*, 1999).

Microcircuitry of the Striatum

The medium spiny neuron is the main target of extrinsic inputs to the striatum. The specificity of these inputs, derived from the cortex, thalamus, and brain stem and their spatial relationship to each other, in addition to interneuron contacts onto the spiny cells, dictates how projection neurons modify cortical information that passes through the basal ganglia. Present evidence suggests that, even though cortex and thalamus do project onto the spines and dendrites of the medium spiny cells, they may not terminate onto the same cells. The location of these glutamatergic synapses varies, with the cortex primarily terminating onto the heads of the spines and the thalamus primarily onto dendritic shafts (Dubé *et al.*, 1988; Smith and Bolam, 1990; Smith *et al.*, 1994b; Wang and Pickel, 2002). Tyrosine hydroxylase (TH)-positive terminals (presumably dopaminergic) also terminate onto both spines and shafts. Electronmicroscopic studies indicate that the dopaminergic terminals are optimally positioned relative to cortical afferent projections to specifically modulate cortical influence (Bouyer *et al.*, 1984b; Wang and Pickel, 2002). For example, cortical terminals are often found on the heads of spines, and dopaminergic terminals are found nearby, but on the dendritic shafts (Bouyer *et al.*, 1984a, b; Dubé *et al.*, 1988; Smith *et al.*, 1994b) (Fig. 21.13). The relationship between dopamine and thalamic terminals is less clear. However, the complexity of glutamatergic and dopaminergic interaction is further emphasized by ultrastructural studies that indicate DA release may be modulated by NMDA receptors (Gracy and Pickel, 1996).

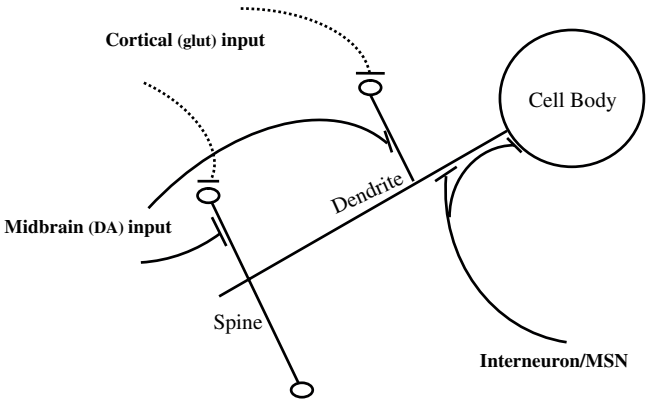

FIGURE 21.13 Schematic illustrating the arrangement of synaptic inputs to the medium spiny neurons. Cortical inputs generally terminate distal to the midbrain dopaminergic (DA) inputs. Interneurons and medium spiny neurons terminate closer to the cell body.

As mentioned earlier, in addition to extrinsic inputs, the medium spiny cells receive specific intrinsic inputs from the aspiny interneurons that terminate onto dendritic shafts, spines, and soma of medium spiny neurons (Izzo and Bolam, 1988). These synapses have an intricate relationship with dopaminergic inputs onto the medium spiny cells indicating a complex cholinergic-dopamine balance in mediating medium spiny neuron response. Finally, the medium spiny neurons receive input from other medium spiny cells (Aronin *et al.*, 1986; Bolam and Izzo, 1988; Pickel and Chan, 1990; Yung, 1996). Since most of the striatal cells (both interneurons and medium spiny neurons) use GABA and are considered inhibitory, their connections to the nearby projection neurons would theoretically indicate lateral inhibition. Little direct evidence has supported this concept (Jaeger *et al.*, 1994), so this remains an unsolved issue (Tunstall *et al.*, 2002).

The ability to record from single striatal cells, the cloning of receptor subtypes, and the development of selective receptor agonists and antagonists have lead to a greater appreciation of how receptor subtypes generate and modulate striatal firing activity. Furthermore, the ability to isolate and manipulate multiple ion channels has provided a clearer picture of how ionic conductances are modulated by a combination of voltage-dependent and ligand-dependent mechanisms to determine ultimately the spiking pattern of the projection cells. In particular, it is now realized that the idea that receptors either depolarize (excitatory response) or hyperpolarize (inhibitory response) is far

too simplistic. Rather, most postsynaptic responses to transmitter release onto MSN are complex and form part of a highly integrative system that ultimately will help determine the conditions under which the cell may fire. Indeed, many of the receptor subtypes do not inherently affect resting potential. In other situations, the postsynaptic response of a receptor may differ depending on other events taking place in the membrane. The D_1 receptor provides an excellent example of this phenomenon. D_1 activation can alter ion channel properties such that when the MSN is in a down-state, it is more difficult to transit into the up-state. However, if the MSN is in the up-state, then D_1 activation can enhance evoked activity. A similar case is made for the muscarinic receptors, in that they can affect synaptic transmission by altering various ion conductances (for reviews of these interactions, see Wilson, 1998; Calabresi *et al.,* 2000b; Nicola *et al.,* 2000).

Compartmentation of the Striatum

While overall the striatum was thought to be a relatively homogenous structure, it is now known that striatal neurons do form clusters, referred to as cell islands (Goldman-Rakic, 1982). Furthermore, histochemical and tracing studies demonstrate discontinuities in transmitter-related molecules, and of afferent terminal distribution patterns (Künzle, 1975; Goldman and Nauta, 1977; Jones *et al.,* 1977; Yeterian and Van Hoesen, 1978; Graybiel and Ragsdale, 1980). These patterns have formed the basis for many studies to investigate how these clusterings of cells, molecules, and terminals may be related to each other in an attempt to determine their functional significance. One of the first markers used to identify compartments chemically was acetylcholinesterase (AChE). AChE-poor striatal regions (termed striosomes) are surrounded by a densely stained 'matrix' (Graybiel and Ragsdale, 1978). The striosomes, embedded in the AChE-rich matrix, correspond to opiate receptor patches as well as to several other transmitter-related compounds (Kunzle, 1975; Künzle, 1977; Kalil, 1978; Herkenham and Pert, 1981; Ragsdale and Graybiel, 1981; Haber and Elde, 1982; Kelley *et al.,* 1982; Graybiel, 1983; Gerfen, 1984; Graybiel, 1984; Herkenham *et al.,* 1984; Gerfen, 1985; Donoghue and Herkenham, 1986; Joyce *et al.,* 1986; Gerfen, 1987; Gerfen *et al.,* 1987; Besson *et al.,* 1988; Gerfen, 1988; Groves *et al.,* 1988; Faull *et al.,* 1989; Zahm, 1989; Graybiel, 1990; Haber and Lu, 1992; Voorn *et al.,* 1994; McFarland and Haber, 2001). Within the striatum, the shape and extent of dendrites of some types of striatal neurons may be restricted by the size and shape of the striatal compartment in which they are found as well as by the proximity of individual cells to the borders of such compartments (Gerfen, 1985; Penny *et al.,* 1988). In contrast, the dendrites of large striatal interneurons (presumably cholinergic cells) readily cross striosomal/matrix boundaries, as do the medium-sized aspiny interneurons (medium-sized aspiny neurons). Thus, these interneurons may help to bridge compartments (Gerfen, 1984; Gerfen, 1985; Chesselet and Graybiel, 1986; Bolam and Izzo, 1988). This suggests that interneurons may function as assemblies that may have a greater impact on particular striatal channels than if these cells were randomly scattered throughout striatal areas. While several hypotheses have been put forth concerning the significance of the compartmental organization in the striatum, it continues to present a challenge in understanding the functional significance of this complex arrangement. For a review of this organization in primates and humans see Faull *et al.* (1989), Martin *et al.* (1993), Selden *et al.* (1994), Selemon *et al.* (1994), Ikemoto *et al.* (1995), Holt *et al.* (1996), and Holt *et al.* (1997).

Unique Features of the Ventral Striatum

Unique Cell Groups

The relative distribution of various striatal cell types differs somewhat between the dorsal and ventral striatum, with greater frequency of small neurons in the ventral striatum (Meyer *et al.,* 1989). The density of small cells is highest in the "fundus striati," while the density of large cells is lowest. Some of this difference may be attributed to the presence of the islands of Calleja in ventral striatal areas (see following discussion). However, clusters of smaller neurons outside the islands, while also found in the dorsal striatum, are particularly frequent in the ventral striatum (e.g., see Chronister *et al.,* 1981; Hedreen, 1981).

Embedded within parts of the ventral striatum are the islands of Calleja or cell islands, identifiable in all mammalian species by their dense core of granule cells (Fallon *et al.,* 1978; Fallon *et al.,* 1983; Meyer *et al.,* 1989). The largest island, Calleja Magna, forms the medial border of the nucleus accumbens. Additional, albeit smaller, islands (referred to as interface islands by Heimer *et al.,* 1999) are located in the basal forebrain in primates, including humans. These are found close to substance-P- and enkephalin-positive ventral pallidal fibers. The islands themselves also contain cholinergic, dopaminergic, and serotonergic fibers and terminals; epidermal growth factor (Fallon *et al.,* 1984) substance P; and glutamic acid decarboxylase (Fallon *et al.,* 1983; Oertel and Mugnaini, 1984; Young III *et al.,* 1984; Mugnaini and Oertel, 1985; Mai *et al.,* 1986; Pioro *et al.,* 1993). In addition, they also have estrogen and gonadotrophic hormone releasing hormone receptors (Fallon, 1983; Fallon *et al.,* 1983; Phelps and Vaughn,

1986). Together, these features have led to the suggestion that the islands may function as a type of "endocrine striatopallidal system." The granule cells in the islands are some of the smallest neurons in the brain (5–10 μm), which are nearly spherical and give rise to thin, mostly spine-sparse dendrites that are generally restricted to the island (Fallon *et al.*, 1978; Meyer and Wahle, 1986; Millhouse, 1987). There is an additional population of granule cells with spiny dendrites (Millhouse, 1987). Electron microscopic studies in rats show that some of these make "ephatic" junctions (Ribak and Fallon, 1982), which allow coupling of adjacent neurons in order to synchronize firing. In support of this morphological evidence that cells in the ventral striatum may communicate via gap junctions, Halliwell and colleagues recently demonstrated that these cells were physiologically coupled. Furthermore, the D3 receptor activation enhances gap junction in granule cells (Halliwell and Horne, 1998). The granule cells of the islands are arranged in a cuplike cluster with invaginations called the hilar area. Adjacent to the granule cells are striatal MSNs, whose dendrites invade the granule cell clusters. These cells stain positively for substance P and enkephalin (Fallon *et al.*, 1978; Fallon *et al.*, 1983; Millhouse, 1987). Although the connections of the islands of Calleja have been difficult to elucidate, ascending afferents include the dopamine, serotonin, and norepinephrine fibers from the substantia nigra, locus coeruleus, and dorsal and median (central superior) raphe nuclei of the brainstem (Azmitia and Segal, 1978; Fallon, 1978; Fallon *et al.*, 1978; Beckstead, 1979; Steinbusch *et al.*, 1981; Kohler *et al.*, 1982; Fallon, 1983; Bjorklund and Lindvall, 1984; Voorn *et al.*, 1986). It has been difficult to demonstrate projections for the granular cells beyond the immediate district of the cell cluster, and projections are thought to be limited to the dendrites that penetrate the islands from striatal cells.

Striatal cells located in and adjacent to the hilar regions stain positively for cholinergic markers and may account for the cholinergic innervation of granule cell clusters (Fallon *et al.*, 1983; Mesulam and Mufson, 1984; Young *et al.*, 1984; Phelps and Vaughn, 1986). Of particular interest is the fact that the cells in the islands are thought to contain quiescent immature cells that remain in the adult brain (Bayer, 1985; Meyer *et al.*, 1989; Heimer, 2000). In support of this idea, studies show that bcl-2 protein, a potent inhibitor of neuronal apoptosis (Zhong *et al.*, 1993; Farlie *et al.*, 1995) and promoter of axonal outgrowth and differentiation (Chen *et al.*, 1997), marks these islands (Bernier and Parent, 1998). Bcl-2 is most abundant in fetal neurons but persists in limited regions of the adult primate brain (Bernier and Parent, 1998; Yachnis *et al.*, 2000). One of the most prominent subcortical regions containing bcl-2 is the granular islands embedded within the ventral striatum. In addition to the small, immature-appearing bcl-2-positive cells, there are patches of larger size, more differentiated bcl-2-positive medium spiny cells within the ventral striatum (VS), at the border of the shell and core (Bernier and Parent, 1998; Fudge *et al.*, 2002).

The Shell and Core of the Ventral Striatum. Recently, a subterritory of the ventral striatum, the shell region, has been identified in rodents dividing the ventral striatum into two parts—a medial/ventral shell region and a central core region (Zaborszky *et al.*, 1985). Experiments aimed at delineating the functional significance of these two regions have been instrumental in understanding the circuitry underlying goal-directed behaviors, behavioral sensitization, and changes in affective states. Studies in rodents have been particularly important in demonstrating the organization of the shell and core and their relationship to distinct ventral striatal afferent and efferent projections. These studies provide critical information on how interactions between specific transmitter/receptor pathways mediate the transition between motivating stimuli and motor outcome (Heimer *et al.*, 1991b; Zahm and Brog, 1992; Brog *et al.*, 1993; O'Donnell and Grace, 1993; Pennartz *et al.*, 1994; Groenewegen *et al.*, 1996). While several transmitter and receptor distribution patterns distinguish the shell/core subterritories, lack of calbindin-positive staining is the most consistent marker for the shell across species (Meredith *et al.*, 1996).

In primates as in rodents, the ventral striatum is divided into two territories: the inner core which is calbindin-rich, and the outer crescent-shaped shell, which is calbindin-poor. Although a calbindin-poor region marks the subterritory of the shell, staining intensity of other histochemical markers varies both within the shell and in distinguishing it from the core. These markers include enkephalin; acetylcholinesterase; neurotensin; the μ opiate receptor; the growth associated protein, GAP-43; the AMPA subunits, GluR1, GluR2/3 & GluR4; the dopamine transporter; and serotonin (Haber and McFarland, 1999b) (Fig. 21.14). In general, compared to the core, the shell is rich in GluR1, GAP-43, acetylcholinesterase, μ receptor binding, serotonin, and Substance P (Alheid and Heimer, 1988; Martin *et al.*, 1991; Martin *et al.*, 1993; Hurd and Herkenham, 1995; Ikemoto *et al.*, 1995; Voorn *et al.*, 1996). Substance P is distributed in patches throughout the striatum, but it is particularly dense in the shell. Acetylcholinesterase is very dense in the medial part of the shell. More laterally, however, the

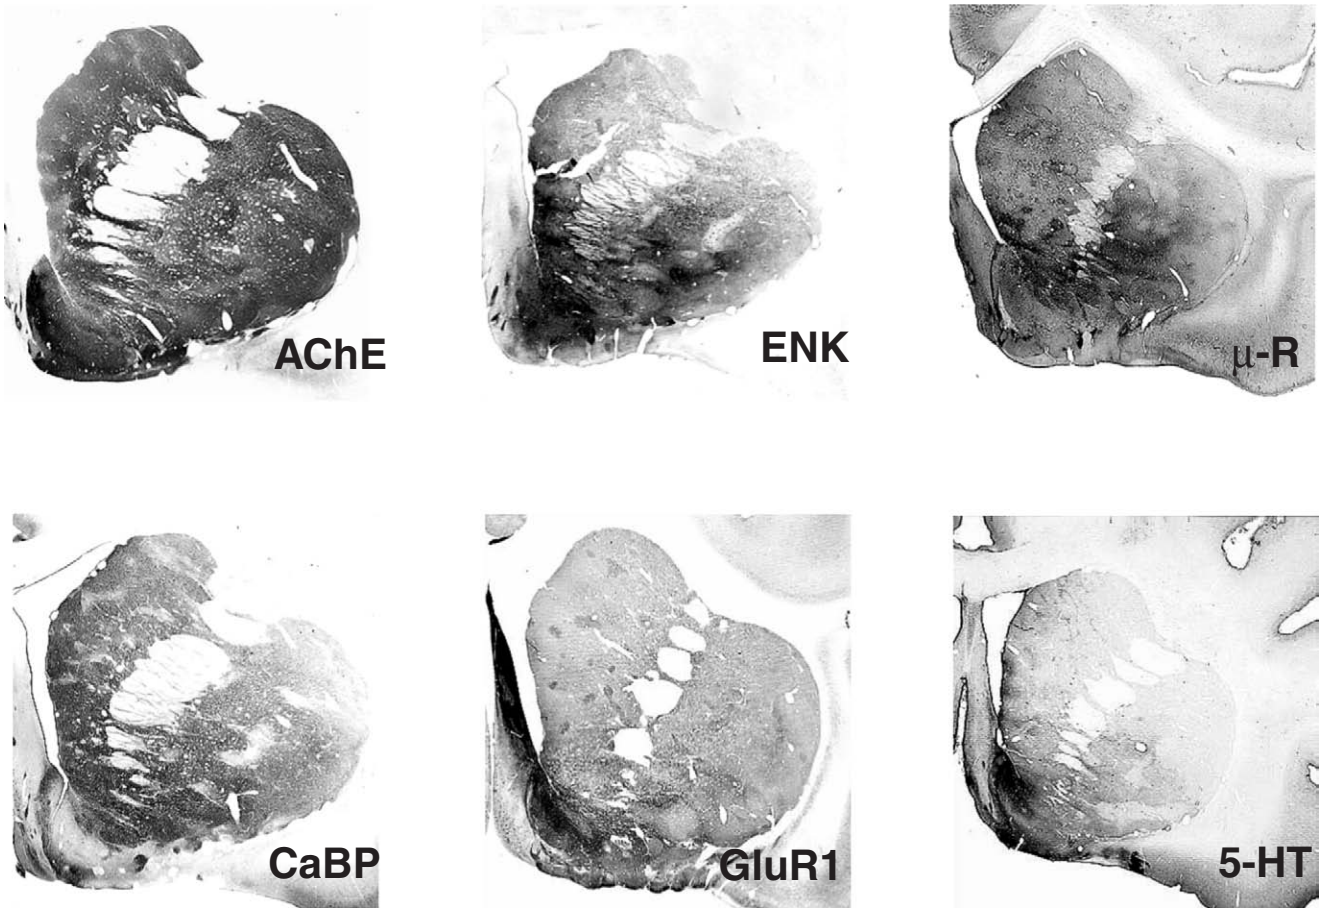

FIGURE 21.14 Photomicrographs of the striatum at the level of the shell and core, immunostained for various transmitter-related molecules. AchE, acetylcholinesterase; ENK, enkephalin; CaBP, calbindin-28; GluR1,GluR1 AMPA receptor subunit; μ-R, μ-opiate receptor; 5-HT, serotonin.

staining blends into the core and becomes indistinguishable from that observed in the remainder of the ventral striatum. Immunoreactivity for neurotensin is relatively low throughout the striatum; however, staining is dense in the medial rim of the shell. Enkephalin immunoreactivity is patchy throughout the striatum and does not show a remarkable differential pattern between the shell and core. Serotonin staining is dense in shell, with the highest immunoreactivity in the medial dorsal portion. The dopamine transporter is relatively low throughout the ventral striatum including the core. This pattern is consistent with the fact that the dorsal tier dopamine neurons express relatively low levels of mRNA for the dopamine transporter compared to the ventral tier (Haber *et al.*, 1995a). While GAP-43 immunoreactivity is found throughout the adult striatum, the shell region stands out with the strongest antisera reaction. The μ receptor distribution is dense but patchy in the ventral striatum. There are dense patches in the medial and ventral shell, with the remainder remarkably free of receptor. In contrast, the core shows numerous patches of immunoreactivity that extend into the medial wall of the ventral caudate. Most of the excitatory amino acid receptors do not distinguish the dorsal striatum and ventral striatum. However, the AMPA receptor subunits do. The GluR1 subunit shows particularly dense immunoreactivity in the shell, with patches of reactivity in the core. In contrast, the GluR4 subunit shows weaker immunoreactivity in the shell than in the rest of the striatum. Taken together, neurotransmitters and receptors help distinguish the ventral and medial borders of the ventral striatum and the shell/core subterritories within it. However, the dorsal and lateral boundaries are more problematic. Here, the ventral striatum merges imperceptibly with the dorsal striatum (see Fig. 21.14).

Afferent Projections of the Ventral Striatum. Finally, while the basic cortical BG loop is similar in all BG

circuits, the ventral striatum alone receives an additional subcortical input from the amygdala and from the hippocampus, for which there is no comprable input to the other basal ganglia territories (Russchen *et al.*, 1985; Fudge *et al.*, 2002) (see Fig. 21.22B).

The Pallidal Complex

Internal Structure, Morphology, and Organization of the Globus Pallidus

The primate globus pallidus forms the most medial cone-shaped portion of the lentiform nucleus for which the putamen forms a cap. In primates, the pallidum lies laterally to the internal capsule and appears as a very pale area in Nissl stains when compared to adjacent striatum. The globus pallidus is separated in part from the putamen by the external medullary lamina, a band of myelinated fibers capping the lateral aspects of globus pallidus (see Fig. 21.3). Dorsolaterally, pallidal neurons are, in general, confined within the border formed by the external medullary lamina, although occasional dendrites may extend into the putamen, and the possibility remains that occasional ectopic pallidal neurons may be found entirely within the striatum (see the previous discussion of striatal cell types). The ventral and rostral limit of the pallidum has been more difficult to define. Pallidal cells are often scattered in an interconnected network in basal forebrain that reaches quite near to the ventral surface of the brain.

The primate globus pallidus is divided by the internal medullary lamina into two zones—the external and internal pallidal segments. In most nonprimate mammalian species the internal pallidal segment extends into the internal capsule so that the bulk of neurons comprising this segment are completely surrounded by capsular fibers to form the entopeduncular nucleus. The distinction between the two segments of the dorsal pallidum can also be visualized with substance P and enkephalin immunohistochemistry (Haber and Elde, 1981)(Fig. 21.15A, B). As mentioned earlier, the internal segment receives striatal input from cells that express primarily substance P, while the external segment receives input from striatal cells that express primarily enkephalin (Del Fiacco *et al.*, 1982; Haber, 1986; Mai *et al.*, 1986; Reiner *et al.*, 1999). In primates, including humans, the separation of these two peptides into the two pallidal segments is not complete. Rather, the external segment contains substance P-positive immunoreactivity along the medial boundary. Likewise, enkephalin immunoreactivity is found in the medial portion of the internal segment (Haber and Elde, 1981; Haber, 1986; Reiner *et al.*, 1999). In humans, some cells of the internal segment may also be found embedded within the ventral portions of the internal capsule, although these might alternatively be considered rostral elements of the pars reticulata substantia nigra (Francois *et al.*, 1987). The internal pallidal segment is further divided into lateral and medial portions by an accessory medullary lamina produced by vertically running fibers of the ansa lenticularis. Furthermore, within the medial part of the internal pallidal segment in the human, a small, posteromedially located zone might be distinguished from the remainder of the internal pallidal segment by an absence of substance-P immunoreactivity. This

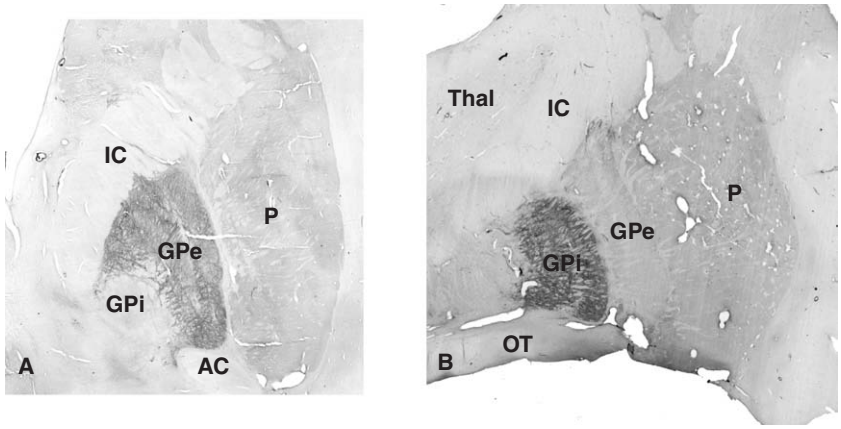

FIGURE 21.15 Photomicrographs of coronal sections through the human globus pallidus demonstrating the different distribution patterns of enkephalin and substance P immunostaining in the external and internal segments, respectively. **(A)** Enkephalin immunostaining of the globus pallidus external segment. **(B)** Substance P immunostaining of the globus pallidus internal segment. cone-shaped posteromedial subdivision, which in a sense could represent a fourth division of the globus pallidus, occurs in an area with somewhat increased density of myelinated fibers. The pattern of substance-P immunoreactivity demarcates this area in humans (see Mai *et al.,* 1986). Significant amounts of neurotensin immunoreactivity are also found in this posteromedial portion of the internal pallidal segment in humans (Michel *et al.,* 1986), which may correspond to similar intrapallidal neurotensin-rich territories noted in rodents (Uhl, 1982; Zahm and Heimer, 1988). The ability to divide the internal pallidal segment into several subdivisions may reflect the fact that projection neurons within this nucleus are more or less segregated based on their targets. Indeed, as we will see later, the topography of these output neurons to their targets is functionally arranged such that cortical representations in the striatum continue to be represented in the pallidal outputs to the subthalamus, thalamus, and brainstem (Carpenter, 1976; Parent, 1979; Carpenter *et al.,* 1981b; Parent and De Bellefeuille, 1982; Parent, 1986; Haber *et al.,* 1993; Hoover and Strick, 1993; Kayahara and Nakano, 1996; Arecchi-Bouchhioua *et al.,* 1997; Hoover and Strick, 1999; Sidibe *et al.,* 2002).

The cellular morphology of neurons in the globus pallidus is more uniform than that of the striatum. The globus pallidus is primarily made of relatively large, quite distinctive cells (20–60 μm) with triangular or polygonal cell bodies giving rise to thick, sparsely spined, poorly branching dendrites (Fox *et al.,* 1974; Schwyn and Fox, 1974; Iwahori and Mizuno, 1981; DiFiglia *et al.,* 1982a; Yelnik *et al.,* 1984; Braak and Braak, 1986). These dendrites are impressive, sometimes creating dendritic radii in excess of 2 mm in their principal plane with the very distal portions often branching elaborately to form complex dendritic endings (DiFiglia *et al.,* 1982a; Francois *et al.,* 1984b; Difiglia and Rafols, 1988). Complex dendritic endings appear to be more common in the external pallidal segment and in the substantia nigra than in the internal pallidal segment (Francois *et al.,* 1984b). The physiological significance of these specialized dendrites is not understood, although it has been suggested that they may contribute to local synapses between neighboring pallidal neurons (Francois *et al.,* 1984b; Yelnik *et al.,* 1984; Shink and Smith, 1995). Another feature of many large pallidal (and substantia nigra, pars reticulata) neurons, which is more frequently observed in humans than in nonhuman primates, is the fine, beaded, generally unbranched axonal-like processes originating at irregular intervals from pallidal dendrites. These extend for moderate distances (mean, 82 μm pallidum; 79 μm pars reticulata) and, in some instances, appear to contact the soma or dendrite of adjacent neurons (Francois *et al.,* 1984b; Yelnik *et al.,* 1987). As with the complex endings of pallidal cells, these thin processes appear to be more frequent within the lateral pallidal segment than in the medial segment (Francois *et al.,* 1984b).

The dendrites in the globus pallidus appear as a disclike territory oriented perpendicular to incoming striatal fibers. Thus each pallidal cell intercepts efferents originating in a column of striatal cells (Percheron *et al.,* 1984a, b). A significant feature of pallidal dendrites is their dense innervation by synapses, which at the electron microscopic level can be seen to cover the entire dendrite (Fox *et al.,* 1974; Schwyn and Fox, 1974; DiFiglia *et al.,* 1982a; Hassler and Chung, 1984; Difiglia and Rafols, 1988). The majority of these synapses represent striatopallidal terminals. Myelinated striatofugal axons cross perpendicular to pallidal dendritic fields and send thin unmyelinated collaterals parallel to pallidal dendrites with which they repeatedly synapse (Difiglia and Rafols, 1988). These axons and their dense field of terminal boutons in pallidal areas are immunopositive for either enkephalin (GPe) or substance P (GPi) (DiFiglia *et al.,* 1982b; Haber and Nauta, 1983; Chang, 1988a; Haber *et al.,* 1990a). The unique pattern of striatopallidal innervation as seen with peptide-postive staining has been termed "wooly fibers" and has been used to define the rostral and ventral extent of the ventral pallidum in rats and primates (Haber and Nauta, 1983; Haber, 1986; Haber *et al.,* 1990a; see discussion that follows).

Although the large cells account for the majority of pallidal neurons, there are other cell types that have been identified using Golgi and Nissl preparations. One type are small "microneurons" with few short thin dendritic processes. Another identified cell type is somewhat larger cells than the microneurons (15–21 μm) with more slender dendrites than the principal pallidal cells and shorter local axons. These two cell types presumably represent interneurons (Francois *et al.,* 1984b). A final cell type observed in the monkey but not in the human was intermediate in size between the small and large pallidal cells (23–34 μm) with slender but long radiating dendrites (Francois *et al.,* 1984b).

Ventral Pallidum

The pallidum, like the striatum, also extends ventrally, below the anterior commissure and into the anterior perforated space (see Fig. 21.2). This ventral extension of the globus pallidus was identified based on histological criteria and found to receive its primary input from the ventral striatum (Heimer, 1978). While determining the extent of the ventral

pallidum in normal Nissl and fiber stains is somewhat problematic, substance-P and enkephalin immunoreactivity are particularly useful for determining its boundaries and extent (Haber and Elde, 1981; DiFiglia *et al.*, 1982b; Haber and Nauta, 1983; Beach and McGeer, 1984; Haber and Watson, 1985; Mai *et al.*, 1986). In particular, the morphology of the peptide-stained fibers bears a stricking resemblence to Golgi-impregnated pallidal fibers (Fox *et al.*, 1974; Haber and Nauta, 1983). These fibers, which appear as tubular-like structures and are also referred to as wooly fibers, demonstrate the continuity of the dorsal and ventral pallidum. The ventral pallidum not only extends ventrally, but also rostrally to invade the rostral and ventral portions of the ventral striatum, sending finger-like extensions into the anterior perforated space. In addition, other histochemical markers such as endogneous iron demonstrate the continuity of the dorsal and ventral pallidum (Francois *et al.*, 1981; Switzer *et al.*, 1982; Alheid and Heimer, 1988; Dwork *et al.*, 1988). The ventral pallidum has common features of both the external and internal segments. It contains both enkephalin- and substance P-positive fibers, which, in turn, project to the STh and thalamus, respectively (Haber and Watson, 1985; Mai *et al.*, 1986; Russchen *et al.*, 1987; Haber *et al.*, 1990a; Haber *et al.*, 1993). Based on the preceding tracing and immunohistochemical studies in primates, the external pallidal component of the ventral pallidum lies ventral and rostral to the external segment. The internal segment component of the ventral pallidum lies primarily in the medial and rostral portion of the internal segment proper. In the human brain, the ventral pallidum extends far into the anterior perforated space, where the structure appears to be rapidly broken up into an interconnected lacework of pallidal areas, interdigitating with striatal cell islands and microcellular islands, including possibly deep islands of Calleja. In sagittal sections, the human ventral pallidum appears to be displaced somewhat more caudally by the nucleus accumbens than seems to be the case in the nonhuman primate. The realization and subsequent support of the concept of the ventral pallidum and striatum served to simplify the structural analysis of ventral forebrain (Heimer and Wilson, 1975; Heimer, 1978; Switzer *et al.*, 1982; Haber and Nauta, 1983; Haber *et al.*, 1985; Heimer *et al.*, 1985, 1987; Alheid and Heimer, 1988; Zahm and Brog, 1992). Thus, a large portion of the rostral forebrain that includes rostral, subcommissural substantia innominata can now be viewed as more or less continuous extensions of the better known dorsal striatopallidal complex.

Circuitry of the External, Internal, and Ventral Pallidum

While the projections of the two pallidal segments GPe and GPi (and the comprable parts of the ventral pallidum) differ, their main input is derived from the striatum (Fig. 21.16). In addition to this GABAergic striatal input, there is the well-characterized glutamatergic input from the STh nucleus to all palldial components (Nauta and Cole, 1978; Carpenter *et al.*, 1981a, b; Smith and Parent, 1988; Smith *et al.*, 1990; Hazrati and Parent, 1992a; Joel and Weiner, 1997). Terminals from STh intermingle with the much greater GABAergic innervation from the striatum (Shink and Smith, 1995). Striatal input to the GPi synapse all along the thick dendrites (Shink and Smith, 1995). All three glutamate receptor families are found in the pallidum. As observed in the striatum, the subunit composition of these receptors dictates the specific membrane properties. For example, AMPA receptors with high Ca^{2+} permeability are found in the globus pallidus (and the STh) in contrast to those with low Ca^{2+} permeability found in the medium spiny neurons of the striatum (Gotz *et al.*, 1997). Of particular interest is

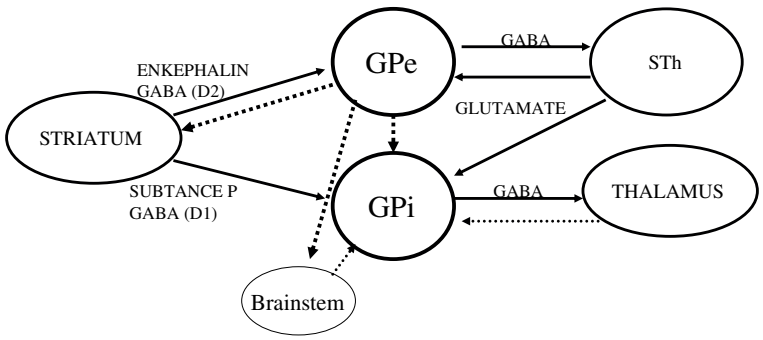

FIGURE 21.16 Diagram demonstrating the connections of the globus pallidus. The main connections (solid lines) and less prominent connections (dotted lines) are indicated. GPe, globus pallidus external segment; GPi, globus pallidus internal segment; STh, subthalamic nucleus.

the fact that glutamatergic receptors (metabotropic receptors) are found not only at postsynaptic specializations of asymmetric synapses but also at postsynaptic specializations of symmetric synapses, presummably formed by striatal GABAergic terminals. Hanson and Smith raised the interesting possibility that one role of these metabotropic receptors may be in modulating the GABAergic input from the striatum (Hanson and Smith, 1999). In addition to afferent input from the striatum and STh, the GPi also receives input from the GPe, which terminates close to, or on the somata (Hazrati *et al.,* 1990a; Shink and Smith, 1995; Smith *et al.,* 1998b). Other inputs to the GPi (and parts of the VP) are derived from the thalamus, brainstem pedunculopontine nucleus, and midbrain dopaminergic cells (Shink *et al.,* 1997; Francois *et al.,* 2000; Fig. 21.16).

It is important to remember that all pallidal neurons use GABA as their transmitter (Smith *et al.,* 1987; Ilinsky *et al.,* 1997). Projection fibers from the GPi are divided into three bundles—the ansa lenticularis, lenticular fasciculus, and pallidotegmental fibers (Nauta and Mehler, 1966; DeVito and Anderson, 1982). Fibers in the ansa lenticularis arise from the outer portion of the GPi, forming a clearly defined bundle that sweeps ventromedially and rostrally, around the internal capsule and continuing caudally to merge with Forel's field H. Fibers of the lenticular fasciculus arise from the medial portion of the GPi, traverse the internal capsule, and form a discete bundle, ventral to the zona incerta. This bundle joins the ansa lenticularis in Forel's field H and both fiber groups than become part of the thalamic fasciculus to terminate in different thalamic nuclei (Kuo and Carpenter, 1973; Carpenter, 1976). These projections are topographic in that they maintain their functional integrity in the thalamus. Thus, information carried via the two efferent fiber bundles is thought to differ somewhat functionally (Kuo and Carpenter, 1973; Carpenter, 1985; Baron *et al.,* 2001). The regions of the pallidum that receive sensorimotor-related input from the striatum project to the ventrolateral thalamic nucleus; those that receive input from association areas of the striatum project to the ventral anterior thalamic nucleus and mediodorsal nuc. of the thalamus, and those that receive input from limbic striatal regions (including the internal segment portion of the ventral pallidum) project to the mediodorsal nuc. and the lateral habenular nuc. (Kuo and Carpenter, 1973; DeVito and Anderson, 1982; Parent and De Bellefeuille, 1982; Haber *et al.,* 1985; Russchen *et al.,* 1987; Inase and Tanji, 1994, 1995; Kayahara and Nakano, 1996; Sidibe *et al.,* 1997; Hoover and Strick, 1999; Sakai *et al.,* 2000). GPi fibers projecting to the thalamic relay nuclei also give off collaterals that terminate in the intralaminar nuclei, the centromedian and parafasicular nuclei (Kuo and Carpenter, 1973; Kim *et al.,* 1976; Parent *et al.,* 2001). The third fiber bundle arising from the GPi, the palllidotegmental fibers, terminates in the pedunculopontine nuc. (Shink *et al.,* 1997). Recent studies using single cell reconstruction demonstrate that there appear to be at least two types of pallidal projection cells. Type I cells, which are centrally located and quite abundant and project to the pedunculopontine tegmentum, give off collateral branches that ascend and also terminate in the thalamus, in both the relay nuclei and in the intralaminar group. Type II cells project to the lateral habenular nucleus (Parent *et al.,* 2001). Pallidal fibers entering the thalamus give off several collaterals that form branches that terminate primarily onto the soma and proximal dendrites of thalamic projection cells. In addition, some synaptic contact is also made with local circuit neurons. This terminal organization indicates that, while pallidal projections to the thalamus are primarily inhibitory on thalamic relay neurons cells, they may also function to disinhibit projection cells via the local circuit neurons (Arecchi-Bouchhioua *et al.,* 1997; Ilinsky *et al.,* 1997). While projections from the GPi to the ventral tier nuclear group of the thalamus have been considered to be segregated from cerebellar inputs to the thalamus, recent evidence suggests that there may be some overlap between them (Middleton and Strick, 1994; Sakai *et al.,* 1996; Hoover and Strick, 1999; Sakai *et al.,* 2000).

The external segment of the globus pallidus projects primarily to the STh via the subthalamic fasciculus, a fiber system that carries both pallidosubthalamic axons and subthalamopallidal fibers (Fig. 21.16). However, in addition, this pallidal segment also projects to the striatum, the internal pallidal segment, and the midbrain. In addition, terminals have also been found from the GPe to synapse in the reticular nuc. of the thalmaus. As observed with the internal segment, these projections are also topographically organized to maintain functional continuity within the target structures (Kim *et al.,* 1976; DeVito and Anderson, 1982; Parent and DeBellefeuille, 1983; Hazrati *et al.,* 1990a; Hazrati and Parent, 1991; Haber *et al.,* 1993; Asanuma, 1994; Smith *et al.,* 1994a; Shink *et al.,* 1996; Sato *et al.,* 2000a). Neurons in the GPe segment have been further classified according to their projection target: those that target the STh and the SNR; those that target the internal segment and the STh; those that target the STh and SNR, and those that target the striatum (Sato *et al.,* 2000a). In general, projections from the GPe, as with the output from the GPi, terminate on the soma or proximal dendrites of its target sites. The two pallidal segments are central to the concept of the direct and indirect pathways through the basal

ganglia. As a result, teasing apart the complexity of these pallidal pathways has been an important avenue of research (see the section on "The Direct and Indirect Basal Ganglia Pathways").

Pallidal neurons are very tonically active cells. GPe and GPi have different firing patterns as indicated in nonhuman primate and human studies (DeLong, 1971; Georgopoulos *et al.*, 1983; DeLong *et al.*, 1985; Mitchell *et al.*, 1987; Filion and Tremblay, 1991; Mink and Thach, 1991a; Boraud *et al.*, 1996; Boraud *et al.*, 2000; Raz *et al.*, 2000). The resting discharge of GPi neurons is relatively homogeneous. They discharge at approximately 60–80 spikes/s during maintenance of a relaxed neutral posture. In contrast, GPe neurons can be divided into two populations based upon their discharge patterns. One population of GPe neurons discharges at relatively high frequencies (50–70 spikes/s) interrupted with long-duration pauses. In contrast, the second population of GPe neurons discharges at lower frequencies (<15 spikes/s) with intermittent, high-frequency bursts. Similar to GPi cells, these neurons change their firing in relationship to behavioral activity. During behavioral activity, all pallidal cells change their resting, tonic activity and either burst or pause. These changes are presumably the result of a combination of inhibitory, GABAergic inputs from the striatum and/or direct excitatory, glutamatergic inputs to the STh from the cortex through what has recently been named the "hyperdirect pathway" (Mink, 1996; Nambu *et al.*, 2002). These changes in firing patterns in association with behavioral activity are similar to those described by Basso and Wurtz (2002) for cells of the substantia nigra, pars reticulata. In addition to the cells that are typically identified as belonging to either GPe or GPi, there is a fourth population of neurons, referred to as "border cells." These are generally located near the perimeter of the pallidal segments or adjacent to, or in, the external or internal medullary laminae (DeLong, 1971). Border cells exhibit a medium-frequency, regular discharge pattern that is not unlike that recorded from the neurons located in the nearby substantia innominata, presumably the cholinergic cells of the nucleus basalis. While border cells have been shown to be modulated in association with movements related to reward, an understanding of their role in voluntary movement remains unclear.

The Subthalamic Nucleus

The subthalamic nucleus is a well-defined compact oval structure that takes the shape of a biconvex lens. It is located medial to the peduncular portion of the internal capsule at its rostral level and extends caudally to overlie the rostral part of the substantia nigra (Fig. 21.4). The principal neurons in the STh nucleus of the primate are medium to large cells (25–49 μm) and are pyramidal, or round in shape. Each cell gives rise to five to eight dendritic stems, which branch extensively to cover a large area of the nucleus (in primates approximately 20%). Secondary dendrites are thin and have varying numbers of dendritic spines ranging from sparse to very frequent (Rafols and Fox, 1976; Yelnik and Percheron, 1979; Hammond and Yelnik, 1983; Sato *et al.*, 2000b). There are important species differences in the extent to which the dendritic arbor innervates the nucleus. For example, in the rodent, the dendritic field of each cell is calculated to cover the entire nucleus, while in primates it covers only a fraction of it (Hammond and Yelnik, 1983). The projection neurons are divided into two groups—one that has axons that collateralize locally and one with axons that do not collatoralize extensively within the STh. Cells with collaterals within the STh terminate often beyond the dendritic radius of the parent cell (Kita *et al.*, 1983). Both types of subthalamic neurons give rise to a single axon that bifurcates, producing one ascending and one descending axon collateral. These axons terminate in pallidum and in pars reticulata substantia nigra, respectively (Kita *et al.*, 1983). Projection cells have been further divided according to their collateralization to target structues (Sato *et al.*, 2000b) (see discussion that follows). There are few interneurons in the STh (less than 5%). These interneurons are relatively small (12–16 μm) cells, with long dendrites that follow a more tortuous course than the radiating dendrites of the principal neurons (Rafols and Fox, 1976).

Connections of the STh include both intrinsic basal ganglia connections as well as extrinsic (Fig. 21.17). The external segment of the globus pallidus and parts of the ventral pallidum provide one of the most massive afferent projections. As seen with the other basal ganglia structures, these inputs terminate in a functionally topographic manner (Nauta and Mehler, 1966; Carpenter *et al.*, 1968; Kim *et al.*, 1976; Carpenter *et al.*, 1981a, b; Haber *et al.*, 1985). This GABAergic input is inhibitory and ensheaths the soma and dendrites of the STh cells (Smith *et al.*, 1990; Shink *et al.*, 1996; Bevan *et al.*, 1997). The main extrinsic inputs to the STN are from the cortex and brainstem. Cortical inputs are also topographically organized, which mirrors the functional organization of frontal cortex (Künzle, 1977; Kunzle and Akert, 1977; Kunzle, 1978; Monakow *et al.*, 1978; Carpenter *et al.*, 1981a; Matsumura *et al.*, 1992; Wichmann *et al.*, 1994; Nambu *et al.*, 1996; Nambu *et al.*, 1997; Takada *et al.*, 2001). Corticosubthalamic inputs make monosynaptic, glutamatergic, asymmetrical

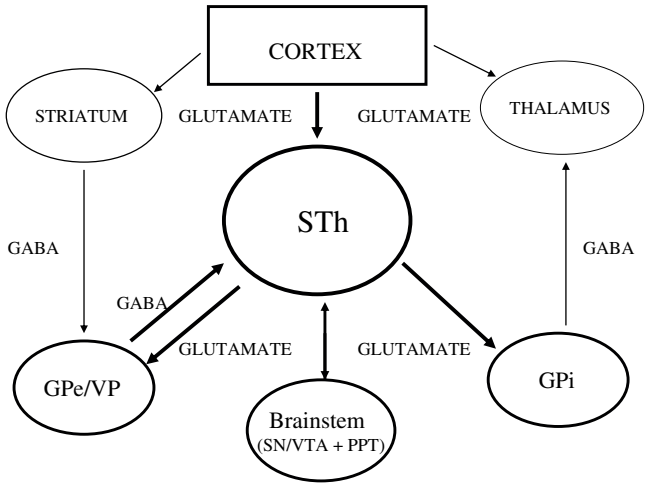

FIGURE 21.17 Diagram demonstrating the connections of the subthalamic nucleus (STh). Direct afferent and efferent projections of the STh are shown in bold lines. Connections between the other basal ganglia nuclei are also indicated. GPe, globus pallidus external segment; GPi, globus pallidus internal segment; PPT, pedunculopontine nucleus; SN, substantia nigra; VP, ventral pallidum; VTA, ventral tegmental area.

synapses onto the distal dendrites and spines of the STh neurons (Romansky *et al.*, 1979; Kitai and Deniau, 1981; Bevan *et al.*, 1995). The STh contains all three glutamatergic receptor subtypes. As with the other basal ganglia structures, the distribution and physiological effects of these have been described in the STh (Gotz *et al.*, 1997; Nambu *et al.*, 2000; Turner *et al.*, 2001). The composition of the different subunits for the AMPA and NMDA receptors emphasizes the functional properties of the different subunit compositions. In the STh, for example, neurons express receptor compositions which lead to highly Ca^{2+} permeable receptors (Gotz *et al.*, 1997). Afferent projections from the cortex and pallidum terminate onto the same dendrites in STh, indicating that these neurons process, simultaneously, information from both cortex and pallidum. However, it should be noted that the cortical input appears to be distal to that of the pallidum.

The idea that dopamine projects directly to the STh, first suggested by immunohistofluorescent staining demonstrating labeled dopamine fibers in the STh of rodents, has been further supported by immunohistochemical staining for tyrosine hydroxylase in the STh and tracing and functional studies (Brown *et al.*, 1979; Rinvik *et al.*, 1979; Bjorklund and Lindvall, 1984; Campbell *et al.*, 1985; Lavoie *et al.*, 1989; Hassani *et al.*, 1996; Hassani *et al.*, 1997; Cossette *et al.*, 1999; Hedreen, 1999). Support of the functional relevance of dopamine in the STh itself, rather than as passing fibers, comes from binding and *in situ* hybridization studies that demonstrate the presence of D_1, D_2, and D_3 receptors in the nucleus (Martres *et al.*, 1985; Weiner *et al.*, 1991; Mansour *et al.*, 1992; Flores *et al.*, 1999). Interest in the direct dopamine innervation of the STh has increased recently because of the recognition of its hyperactivity in Parkinson's disease (Bergman *et al.*, 1990; Limousin *et al.*, 1997; Rodriguez *et al.*, 1998; Francois *et al.*, 2000) and the fact that at least a subpopulation of the dopamine cells that project to the STh are vulnerable to degeneration in Parkinson's disease and in animal models of PD (Francois *et al.*, 2000).

Additional brainstem inputs to the STh are derived from cholinergic cells of the pedunculopontine region; more medially placed cells of the extrapyramidal area, which are noncholinergic; and cells from the laterodorsal tegmental nucleus (Rye *et al.*, 1987; Lavoie and Parent, 1994; Bevan and Bolam, 1995). It should be noted that projections from the PPTg are reciprocal.

The STh projects topographically to all pallidal regions including the GPe, GPi, and VP, and to the substantia nigra, primarily terminating in the pars reticulata. Single-cell labeling techniques, along with electrophysiological studies in rodents, demonstrate that these target structures receive input from collateral axons that the stem from the same cell (Van der Kooy and Hattori, 1980; Hammond *et al.*, 1983; Hammond and Yelnik, 1983; Kita *et al.*, 1983). A recent study in primates supports the notion that single STh cells send collateral fibers to the different output basal ganglia nuclei (Shink *et al.*, 1996). This study found several subpopulations of neurons, each with different branching patterns. One population projects to all three target regions, the GPi, GPe, and SN; a second population, the largest, sends axons to the GPi and

GPe; a third group of cells innervates only GPe; a fourth population innervates only the striatum; and finally a very small group of cells targets the GPe and SN (Sato *et al.,* 2000b). STh neurons use glutamate as the transmitter, and all the target regions of the STh show ultrastructural features that are consistent with an enriched glutatmatergic synaptic innervation. These terminals make synaptic contact along the entire cell and dendrites of the target structures (Shink and Smith, 1995; Smith *et al.,* 1998a). Other outputs of the STh include the striatum (as mentioned previously) and the pedunculopontine tegmental nuc.

As with the pallidal neurons, cells of the STh are tonically active, firing at a low frequency (approximately 24 spikes/s)(Georgopoulos *et al.,* 1983; DeLong *et al.,* 1985). Culture studies show that the rhythmic discharge pattern, albeit slow, is not dependent upon excitatory input, but rather on intrinsic membrane properties (Bevan and Wilson, 1999). Furthermore, the same group examined the intrinsic membrane properties of STh neurons *in vitro* using intracellular recording methods and pharmacological manipulation of the GABAa receptor and found that the diverse firing patterns manifest by STh neurons were likely to be the produced as a result of inhibitory input from GP in combination with the intrinsic membrane properties of STh cells (Bevan *et al.,* 2002). Both excitatory glutamatergic, cortical input and inhibitory GABAergic pallidal input are the main extrinsic sources that control the firing pattern of STh. Thus, when these cells respond with a burst firing pattern in association with the direction of movement, it is the result of a combination of intrinsic properties and the excitatory and inhibitory influences of cortex and the pallidus, respectively.

The Direct and Indirect Basal Ganglia Pathways

At this, point we can review the concept of the direct and indirect pathways (refer to Fig. 21.7; Albin *et al.,* 1989; Alexander and Crutcher, 1990; DeLong, 1990; Kato and Hikosaka, 1995; Joel and Weiner, 1997; Smith *et al.,* 1998b). This organizational scheme has played an important role in formulating the functional organization and underlying mechanisms of motor control through basal ganglia circuits (Kato and Hikosaka, 1995; Mink, 1996; Boraud *et al.,* 2002). While this concept has been further theoretically extended to the other BG functions, including cognition and emotion, the experimental data have been primarily focused on the control of movement and the pathophysiology that underlies movement disorders such as Parkinson's disease and Huntington's chorea (DeLong, 1990). Review of the pathways and transmitter-related compounds as described in previous sections (see Fig. 21.8) shows that (1) the direct pathway includes projections from the cortex (glutamatergic) that terminate onto MSN that primarily co-contain substance P and GABA, along with the D_1 dopamine receptor. Recall that this receptor increases cAMP but also has a number of important effects on the channel properties of the MSN. The MSNs of the direct pathway project primarily to the GPi. This inhibitory input to the GABAergic neurons of the GPi decreases the firing of these cells. Since the GPi also uses GABA and is inhibitory, the net effect of this striatal inhibition, and decreased GPi firing, is to disinhibit the thalamus (decreased inhibition of thalamic cells = increased thalamic firing). Thus, through the direct pathway cortical excitation of the striatum should result in promoting thalamic output back to cortex, thereby reinforcing cortical activity. In this way, the direct pathway retains and reinforces the cortico-basal ganglia activity. This can be further reinforced by the dopaminergic input (via the D_1 receptors), especially if the cortical drive is maintained with temporally coherent excitatory inputs, thus maintaining the MSN in an upstate. This activity can be further reinforced by the direct, excitatory thalamic input to MSN (Fig. 21.18).

The indirect pathway includes projections from the cortex (glutamatergic) that terminate onto the MSN, which primarily co-contain enkephalin and GABA, along with the D_2 receptor subtype (see Fig. 21.11). This receptor, we will recall, inhibits cAMP and therefore tends to be inhibitory. The MSNs of the indirect pathway project primarily to the GPe. This inhibitory influence on the GPe results in a decreased inhibition of the STh (or disinhibition), thereby causing an increased glutamatergic excitation of both pallidal segments. The increase in GPi output results in an inhibition of the basal ganglia thalamic relay nuclei, thereby decreasing its excitatory influence on cortex. The net result, therefore, of this pathway is the opposite of the direct pathway in that, rather than reinforcing cortico-basal ganglia activity, it decreases (or inhibits) it. The action of dopamine on this system is to further decrease the output, by reinforcing the inhibition of the striatopallidal output (Fig. 21.18). There are several excellent and detailed reviews of the direct and indirect pathways (Albin *et al.,* 1989; DeLong and Georgopoulos, 1991; Gerfen and Wilson, 1996; Smith *et al.,* 1998b). Less is known about the details of this organization for the ventral striatopallidal system, (Haber *et al.,* 1993; Groenewegen and Berendse, 1994b).

This scheme of two opposing pathways has led to the hypothesis that the balance between the direct and indirect pathways is critical for the smooth execution

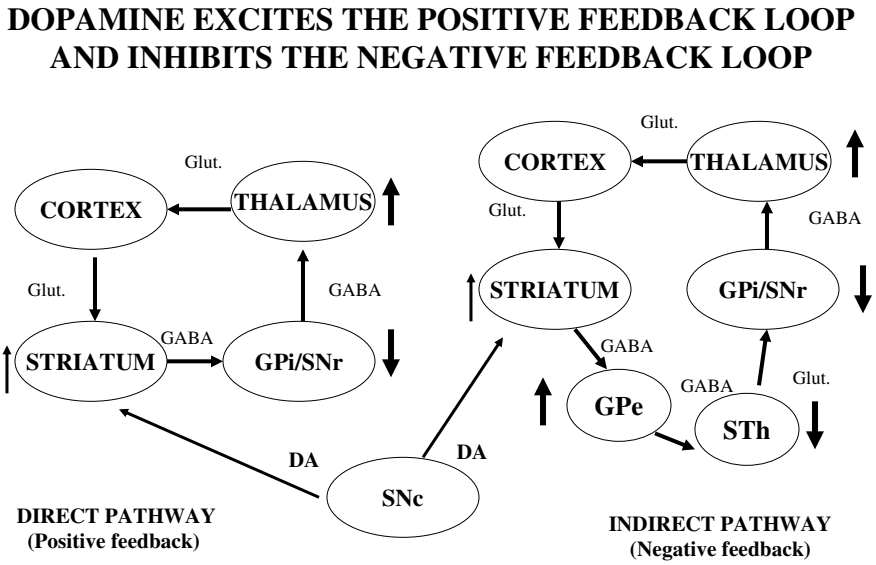

FIGURE 21.18 Diagram demonstrating how dopamine influences the direct and indirect pathways. Larger arrows indicate the changes of normal pathway interactions by DA modulation. The consequences of this DA modulation are to enhancement of the positive feedback to cortex through the direct pathway and inhibit the negative feedback to cortex through the indirect pathway. Glut, glutamate; GPe, globus pallidus external segment; GPi, globus pallidus internal segment; STh, subthalamic nucleus.

of behavior, and that in pathological situations, this equilibrium is disrupted. This core model for BG function has helped explain some of the pathophysiological mechanisms for both hypokinetic (Parkinson's disease) and hyperkinetic (Huntington's disease and hemibalismus) states in which there is either an increased inhibition of the thalamocortical pathway, resulting in hypokinetic disorders, or a decreased inhibition of thalamocortical output, resulting in hyperkinetic disorders (DeLong, 1990). The assumption that these two pathways are separate suggests two functional schemes: one in which the output from the indirect pathway merges at the cellular level with the direct pathway (in the GPi, or SNR); and one in which these two pathways remain separate and terminate on different neurons in the output nuclei (GPi or SNR). In the first situation, a temporal scaling of inputs onto the GPi/SNR cells results in an output that eventually drives the feedforward loop to the thalamus. In the second situation, it is the thalamus and/or cortex that collects these opposing inputs. In this scheme, two pathways send competing signals to the thalamus, one that broadly inhibits (via the indirect pathway), and one that focally stimulates (through the direct pathway), allowing what has been termed focused selection (Mink, 1996). In this model, the output of the two pathways effectively creates a "center-surround" inhibition, in which motor programs which underlie the desired movement are encouraged, while competing programs are inhibited. The model has the advantage of explaining some of the physiology associated with normal movement and the pathophysiology in PD. For example, the "focused-selection" model helps explain some of the timing of spike firing during movement. It also predicts that the majority of pallidal cells would be activated in movement-related activity (thereby inhibiting thalamocortical output), and the minority would be inactivated, (thereby "focusing" the thalamocortical ouput). Experimental evidence supports this prediction. Dopamine depletion results in the inability to disinhibit (thereby not releasing desired movements) through the direct pathway, and the inability to inhibit competing motor programs (thereby not inhibiting undesired movements) through the indirect pathway.

While the concept of the direct and indirect pathways has stimulated interesting and provocative models of BG function, recent studies show that there are anatomical, physiological, and cellular inconsistences with the idea that there are two completely separate pathways. These inconsistences force a reexamination of the role of a direct and indirect pathway as a fundamental feature that drives the BG. First, review of the anatomical data described in the previous section, shows that these two pathways are not completely separate. For example, there is a subpopulation of MSNs that project to the GPe (part of the indirect pathway) and also send collaterals to

either the GPi or to GPi and SNR (part of the direct pathway) (Kawaguchi *et al.,* 1990). Futhermore, MSNs of the direct and indirect pathways are interconnected via collaterals within the striatum (Aronin *et al.*, 1986; Yung, 1996) The GPe neurons (the indirect pathway) project directly to the GPi/SNR (the direct pathway) and collaterals from the STh project to all three striatal output structures (Hazrati *et al.,* 1990b; Smith *et al.,* 1994a; Parent *et al.,* 2000; Sato *et al.,* 2000a; Sato *et al.,* 2000b). Second, physiological experiments designed to test inhibition and disinhibition in the output pathways related to movement do not support the expected outcomes in all the structures. For example, there is little correlation of cell activitiy between the GPe and GPi during movement (Raz *et al.,* 2001). Furthermore, while hyperactivity in the GPi has been reported in dopamine-depleted animals (Wichmann *et al.,* 1999; Raz *et al.,* 2000), there is no evidence for hypoactivity in the GPe in these animals (Bezard *et al.,* 1999; Boraud *et al.,* 2001). Finally, molecular and immunohistochemical studies that demonstrate the transmitters and receptors assumed to be specific for each pathway are colocalized in some cells. As we have seen from the preceeding descriptions, several populations of MSN co-contain different dopamine receptor subtypes (Surmeier *et al.,* 1998; Aizman *et al.,* 2000). In addition, enkephalin is found in parts of the GPi and substance P is found in regions of the GPe (Haber and Elde, 1981; Haber and Watson, 1985; Reiner *et al.,* 1999).

Experiments directed at developing the functional utility of the direct and indirect pathway model are largely based on how motor programs are executed. As a result, while this models a microcircuit of function, it does not address the overall issue of how BG work with cortex to mediate goal-directed behaviors. In other words, it helps understand how, once a particular movement (or behavior) has been selected, it is carried out smoothly, without interference of "unwanted" actions. However, in reality, each action (or behavior) is made up of many decisions, both small (should I move slightly to the right to grasp the pencil?) and large (do I pay attention to the sweet smell coming from the bakery, turn and walk in to buy a treat?). While clearly many decisions are made at the cortical level, the BG play an important role in modifying behaviors based on reinforcement. This requires more than simple opposing pathways, mediating a particular outcome. It requires continual on-line adjustments, not only to keep a behavior on target, but also to be able to switch to accommodate adjustments. Consistent with this idea, the BG are now an accepted part of the learning process, plasticity, and reward acquistion, which requires immediate online modifications (Robbins *et al.,* 1989; Hikosaka, 1991; Everitt and Robbins, 1992; Saint-Cyr and Taylor, 1992; Kalivas *et al.,* 1993; Kombian and Malenka, 1994; Baev, 1995; Kimura, 1995; Kimura and Graybiel, 1995; Jueptner *et al.,* 1997; Kawagoe *et al.,* 1998; Schultz *et al.,* 1998; Wise, 1998; Bonci and Malenka, 1999; Jog *et al.,* 1999; Robbins and Everitt, 1999; Thomas and Malenka, 1999; Doya, 2000; Schultz *et al.,* 2000; Thomas *et al.,* 2000; Kerr and Wickens, 2001). As we will see later, the dopamine system plays an important role in these functions.

Another assumption that is made in most current models (including the direct and indirect pathway model) of BG function is that these pathways are organized in functionally discrete channels and that the model created for the motor system can than be applied to the other functional systems. A major drawback to this assumption is that most actions do not occur in isolation of motivation and cognition, and it is unlikely that the BG would operate to isolate these cortical functions. Several alternative schemes have been developed to address how the BG help cortex integrate information between these channels. An important issue here is not only the fact that there is potential cross-talk between different channels (Nauta *et al.,* 1978; Somogyi *et al.,* 1981b; Haber *et al.,* 1994; Bevan *et al.,* 1997), but how that information moves through the BG pathways to account for the development of coordinated, goal-directed behaviors (Bar-Gad *et al.,* 2000; Haber *et al.,* 2000, 2002; McFarland and Haber, 2002a, 2001). We will return to this topic in more detail later when we discuss the functional organization of BG circuits.

The Substantia Nigra and Ventral Tegmental Area

The substantia nigra appears as a flattened oval structure on the dorsal aspect of the base of the cerebral peduncle (Fig. 21.5). On the basis of cytoarchitectonic and chemical criteria, the substantia nigra is subdivided into two cell groups, the pars compacta (SNC) and the pars reticulata (SNR) (Olszewski and Baxter, 1982; Poirier *et al.,* 1983; Francois *et al.,* 1985; Halliday and Tork, 1986). This subdivision into two components is supported by the chemical anatomy of this nuclear complex. Some surveys in the monkey and human suggest further divisions—a pars lateralis and a mixed region at the dorsomedial surface of pars compacta (Francois *et al.,* 1984a; Francois *et al.,* 1987; Yelnik *et al.,* 1987 Percheron *et al.,* 1987). This latter subdivision contains some cells characteristic of the pars compacta and others more closely related to the pars reticulata, while the pars lateralis resembles for the most part the remainder of pars reticulata, except that cell bodies are somewhat larger and they may specifically target the

superior colliculus (Beckstead *et al.*, 1981; Beckstead and Frankfurter, 1982; Beckstead, 1983; Francois *et al.*, 1984a; Yelnik *et al.*, 1987; Paxinos *et al.*, 2000). In general, when using the term "pars reticulata," we will be referring to all of the cells not belonging to the dopaminergic, melatonin-rich class that composes the pars compacta.

The pars reticulata, while clearly a separate entity, is often considered a caudomedial extension of the internal pallidal segment based on morphology, connections, neurochemistry, and physiology (Fox *et al.*, 1974; DeLong and Georgopoulos, 1981; Percheron *et al.*, 1984a; Nauta, 1986; Francois *et al.*, 1987; Yelnik *et al.*, 1987; Percheron *et al.*, 1994). The pars compacta is part of an extensive midbrain dopaminergic system that includes the ventral tegmental area and the retrorubral group. The following discussion of the pars reticulata will be brief, since its characteristics are similar to that of the internal pallidal segment. In this section, we will discuss the entire midbrain dopamine system, including the ventral tegmental area (VTA) and retrorubral cell group.

Pars Reticulata Substantia Nigra

Even though the SNR can be considered as a caudomedial extension of the internal pallidal segment, it does not seem to be derived from the same developmental anlage as either the external or internal pallidal segments which appear to follow somewhat independent developmental courses (Marchand and Poirier, 1983; Marchand and Lajoie, 1986; Marchand *et al.*, 1986). The pars reticulata, like the pallidum, consists primarily of large neurons with long, thick dendrites, which are almost completely ensheathed with synaptic contacts (Kemp, 1970; Fox *et al.*, 1974; Francois *et al.*, 1987; Yelnik *et al.*, 1987). Histochemically, there are also striking similarities between the pars reticulata and the internal pallidal segment with dense substance P-positive woolly fibers (Beach and McGeer, 1984; Inagaki and Parent, 1984; Mai *et al.*, 1986; Haber and Groenewegen, 1989), as well as a dense histochemical reaction for iron (Francois *et al.*, 1981; Dwork *et al.*, 1988). As we have seen in the previous discussions, the connections of the pars reticulata are similar to those of the GPi. In addition, the SNR projects to the superior colliculus. This projection, which arises primarily from the lateral SNR, is important in the control of eye movements (Hopkins and Niessen, 1976; Beckstead, 1983; Hikosaka and Wurtz, 1983a; Vila *et al.*, 1996). The cell population of the pars reticulata contains predominantly GABAergic neurons, as can be shown with GAD or GABA immunohistochemistry (Oertel *et al.*, 1982; Mugnaini and Oertel, 1985). In primates, a clear demarcation between the pars compacta and the pars reticulata is often difficult to visualize, particularly in caudal regions, because of the invasion into the SNR by dopamine neurons and their dendritic arborizations.

Midbrain Dopamine Neurons (Pars Compacta and the VTA)

The midbrain dopamine neurons play a unique role in basal ganglia and cortical circuits modulating a broad range of behaviors from learning and "working memory" to motor control. Dopamine neurons are considered to be key for focusing attention on significant and rewarding stimuli, a requirement for the acquisition of new learned behaviors (Schultz *et al.*, 1997; Yamaguchi and Kobayashi, 1998; see also Wickelgren, 1997). Consistent with its role as a mediator of complex behaviors as a function of the environment (Ljungberg *et al.*, 1992; Schultz *et al.*, 1995), as we will see later, the dopamine pathways are in a position to provide an interface between cognitive, motor, and limbic functional domains of the forebrain, through complex forebrain neuronal networks (Haber *et al.*, 2000). Vicq d'Azyr first identified the substantia nigra in 1786, as "tache noire" or "locus niger crurum cerebri" (Vicq D'Azyr, 1786) when he described "black granules" (neuromelanin) in the human brainstem. It was then considered to be part of the oculomotor nerve because of its close proximity with the oculomotor nerve rootlets. The link between the substantia nigra and the motor system did not occur until the turn of the 19th century when several investigators associated this brainstem nucleus with Parkinson's disease (Brissaud, 1895; Bremer, 1920). This was later confirmed by Hassler's demonstration of progressive cell loss in the substantia nigra of Parkinson's patients (Hassler, 1938, 1939). The connection between the neurotransmitter dopamine and the substantia nigra was made by Ehringer and Hornykeiwicz's discovery that DA was depleted in Parkinson's disease patients (Ehringer and Hornykiewicz, 1960; Hornykiewicz, 1966). The hypothesis that DA is involved in the pathogenesis of major psychoses evolved in the early 1950s as a result of the empiric discovery that the phenothiazines could be effectively used for the treatment of psychosis (Baldessarini, 1985). Since that time the midbrain dopamine system has been linked to psychosis and behavioral disorders including schizophrenia, Gilles de la Tourette's disease, and drug abuse. Subpopulations of dopamine neurons have been associated with different functions and include reward, cognition, and motor control. Classically, these functions are related to the mesolimbic system, mesocortical system, and striatonigral pathways, respectively.

In the primate, dopaminergic neurons can be distinguished from the underlying pars reticulata by their content of melatonin, a dark pigment generally accumulated in catecholamine neurons, especially in the human brain (Braak and Braak, 1986). The colocalization of DA with neuromelanin, a byproduct of catecholamine metabolism, was first described in detail in 1967 (Bazelton *et al.*, 1967). Melanins are heterogeneous compounds that are formed oxidatively from various subunits such as tyrosine. Neuromelanin may be unique in that it is formed by autooxidation of dopamine, rather than enzymatically, and its synthesis generates free radicals. Quantitative examination of neuromelanin shows that it is found less in lower mammals but is very dense in primates (Bogerts, 1981; Marsden, 1983; McRitchie *et al.*, 1995). An important distinction between human and nonhuman primates may be a lower amount of neuromelanin per catecholamingeric cell in the nonhuman primates (Marsden, 1983; Herrero *et al.*, 1993). The neuromelanin content in midbrain neurons is age-dependent, increasing progressively until the sixth decade when it begins to decline, possibly because of neuronal degeneration of the pigmented cells (Mann and Yates, 1983; Marsden, 1983). Neuromelanin is particularly dense in the SNC cells.

Neurons of pars compacta are large in size (33 μm mean diameter) and larger than the adjacent cells of the pars reticulata (25 μm) or pars lateralis (28 μm) of substantia nigra (Yelnik *et al.*, 1987). Their dendrites are long and spine-poor, often radiating in a plane confined to pars compacta, but more frequently with dendrites extending into the underlying pars reticulata (Wassef *et al.*, 1981; Yelnik *et al.*, 1987). Pars compacta cells have been shown to make dendrodendritic synapses, releasing dopamine. Some of these intrinsic connections are electrotonically coupled. The D_2 dopamine receptor mRNA is high in the midbrain and functions here as an autoreceptor (Hajdu *et al.*, 1973; Groves *et al.*, 1975; Cheramy *et al.*, 1981; Grace and Bunney, 1983; Llinas *et al.*, 1984; Haber *et al.*, 1995a).

The midbrain dopamine neurons are divided into the substantia nigra pars compacta; the ventral tegmental area; and the retrorubral cell groups (Hokfelt *et al.*, 1984b) (Fig. 21.20, also see Fig. 21.5). The densely populated, relatively large melanin-containing pars compacta is mainly constituted by dopaminergic cell bodies. This was first visualized by dopamine- or TH-immunohistochemistry in rats (Ungerstedt, 1971; Bjorklund and Lindvall, 1984) and later in monkeys (Garver and Sladek, 1875; Hubbard and Di Carlo, 1974; Schofield and Everitt, 1981; Tanaka, 1982; Pearson *et al.*, 1983; Robert *et al.*, 1984). The SNC has been further divided into three groups: a dorsal group (the α group), also referred to as the pars dorsalis; a main, densocellular region (the β group); and a ventral group (the γ group), or the cell columns (Olszewski and Baxter, 1982; Poirier *et al.*, 1983; Francois *et al.*, 1985; Halliday and Tork, 1986; Haber *et al.*, 1995a). The dorsal group is composed of loosely arranged cells, extending dorsolaterally circumventing the ventral and lateral superior cerebellar peduncle and the red nucleus. These dorsal neurons are oriented horizontally, just dorsal to a dense cluster of neurons referred to as the densocellular region (Fig. 21.19). The dorsal cells merge with the immediately

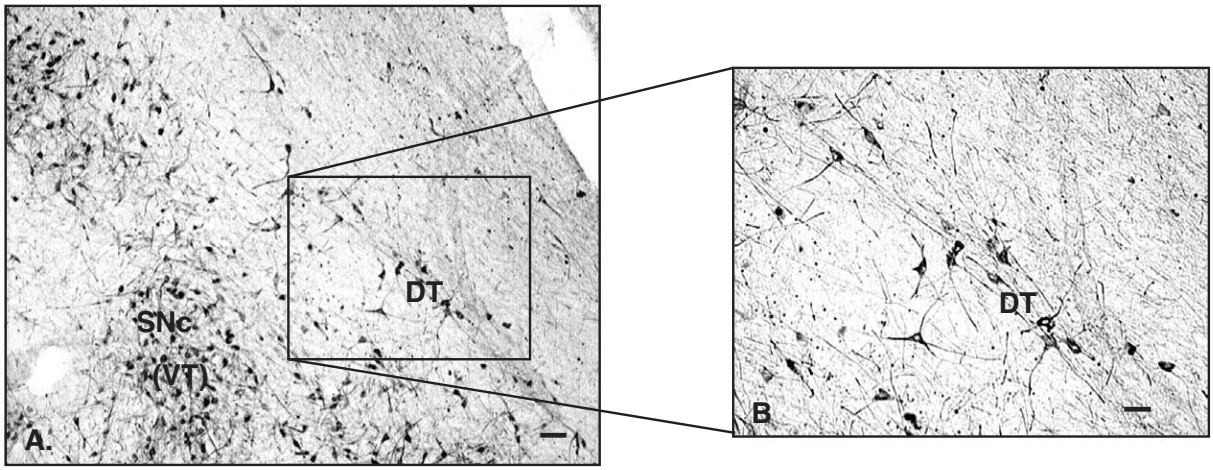

FIGURE 21.19 Photomicrograph of the tyrosine hydroxylase positive-staining in the midbrain. **(A)** TH-positive fibers and cells of dorsal and ventral tiers. Scale = 100 μm. The cells and processes of the dorsal tier indicated by the box are shown magnified in **(B)** revealing the horizontal arrangement of their dendritic processes. Scale = 50 μm. VT, ventral tier; DT, dorsal tier.

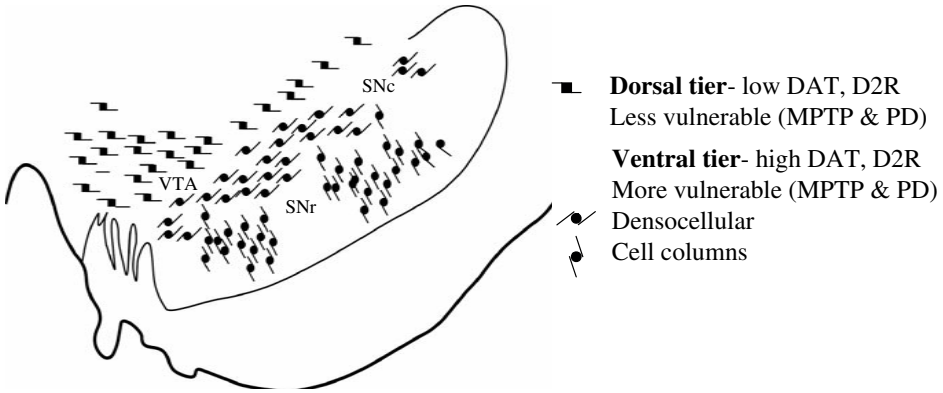

FIGURE 21.20 Schematic demonstrating the arrangement of the different dopaminergic cell groups in the midbrain. The dorsal tier includes the ventral tegmental area and the retrorubral cell groups; the ventral tier includes the densocellular cells and the cell columns. DAT, dopamine transporter; D2R, D2 dopamine receptor; MPTP, 1-methyl-4-phenyl-1,2,3,6,tetrahydropyridine; PD, Parkinson's disease; VTA, ventral tegmental area; SNr, substantia nigra pars reticulata; SNc, substantia nigra pars compacta.

adjacent dopamine cell groups of the ventral tegmental area to form a continuous mediodorsal band of cells. The dendrites of this dorsal group stretch in a mediolateral direction and do not extend into the ventral parts of the pars compacta or into the pars reticulata. Calbindin (CaBP), a calcium-binding protein, is an important phenotypic marker for both the VTA and the dorsal SNC.

In contrast, the ventral cell groups (the densocellular group and the cell columns) are calbindin-negative. Thus the distribution of calbindin-positive cells illustrates the continuity between the VTA and the dorsal SNC (Lavoie and Parent, 1991; Haber *et al.*, 1995a; McRitchie and Halliday, 1995). Furthermore, the dendritic arborizations of the densocellular region and cell columns are oriented ventrally and occupy the major portion of the pars reticulata in primates. These TH-labeled dendrites can be followed deep into the pars reticulata extending to, and in some instances into, the cerebral peduncle. The cell columns are finger-like extensions of cell clusters that lie within the pars reticulata and are particulaly prominent in primates. The densocellular group and the cell columns, in addition to being calbindin-negative, have high expression levels for dopamine transporter (DAT) and for the D2 receptor mRNAs.

Based on the phenotypic characteristics of the midbrain dopamine neurons, these cells can be divided into two tiers: a dorsal tier and a ventral tier (Fig. 21.20). The cells of the dorsal tier include both the dorsal SNC and the contiguous VTA. These cells are oriented horizontally and are calbindin-positive. The ventral tier cells include both the densocellular and the ventral group. They have dendrites that penetrate deep into the pars reticulata. Furthermore, the ventral tier cells are calbindin-negative and have relatively high levels of neuromelanin and expression of DAT and the D2 receptor mRNA. The ventral tier cells are more vulnerable to degeneration in Parkinson's disease and to *N*-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-induced toxicity, while the calbindin-positive dorsal tier cell are selectively spared (Fallon and Moore, 1978; Gerfen *et al.*, 1985; Lavoie and Parent, 1991; Pifl *et al.*, 1991; Parent and Lavoie, 1993; Haber *et al.*, 1995a).

Finally, it should be noted that in some instances, particularly for cells in the ventral tegmental area, multiple transmitters coexist within the same neuron. For example, cholecystokinin or neurotensin may be found within cells that also contain dopamine (Hokfelt *et al.*, 1984a; Seroogy *et al.*, 1988).

Connections

Many of the dopamine connections (Fig. 21.21) with other structures in the basal ganglia have already been described in the previous sections and (other than the striatum) will only be briefly referred to later. In addition, to reciprocal connections with the striatum, pallidum, and STh, the dopamine cells also are linked to the cortex, hippocampus, and amygdala. Most of these projections are reciprocal and will therefore be discussed together.

The Striatum. The main target of the dopaminergic neurons is the striatum. Even though many tracing studies have not used double-labeling techniques demonstrating retrogradely labeled cells containing TH or other markers indicative of dopamine, since the majority of SNC cells are dopaminergic, projections from the ventral tier are presumed to be largely dopaminergic. The percentage of cells from the dorsal

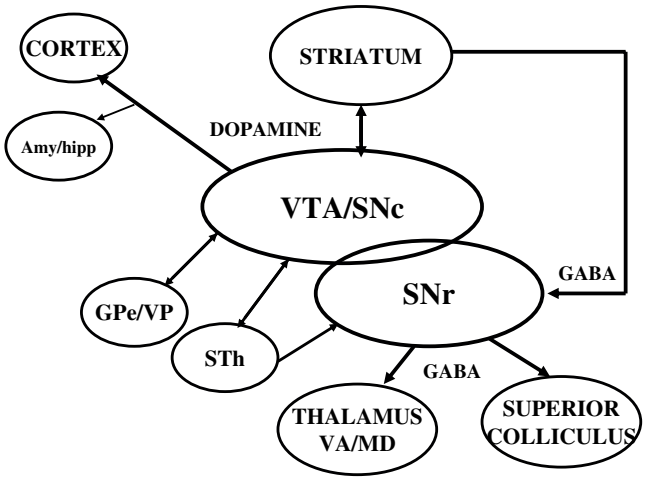

FIGURE 21.21 Diagram demonstrating the connections of the substantia nigra and ventral tegmental area. VTA, ventral tegmental area; SNc, substantia nigra pars compacta; SNr, substantia nigra pars reticulata; Amy, amygdala; hipp, hippocampus; GPe, globus pallidus external segment; VP, ventral pallidum; STh, subthalamic nucleus; VA, ventral anterior nucleus of the thalamus; MD, mediodorsal nucleus of the thalamus.

tier presumed to be dopaminergic may be somewhat less, in that there are a greater number of non-dopaminergic cells here. Both the dorsal and ventral tiers contribute to these pathways (Szabo, 1967, 1970; Johnson and Rosvold, 1971; Carpenter and Peter, 1972; Fallon and Moore, 1978; Nauta *et al.*, 1978; Szabo, 1979, 1980; Parent *et al.*, 1983; Francois *et al.*, 1984a; Parent *et al.*, 1984; Deutch *et al.*, 1986; Smith and Parent, 1986; Haber *et al.*, 1990b; Selemon and Goldman-Rakic, 1990; Hedreen and DeLong, 1991; Lynd-Balta and Haber, 1994b, c; Parent and Hazrati, 1994).

Szabo (1979, 1980) described the general topography of ascending striatal afferents demonstrating a mediolateral and rostrocaudal organization. He also described an inverse dorsoventral topography such that ventral compacta neurons project to the dorsal caudate nucleus and putamen and dorsal neurons project to the ventral parts of the striatum. These studies confirmed earlier ones that used fiber degeneration techniques (Carpenter and Peter, 1972). Parent *et al.* (1983) further extended these organizational studies by examining the relationship between nigral efferent projections to the caudate nucleus and to the putamen. They showed that retrogradely labeled cells projecting to either the caudate nucleus or the putamen are derived from different populations of pars compacta cells, thereby demonstrating that a single neuron did not send collaterals to both parts of the striatum. Retrogradely labeled cells from the caudate nucleus were distributed in clusters which interdigitate with clusters of retrogradely labeled cells from the putamen. These two populations of neurons were found throughout the extent of the substantia nigra.

The striatum projects massively back to the substantia nigra (Nauta and Mehler, 1966; Szabo, 1967, 1970; Johnson and Rosvold, 1971; Parent *et al.*, 1984; Haber *et al.*, 1990b; Selemon and Goldman-Rakic, 1990; Hedreen and DeLong, 1991; Lynd-Balta and Haber, 1994c; Parent and Hazrati, 1994). As described earlier, the striatonigral projection is GABAergic with subpopulations of cells co-containing primarily substance P, but also some populations co-contain enkephalin (DiFiglia *et al.*, 1981; Haber and Elde, 1982; Beach and McGeer, 1984; Inagaki and Parent, 1984; Pioro *et al.*, 1984; Inagaki *et al.*, 1986). Substance P-containing axons are found throughout the pars reticulata, whereas the enkephalinergic fibers are found in a more limited medial region. A common feature of the ventral and dorsal striatonigral connections is that all areas project throughout the rostro-caudal extent of the substantia nigra. Ventral striatonigral inputs terminate in the medial pars reticulata and much of the densocellular part of the pars compacta, whereas dorsolateral striatonigral inputs are concentrated in the ventrolateral pars reticulata. At the rostral level of the substantia nigra, ventral striatal fibers terminate medially. However, more caudally, these terminals spread dorsally and laterally to innervate the region of the densocellular SNC and, just ventral to it, in the SNR (Haber *et al.*, 1990b). Thus the ventral striatum not only projects throughout the rostrocaudal extent of the substantia nigra, but also covers a wide mediolateral range (Haber *et al.*, 1990b; Hedreen and DeLong, 1991). There are remarkably few ventral striatal terminals in the ventral tegmental area as compared to the heavy projections to the substantia nigra proper. The functional organization of the striatonigralstriatal pathway will be addressed in detail in "Functional Basal Ganglia Connections."

The Pallidum and Brain Stem. Both the external segment of the globus pallidus and the ventral pallidum project to the substantia nigra. The internal segment of the globus pallidus does not. The pallidal projection follows a similar organization as does the striatonigral projection. The region of the external segment that receives input from the sensorimotor part of the striatum projects ventrally to the pars reticulata. The more rostral regions of the pallidum that receive input from the association areas projects more dorsally in the region of, and just ventral to, the dopamine cells. Finally, the ventral pallidum projects dorsally, primarily to the densocellular region of the pars compacta (Haber *et al.*, 1993). Thus the pattern of projection from

the striatum to the pallidum and nigra is repeated again in the pallidal projection to the substantia nigra. In addition, the pedunculopontine nucleus terminates in the region of the dopaminergic cells bodies. At the light microscopic level, these fibers appear to form close contacts with the cells and dendrites of the dorsal pars compacta (Lavoie and Parent, 1994). Finally, studies demonstrate a serotonergic innervation from the dorsal raphe nucleus to the substantia nigra, though there is disagreement regarding whether fibers terminate primarily in the pars compacta or pars reticulata (Lavoie and Parent, 1990).

The Cortex. The presence of cortical dopamine and dopamine fibers in the cortex is clearly demonstrated using a variety of methods, including measurements of dopamine levels, immunohistochemistry for TH, dopamine uptake, specific antibodies against dopamine, and receptor autoradiography (Levitt *et al.,* 1984; Fallon and Loughlin, 1987; Lewis *et al.,* 1987; Gaspar *et al.,* 1989; Lidow *et al.,* 1991; Gaspar *et al.,* 1992; Verney *et al.,* 1993; Sesack *et al.,* 1998). The dopamine innervation of primate cortex is more extensive than in rats and found not only in granular areas but also in agranular frontal regions, parietal cortex, temporal cortex, and, albeit sparsely, occipital cortex. Dopamine terminals in layer I, which are prevalent throughout cortex, provide a rather general modulation of many cells at the distal apical dendrites. The terminals in layers V–VI, on the other hand, are found in specific cortical areas and are in a position to provide a more direct modulation of cortical efferent projections, including corticostriatal and corticothalamic projections. Dopamine fibers are also found in the hippocampus, albeit to a lesser extent than found in neocortex. The terminals are densest in the molecular layer and the hilus of the dentate gyrus and in the molecular layer and polymorphic layer of the subiculum (Samson *et al.,* 1990).

In rats, the majority of midbrain neurons projecting to the cortex arise from both the VTA and the medial half of the SNC, throughout its rostrocaudal extent. In primates, the majority of DA cortical projections are from the parabrachial pigmented nucleus of the VTA and the dorsal SNC (Amaral and Cowan, 1980; Porrino and Goldman-Rakic, 1982; Fallon and Loughlin, 1987; Gaspar *et al.,* 1992). The ventral tier does not project extensively to cortex. The VTA projects throughout prefrontal cortex including orbital, medial, and dorsolateral areas with fewer projections to motor areas. Midbrain projections to the hippocampus are also derived primarily from the VTA with few cells from the pars compacta proper terminating there. The dorsal SNC primarily innervates dorsolateral prefrontal cortex, motor, and premotor regions. The midbrain dopamine cells that project to functionally different cortical regions are intermingled with each other. Double label studies show that many cells send collateral axons to different cortical regions (Gaspar *et al.,* 1992). The nigrocortical projection appears to be a more diffuse system compared to the nigrostriatal system and can modulate cortical activity at several levels.

There is a general acceptance of descending cortical projections to the substantia nigra, based primarily on studies in rats and cats. Cortical lesions result in reduced glutamate content in the rat substantia nigra as well as fiber degeneration in the corticonigral pathway (Afifi *et al.,* 1974; Carter, 1980; Kornhuber, 1984). Retrograde tracing studies confirm these projections (Bunney and Aghajanian, 1976). However, these projections have been difficult to definitively demonstrate in primates (Leichnetz and Astruc, 1976; Kunzle, 1978). While descending corticonigral fibers have been demonstrated with fiber degeneration and anterograde tracing techniques in primates, the authors in both studies point out that the results must be interpreted with care. Neither technique clearly showed that fibers actually terminated in the substantia nigra.

In summary, the dorsal tier neurons (the VTA and the dorsal substantia nigra) are the source for the midbrain dopamine cortical projections. The ventral tier neurons, for the most part, do not contribute. Furthermore, this dorsal tier projection does not appear to be organized with respect to function. Cells projecting to functionally different cortical regions are intermingled with each other, many of which send collateral axons to different cortical regions. This is somewhat different than the nigrostriatal projection where some functional organization, although a rather loose one, does exist. The nigrocortical projection on the other hand is a diffuse system that can modulate cortical activity at several levels. Terminals in layer I, which are prevalent throughout cortex, provide a rather general modulation of many cells at the distal apical dendrites (Gaspar *et al.,* 1992). The terminals in layers V–VI, on the other hand, are found in specific cortical areas and are in a position to provide a more direct modulation of cortical efferent projections, including corticostriatal and corticothalamic projections. Thus, parts of the striatum can be influenced by dopamine directly via the nigrostriatal pathway and indirectly via a nigrocortical/striatal pathway.

Amygdala Projections. The basolateral complex and the central amydala nuclei are most consistently associated with projections to and from the midbrain. Dopamine fibers in the amygdala predominate in these areas supporting the midbrain projection here

(Sadikot and Parent, 1990). The densent innervation is in the central and medial part of the central nucleus. Projections to the amygdala arise from both the VTA and the adjoining dorsal pars compacta (Aggleton *et al.*, 1980; Mehler, 1980; Norita and Kawamura, 1980). These terminals form symmetric synapses primarily with spiny cells, indicating that direct contact is made with the projection neurons of the amygdala (Asan, 1997). Descending projections from the central nucleus of the amygdala terminate in a wide mediolateral region of dopamine cells (Price and Amaral, 1981; Fudge and Haber, 2000). These fibers descend in the ventral amygdalofuglal pathways and terminate primarily in the dorsal SNC and in the densocellular regions. In addition, there are projections to the VTA and the dorsomedial SNC from the bed nucleus of the stria terminalis and from the sublenticular substantia innominata (Price and Amaral, 1981; Parent and DeBellefeuille, 1983; Haber *et al.*, 1993; Lavoie and Parent, 1994; Fudge and Haber, 2000; Fudge and Haber, 2001). These fibers travel together with those from the amygdala, which travel together with those from the bed nucleus of the stria terminalis and the cells of the sublenticular substantia innominata, together forming the "extended amygdala" (Alheid and Heimer, 1988; Heimer *et al.*, 1991a).

FUNCTIONAL BASAL GANGLIA CONNECTIONS

The basal ganglia and frontal cortex operate together to execute goal-directed behaviors. This requires not only the execution of motor plans but also the behaviors that lead to this execution, including emotions and motivation that drive behaviors, cognition that organizes and plans the general strategy, motor planning, and finally the execution of that plan. Frontal cortex is organized in a hierarchical manner to mediate the smooth execution of behaviors (Fuster, 2001). Therefore, the connectivity of basal ganglia circuitry is best appreciated within the context of frontal cortical organization. The components of the frontal cortex that mediate behaviors, including the motivation and emotional drive, coupled with the planning and cognitive components to plan the action, and finally, the movement itself, are reflected in the organization, physiology, and connections between areas of frontal cortex and in their projections to striatum. The frontal cortex can thus be divided into several regions: the orbital and medial prefrontal cortex, involved in emotions and motivation; the dorsolateral prefrontal cortex, involved in higher cognitive processes or "executive functions"; the premotor areas, involved in different aspects of motor planning; and the motor cortex, involved in the execution of those plans. Since the basal ganglia are linked to each of these areas, we include a brief description of frontal cortical areas before turning to the associated BG circuitry (Fig. 21.22a). While the striatum receives input from other cortical areas, we focus on the frontal cortex because that receives the main BG output via the thalamus. Furthermore, inputs from other cortical areas are also functionally organized, such that they overlap with frontal projections in the striatum, which are both functionally related and closely connected with specific frontal regions (Yeterian and Van Hoesen, 1978; Selemon and Goldman-Rakic, 1985; Flaherty and Graybiel, 1993). As Yeterian and Van Hoesen suggested, "cortical areas related via reciprocal corticocortical connections project, in part, to similar areas within the caudate nucleus" (Yeterian and Van Hoesen, 1978; Van Hoesen *et al.*, 1981). The phenomenon of overlapping projections from reciprocally connected cortical areas often consists of interdigitated terminals rather then complete overlapping fields. However, the regional topography was similar (Selemon and Goldman-Rakic, 1985). We will briefly review these corticostriatal connections as appropriate along with the frontostriatal projections.

The Frontal Cortex

Recent studies of "motor" cortices have expanded the number of cortical areas involved in motor processing as well as the database of information on their physiology and connectivity—both cortical and subcortical (Dum and Strick, 1991a; Luppino *et al.*, 1991; Matelli *et al.*, 1991; Mushiake *et al.*, 1991; Dum and Strick, 1993; Luppino *et al.*, 1993; Lu *et al.*, 1994; Matelli and Luppino, 1996; Picard and Strick, 1996; Tanji and Mushiake, 1996; Strick *et al.*, 1998). Based on anatomical and physiological studies, motor areas are organized by connections and involvement in movement execution with regards to microexcitability and the temporal association between movement and neuronal reponse along with their involvement (or lack thereof) in cognitive motor processing (Schieber, 1999; McFarland and Haber, 2000). Caudal motor areas, including motor cortex (M1); supplementary motor area (SMA); cingulate motor area, caudal part (CMAc); and caudal premotor area (PM) areas are those areas most closely involved with movement execution. These areas also send a direct descending projection to spinal motor nuclei. They are highly microexcitable and closely timed to the execution of movment (Hutchins *et al.*, 1988; He *et al.*, 1993; Dum and Strick, 1996; Schieber, 1999). Rostral motor areas, including PreSMA, CMAr, and rostral PM areas, project to caudal motor areas and process more "cognitive" aspects of motor control,

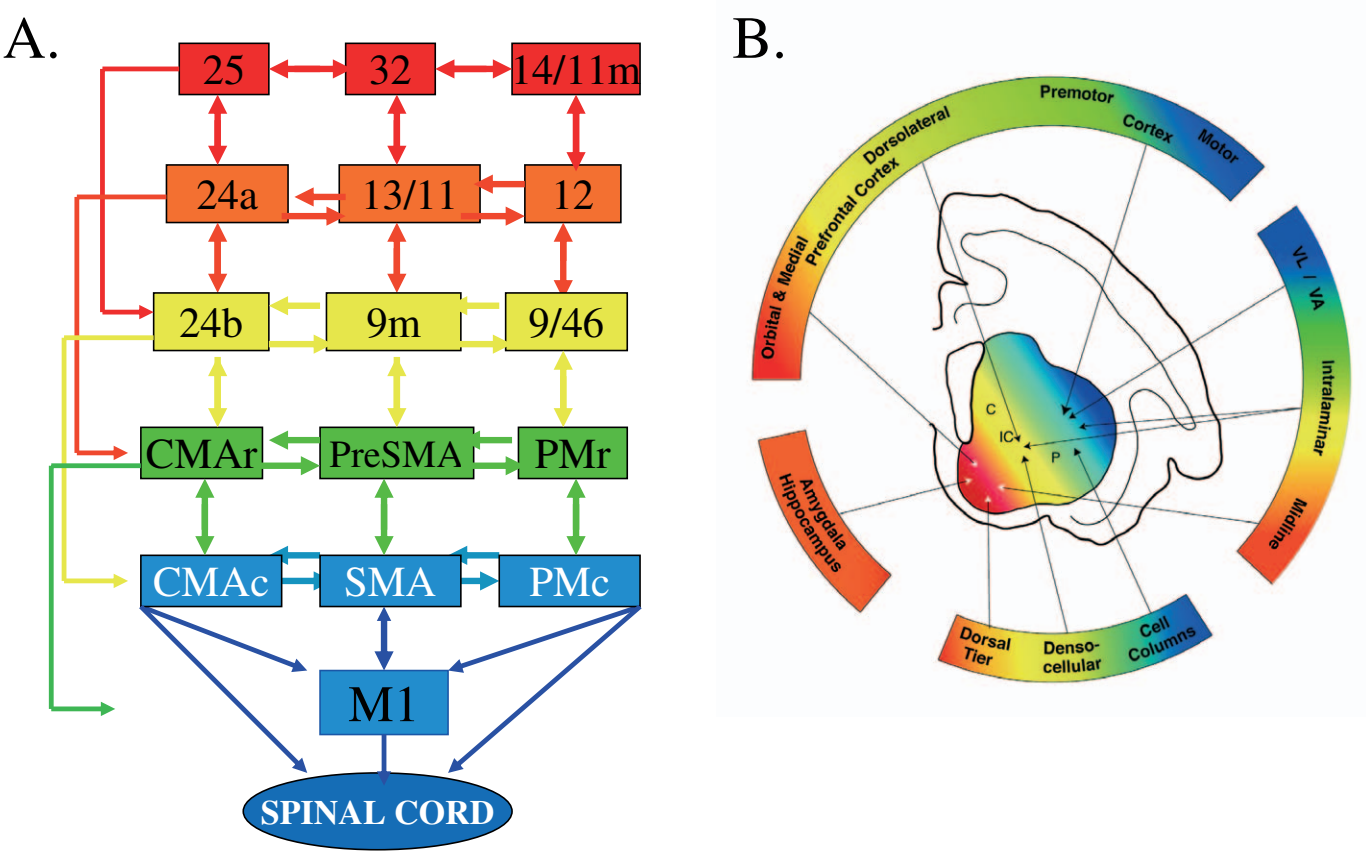

FIGURE 21.22 Diagram demonstrating the functional organization of frontal cortex and striatal afferent projections. **(A)** Schematic illustration of the functional connections linking frontal cortical brain regions. **(B)** Organization of cortical and subcortical inputs to the striatum. The colors denote functional distinctions. *Blue,* motor cortex, execution of motor actions; *green,* premotor cortex, planning of movements; *yellow,* dorsal and lateral prefrontal cortex, cognitive and executive functions; *orange,* orbital prefrontal cortex, goal-directed behaviors and motivation; *red,* medial prefrontal cortex, goal-directed behaviors and emotional processing.

such as sensorimotor integration, sequence generation, and motor learning. These areas are less microexcitable than the caudal motor areas, but more so than the prefrontal cortex. Furthermore, the temporal firing pattern of the rostral motor areas is less directly associated with movement than the caudal motor areas. In addition, although there are some direct connections to spinal cord, they are far fewer than those arising from the caudal motor areas. However, these areas are tightly connected both to caudal motor areas and to the prefronatal cortex (Bates and Goldman-Rakic, 1993; Lu *et al.,* 1994; Carmichael and Price, 1996a; Graziano *et al.,* 1997; Nakamura *et al.,* 1998). As we will see later, projections from this collective region of frontal cortex to the striatum define the striatal region associated most with the control of movement.

All three prefrontal cortical regions—dorsolateral, orbital, and medial—are the least microexcitable of frontal cortex (Fuster, 1997a). The dorsolateral prefrontal cortex, as mentioned earlier, is tightly linked to the rostral motor areas that are stimulation-responsive. Dorsal and lateral prefrontal cortical areas (DLPFC) are involved in working memory, set shifting, and strategic planning, often referred to as 'executive functions'. Delayed memory tasks are used as one measure of this function. These tasks require the subject to retain information during a delay period in which the stimuli have been removed. The DLPFC plays a critical role in this retention as has been demonstrated both experimentally and in patients with cognitive impairments (Goldman-Rakic, 1987; Jonides *et al.,* 1993; Smith and Jonides, 1997; Fuster, 2000, 2001). The most common deficit in this area following lesions is an inability to formulate a cohesive plan or sequence of actions that result in a desired goal. (Passingham, 1972a, b, 1975, 1995; Goldman-Rakic, 1994, 1996; Fuster, 1997b, 2000, 2001; Fuster *et al.,* 2000). The DLPFC has close connections with the orbital and medial prefrontal cortex. The orbital prefrontal regions are tightly linked to dorsolateral prefrontal areas (lateral 9 and 46) rostral and the dorsal cingulate cortex is tightly linked to rostral medial dorsal prefrontal areas, 9 and medial 10 (Carmichael and Price, 1996b; Fogassi *et al.,* 1996; Graziano *et al.,* 1997; Petrides and Pandya, 1999).

The medial prefrontal cortex, or anterior cingulate cortex, contains a number of different functional regions and has been divided into a ventral subgenual area (area 25) and two dorsal areas (24a/b and 24c). The subgenual region (area 25) is particularly important in the expression of emotion and, based on imaging studies, is associated with increased activity during depression (Mayberg *et al.,* 1999, 2000). It receives one of the densest innervations from the amygdala and the hypothalamus (Carmichael and Price, 1995). The more dorsal parts of cingulate cortex (area 24a/b), while also associated with emotion and motivation, and receiving amygdala input, are, in addition, closely connected to the dorsolateral prefrontal cortex (Carmichael and Price, 1996b). The most lateral and caudal areas of cingulate cortex (area 24c) are referred to as motor cingulate and are associated with premotor and motor areas (Dierssen *et al.,* 1969; Vogt and Pandya, 1987; Luppino *et al.,* 1991; Matelli *et al.,* 1991; Morecraft and VanHoesen, 1993; Showers, 1959). Orbital prefrontal cortex is involved in the development of reward-based learning and goal-directed behaviors. Consistent with its sensory inputs, coupled with those from the amygdala and other limbic-related regions, the orbital cortex has been linked with the development of reward-based behaviors (Benjamin and Burton, 1968; Butter and Snyder, 1972; Benevento *et al.,* 1977; Porrino *et al.,* 1981; Amaral, 1986; Mishkin and Bachevalier, 1986; Rolls and Baylis, 1994; Baylis *et al.,* 1995; Carmichael and Price, 1995, 1996a; Meunier *et al.,* 1997; Baxter *et al.,* 2000; Hikosaka and Watanabe, 2000; Schultz *et al.,* 2000). Lesions of the orbital and medical prefrontal areas result in an inability to initiate and carry out goal-directed behaviors and lead to socially inappropriate and impulsive behaviors (Butter, 1969; Rolls *et al.,* 1980; Eslinger and Damasio, 1985; Scott *et al.,* 1986; Fuster, 1989; Cummings, 1993, 1995; Filley, 1995; Schall, 1997). Furthermore, changes in the recruitment of activity in the orbitalfrontal and cingulate cortices are associated with several mental health disorders including anxiety, depression, drug addiction, and obsessive compulsive behaviors (Breiter *et al.,* 1996, 1997; Miguel *et al.,* 1997; Mayberg *et al.,* 1999, 2000). As we will see, together, the orbital and medial prefrontal cortical (OMPFC) projections to the striatum define the ventral striatum as that part of the striatum that mediates reward and motivation.

Afferent Connections to the Sriatum

Corticostriatal Projections

The origin of the neocortical striatal projection in primates is primarily derived from the pyramidal neurons of layer five (Jones *et al.,* 1977; Arikuni and Kubota, 1986; Goldman-Rakic and Selemon, 1986; Haber *et al.,* 1995b; McFarland and Haber, 2000). In addition, in some areas of cortex, layer three also contributes to the corticostriatal pathway (Jones *et al.,* 1977; Arikuni and Kubota, 1986; Goldman-Rakic and Selemon, 1986; Haber *et al.,* 1995b; McFarland and Haber, 2000). It has long been thought that corticostriatal projections arise as collaterals of other corticofugal axons. This certainly seems to be the case for many of the cortical afferents to striatum, based on examination of axons impregnated by the Golgi method and after intracellular filling of cortical neurons and their axons (Donoghue and Kitai, 1981; Ramón y Cajal *et al.,* 1988; Levesque *et al.,* 1996a, b). Corticothalamic fibers send a collateral projection to the striatum, and it is thought that all striatal projections indeed arise from these corticothalamic cells. However, it should be pointed out that not all cells that project to the thalamus send a collateral projection to the striatum. In addition, some evidence suggests that cells in layer three of cortex that give rise to corticocortical projections, also send collaterals to the striatum (Wilson, 1987). Cortical terminals within the striatum are distributed such that densely innervated areas are surrounded by areas relatively free of terminals. This patchy pattern is consistent with patterns found with other afferent projections as well as with transmitter-related compounds (see "Compartmentation of the Striatum").

Current views on the precise topography of corticostriatal connections are in a state of flux. The older idea is that the cortex projects in a more or less direct fashion to the closest portion of underlying striatum (Kemp and Powell, 1970). Moreover, behavioral, physiological, and clinical evidence has capitalized on this apparent topography to demonstrate functional similarities between particular areas of cortex and their "most closely" associated striatal subdivision (we will come back to this later). However, tracing studies have demonstrated a wide rostrocaudal projection area for each cortical region suggesting that corticostriatal innervation is organized in a longitudinal topography (Selemon and Goldman-Rakic, 1985). For example, prefrontal cortex projects not only to the head of the caudate but also to the body and tail of the caudate nucleus (Goldman and Nauta, 1977; Yeterian and Van Hoesen, 1978). Selemon and Goldman-Rakic (1985) concluded on the basis of such data that a significant feature of corticostriatal topography is a medial to lateral arrangement that extends throughout the length of the caudate including the head, body, and tail of this structure. More careful analysis of these pathways demonstrates that both schemes have merit. Projections from cortex to the striatum have a wider

rostrocaudal projection than initially described and indeed do project throughout a large extent of the striatum. However, while the extent is large, the main terminal region (as defined by the densest mediolateral, dorsoventral terminal area) is often found in a relatively localized rostrocaudal region and indeed in the most adjacent position to its cortical input. It is important to remember that the separation between the caudate nuc. and the putamen is merely a structural one, based solely on the interal capsule separation, not a functional one However, based on anatomical and physiological studies of the central and caudal aspects of the striatum, the putamen is mostly associated with the sensorimotor system, and the caudate, with association or prefrontal cortex. While these generalities are useful, we must be careful here because the rostral striatum does not fit well with this distinction.

Many of the tracing studies of BG circuitry have been done in primates, and, as such, we will focus on those. Perhaps the area that receives the most attention is that area associated with the motor system. The projections from motor and premotor cortices were some of the first to be identified (Kemp and Powell, 1970; Kunzle, 1975, 1978; McFarland and Haber, 2000). Projections from M1 terminate almost entirely in the putamen, in the dorsolateral and central region. There are some terminals, albeit few, rostral to the anterior commissure; however, the main projection lies caudal to the anterior commissure, with few terminals extending rostrally. Indeed, the motor cortex does not project to the rostral pole of the striatum or, in fact, to most of the area rostral to the anterior commissure. The caudal premotor area projects to a striatal region that is just adjacent to M1 projections. These terminals extend only slightly into the caudate nucleus. The rostral premotor areas terminate in both the caudate and putamen, bridging the two with a continuous projection. These premotor motor area terminals extend more rostrally than those from the motor cortex, although they do not extend into the rostral pole of the striatum. Both motor and premotor areas extend through much of the putamen caudally. This dorsolateral sector of the striatum also receives overlapping projections from parietal areas associated with somatosensory function. Furthermore, these parietal projections follow the same somatotopic organization (Künzle, 1977; Aosaki *et al.,* 1994b; Flaherty and Graybiel, 1994). Thus, the dorsolateral striatal region has been referred to as the sensorimotor striatal area (Alexander and Crutcher, 1990; Parent and Hazrati, 1995; McFarland and Haber, 2000). Physiological studies support the involvement of this region in sensorimotor control and motor plans. Within this area, a somatotopic map has been identified both through connectional as well as physiological studies demonstrating the somatotopic microexcitable striatal zones (Alexander and DeLong, 1985a, b). In addition, studies also show neuronal reponses to specific movement. For example, using arm-movement tasks in different behavioral paradigms, several investigators have demonstrated that neurons in the putamen fire in association with movement selection or initiation. Cells are also active during movement monitoring (DeLong and Strick, 1974; DeLong and Georgopoulos, 1979; Aldridge *et al.,* 1980b; DeLong and Georgopoulos, 1981; Alexander and DeLong, 1985a, b; Alexander and DeLong, 1986; Kimura, 1986, 1990; Flaherty and Graybiel, 1991b). Imaging studies in humans support these nonhuman primate physiological experiments revealing activity associated with repetitive and well-learned movements that require little cognitive effort, centered in both the caudal motor areas of cortex and in the lateral putamen. In contrast, activity recorded during the learning of sequential movements in both monkey physiological experiments and human imaging studies demonstrate activity in the rostral motor regions (pre SMA) and more anterior striatal areas including the caudate nucleus (Aizawa *et al.,* 1990; Kermadi and Joseph, 1995; Hikosaka *et al.,* 1996; Jueptner *et al.,* 1997; Miyachi *et al.,* 1997; Boecker *et al.,* 1998). The frontal eye fields send projections to the striatum that terminate in the central lateral part of the head and body of the caudate nucleus (Kunzle and Akert, 1977; Huerta *et al.,* 1986; Stanton *et al.,* 1988; Hikosaka *et al.,* 1989a). This area of cortex also contains a rostral region, referred to as the supplementary eye fields, which has a relationship to the frontal eye fields, with respect to learned acquistion of oculomotor behaviors, similar to that which the rostral and caudal motor regions have to learned behavioral sequences of hand movements (Chen and Wise, 1995). Finally, the motor cingulate cortex also sends an overlapping projection to the sensorimotor region of the striatum (Kunishio and Haber, 1994; McFarland and Haber, 2000). Taken together, the motor and premotor areas (and the frontal eye fields) mediate different aspects of motor behavior, including planning, learning, and execution, which are in turn reflected both anatomically and physiologically in the central and lateral caudate nuc. and in the central, dorsal, and lateral putamen, respectively. The pattern of neuronal discharge in these striatal regions that accompanies these behaviors has been proposed to underlie procedural learning. This corticostriatal interface has further been associated with the development of "habits", in which a discrete sequence of behaviors can be triggered by particular sets of stimuli (Hikosaka, 1991; Hikosaka *et al.,* 1995;

Kermadi and Joseph, 1995; Jueptner *et al.*, 1997; Graybiel, 1998; Jog *et al.*, 1999).

The DLPFC projects primarily to the rostral central region of the caudate nuc. However, the rostrocaudal extent of this projection is quite large and continues from the rostral pole of the striatum through its caudal extent (Selemon and Goldman-Rakic, 1985; Arikuni and Kubota, 1986). This innervation is one of the largest to the striatum and interfaces with several other cortical areas. These projections are organized somewhat topographically such that, for example, input from the rostral pole of frontal cortex terminates most densely in the rostral part of the striatum, including both the caudate and putamen. The entire DLPFC projection extends continuously throughout the caudate nuc., with few terminals in the central and caudal putamen (Selemon and Goldman-Rakic, 1985). The majority of this projection is centered in the head of the caudate nuc. As described earlier, the DLPFC plays an important role in executive functions, with delayed memory tasks as a classic measurement (Goldman-Rakic, 1987; Jonides *et al.*, 1993; Smith and Jonides, 1997; Fuster, 2000, 2001). Consistent with input from this cortical area, cells in the head of the caudate nuc. demonstrate spike-firing activity during the delayed portion of the task. This activity resembles that observed in the DLPFC (Hikosaka *et al.*, 1989b; Apicella *et al.*, 1992). Furthermore, imaging studies support the idea that the head of the caudate is instrumental in delayed tasks, particularly in specific working memory tasks (Levy *et al.*, 1997; Elliott and Dolan, 1999). Finally, lesions of the caudate nuc. in both human and nonhuman primates produce deficits in working memory as measured by delayed response tasks (Battig *et al.*, 1960; Butters and Rosvold, 1968; Partiot *et al.*, 1996). Taken together, the caudate nuc., and in particular the head of the caudate, is involved in working memory and strategic planning processes, working together with the DLPFC in mediating this function.

The orbital and medial prefrontal cortex projects primarily to the rostral striatum and includes terminals in the medial caudate nuc., the medial and ventral rostral putamen, and the nucleus accumbens (both the shell and the core). This projection extends caudally and occupies a small ventromedial portion of the caudate nuc. and the most ventral and medial part of the putamen (Pandya *et al.*, 1981; Kunishio and Haber, 1994; Haber *et al.*, 1995b; Chikama *et al.*, 1997; Ferry *et al.*, 2000; Freedman *et al.*, 2000). Indeed, the caudal, ventral putamen has been suggested as the caudal extension of the ventral striatum (Fudge and Haber, 2002). In addition, the ventral striatum receives input from the amygdala. The shell receives the densest innervation from medial areas 25, 14, and 32 and from agranular insular cortex areas involved in monitoring the internal mileu. Medial areas 24, 25, and 32, also project to the medial wall of the caudate nucleus. Projections from area 24 extend dorsally and somewhat more centrally into the caudate nuc. and overlap with inputs from the medial parts of the DLPFC (particularly rostral area 9). In addition, this medial area of the caudate nucleus receives a dense innervation from areas 13a/b and 14 and from parts of dysgranular insular cortex. In contrast, the central and lateral parts of the ventral striatum receive fewer inputs from medial prefrontal cortex. Their main input is derived from the lateral OMPFC regions, areas 13 and 12, and dysgranular insular cortex (Kunishio and Haber, 1994; Haber *et al.*, 1995b; Chikama *et al.*, 1997; Ferry *et al.*, 2000). These projections extend more centrally and overlap with inputs from the lateral aspects of the DLPFC. As noted previously, area 24, that part of the cingulate cortex closely connected to motor areas, does not project to the ventral striatum but rather to the dorsolateral striatum (Kunishio and Haber, 1994). As indicated earlier, these orbital and medial prefrontal areas are primarily associated with the development of reward-based behaviors. Physiological as well as imaging studies support the idea that the ventral striatum plays an important role in the aquistion and development of reward-based behaviors (Apicella *et al.*, 1991b; Apicella *et al.*, 1992; Bowman *et al.*, 1996; Tremblay *et al.*, 1998; Hassani *et al.*, 2001). This striatal area is a main focus of research in drug addiction and drug-seeking behaviors. These studies demonstrate activity changes in the ventral striatum during different aspects of addiction (Bowman *et al.*, 1996; Lyons *et al.*, 1996; Freeman *et al.*, 2001; Letchworth *et al.*, 2001). In addition, pharmacologic and molecular biological studies support the central role of the ventral striatum in drug addiction (Nestler *et al.*, 1993; Koob, 1999). That the ventral striatum is the striatal region most often associated with the limbic system, emotions, and motivation is supported by its central position in mediating reward-based learning (Everitt and Robbins, 1992; Kalivas *et al.*, 1993; Wise, 1998; Robbins and Everitt, 1999).

In summary, projections from frontal cortex form a functional gradient of inputs from the ventromedial sector through the dorsolateral striatum, with the medial and orbital prefrontal cortex terminating in the ventromedial part and the motor cortex terminating in the dorsolateral region (Fig. 21.22B). Within this gradient, the cortical projections to the striatum are quite precise. For example, the dorsolateral putamen receives input from the dorsal premotor, the dorsal primary motor, and the supplementary motor cortices. More ventral putamen areas receive input from the

ventrolateral premotor cortex and the lateral precentral gyrus (McFarland and Haber, 2000). In general, frontal projections from motor areas (areas 4, 6, and 8), but not from the medial and orbital prefrontal cortex, reach the dorsolateral striatum. In contrast, the medial and orbital prefrontal cortex projects to the ventral striatum but not to the dorsolateral striatum. Dorsolateral prefrontal cortex (areas 9, 46, and 45) project centrally, with little or no afferent projection to the calbindin-poor shell region or to the ventral rostral putamen, the ventral caudate nucleus, and the medial wall of the rostral caudate nucleus.

Fewer studies have focused on projections from other cortical areas to the striatum. As with the frontal lobe, temporal lobe projections terminate throughout wide areas of the striatum (Yeterian and Van Hoesen, 1978; Van Hoesen *et al.*, 1981; Selemon and Goldman-Rakic, 1985; Yeterian and Pandya, 1998). Superior temporal gyrus terminates primarily in the central half of the caudate nuc. and overlaps and interdigitates with inputs from DLPFC. Inferior temporal areas terminate more ventrally, including the caudal and ventral putamen. These inputs overlap to some extent with those from the medial and orbital prefrontal areas. Visual areas in the temporal lobe terminate primarily in the caudal part of the striatum. However, these projections reach quite rostrally into the medial part of the body of the caudate, extending into the tail of the caudate and reaching caudal parts of the putamen (Maioli *et al.*, 1983; Maunsell and van Essen, 1983). As mentioned earlier, projections from the parietal lobe terminate in striatal areas that complement those that are interconnected with frontal lobe projections. Finally, axons from visual cortex apparently terminate in posterior portions of the body of the caudate nucleus as it arcs ventrally into the temporal lobe (Saint-Cyr *et al.*, 1990).

Thalamostriatal Projections

Like the cortex, the thalamostriatal projection is topographically organized. Thalamic nuclei are associated with sensory, motor, association, and limbic systems by virtue of their connectivity with cortical and subcortical regions. Furthermore, as we will see later, comparison of the distribution of cortical and thalamic projections to the primate striatum demonstrates that interconnected thalamic and cortical areas project to the same region of the striatum (Künzle, 1975, 1977; Kunzle and Akert, 1977; Kunzle, 1978; Yeterian and Van Hoesen, 1978; Pandya *et al.*, 1981; Selemon and Goldman-Rakic, 1985; Flaherty and Graybiel, 1991a; Yeterian and Pandya, 1991; Parthasarathy *et al.*, 1992; Flaherty and Graybiel, 1994; Haber *et al.*, 1995b; Chikama *et al.*, 1997). Thus, afferents from these interconnected thalamic and cortical areas are likely to modulate the same striatal output circuits.

The midline and intralaminar nuclei are often referred to as part of the nonspecific thalamic cell groups. These are the source of the most widely reported thalamostriatal projections (Jones and Leavitt, 1974; Dubé *et al.*, 1988; Nakano *et al.*, 1990; Sadikot *et al.*, 1990; Fenelon *et al.*, 1991; Francois *et al.*, 1991; Sadikot *et al.*, 1992a; Smith *et al.*, 1994b; Giménez-Amaya *et al.*, 1995; McFarland and Haber, 1995; Nakano *et al.*, 1999; McFarland and Haber, 2000). These thalamic nuclei are associated with specific cortical areas, and, as such, with those cortical functions. Both the midline and the intralaminar nuclei are further subdivided. The midline and medial intralaminar nuclei (including central medial and medial parafascicular nuc.) project to medial prefrontal areas, the amygdala, hippocampus, and perihippocampal cortex. The rostral intralaminar nuclei and centromedian and parafascicular (CM/Pf) complex have connections with association areas, such as the prefrontal and posterior parietal cortices. The lateral CM nucleus projects to both the primary motor and sensory cortices (Herkenham, 1978, 1986; Groenewegen and Berendse, 1994a; Jones, 1998). These nuclei project topographically to the striatum such that the midline, medial parafascicular and central medial nuclei project mainly to ventral (limbic) striatal areas, whereas the more lateral intralaminar nuclei have connections with the dorsolateral (sensorimotor-association) caudate and putamen. A medial to lateral topography has been described for striatal projections from the CMPf complex in the squirrel monkey, such that the medial Pf projects to the ventral "limbic" striatum, the central part projects to association-striatum, and the lateral CM projects primarily to the sensorimotor putamen and dorsolateral caudate nucleus (Francois *et al.*, 1991; Sadikot *et al.*, 1992a; Giménez-Amaya *et al.*, 1995; McFarland and Haber, 2000). In this way, projections from the so-called nonspecific thalamic nuclei project to discete striatal areas that are consistent with the cortical area they are most associated with. This thalamostriatal projection thus maintains the functional distinction of different striatal regions.

In addition to intralaminar thalamic projections, there is an equally large projection to the dorsal striatum from the "specific" thalamic nuclei, including the mediodorsal (MD), ventral anterior and ventral lateral nuclei. While significant thalamostriatal projections from these areas are not observed in rodents, they are found in larger mammals, including primates (Jones and Leavitt, 1974; Parent *et al.*, 1983; Smith and Parent, 1986; Nakano *et al.*, 1990; Druga *et al.*, 1991; Fenelon

et al., 1991; Giménez-Amaya *et al.*, 1995; McFarland and Haber, 2000, 2001).

These thalamic nuclei are also intimately connected with specific frontal cortical areas (Akert and Hartmann-von Monakow, 1980; Goldman-Rakic and Porrino, 1985; Wiesendanger and Wiesendanger, 1985; Giguere and Goldman-Rakic, 1988; Matelli *et al.*, 1989; Nakano *et al.*, 1992; Dum and Strick, 1993; Matelli and Luppino, 1996). Thus, different regions of the ventral motor nuclei (VA-VL) have reciprocal projections with specific premotor, motor and cingulate cortices (Akert and Hartmann-von Monakow, 1980; Schell and Strick, 1984; Rouiller *et al.*, 1994; Matelli and Luppino, 1996). Different parts of the MD nucleus are linked to specific prefrontal areas (Akert and Hartmann-von Monakow, 1980; Goldman-Rakic and Porrino, 1985; Giguere and Goldman-Rakic, 1988). As with the midline and intralaminar nuclei, interconnected ventral thalamic and MD nuc. and cortical areas project to the same region of the striatum. For example, VPLo projects to M1 and most of the caudal "secondary" motor areas. These areas issue dense projections to the dorsolateral putamen. VLo projects densely to SMA and the dorsal part of CMAc. VLo and SMA projections converge in the dorsal, central putamen. VLc is predominately connected with PMd, but it also has connections with PMv and the ventral part of CMAc. VLc and PMd projections mainly target the dorsolateral caudate nucleus. Rostral motor areas, including PMdr, PreSMA, and CMAr, receive inputs from VApc. Striatal projections from these areas converge within the ventral putamen and dorsolateral caudate. These findings demonstrate a tight, anatomical and functional triad of basal ganglia input and output structures, involving the frontal motor cortices, the striatum, and the thalamic relay nuclei. Furthermore, these results also suggest that these thalamic projections play a dual role in basal ganglia circuitry: (1) relaying basal ganglia output to frontal cortical areas and (2) providing direct feedback to the striatum (McFarland and Haber, 2000, 2002a).

Midbrain Dopamine-Striatal Projections

Dopamine neurons, which comprise the majority of cells in the SN pars compacta, the VTA, and the retrorubral group, play a key role in the acquisition of newly acquired behaviors. The role of dopamine in reward has been well established (Fibiger and Phillips, 1986; Wise and Rompre, 1989); its primary function is to direct attention to important stimuli likely to bring about a desired outcome (Ljungberg *et al.*, 1991; Schultz, 1998). Dopamine cells discharge when presented with relevant stimuli for which a response is required (Grace and Bunney, 1995; Schultz, 1997). However, when the animal is overtrained, cells no longer respond, suggesting that it is not the movement but the relevance of the stimulus that is important (Schultz, 1992; Schultz *et al.*, 1993; Wilson *et al.*, 1995; Richardson and Gratton, 1996). While behavioral and pharmacological studies of dopamine pathways have lead to the association of the mesolimbic pathway and nigrostriatal pathway with reward and motor activity, respectively, more recently both of these cell groups have been associated with reward. Indeed, physiological experiments demonstrate that 75% of dopamine neurons (including neurons from the so-called nigrostriatal pathway) respond with burst firing activity when food is unexpectedly found (Romo and Shultz, 1990). These are not pure motor responses since the DA neurons are not modulated by the movements that are generated during exploratory behaviors performed in exclusion of touching the food reward. Instead, the DA neurons respond in association with identifying, obtaining, or predicting rewards. In contrast, DA neurons will pause if a predicted reward fails to occur (Schultz and Romo, 1990; Ljungberg *et al.*, 1991; Schultz, 1998; see also Schultz *et al.*, 2000). Thus, unlike the other major inputs to the striatum (the cortex and thalamus), the dopamine cells are more difficult to categorize based on their association with different cortical functions. Rather, as a group, they appear to mediate aspects of the reward response. In this respect, the dopamine system has been an intense focus of productive research in the development of reward-based learning, drug addiction, and plasticity (Weihmuller *et al.*, 1990; Anglade *et al.*, 1996; Montague *et al.*, 1996; Berridge and Robinson, 1998; Hollerman and Schultz, 1998; Bonci and Malenka, 1999; Contreras-Vidal and Schultz, 1999; Koob, 1999; Matsumoto *et al.*, 1999; Berke and Hyman, 2000; Calabresi *et al.*, 2000c; Song and Haber, 2000; Nestler, 2001). Therefore, from a functional perspective, the dopamine projection to the striatum is likely to have a similar impact on all striatal reigons.

You will remember that the dopamine synapses are in a position on the dendrites of the MSNs to modulate incoming cortical information. Therefore, with relatively few synapses, the impact of the dopaminergic innervation is nonetheless likely to be great. Striatal response to dopamine is heterogenous and, as described previously, determined by multiple variables including complex interactions between several receptors. Converging evidence indicates that tonic release of dopamine attenuates medium spiny neuronal response, while phasic release potentiates striatal response (Di Chiara *et al.*, 1994; Arbuthnott and Wickens, 1996; Cepeda and Levine, 1998; Calabresi *et al.*, 2000b; Wickens and Oorshcot, 2000). In this way, dopamine can both inhibit background corticostriatal input but

facilitate (and therefore "focus") specific corticostriatal synaptic transmission. Even though projections from the different dopamine cell groups are not as tightly arranged topographically as are inputs from the cortex and thalamus, there is an important organization to this input that underlies a mechanism for modulating the different striatal regions, both separately and across functional domains. This complex system includes both the dopamine-striatal pathway as well as the striatal input to the dopamine neurons. Here we will only address the dopamine input to the striatum and will return to the complexity of this interface later.

As previously described, the midbrain dopamine system is divided into the dorsal tier and ventral tier cells. The dorsal tier cells include the VTA, the retrorubral group, and the dorsal cells of the pars compacta. The ventral tier cells include the densocellular group and the cell columns that extend deep into the pars reticulata. In general, there is an inverse dorsal-ventral topographic organization to the midbrain projection to the striatum. The dorsal dopamine cells project to the ventral parts of the striatum, while the ventrally placed cells project to the dorsal parts of the striatum (Carpenter and Peter, 1972; Szabo, 1979, 1980; Parent *et al.*, 1983; Hedreen and DeLong, 1991; Lynd-Balta and Haber, 1994a, b; Haber *et al.*, 2000). Thus, the dorsal tier projects to the ventromedial striatum; the densocellular part of the ventral tier projects centrally and throughout different regions of the striatum; and the cell columns project primarily to the dorsolateral (sensorimotor) striatum. The shell region of the ventral striatum receives the most limited input, primarily derived from the VTA. The rest of the ventral striatum receives input from the entire dorsal tier. In addition, there are some afferent projections from the most medial region and dorsal part of the densocellular group. In contrast to the ventral striatum, the central striatal area (the region innervated by the DLPFC) receives input from a wide region of the densocellular group. The ventral tier projects to the dorsolateral striatum, with the cell columns projecting almost exclusively to there. The dorsolateral striatum receives the largest midbrain projection from cells throughout the ventral tier. In contrast to the dorsolateral region of the striatum, the ventral striatum receives the most limited dopamine cell input. Of this area, the shell is most limited in terms of relative distribution of cells projecting there. Thus, in addition to an inverse topography, there is also a differential ratio of dopamine projections to the different striatal areas. The input to the ventral striatum is derived from the most limited midbrain region, while the input to the dorsolateral striatum is derived from the largest midbrain area (Haber *et al.*, 2000).

Striatopallidal/Substantia Nigra Reticulata Connections

The striatum projects primarily to the pallidal complex and to the SNR. These projections are topographically organized, thus maintaining the functional organization of the striatum in its projections to the output nuclei of the basal ganglia (Szabo, 1962; Nauta and Mehler, 1966; Szabo, 1967, 1970, 1980; Carpenter *et al.*, 1981b; Parent *et al.*, 1984; Haber *et al.*, 1990b; Selemon and Goldman-Rakic, 1990; Hedreen and DeLong, 1991; Lynd-Balta and Haber, 1994c; Parent and Hazrati, 1994). Projections from the sensorimotor areas of the striatum terminate in the ventrolateral part of each pallidal segment. In the SNR they are also found in the ventrolateral part of the nucleus. Projections from the central striatum terminate more centrally in both the pallidum and the SNR. Finally, the ventral striatum terminates topographically in the ventral pallidum and in the dorsal part of the midbrain. The projection to the midbrain terminates both in the region of the dopamine neurons and in the pars reticulata (Parent *et al.*, 1984; Haber *et al.*, 1990b; Lynd-Balta and Haber, 1994c). Projection to the dopamine neurons has been considered one mechanism by which the limbic system can interface with the motor system through the basal ganglia pathways (Nauta and Domesick, 1978; Somogyi *et al.*, 1981b; Heimer *et al.*, 1982; Haber *et al.*, 2000). We will return to this concept later.

Physiological studies demonstrate the continuity of striatal functional areas in the pallidal complex. However, it must be recognized that here the functional organization within the pallidum is more complex than that of the striatum. This may, in part, be due to the fact that there is a certain amount of compression of terminals from a relatively large striatum to a much smaller pallidum (Oorshcot, 1996). It may also be the result of integrative networks linking different functional domains (Nauta *et al.*, 1978; Somogyi *et al.*, 1981b; Bevan *et al.*, 1997; Haber *et al.*, 2000; Haber, 2002; McFarland and Haber, 2002a). Pallidal neurons that receive information from motor cortical areas (via the striatum) are somatotopographically arranged such that, for example, those representing the face are located most ventrally and arm-related neurons are located more dorsally (DeLong *et al.*, 1985; Nambu *et al.*, 1990). Although the pallidal segments are differentiated anatomically and neurophysiologically, most behavioral studies have treated both segments as a single neural population. Studies have explored the relationship of pallidal response to different aspects of movement, including movement duration, movement direction, and movement amplitude or velocity. While most cells

increase their neural activity associated with motor tasks, a smaller proportion of cells do decrease (pause) their activity (Aldridge *et al.*, 1980a; Georgopoulos *et al.*, 1983; Anderson and Horak, 1985; Mitchell *et al.*, 1987; Anderson and Turner, 1991; Brotchie *et al.*, 1991b; Mink and Thach, 1991a; Mink and Thach, 1991b). Of particular interest is that these studies do not support the notion that GP neurons play a direct role in the initial activation of muscles to generate voluntary movement. Indeed, GP activity usually precedes muscle activation, but by too short a time increment to be instrumental in movement production. Taken together, these findings suggest that GP plays an integral role in the coordination of voluntary movement, but not necessarily in movement initiation. In fact, a growing body of evidence suggests that GP neurons are selectively modulated during movement behaviors performed in different behavioral contexts.

Experiments have also tested the potential role of the pallidum in learning paradigms. In one study, the investigators found that GPi neurons were modulated during the delay between the presentation of the visual instruction cue and the "go" cue signaling movement initiation. Furthermore, many of these cells were responsive during the novel cue condition suggesting that the pallidum participates in the association learning processes (Inase *et al.*, 2001). Other studies support the role of both pallidal segments in developing multiple-segment movement sequencing (Georgopoulos *et al.*, 1983; Brotchie *et al.*, 1991a; Jaeger *et al.*, 1993; Mushiake and Strick, 1995). These studies provide evidence for the diversity of neural activity that is exhibited by pallidal neurons in association with different behavioral conditions. Of particular importance is the change in response of these neurons in animal models of PD or in dopamine-depleted animals. These studies help explain some of the pathophysiological signs that become manifest as consequence of disease progression and may provide a mechanism to identify early cognitive and oculomotor deficits in nonhuman primates that may serve to facilitate early diagnosis in human patients (Nini *et al.*, 1995; Bergman *et al.*, 1998; Slovin *et al.*, 1999; Raz *et al.*, 2001). Furthermore, these animal models have been instrumental in developing and testing therapies that have proven to be useful in the treatment of humans with PD (Bergman *et al.*, 1990; Boraud *et al.*, 1996).

The neurons of the SNR are often related to oculomotor function. However, these cells not only are involved in the eye movement itself, but also are associated with the context in whch the movement occurs (Hikosaka and Wurtz, 1983b; Basso and Wurtz, 2002). For example, changes in modulation are observed when the eye movements were made within the constraints of the task, but not when the same eye movements were spontaneously generated (Hikosaka *et al.*, 1989b; Hikosaka and Watanabe, 2000).

Striatal Innervation of the Dopamine Neurons

While afferent control of dopaminergic neurons arises from a number of structures, the striatum is a major source. The striatum inhibits neurons in SNC. However, stimulation of the striatum can also lead to an increase in dopamine cell firing through inhibition of GABAergic interneurons (or pars reticulata cells) that terminate on dopaminergic cells and dendrites, resulting in disinhibition of pars compacta cells (Francois *et al.*, 1979; Grace and Bunney, 1979; Johnson and North, 1992; Grace and Bunney, 1995). This dual effect of both inhibition and disinhibition may be an important mechanism underlying the control of dopamine cell-firing patterns. Projections from the striatum to the midbrain are arranged in an inverse dorsal-ventral topography as are the ascending midbrain projections. Thus, the dorsal aspects of the striatum terminate in the ventral regions of the midbrain, while the ventral areas terminate dorsally (Szabo, 1967, 1970, 1980; Haber *et al.*, 1990b; Selemon and Goldman-Rakic, 1990; Hedreen and DeLong, 1991; Lynd-Balta and Haber, 1994c; Parent and Hazrati, 1994). Specifically, efferent projections to the midbrain from the ventromedial striatum, including the shell, terminate throughout an extensive dorsal region, including the VTA and the medial SNC, along with the medial pars reticulata. Thus the ventral striatum not only projects throughout the rostrocaudal extent of the substantia nigra but also innervates a wide mediolateral range of dopaminergic cells. At central and caudal levels, this projection field extends laterally and includes much of the densocellular SNc. The central striatum projection terminates more ventrally, primarily in the ventral densocellular region (and associated pars reticulata). The dorsolateral striatum projections to the midbrain terminate in the ventrolateral midbrain in the pars reticulata, which includes some of the dopaminergic cell columns that extend into this region.

You will remember that projections from the midbrain to the striatum differ in the proportion of cells projecting to each region of the striatum. Likewise, there are important differences in the extent of the terminal fields from each of the striatal regions to the midbrain. However, there is an inverse relationship to the extent of the midbrain innervation of the striatum. For example, in contrast to its relatively limited afferent midbrain input, the ventral striatum innervates a large area of the midbrain, including much of the dorsal tier and the densocellular area of the ventral tier and associated pars reticulata. On the other hand,

the dorsolateral striatum, which has a relatively extensive midbrain input, projects to a limited midbrain region, primarily to the ventrolateral pars reticulata and the cell columns that invade this area (Haber *et al.*, 2000). The central striatum terminates in both the densocellular region and the cell columns along with the pars reticulata associated with these areas. We can see from this relationship that there is a loose topographic organization demonstrating that the VTA and medial SN are associated with the limbic system, and the lateral and ventral midbrain are related to the associative and motor striatal regions, respectively. The ventral striatum receives a limited midbrain input but projects to a large region that includes dorsal and ventral tiers and the dorsal pars reticulata. In contrast, the dorsolateral striatum receives a wide input but projects to a limited region. This arrangement suggests that the ventral striatum influences a wide range of dopamine neurons but is itself influenced by a relatively limited group of dopamine cells. On the other hand, the dorsolateral striatum influences a limited midbrain region but is affected by a relatively large midbrain region. We will return to this later as we consider the role of the midbrain in integrating information flow across the functional domains of the striatum (Fig. 21.23).

Thalamus—The Final Basal Ganglia Link Back to Cortex

The ventral tier and mediodorsal thalamic nuclei receive the bulk of basal ganglia output (from the pallidum and substantia nigra). These BG thalamic relay nuclei are the source of the direct feedback to the cortex. The primate ventral anterior (VA) nucleus can be distinguished cytoarchitecturally from the ventral lateral nucleus. Both are composed of several distinct nuclear subdivisions (Ilinsky and Kultas-Ilinsky, 1987). The magnocellular portion of VA specifically receives nigral inputs and can be delineated by these projections (Ilinsky *et al.*, 1985). Moreover, the parvicellular and densocellular (VAdc, or VLo) portions receive pallidal projections (Kuo and Carpenter, 1973; Kim *et al.*, 1976; DeVito and Anderson, 1982; Parent and DeBellefeuille, 1983; Ilinsky *et al.*, 1993). In addition, the MD nucleus receives input from the SNR and from the ventral pallidum (Haber *et al.*, 1985; Ilinsky *et al.*, 1985). As we have seen in previous sections, the thalamus is linked to cortex both anatomically and physiologically. Areas of VL that receive the main ouput from motor regions of the pallidum terminate in motor areas of frontal cortex. Likewise VA nucleus is associated with premotor and DLPFC, and the MD nucleus is linked to the DLPFC and orbital and medial prefrontal cortex (Giguere and Goldman-Rakic, 1988).

Striato-nigro-striatal projections: a mechanism for integrating information across parallel pathways

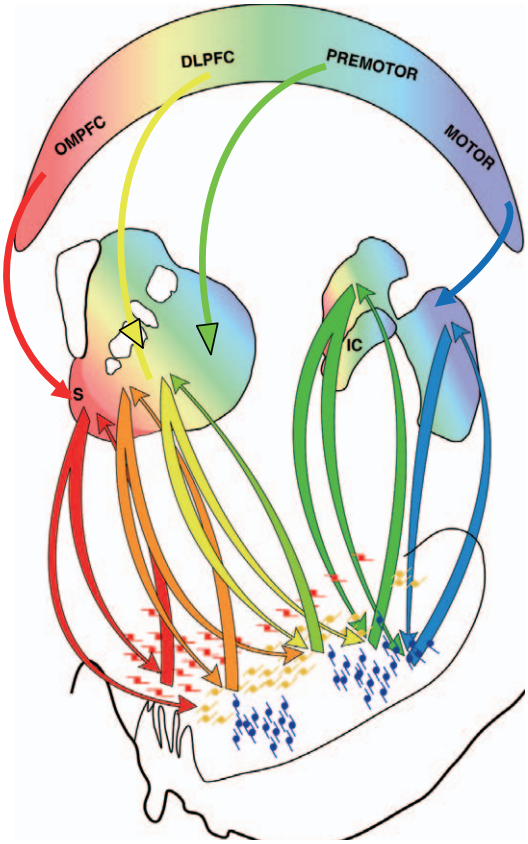

FIGURE 21.23 Diagram of the organization of striatonigrostriatal (SNS) projections (Haber *et al.*, 2000). The colored gradient in rostral and caudal schematics of the striatum illustrates the organization of functional corticostriatal inputs (see Fig. 21.22A). Midbrain projections from the shell target both the VTA and ventromedial SNc (red arrows). Midbrain projections from the VTA to the shell form a "closed," reciprocal SNS loop (red arrow). Projections from the medial SN feed-forward to the core forming the first part of a spiral (orange arrow). The spiral continues through the SNS projections (yellow and green arrows) with pathways originating in the core and projecting more dorsally (blue arrows). In this way, ventral striatal regions influence more dorsal striatal regions via spiraling SNS projections. IC, internal capsule; S, shell.

Thus, the functional topography of cortex is maintained from cortical connections to the striatum, from the striatum to the pallidum/SNR, from these output structures to the thalamus, and, finally, back to cortex.

FUNCTIONAL CONSIDERATIONS

As we have seen, the basal ganglia are connected with frontal cortex in a series of functional modules that maintain a relatively consistent anatomical and physiological organization. This organization has lead

to the concept of parallel processing of cortical information through segregated BG circuits. Parallel processing is based on the finding that each general functional area of cortex (limbic, associative, and sensorimotor) is represented in specific regions in each basal ganglia structure. Furthermore, within each of these three general circuits, additional channels have been proposed, each of which are linked to a subregion of frontal cortex (Alexander *et al.,* 1986; Hoover and Strick, 1993). This concept first arose in the late 1970s with the development of Heimer's classic concept of the ventral striatum (Heimer, 1978). While the basal ganglia was classically considered part of the motor control system, the inclusion of the ventral striatum and associated structures added an additional (and separate) functional loop within the basal ganglia. Indeed, tracing the pathways from the ventral striatum to the ventral pallidum, from the ventral pallidum to the thalamus and back to cortex was a fundamental discovery that pushed the field forward to consider other functional loops in addition to the motor circuit (Heimer *et al.,* 1982; Young *et al.,* 1984; Haber *et al.,* 1985). The idea of separate cortical loops in the basal ganglia was expanded in primates to include several parallel and segregated circuits based on frontal cortical regions (Alexander *et al.,* 1986). Collectively the studies reviewed in this chapter support the anatomical and general physiological organization of discrete cortical basal ganglia circuits and demonstrate three general regions: sensorimotor, associative, and limbic areas.

Superimposed on this model is the concept of direct and indirect pathways for each of these circuits. Together, these two organizational schemes (parallel processing and direct and indirect pathways) have helped us to formulate models concerning the role of the basal ganglia in processing cortical information within each circuit. The motor circuit has been commonly used to develop these models, which are then applied to each of the other circuits as well as to the general the overall function of the BG. Thus, the assumption is that, while each circuit mediates different behaviors (motor, cognition, motivation), the BG processes cortical information in a similar fashion within each circuit. One model that has received much attention focuses on the role of the BG in the selection and implementation of appropriate actions (or behaviors) while inhibiting unwanted ones. As you will recall, in the motor system this is viewed as inhibiting "unwanted" movements, while focusing on '"wanted and directed" movements. This model has been phrased in a number of different ways, including "focused selection," the modulation of action through temporal scaling and balance between the positive feedback via the direct pathway, and inhibition via the indirect pathway (Alexander and Crutcher, 1990; Mink, 1996; Wise *et al.,* 1996). Although helpful in understanding how the BG might play a role in the control of movement, it may not apply to the other circuits since these models are primarily based on the motor system and the execution of motor actions. Furthermore, since it is also based on parallel processing, this model does not address how information is transformed across functional regions to generate goal-directed behaviors. These two issues will be addressed later.

As mentioned in previous sections, in addition to the control of movement, the basal ganglia are now considered to be critical in the learning process. Indeed, based on experimental data and deficits caused by either cortical or basal ganglia disruption, several hypothesis that address the different roles for frontal cortex versus the basal ganglia in mediating the learning process now emerge. For example, based on comparing patients with frontal lesions with those suffering from PD, Owen and colleagues propose that the basal ganglia is critical for "shifting to" a new set of rules, while the frontal cortex is important for shifting from a new set of rules (Owen *et al.,* 1993). Wise and colleagues argue that frontal cortex is instrumental in learning new behaviors–guiding rules, while the basal ganglia potentates or reinforces those rules. Similarly, others have singled out the reward system of the basal ganglia for reinforcing cortically driven behaviors (Passingham, 1995). The role of reinforcement (particularly through the midbrain dopamine system) is now considered a critical component for basal ganglia function and is central to the newer models of BG function, which focus attention on its role in adaptation and adjustments to accommodate the past in predicting future outcomes and forming behavioral responses (Aosaki *et al.,* 1994a; Haber *et al.,* 2000; Bar-Gad and Bergman, 2001). This adaptability implies the necessity to evaluate continually and to adjust to stimuli throughout the execution of behaviors. This sort of "learning" has been physiologically demonstrated in several different tasks in which the firing pattern of BG neurons changes as during the learning process. Imaging studies further support the idea that different striatal cell groups change their activity during different phases of sequence learning (Grafton and Hazeltine, 1995; Hikosaka *et al.,* 1995; Jaeger *et al.,* 1995; Doyon *et al.,* 1997; Hikosaka *et al.,* 1998; Jog *et al.,* 1999). Thus, the emphasis is now on the role of the basal ganglia in the learning process, acquisition of new behaviors, and development of habits. The development of new behaviors and habits is dependent on response

learning (Passingham, 1995). That is, the ability of the animal to learn a new response, the learning rules, and the reinforcement of those behaviors. Indeed, the reinforcement properties of the dopamine system are critical for normal BG function. This, you will remember, is a neuronal system that primarily mediates different aspects of reward and affects all functional domains of the striatum (Aosaki *et al.*, 1994a; Schultz, 1997; Matsumoto *et al.*, 1999; Haber *et al.*, 2000; Bar-Gad and Bergman, 2001).

Most models of BG function rely on the concept of parallel processing. This is based on the idea that each cortical area mediates a parallel and segregated circuit through each of the BG structures. Therefore, these models do not address how information flows between circuits thereby developing new learned behaviors (or actions) from a combination of inputs from emotional, cognitive, and motor cortical areas. While frontal cortex is indeed divided based on specific functions, expressed behaviors are the result of a combination of complex information processing that involves all of the frontal cortex. The development and execution of appropriate responses to environmental stimuli require continual updating, as well as learning and adjusting to the response. Thus, response learning does not represent a separate motor, cognitive, and motivational tract, rather the combination of these areas working together forms a smoothly executed, goal-directed behavior. While the anatomical pathways appear to be generally topographic from cortex through BG circuits and there are some physiological correlates to the functional domains of the striatum, as we saw with the direct and indirect pathway concept, there are major points that argue against a strict parallel processing system. In this respect, a number of studies demonstrate that these pathways are not are as segregated as once thought (Nauta *et al.*, 1978; Somogyi *et al.*, 1981b; Bevan *et al.*, 1997; Haber *et al.*, 2000; Kolomiets *et al.*, 2001; McFarland and Haber, 2002a). As we've already seen, the dendrites and axons of the striatal interneurons often cross functional boundaries and have been suggested to be one mechanism that integrates information across regions. Furthermore, the dendritic arbors in the STh and in GP are extensive and cross functional boundaries. In this way, distal dendrites from another region invade an adjacent functional region. Finally, experiments have demonstrated that following injections of tracer molecules into different functional regions of the pallidum resulted in overlapping terminals at the interface between these two projection fields in the STh (Yelnik *et al.*, 1984; Wilson *et al.*, 1990; Percheron and Filion, 1991; Kawaguchi *et al.*, 1995; Bevan *et al.*, 1997). Electrophysiological studies support this notion of integration by demonstrating cell activation in response to unexpected types of stimuli within a functional region, or a lack of expected functional topography following specific stimuli (Kolomiets *et al.*, 2001). The fact that the adjacent areas overlap in function is not surprising. Many cortical areas are tightly linked to the immediately adjacent cortex. Thus, "edges" of functionally identified regions are likely to process mixed signals. Furthermore, the interface between functional circuits increases with the complexity of interconnections within the intrinsic BG circuitry and with the compression of pathways to successively smaller structures (Smith *et al.*, 1998b; Bar-Gad *et al.*, 2000).

However, interaction at the interface of functions may not be sufficient to link across circuits to accommodate adaptive responses during the learning process, or in response to new environmental cues. As such, mechanisms, by which information "flows" through functional circuits occurs, are less well understood, but fundamental for understanding how the execution of goal-directed actions evolves from reward and cognitive inputs. Recent anatomical evidence from primates demonstrates that the pathways within two basal ganglia subnetworks are in a position to move information across functional circuits (Haber *et al.*, 2000; McFarland and Haber, 2002a) (Figs. 21.23–21.25). The two networks are the striatonigrostriatal network and the thalamocorticothalamic network. Within each of these sets of connected structures, there are both reciprocal connections linking up regions associated with similar functions. However, in addition, there are nonreciprocal connections linking up regions that are associated with different cortical basal ganglia circuits. Each component of information (from limbic to motor outcome) sends both a feedback connection and a feedforward connection, allowing the transfer of information. Goal-directed behaviors require the processing of a complex chain of events beginning with motivation and proceeding through cognitive processing that shapes final motor outcomes. This sequence is reflected in the feedforward organization of both the striatonigral connections and the thalamocortical connections. Information is channeled from limbic to cognitive to motor circuits. Action decision-making processes are thus influenced by motivation and cognitive inputs, allowing the animal to respond appropriately to environmental cues.

Acknowledgments

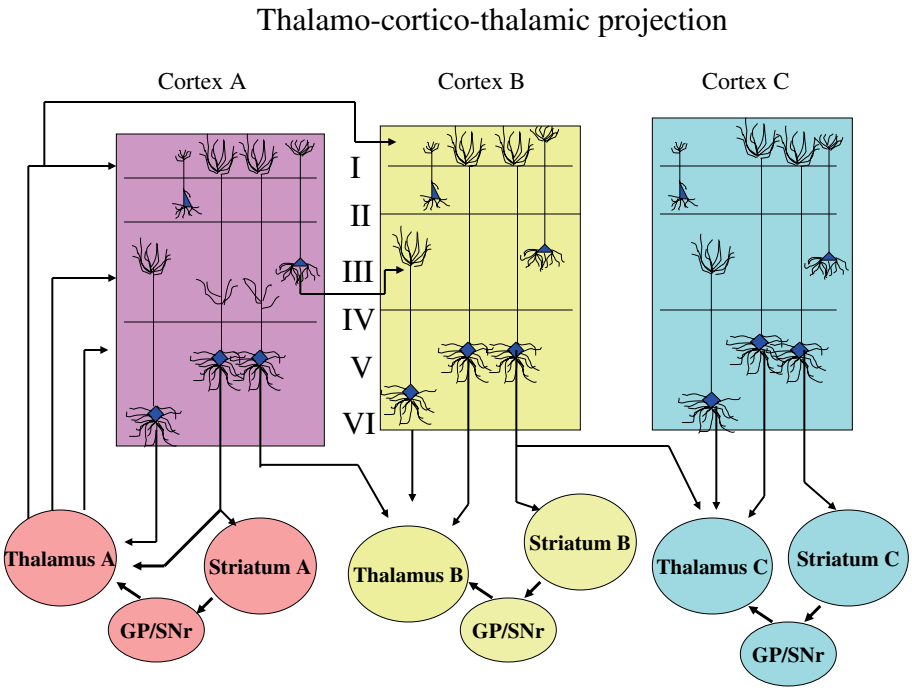

FIGURE 21.24 Summary diagram of thalamic terminal organization in cortical layers and information flow between thalamic relay nuclei and frontal cortical areas (McFarland and Haber, 2002b). Projections to the deep layers may interact with neurons that, in turn, project back to both the thalamus and striatum. These terminals therefore are in a position to reinforce directly information flow within a specific corticobasal ganglia circuit. In addition, through the nonreciprocal corticothalamic projection, terminals in layer V may also interface with other cortico-basal ganglia circuits by projecting into a thalamic region that is part of another circuit system. Thalamocortical projections to the superficial layers may also have this dual function. Projections may interact with the apical dendrites of layer V cells further reinforcing each parallel circuit. In addition, through corticocortical projections from layer III, these terminals may influence with adjacent circuits. GP, globus pallidus; SNr, substantia nigra pars reticulata.

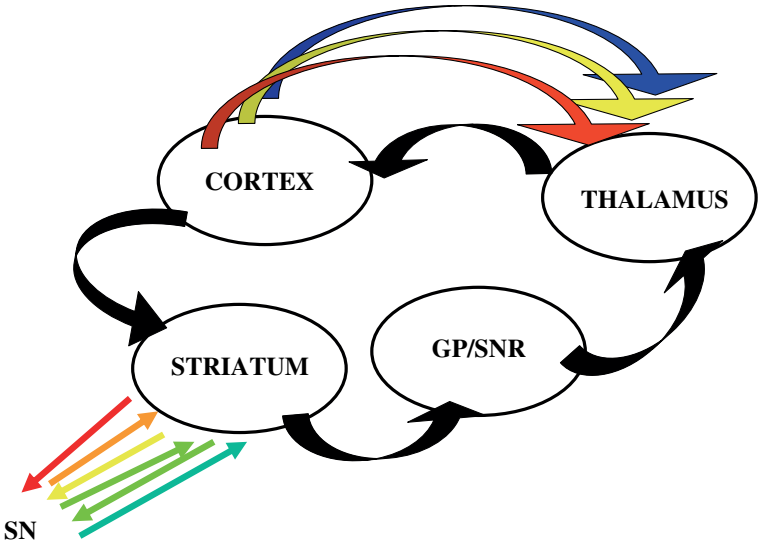

FIGURE 21.25 Schematic illustrating two potential mechanisms for relaying and integrating information within the cortico–basal ganglia circuitry. Information from distinct cortical regions could be processed separately and in parallel through functionally related neurons participating direct or indirect pathways *(black lines)*. Information from these distinct, parallel pathways could be integrated in two ways: (1) by spiraling connections between the midbrain dopamine cells and the striatum and (2) via thalamocorticothalamic projections.

Hagai Bergman and Yoland Smith for reading parts of this manuscript and their helpful comments. Finally, we thank George Alheid for his contributions to this chapter.

CHAPTER

22

Amygdala

JOSE S. DE OLMOS
Instituto De Investigacion Medica "Mercedes Y Martin Ferreyra"
Cordoba, Argentina

TERMINOLOGY

The primate amygdaloid body is a relatively large conglomerate of gray substance lying in the depth of the anteromedial temporal lobe ventral to the lentiform nucleus from which it is separated by the magnocellular basal forebrain neuronal complex (MCBFC) constituting the basal nucleus of Meynert and related cell groups, or the so-called substantia innominata sensu ampliori. Massive fiber systems separate the amygdala from the basal forebrain and form part of the telencephalic and diencephalotegmental radiations, bidirectionally connecting the amygdala and other gray formations of the temporal lobe with those in the basal and medial telencephalon, the diencephalon, the brain stem tegmentum, and even the spinal cord. Although the amygdala has been generally thought of as a single structure, it is actually a very heterogeneous one shown to be involved in the modulation of neuroendocrine functions, visceral effector mechanisms, and complex patterns of integrated behavior, such as defense, ingestion, aggression, reproduction, memory, and learning (Beltramino and Taleisnik, 1978, 1980; Benjamin and Jackson, 1974; Carrer, 1978; Carrer *et al.*, 1973, 1980; De Vito and Smith, 1982; Dunn, 1987; Fahrbach *et al.*, 1983; Fuchs and. Siegel, 1984; Fuchs *et al.*, 1985; Ghashghaei H.T., and Barbas, H., 2000, Gloor *et al.*, 1982, 1997; Lehman and Winans, 1982, 1983; Mishkin and Aggleton, 1981; Sarter and Markowitsch, 1985; ; Squire and Zola-Morgan, 1985; LeDoux, 1993; Maren, 1999; Adolphs, R., and Tranel, D., 2003; Hurd, 2002). This modulation is exercised, at least in part, through a vast network of connections with other brain regions, such as the hypothalamus. These other regions have been thought to have the most direct involvement in the regulation of these functions. Recent experimental anatomical, physiological, and behavioral data suggest that the amygdala is involved in more direct action than was previously suspected. This action is subserved by some of the nuclear groups into which the amygdala has been divided on the basis of cytoarchitectonic, histochemical, immunohistochemical, and hodological studies (de Olmos *et al.*, 1985; de Olmos, 1990; Alheid *et al.*, 1995; Heimer *et al.*, 1999). Furthermore, the amygdaloid complex has been shown to be significantly involved in a number of human neurodegenerative diseases, including Alzheimer's disease, the chorea of Huntington, and neuronal ceroid lipofuscinosis (Brockhaus, 1940; Cipollini and Corsellis, 1970; Herzog and Kemper, 1980; Braak and Braak, 1983, 1987, 1995; Brashear *et al.*, 1988; Brady and Mufson, 1989; Powers *et al.*, 1987; Benzing *et al.*, 1990, 1992; Hunger *et al.*, 1991, 1992; Emre *et al.*, 1993; Hudson *et al.*, 1993; Pitkänen *et al.*, 1998; Hurd, 2002; Heimer, 2002).

This review of the main anatomical and cytochemical features of the human amygdala is based on the thorough cytoarchitectonic studies of Brockhaus (1940), Crosby and Humphrey (1941), Hilpert (1928),

Sanides (1957b), and Stephan (l975), the pigmento-architectonic studies of Braak and Braak (1983, 1987) and Strenge *et al.* (l977), the histochemical reports by Svendsen and Bird (l98S), as well as on a recent descriptions by Sorvari *et al.* (1995–1996), Gloor (1977), and Heimer *et al.* (1999). In a previous version of this chapter, and in order to provide grounds for inferring connectional and functional meaning to the cytoarchitectonic and chemoarchitectonic human data reviewed here, a parallel though somewhat restricted account of information of the same concerning the nonhuman primate amygdala is given, since it is in these mammals—the closest phylogenetically speaking to the humans—that it has been possible to obtain by experimental means the connectional, physiological, and behavioral data mentioned above.

In analyzing the nuclear arrangement of the human amygdala and in critically reviewing the literature on the hodological relationships of the amygdala with the cerebral cortex, the basal ganglia, the diencephalic nuclei. and the tegmental grisea distributed along the brain stem and the spinal cord, the nomenclature employed will be based substantially on the seminal comparative neuroanatomical work of Johnston (l923), who examined the basal forebrain but more particularly the amygdala of the opossum, bat, rat, rabbit, macaque monkey, as well as human embryos. In many regards the terminology is also inspired by the work by Brockhaus (l938) on the human amygdala, and by that of Price *et al.* (1987) on the macaque monkey; finally, it is consistent with the terminology used in the last edition of Paxinos and Watson's (l997) stereotaxic atlas of the rat brain. In my view, this nomenclature is supported not only by well-established cyto- and fibro-architectonic criteria but also by ontogenetic, histochemical, immunohistochemical, and hodological data (Bayer, 1980; de Olmos *et al.*, 1985; Grove, 1988a, b; Barbas and de Olmos, 1991). In this regard, it is important to point out that Johnston (l923) used for the monkey and human amygdala the same terminology he proposed for the other subprimate mammals he examined. However, Johnston's proposition was only partially followed by Crosby and Humphrey (l94l) in describing the human amygdala and later by Lauer (l945) in his account of the macaque monkey amygdala. Lauer renamed Johnston's medial small-celled basal amygdaloid nucleus as the basal accessory amygdaloid, a term Johnston reserved for a completely different nucleus in the opossum amygdala and which he claimed was present only in this latter mammal [see also Young (l936) for the rabbit and Fox (1940) for the cat].

Nevertheless, this terminology eventually became common in American experimental neuroanatomical studies of primates and in evaluating of pathological changes in the human amygdala. However, hodological studies in the macaque monkey brain by Mehler (1980) encouraged me to suggest that the basal accessory amygdaloid nucleus of the primates is, at least in part, homologous to the basomedial amygdaloid nucleus in the rat and the cat [see also Barbas and de Olmos, 1990). On the other hand, Price (1981) not only accepted this possibility but also suggested that the medial small-celled basal nucleus (MB) [or *parvicellulare* basal amygdaloid nucleus (Bpc) of his own terminology] is homologous with the smaller celled part of the basolateral amygdaloid nucleus in the rat and the cat (see also Price *et al.*, 1987). On this basis, it seems more reasonable to maintain the earlier naming suggested by Johnston (1923) for the laterobasal nuclear complex (LBNC) and consider Crosby and Humphrey's (1941) medial basal nucleus as just one of the subdivisions of the basolateral amygdaloid nucleus.

In other order of subjects, it should be mentioned that our studies (de Olmos, 1990; Heimer *et al.*, 1999) have confirmed entirely the basic architectonic principle established by Brockhaus (1938). According to this plan (allowing for small variations in different species of monkeys), neurons within the LBNC, including the lateral amygdaloid nucleus as its third main member, tend to be arranged in such a manner that the smaller neurons are 1ocated closer to the walls of the inferior horn of the lateral ventricle and the largest ones are farther away, with the intermediate-sized neurons being located in an intermediate position within the respective members of the LBNC. Such a basic distribution pattern as well as a parallel variation in the density of the satellite glial cell population (i.e., densest around large-celled subdivisions, poorest at the smaller celled ones) provides the backbone of the subdivisions proposed here. On the other hand, at difference with what was done in the previous version of this chapter (de Olmos, 1990), the so-called "posterior amygdaloid nucleus" will be considered to be a subdivision (i.e., the posteromedial PM AHi) of now a larger amygdalo-hippocampal transition area (AHi), then recognizing the existence of only the anterior cortical nucleus as previously proposed by Price *et al.* (1987) and later by Price alone (1990). As a consequence, Johnston's (1923) cortical amygdaloid nucleus comes then to lie medio-ventrally to both ACo and AHi. Therefore, it is appropriately named the ventral cortical amygdaloid nucleus (VCo). Furthermore, in Johnston's description of the cortical amygdaloid nucleus, this structure does not seem to encompass what Crosby and Humphrey (1941, 1944) and Lauer (1945) labeled the corticoamygdaloid transition area, or what Humphrey (1968, 1972) later called the amygdalopiriform transition area (APir). By contrast, the "periamygdaloid cortex" of some authors (Rose, 1927; Koikegami, 1963; Mikami, 1952; Price *et al.*,

1987) encloses both the VCo and the amygdalopiriform transition area (APir) as here defined. Against the concept of the periamygdaloid cortex is the fact [shown in the thymidine autoradiographic studies by Bayer (1980) in the rat] that the cortical nucleus shows developmental features coincidental with those of a subcortical or nuclear gray formation. In addition, the neuronal maturation in APir seems to precede that of the surrounding structures (Hilpert, 1928; Brockhaus, 1940; Humphrey, 1968). In my view and in that of several colleagues (Barbas and de Olmos, 1990; Heimer *et al.,* 1999), these facts are compelling enough to permit consideration of APir as a separate anatomical entity from the VCo nucleus and to reaffirm the nuclear (rather than truly cortical) subcortical nature of the so-called periamygdaloid cortex. With these remarks in mind, I recognize in the human amygdala, as in the rat amygdala, four major nuclear groups: laterobasal amygdaloid nuclear complex, extended amygdala, superficial cortical-like olfactory amygdala; and non-assignable amygdaloid formations. By taking into consideration the hodological studies concerning the connectional relationships between the olfactory bulb and the amygdala in the macaque monkey (Turner *et al.,* 1978; Price 1990; Carmichael *et al.,* 1994) and by applying the modifications mentioned above with respect to the parcellation of the superficial nuclei of the amygdala, the superficial cortical-like secondary olfactory amygdala in humans at least will be considered to comprise the following three structures: the anterior (ACo) and ventral (VCo) cortical nuclei and the amygdalopirform transition (APir) areas.

With respect to the so-called medial nuclear group of the amygdala, it should be stressed that a division into medial "main olfactory" and "accessory" subgroups, as in the rat amygdala, does not apply to higher primates, including humans, since these mammals lack an accessory olfactory formation and, therefore, its corresponding fiber projection system, the accessory olfactory tract. This, together with the fact that the medial amygdaloid nucleus (Me) in primates does not seem to receive direct afferent projections from the main olfactory bulb, leaves this nuclear group outside the group of amygdaloid nuclei that are direct recipients of the lateral olfactory tract. In addition, as will be seen below, the Me nucleus is just a part of a major nuclear group, the medial extended amygdala (MExA) that comprises also the medial sublenticular extended amygdala (SLEAM) and the medial division of the bed nucleus of the stria (BSTM). The central extended amygdala group (CExA) consists of the central amygdaloid nucleus (Ce), the central sublenticular extended amygdala (SLEACn), the lateral division of the bed nucleus of the stria terminalis (BSTL), and the interstitial nucleus of the posterior limb of the anterior commissure (IPAC). Adding to either division of the extended amygdala is also medial (BSTSM) and lateral (BSTSL) supracapsular extent of the BST nucleus, respectively.

Although on the basis of structural organization and neurogenetic development (Bayer 1980, Bayer and Altman 1995), the amygdalohippocampal transition area (AHi) will be considered a member of the superficial cortical-like amygdaloid nuclei, this gray formation in humans does not seem to receive direct projections from the olfactory bulb. Therefore, it will be classified here as a putative nonolfactory component of the superficial cortical-like amygdaloid nuclei. However it is not possible to discard that it may receive olfactory information relayed through the superficial cortical-like secondary olfactory amygdala.

The laterobasal nuclear gray complex (LBNC), as mentioned before, is constituted by the lateral (La), basolateral (BL), basomedial (BM), and paralaminar (PL) amygdaloid nuclei and holds a deep juxtaventricular position within the amygdaloid complex. These four main members of the LBNC can in turn be divided into several subnuclei. Finally, the fourth group of amygdaloid nuclei, which includes the amygdalostriatal transition zone (AStr), the granular and parvicellular interface islands, the intercalated masses (ICMs), and the intramedullary griseum (IMG), is not clearly assignable to any particular amygdaloid group although the first two named cell groups have been considered to represent a transition to pallidostriatal formations (Heimer *et al.,* 1999) and the last two cell groups to the extended amygdala (de Olmos, 1969).

DESCRIPTION

This section is concerned with some of the main architectonic and histochemical features that distinguish each of the main nuclei and respective subnuclei, as well as main areas and corresponding subareas that form the amygdaloid body. This description is based on the examination of frontal, sagittal, and horizontal sections of normal human brains as well as macaque *(rhesus* and *fascicularis),* squirrel, and marmoset monkey brains, which were alternatively stained for the demonstration of Nissl substance (thionin, cresyl violet), myelinated fibers (Weigert), neurofibrillary frameworks (Bielschowsky–Gross modifications), acetylcholinesterase (AChE) activity [Geneser-Jensen and Blackstad's (1971) modification of the Koelle method], and heavy metals [Danscher's (1981) modification of the Timm method] or immunostained for neuropeptides such as substance P, somatostatin (SOM), and leu-enkephalin (ENK). It should be stressed here that a

wealth of the human and monkey material processed with the abovementioned histological procedures on which is partly based the present account, was generously placed at the disposition of the present writer by Drs. Lennart Hiemer and George A. Alheid during several visits to their Laboratory of Neuroanatomy in the Department of Neurosugery, Health Sciences Center of the UVA, in Charlottesville. Virginia, USA

Laterobasal Amygdaloid Nuclear Complex (LBNC)

The laterobasal amygdaloid complex constitutes the main part of the amygdaloid body and is regarded as "sensory input" to this structure. It has a very important role in so-called emotional memory and learning, which is particularly important in early developmental stages. It has been proposed that interference with its integrity at this particular time may cause psychiatric problems in later life, like neurosis, phobia, unconscious fear, or panic attacks. Furthermore, it has been established beyond doubt that the amygdala is one of the main sites of action for the clinically important antianxiety and anticonvulsant effects of benzodiazepines, and subsequent studies have shown that it is the basolateral portion of the amygdala (BL) which is critical for the anxiolytic actions of benzodiazepines. Recent studies have also raised the importance of the amygdala in the processing of facial expressions in humans (Morris *et al.*, 1996). Clinical and electrophysiological evidence indicates that the amygdala has an important role in the pathogenesis of the temporal lobe, and it has been demonstrated that γ-aminobutyric acid (GABA) function is disrupted in this condition (Hudson *et al.*, 1993; Wolf *et al.*, 1997).

Lateral Amygdaloid Nucleus (La)

It is clear that the lateral nucleus is the primary entry point for sensory information to the amygdala (Royer *et al.*, 1999; Stefanacci and Amaral, 2000), and although, as will be described shortly, its cholinergic innervation is one of the weakest in the human amygdala, it is the one that is most severely affected in Alzheimer's disease. It is sustained that many of the computations required to perform complex tasks are presumably initiated by the activation of neurons in the La nucleus via sensory inputs from the thalamus and from unimodal and polymodal sensory cortices (Le Doux, 1998). From the La nucleus, the information is conveyed to other amygdaloid nuclei through intra-amygdaloid connections, and finally relayed to motor, endocrine, and autonomic centers that elicit appropriate behavioral responses to sensory stimuli.

On the other hand, it has been reported that the La nucleus undergoes severe damage (mean neuronal loss: 50%) in most patients with temporal lobe epilepsy (Hudson *et al.*, 1993; Wolf *et al.*, 1997). These changes occur independently of any that occur in the hippocampus (Wolf *et al.*, 1997).

Topographical Landmarks The La nucleus is the largest among all the nuclei that make up the human amygdala, both as compared by direct measurements or by allometric procedures (Stephan *et al.*, 1977). It conforms an irregularly shaped, polygonal gray mass that occupies the rostral three fourths and the lateral one-third of the human amygdaloid complex (see Figs. 22.1a,b; 22.2–22.5a, 22.6a, 22.7a, 22.9–22.12). As such, it stretches between a plane cutting –0.6 mm rostrally to the midline crossing the anterior commissure (plane 0.0 mm) to another 10.7 mm caudally to it in Mai *et al.*'s (1997) *Atlas of the Human Brain*. In this manner, the La nucleus occupies approximately three-fourths of the rostrocaudal extent of the amygdala (Darvesh *et al.*, 1998). According to Murphy *et al.* (1987), the La nucleus is, of all of the amygdaloid nuclei, the one that contributes the most to the volumetric asymmetry existing between the amygdaloid nuclear complex of each hemisphere, since the right La nucleus was found significantly larger than its left counterpart.

The La nucleus is flanked laterally and ventrally by the temporal limb of the external capsule that interposes between it and the ventral claustrum [VCl in plates Kl B6 to Kl B9 in Sakamotos *et al.*'s (1999) collection of coronal sections through the human brain or the gray complex conformed by the laterocaudal extension of Mai *et al.*'s (1997) preamygdalar (PACl) and limitans(LiCl) divisions of their claustrum]. Transversally oriented branches of the external capsule detached from the main body of the external capsule also separate the La nucleus from the endopiriform nucleus [En, in the Kl B6 plate of Sakamoto *et al.*'s (1999) series, or the periamygdalar area, PAA, and more medial aspects of the PACl in plates 21–23 of Mai *et al.*'s (1997) atlas] rostrally as well as rostrodorsally. The rostrodorsal lateral pole of the La nucleus is almost completely separated from the main body of the nucleus by descending radiations of the temporal limb of the anterior commissure (Figs. 22.1a,b, 22.2, 22.5a, and 22.6a) giving place to the formation of characteristic cells columns that constitute what Brockhaus (1938) denominated the pars limitans of the amygdaleum profundum laterale, or Apl. More caudally the La nucleus is bordered by the amygdalostriatal transition zone [AStr, plates 26–30 of Mai *et al.*'s (1997) atlas]. Medially, the lateral medullary lamina separates the La nucleus from the basolateral amygdaloid nucleus (BL). Ventrally and rostrally small fascicles of fibers separates

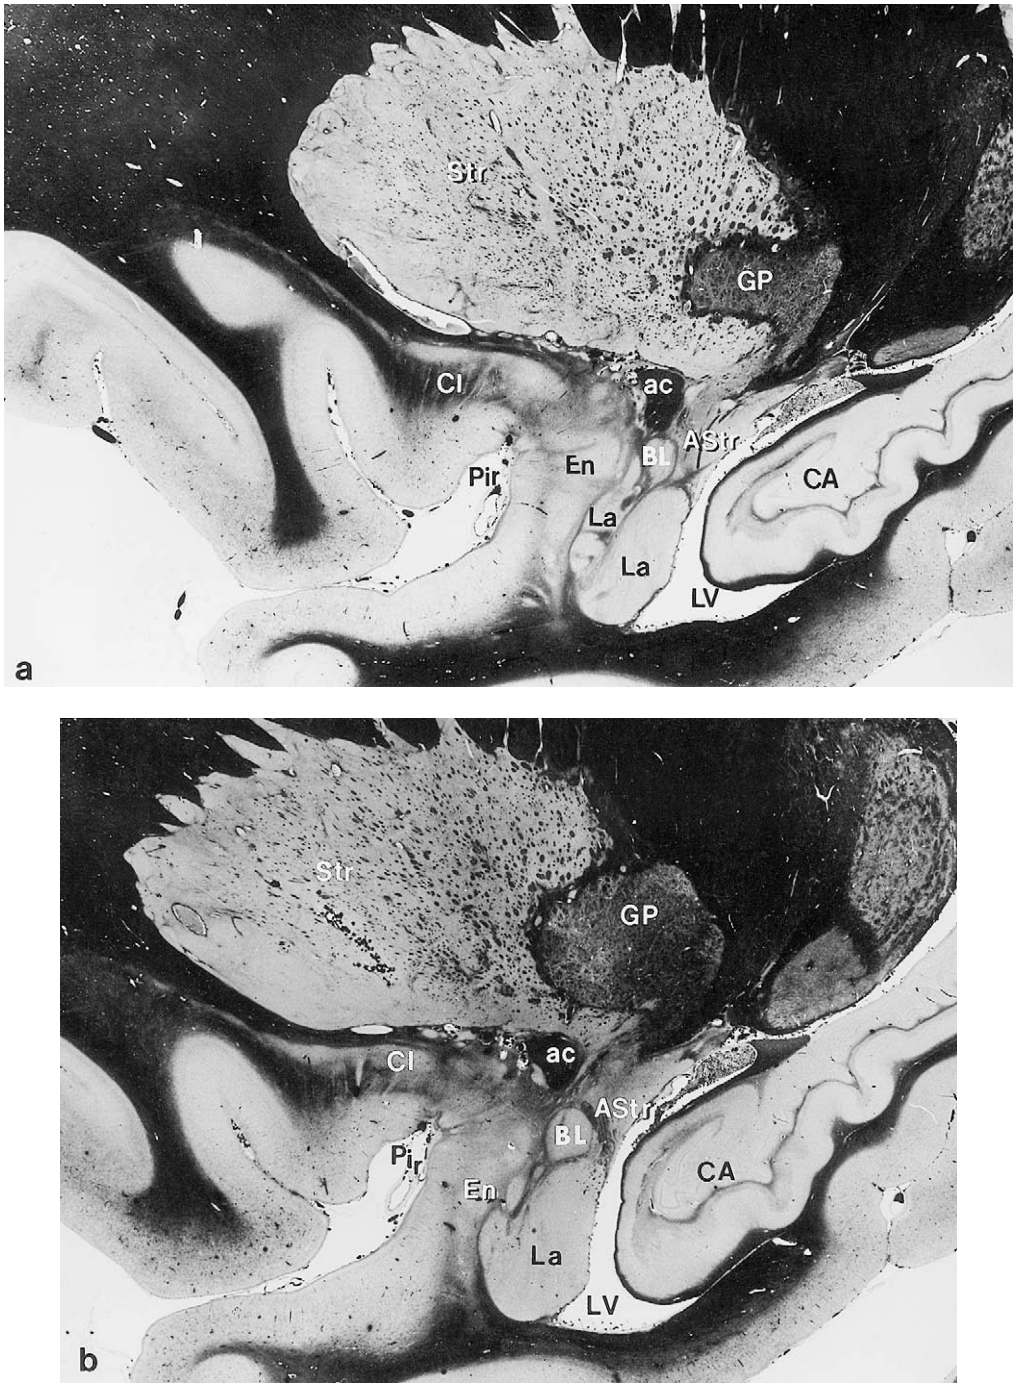

FIGURE 22.1 (a) Low-power photomicrograph of a sagittal section through the dorsal anterior portion of the lateral amygdaloid nucleus (La) showing its topographical relationships with the claustrum (Cl) rostrally, with the striatum (Str) and the amygdalostriatal zone (AStr) dorsocaudally, and the inferior horn of the lateral ventricle (LV) caudally. A fiber capsule surrounds the DL BL underneath the temporal limb of the anterior commissure (ac). (b) A more medial sagittal section showing the topographical relationships of the amygdaloclaustral area (ACA) with the basolateral amygdaloid nuclear group (BLNG) caudally, with the endopiriform (En) dorsally and ventrally, and the piriform cortex (Pir) rostrally. Even at this magnification the lobulations in the ventrolateral subdivision (VL) of the lateral amygdaloid nucleus (La) (white arrow) can be appreciated.

Continued

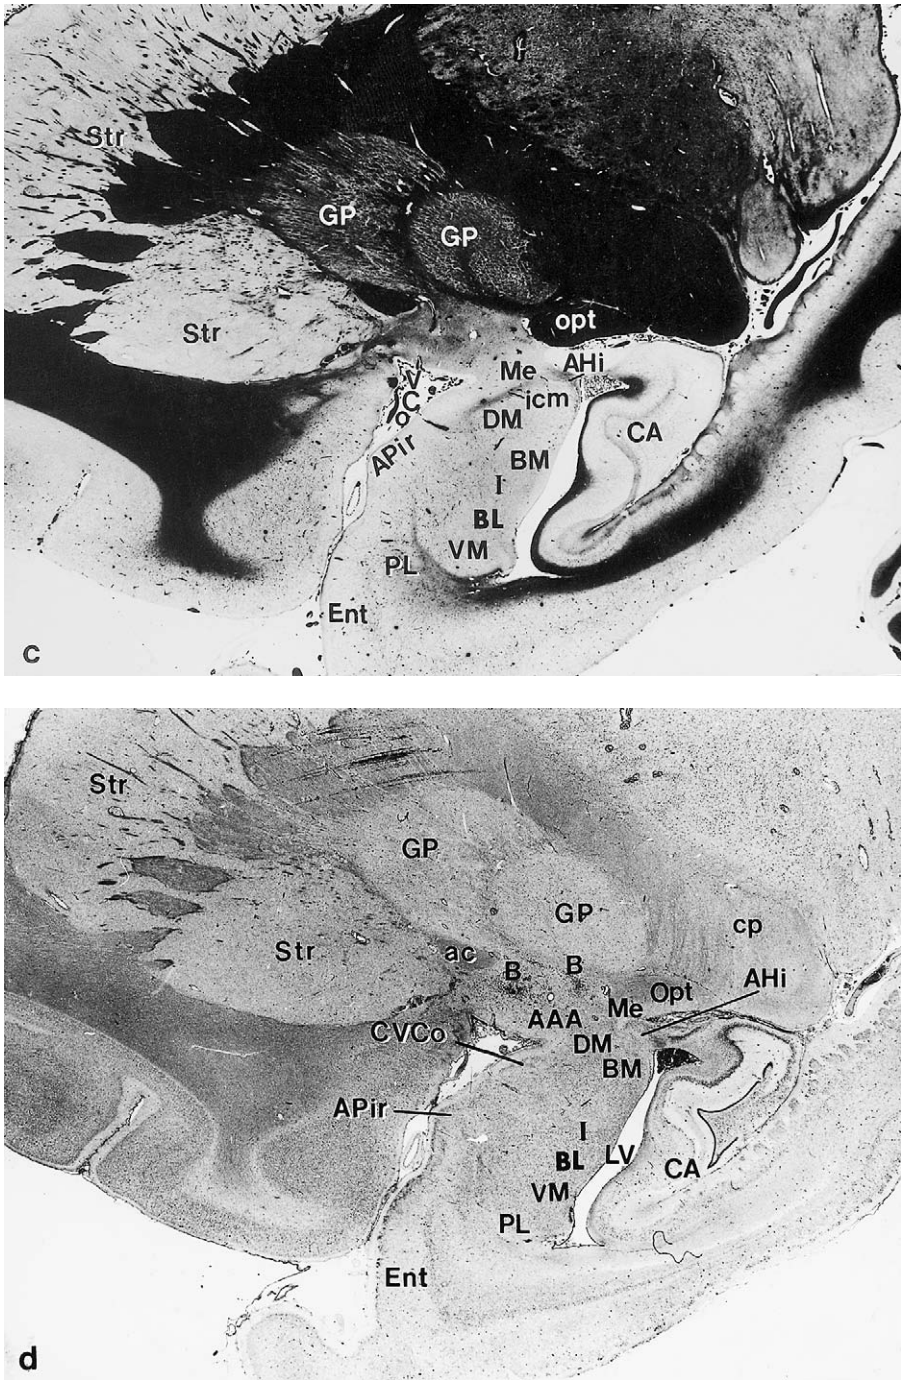

FIGURE 22.1 cont'd (c) A sagittal section close to the junction of the temporal pole with the basal telencephalon showing the intermediate caudomedial fiber masses (icm) as they form an oblique caudally coursing bundle in the interface between the superficial superior subdivision of caudal ventral cortical amygdaloid nucleus (CVCo) and medial amygdaloid nucleus (Me), on one side, and the deep lying dorsomedial division of BM (DM BM) on the other side. In the middle third of the basolateral nuclear group (BLNG) a densification marks the transitional region between the medium-celled I BL and the small-celled VM BL. Just rostral to it, the amygdalopiriform transition area (APir) forms a small eminence. (d) A Nissl-stained sagittal section cut approximately through the same plane as (c). Divisions of the nucleus basalis of Meynert (B) marks the approximate dorsal boundary of the Me and AAA.

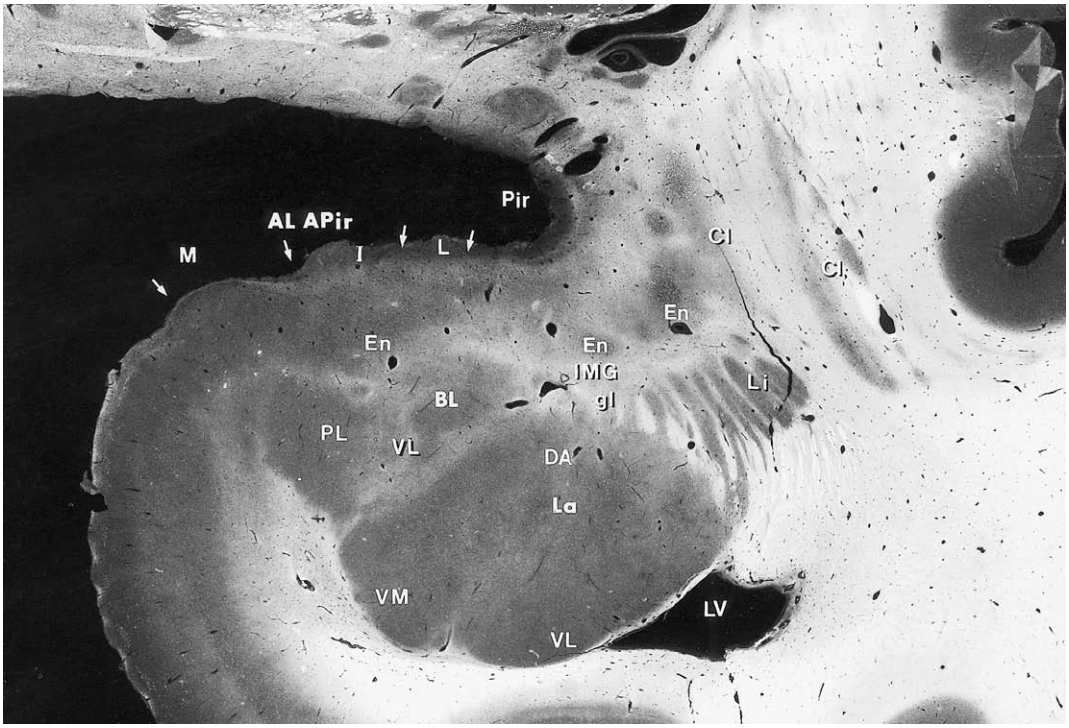

FIGURE 22.2 The human amygdala cut longitudinally at the rostral end of the BL to show the caudal sectors of the anterolateral APir and the expansion of PL BL as well as the broomlike arrangement of the limitans divisions of the La and its topographic relationships to the endopiriform-claustrum complex. The figure, like Figures 22.3–22.8, were prepared by projecting the image from a fixed, unstained, wet-mounted section onto a panchromatic photographic paper. This procedure displays all the medullary laminae separating the different gray nuclei of the human amygdala.

the La nucleus from island-like gray formations that constitute the lateral glomerular division of the paralaminar amygdaloid nucleus (PLgl) which is not delineated in Mai *et al.*'s (1997) atlas but can be found clearly depicted in de Olmos' (1990) Figure 22.5a. More caudally the La nucleus the ventral border of the lateral nucleus forms part of the roof of the temporal horn of the lateral ventricle (TLV, Plates 27–29 of Mai *et al.*'s atlas).

Cytoarchitectonics The La nucleus is made mostly of medium-sized to large neurons (Fig. 22.12), but it also includes within its neuronal population neurons of smaller size that become more numerous toward the ventricle. This feature, together with some correlative variability in the body shape and width of the fields covered by the branches of their dendritic trees, provides the nucleus a very characteristic cytoarchitectonic feature. By contrast, the glial cell population becomes more abundant away from the ventricle, i.e., rostrodorsally and parallel with an increase in the density of medullary nerve fibers. Horizontal and sagittal sections through this nucleus confirm an increased neuroglial density toward the ventricle, an arrangement already stressed by Brockhaus (1938).

As pointed out by Sorvari *et al.* (1995), the neuronal population in La is very heterogeneous even though they choose to reduce drastically its subdivision to just medial and lateral subdivisions in order to make it fit with that proposed by Price *et al.* (1995) for the monkey. However, according to the comparative appraisal of Koikegami (1963), who refers specifically to the findings reported by Mikami (1952), Sasagawa (1960a, b, 1961) and Koikegami (1963), the existence in this nucleus of a less simple grouping becomes meaningful when considering that some of the subdivisions that can be recognized in the human amygdala are not present in the monkey; such absences may have connectional implications. For this reason it seems necessary to insist on applying full fibro- and cytoarchitectonic criteria as well as topographical landmarks in describing the architectonical arrangement of La, and as a consequence to subdivide the nucleus, as was previously done (de Olmos, 1990), into five subnuclei: dorsal anterior (DA La), intermediate (I La), ventral [divisible into lateral (VL La) and medial (VM La) parts], dorsomedial

(DM La), and dorsolateral (DL La). On a similar basis, the broken-up laterorostral extension of DL La, on account of its close neighborhood with the claustrum and related grisea, merits to be labeled as the limitans (Li La) subdivision of La. The comb like appearance of Li La, the lobular disposition of VL La, and the tightness of the cells in DM La characterize well to all these subdivisions, as clearly as does the larger size of the neurons in DL La, the medium size of those in I La, and their smallness in VM La.

Fibroarchitectonics In myelin preparations the La nucleus appears as a poorly fibered nucleus, although in its caudomedial aspect a moderate number of myelinated fibers oriented in a dorsolateral to ventromedial direction [Brockhaus' (1940) fascicles laterales] traverse the nucleus, becoming more numerous near the lateral medullary lamella [lml] but decreasing in number and thickness rostrally. Numerous myelinated fibers cross the dorsolateral aspect of the La nucleus following a ventrolateral direction to join the white matter of the temporal lobe. The different subdivisions of La can also be distinguished in myelin preparations though not as clearly as in cell preparations. Thus, the dorsal anterior La subdivision can he distinguished from the intermediate La subdivision by a somewhat richer plexus of myelinated fibers. The ventral La subdivision has even fewer fibers than the dorsal and intermediate subdivisions of the La nucleus, and these fibers become less numerous at the level of its superficial lobulations, where the plexuses of myelinated fibers become more rare. In coronal sections stained with reduced silver for normal fibers, the neuropil formed by a dense network of fine fibers appears more homogeneously distributed except in the medial aspect of the intermediate (La I) and ventromedial (La VL/VM) subdivisions of the La nucleus, where fiber bundles of different thickness oriented in a dorsoventral direction can be seen. On the other hand, an abrupt change in fiber density at the level of the PL nucleus helps to identify the boundary between this latter and the ventral subdivisions of the La nucleus.

Chemoarchitectonics

Cupric Silver Stain In cupric silver preparations the La nucleus in macaque and squirrel monkeys, the La nucleus proper does not show, either in its neuropil or in its neuronal population, any argyrophilic reaction of the type seen at the level of the central division of the extended amygdala. However, at the boundary that separates the La nucleus from the striatum, which is lined by small to medium-sized spindle-shaped neurons with their main axis parallel to the boundary line, a granular argyrophilic neuropil is present extending along this interface.

Heavy Metals In Timm/Danscher's preparations of the marmoset monkey brain, the La nucleus shows a differential distribution of the silver disulfide precipitate which, though increasing in density from comparatively poorly labeled dorsolateral polar sectors of the nucleus, reaches very high levels in the medial, ventral, and caudal sectors of nucleus corresponding to approximately two-thirds or more of its extent. While in this latter aspect of the nucleus the silver sulfide precipitate shows a rather homogeneous distribution with very few profiles showing a rail-rod-like arrangement, this type of disposition becomes predominant in the above-mentioned rostrodorsolateral sectors of the nucleus (Fig. 22.23b). As happens in other amygdaloid nuclei showing this type of reaction, the neuronal perikarya remain free of precipitate.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) The neuropil of the La nucleus presents a generally weak to moderate AChE staining throughout its extent with an almost complete disregard for its cytoarchitectonic complexity (see also Sims and Williams, 1990; Emre *et al.,* 1993; de Olmos, 1990; Sorvary *et al.,* 1995; Heimer *et al.,* 1999). Such weakness and rather even staining contrasts sharply with the dense and nonhomogeneous reaction in the adjacent BL nucleus. The neuronal population in general remains unstained. However, Nitecka and Narkiewicz (1976) stressed that the AChE staining in the La nucleus varies topographically, with the intensity of the reaction decreasing in an anteroposterior direction, an observation that has been confirmed by other authors (Darvesh *et al.,* 1998; de Olmos, 1990; Simms and Williams, 1990). On the other hand, Svendsen and Bird (1985) were able to detect in *my* material a moderately stained ventral region that contrasted with a more lightly stained dorsolateral one. Finally, Darvesh *et al.* (1998) reported the detection of isolated small and medium-sized AChE-positive neurons with fusiform or triangular profiles which were loosely distributed within La.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Emre *et al.,* (1993), the human La nucleus shows, in comparison with other amygdaloid nuclei, a low density of ChAT-ir fibers. Most of them are thin and varicose, whereas others are thick and straight. Although the general distribution of the ChAT-ir in these nucleus seems to match that of the AChE quite closely, its overall density appears to be somewhat higher in the posterior part of the nucleus. There are also patches with a higher density of ChAT-ir fibers.

In the macaque monkey, the La nucleus contains the lowest density of ChAT of all the deep amygdaloid

nuclei, and only the sector that has been labeled as Lvl shows appreciable staining for this enzyme. Occasional ChAT-positive neurons are found in the monkey La nucleus, but it corresponds to point out that within the area traversed by *fibers* that run along the lateral aspect of the nucleus ChAT-positive neurons can be found (Amaral and Basset, 1989), which would go along with the Lopez-Gimenez *et al*. (2001) findings according to which there is no specific signal for ChAT mRNA in this nucleus.

Irrespective of this apparent discrepancy in the distribution of the cholinergic markers, the point has been made that in Alzheimer's disease the La nucleus appears to display a more severe loss of ChAT-positive profiles than most other amygdaloid nuclei (Emre *et al*., 1993).

EXCITATORY AMINO ACIDS

GLUTAMATE (GLU) Retrograde tracing experiments made in rats using tritiated D-aspartate indicate that a considerable number of the La neurons would be source of GLU/ASPergic projections to the nucleus accumbens and olfactory tubercle (Fuller *et al*., 1987). According to Amaral and Insausti (1992), in the macaque monkey, injections of tritiated D-aspartate in the basal amygdaloid nucleus resulted in labeling of many scattered neurons throughout the La nucleus providing arguments for inferring that this nucleus would be a source of GLU/ASPergic intra-amygdaloid projections to the above-mentioned nucleus, giving further support to the concept that at least many of the extranuclear efferent projections originated from this nucleus are of a GLU/ASP nature.

On the other hand, this nucleus seems to be the target of GLU/ASPergic afferent projections coming from cortical fields after injections of tritiated D-aspartate in the medial aspect of the La nucleus, which also included the lateral aspect of the magnocellular basal lateral nucleus. Among the cortical areas involved in these projections are neurons in layers 5 and 6 of the entorhinal cortex, and neurons in layers 3 and 5 of the parainsular area, insular proper (agranular, disgranular, and granular), caudal portion of area 13a, area 13, cingulate areas 25 and 24, perirhinal areas 35 and 36, area TF, etc.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) No information is so far available until now about the distribution of this neurotransmitter for the human amygdala. According to Pitkänen and Amaral (1994), in the monkey amygdala the La nucleus shows the highest density of GABA-ir cells among the deep amygdaloid nuclei. These types of cells are distributed throughout the nucleus and with no obvious difference in distribution or density of the GABA-ir cells in the ventrolateral and dorsomedial divisions of the nucleus. In the La nucleus, and throughout the amygdala, the GABA-ir cells tend to be organized in small clusters separated by acellular regions. A gross estimate indicated that they account for approximately 20% of the neuronal population in the La nucleus. On the other hand, the GABA-ir fibers and terminals in the La nucleus are more densely distributed than in any other nucleus of the LBNC. The ventrolateral sector of the La nucleus apparently has a higher density of GABA-ir punctate neuropil and many non-ir neurons surrounded by GABA-ir varicosities.

MONOAMINE MARKERS

DOPAMINE β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey the La nucleus displays light DBH-ir.

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey, in the La 5-HT-ir is dense in the rostral one-third and moderate to dense in the caudal two-thirds, with 5-HT-ir terminal labeling being denser in the dorsolateral aspect of the nucleus.

TYROSINE HYDROXYLASE (TH) According to Pearson (1990) in the human amygdala, the La nucleus has a moderate network of catecholaminergic axons. In general, the TH-ir innervation diminishes anteriorly.

In the squirrel monkey, Sadikot and Parent (1990) describe for the La nucleus a dense terminal TH-ir in its rostral third, and density that remains heavy in its middle third except for a dorsomedial area of light density of varicose TH-ir fibers. At its caudal third, the La nucleus of the squirrel monkey shows a light density of varicose TH-ir fibers in all but its most dorsolateral aspect, where dense TH-ir can be seen.

NEUROPEPTIDES

CHOLECYSTOKININ (CCK) According to the findings by Savasta *et al*. (1990) in the human amygdala, the concentration of neurons containing cholecystokinin (CCK) mRNA was higher in this nucleus than in the BL, BM, or PL nuclei. In the macaque monkey, Sadikot *et al*. (1988) described the presence of CCK-ir fibers and CCK-ir cells bodies in the La, more particularly in its ventral subdivisions.

CHROMOGRANIN B According to Marksteiner *et al*. (1999), the human La nucleus contains a high-density PE-11-like ir consisting of varicose fibers with mixed-size varicosities. No PE-11-like ir neurons are present.

CORTICOTROPIN-RELEASING FACTOR (CRF) Although the La nucleus presents only a sparse population of

small CRF-ir bipolar cells, a significant reduction in the number of CRF-ir fibers have been reported to occur in AD (Powers *et al.*, 1987). On the other hand, highly dense plexus of corticotropin-like intermediate lobe peptide (CLIP) containing fibers with large varicosities and terminals could be detected in this nucleus (Zaphiropoulos *et al.*, 1991).

ENKEPHALIN (ENK) According to Piorio *et al.* (1990), the human La nucleus, like the rest of the LBNC, contains only lightly stained delicate networks of varicose fibers.

GALANIN (GAL) According to Kordower *et al.* (1992), in the macaque monkey amygdala this member of the LBNC, like all of its remaining components, does not contain GAL-ir cell bodies and few if any GAL-ir fibers.

NEUROTENSIN (NT) In the human La nucleus the density of the NT–ir is sparse and is made up exclusively of fibers since no NT-ir neurons could be detected. These NT-ir plexus in the La nucleus is made up of a mixture of both fine and coarsely-beaded fibers, which are more abundant in the ventral than in the dorsal regions of this nucleus (Benzing *et al.*,1992).

NEUROPEPTIDE Y (NPY) According to Mai *et al.* (1990), NPY-ir cells and fibers were numerous in the human La nucleus. As in the other members of the LBNC, NPY-ir cells appeared to be concentrated in dorsal regions of the nucleus, while the reverse is true concerning the distributions of NPY-ir fibers and terminals.

In the macaque monkey, the La nucleus would contain, broadly speaking, a moderate amount of NPY-ir neurons, with the highest concentration occurring in the dorsal portion of La. The NPY-ir neurons closely resemble SOM-ir neurons, which coincides with the extensive colocalization that is taking place in the monkey La amygdala. Both spiny and spine-sparse types (ovoid or fusiform) of neurons of diverse sizes exhibit NPY/SOM-ir, and they are thought to be a local circuit of neurons contributing to the formation of the peptide-containing neuropil present in the nucleus. Spiny NPY-ir and/or SOM-ir neurons appear primarily in the dorsal part of the La nucleus. As with other amygdaloid nuclei, the La nucleus contains NPY-ir fibers and puncta, which are particularly abundant in its ventral third while of moderate concentration in the remaining dorsal sectors.

SECRETONEURIN (SCR) The La nucleus shows rather poor if any SCR-ir either in its neuropil or in perikarya (Marksteiner *et al.*, 1995).

SOMATOSTATIN (SOM) In the human brain, Mufson *et al.* (1988) reported the presence of SOM-ir neurons in the La nucleus, but they did not provide further detail on the distribution pattern of cells and fibers within the nucleus. Bouras *et al.* (1987), in turn, described rather low densities of SOM-ir cell bodies and low to medium concentrations of SOM-ir fibers and terminals at the level of all the subdivisions of the amygdaloid body, but without giving more comprehensive data.

According to McDonald *et al.* (1995), the La nucleus in the amygdala of the macaque monkey would contain numerous SOM-ir neurons, but in the ventral portions of the nucleus where they outnumber the NPY-ir neurons. The dorsal part of La can be differentiated from the other amygdaloid nuclei because it is the only sector of the amygdala that contains a large population of SOM-ir neurons that do not exhibit NPY-ir.

In the squirrel monkey, the La nucleus shows a light to moderate SOM-ir in its neuropil with a ventrodorsal decreasing gradient. SOM-ir perikaria are abundant but increase in number caudally and toward its border with the large-celled BL nucleus (Desgardins and Parent, 1992).

SUBSTANCE P (SP) According to Piorio *et al.* (1990), the La nucleus, like in the rest of the LBNC except for their dorsal magnocellular part of the accessory basal nucleus (DM/CM BM, here), contains few scattered SP-ir neurons together with branching fibers and punctate material.

BRAIN–DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human amygdaloid complex all of their nuclear components show BDNF-ir neurons and fibers, but in contrast with the rest of the La nucleus contains abundant neurons with an intense cell body ir within a lightly ir plexus.

ENZYMES

ANGIOTENSIN-CONVERTING ENZYME (ACE) According to Chai *et al.* (1990), the La nucleus, in contrast to its immediate neighbor (the BL nucleus), shows a rather low binding level for ACE.

BUTYRYLCHOLINESTERASE (BUCHE) The lateral nucleus also contains numerous BuChE-containing neurons. Most of these neurons are medium sized to small and have round fusiform or triangular profiles and can be found throughout the rostrocaudal and dorsoventral extent of the nucleus. Some of these neurons have multiple branching processes that could be followed for a distance up to 150 µm from the cell body. These BuChE-positive neurons constitute approximately an 8% of the total neuronal population of the La (Darvesh *et al.*, 1998).

NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) According to Sims and Williams (1990), in the human amygdala the NADPH-d staining is light and multipolar Golgi like cells are scattered throughout Li La (their pars externa). The DL/I/VL subdivisions (their lateral subdivision) would contain weakly stained, mostly pyramidal-shaped NADPH-d-containing neurons, but also a few bipolar ones. In the DM La (their dorsal subdivision) as well as in the VM La (their medial subdivision), the NADPH-d-containing neurons would present a similar immunoreactivity. In the La nucleus of the macaque monkey (Sorvari *et al.*, 1995), the NADPH-d-containing neurons show a similar appearance in all of its subregions, their perikaria being predominantly medium sized and presenting fusiform or stellate shape from which extend bipolar or multipolar dendrites. Furthermore, although they show a relatively homogeneous distribution, their presence is more prominent in the DL subdivision of the nucleus. As in other members of the laterobasal nuclear group, the La nucleus displays a very densely stained network of NADPH-d fibers and terminals (see also Brady *et al.*, 1992). This staining pattern is very similar to that observed in the squirrel monkey (*Saimiri sciureus*) (Brady *et al.*, 1992; Unger and Lange, 1992). Sorvari *et al.* (1995) estimated that in the monkey La nucleus, the multipolar NADPH-d-containing neurons in DL/Li/VL subdivisions closely resemble the type 2 multipolar PAV-ir neurons described by Pitkänen and Amaral (1993).

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, the La nucleus presents a lesser expression of this enzyme than other amygdaloid nuclei, more particularly the superficial ones.

CALCIUM-BINDING PROTEINS

CALBINDIN-D28K (CAL) According to Sorvari *et al.* (1996b), the La nucleus has a moderate density of CAL-ir neurons. The density of CAL-ir neurons appears to be higher in the DM/VM La (their medial division) than in the DL/I/VL La (their lateral division). Morphologically, a large majority of the CAL-ir neurons in La belong to what they call the type 1 category, but numerous type 2 cells and a few type 3 cells were also reported. Typically, the primary dendrites emanating from the soma of immunopositive neurons were thin and straight and branched near the soma, giving off few secondary branches. Also, according these authors, the La nucleus contains a moderate to high density of CAL-ir fibers and terminals. In accordance with the density of the calbindin cells, the fiber and neuropil staining was higher in the DM/VM La than in the DL/I/VL La. The density of neuropil labeling in the La nucleus is, however, one of the lowest in the amygdala. (For more details, the reader is referred to the original paper by Sorvari *et al.*, 1998b.)

CALRETININ (CR) The density of CR-containing neurons in the La nucleus is considerably higher in its so-called medial division (i.e., DM/VM subdivisions of the present account) than in the lateral one (i.e., LD/Li/LV of the present account). Most of the neurons were small type 1 cells (i.e., small multipolar cells with typical spherical somata provide 3–11 dendrites of about equal thickness). The La nucleus, particularly its medial (DM/VM) subdivision, contains a high density of CR-ir fibers and terminals that are located near the clusters of CR-ir neurons. Thick varicose CR-ir fibers are found in the dorsal part of the La nucleus, probably fibers of passage. Finally, there is a gradient in the density of the neuropil so that it is low rostrally but increases lightly caudally. On the other hand, an analysis of the immunohistochemical data by Sorvari *et al.* (1996a) induces them to conclude that CR-ir and PAV-ir cells in the human amygdala constitute different subpopulations of nonpyramidal neurons. In another study, Sorvari *et al.* (1998a) were able to show that CR-ir terminals make synapses onto CAL-Dk28-ir neurons in the La nucleus. All synapses resemble symmetrical synapses (type II of Gray), which are typical of inhibitory synapses; this harmonizes with the fact that virtually all of the Cal-ir neurons in the La nucleus show morphological characteristics of local interneurons (Braak and Braak, 1983; Sorvari *et al.*, 1996a).

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995, 1996c), the La nucleus has the highest density of PAV-ir neurons in the entire amygdala. Also, all the different types of PAV-containing neurons are present here. However, the PAV-ir neurons are unevenly distributed in the La nucleus. Their lateral division, which would include the DL, VL, and Li subdivisions in the present account, particularly its dorsal half, has a higher density of PAV-ir cells than their medial division, i.e., the DM, I, VM subdivisions of the present account. This nucleus also shows a high density of PAV-ir fibers and terminals and, as it happens with the PAV-ir neurons, their density is higher in their lateral division. In fact, the DL/Li shows, together with DL/D subdivisions of the BL nucleus, the highest density of PAV-ir fibers and terminals in the human amygdaloid complex. Furthermore, although the fiber density was lower in BM/I/VM, it was always higher in the VL/VM subdivisions of the adjacent *BL* nucleus. The DL/Li/VL subdivisions also contained a very large number of PAV-ir terminal cartridges than the medial subdivisions. This is also true for the pericellular

baskets, which, on the other hand, are more abundant in the dorsal sectors of the nucleus. It should be stressed that in recent studies in the human amygdala it was shown that PAV-ir terminals make synaptic contacts on the axon initial segments and somata of pyramidal cells (Sorvari *et al.*, 1996).

OTHER PROTEINS

DOPAMINE- AND ADENOSINE 3',5'-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR According to Barbas *et al.* (1998), in the macaque monkey, the DARP-32-ir and I-1-ir neurons are restricted to the ventral third of the La nucleus in some levels but extended up to the ventral half at other levels. Other parts of the nucleus contained fewer and more moderately stained DARPP-32-ir neurons. Among them, the dorsomedial third of the La nucleus contains few of this type of neuron but spares the dorsolateral sector. Though the distribution is similar for the two phosphoproteins, I-l-ir neurons can also be seen laterally.

DOPAMINE TRANSPORTER (DAT) The La nucleus, like the BM nucleus, presents markedly fewer DAT-containing axons than BL, although the DL region of the lateral had a higher density of axons than the rest of the subnucleus (Ciliax *et al.*, 1999).

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996) in the macaque amygdala, LAMP-ir is very weak in the La nucleus. At midamygdaloid levels, the ventral one-third of the La nucleus shows intense LAMP-ir, and this staining is continuous medially with that of the small-celled division of the BL nucleus. In the caudal third of the La nucleus, the entire ventral half of this nucleus displays LAMP-ir that is as intense as that in the adjoining BL nucleus. At this level, the dorsal part of the La nucleus is devoid of LAMP-ir.

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low magnification atlas published by Petrides *et al.* (2000), it seems that dorsal sectors of La contain some SMI32-ir.

RECEPTORS

ADENOSINE RECEPTOR (A–R) According to Svenningsson *et al.* (1997), the La nucleus contains a high concentration of A1 receptors, a potent modulator of cholinergic neurotransmission. No mention is made about the presence of A_2 receptors in this nucleus.

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988), the human La nucleus contains very high concentrations of BNZ-R.

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), the human La nucleus, in sharp contrast with the ICMs that surround it, presents one of the lowest densities in mACh-R.

GABAERGIC RECEPTORS (GABA-R)

GABA A /β 2 AND 3 SUBUNITS/BENZODIAZEPINE RECEPTOR (GABA A-R) In the macaque monkey, the neuropil of the La nucleus exhibits very dense immunoreactivity for the GABA A-R. This ir is also seen in neuronal perikarya and dendrites where it is localized to the cytoplasm and/or surface membrane. The cell type with the strongest ir is a subpopulation of small non-pyramidal neurons that had numerous thin dendrites. Other larger nonpyramidal neurons are also stained. In its whole, GABA A-R-containing neurons compose approximately 14% of the neuronal population of La (McDonald and Mascagni, 1996).

MONOAMINERGIC RECEPTORS

ADRENORECEPTOR α_1 According to Flügge *et al.* (1994), in the tree shrew, the La nucleus shows a strong binding of [^{3}H]PRA, an α-adrenoreceptor antagonist that indicates the presence of this type of adrenoreceptors.

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the La nucleus shows a low number of [^{3}H]rauwolscine (α_2-adrenoreceptor antagonist) binding sites. The labeling in the La nucleus is nonuniform with a high number of binding sites at rostral levels and no binding sites at caudal ones.

SEROTONINERGIC RECEPTORS (5-HT-R)

SEROTONIN 2A RECEPTOR (5-HT_{2A}-R) According to Lopez-Gimenez *et al.* (2001), the dorsomedial subdivision of the La nucleus contains high densities of 5-HT_{2A} receptors.

NEUROPEPTIDE Y RECEPTOR (NPY-R) Double-labeling studies have found coexpression of NPY mRNA with the NPY-R2 but not with the NPY-R1 (Caberlotto *et al.*, 2000).

OPIOD RECEPTOR μ In the amygdaloid complex of cinomolgus monkeys, moderate to sparse densities of opioid receptors μ are distributed throughout the rostrocaudal extent of the dorsal sectors of the La nucleus, whereas much higher concentrations appear in the ventral sectors. Within the latter sectors, heavier concentrations are apparent in the posterior two-thirds of the La nucleus than in the anterior one-third (Daunais *et al.*, 2001). An approximately similar distribution pattern has been reported for the human La (Pilapil *et al.*, 1986; Quirion *et al.*, 1995), in which very

dense concentrations of μ receptors have been also observed in this sector. It should be mentioned than in humans, the μ receptors have been characterized with positron emission tomography, and, consistent with *in vitro* studies, high levels of ligand binding were found in the amygdala (Frost *et al.,* 1989). Moreover, the levels of opioid μ receptors in the amygdala have been shown to fluctuate with changes in circulating estradiol levels (Smith *et al.,* 1998), function of age and gender (Zubieta *et al.,* 1999), and in psychiatric (Mayberg *et al.,* 1991; Zubieta *et al.,* 1996) and neurological (Madar *et al.,* 1997) disease states.

At this point, it should be recalled that the ventral portions of the lateral nucleus have extensive connections with the small-celled VL/VM subdivisions of the BL as well as with the BM nucleus (Pitkanen and Amaral, 1998), each of which contains dense concentrations of μ binding sites. In contrast, the ventral small-celled La has few connections to the magnocellular sectors of both BL and BM, and with the central nuclei (Pitkanen and Amaral, 1998), each of which contains low levels of μ-receptor binding sites.

STEROID RECEPTORS

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), low ER-α mRNA labeling can be detected in the human La.

Basolateral Amygdaloid Nucleus (BL)

Pharmacobehavioral investigations in the 1970s indicated that the amygdala is one of the main sites of action for the clinically important antianxiety and anticonvulsant effects of benzodiazepines. Subsequent studies have shown that it is the basolateral portion of the amygdala (BL) that is critical for the anxiolytic actions of benzodiazepines.

Topographical Landmarks The basolateral amygdaloid nucleus (Figs. 22.1–22.12) [lamina 23 to lamina 32 (1.3–13.3 mm of Mai *et al.* (1997), *Atlas of the Human Brain*] lies medially but also dorsomedially to the La nucleus from which it is separated, throughout most of its extent, by a thin medullary lamina [lateral medullary lamina (lml)]. This nucleus occupies the central and the ventral third of the LBNC enclosing laterally and ventrally the BM amygdaloid nucleus from which it is separated by another septa of myelinated fibers, the medial medullary lamina (mml). In transverse sections cut at midcoronal levels of the amygdaloid gray complex, it stands out clearly from surrounding gray masses on account of its hook-like appearance (Figs. 26–28 of Mai *et al.,* 1997, *Atlas of the Human Brain*; Figs. 22.5a, 22.7b, 22.11, 22.4, 22.5, 22.6, 22.7a, 22.9, 22.10). Rostrally, however, this characteristic arrangement is lost, and the nucleus becomes then less clearly definable in part by reason of a looser arrangement of its cell components. Nevertheless, in both horizontal and sagittal unstained transilluminated sections, as well as on equally oriented sections stained with Weigert or reduced silver stain, it is possible also to appreciate its clear separation from surrounding rostrally located basal forebrain grisea by the interposition of dense fiber septa. Much less clearly definable is its separation from the paralaminar (PL) nucleus, more particularly at the level of its boundary with the medial division of this latter griseum. However, the existence of such separation is not only suggested by the presence of small collections of finely myelinated fibers in the interface between both cell aggregations and by the more transparent background of the PL divisions, but more specially by the larger size of the neuronal constituents of the BL VM subdivision.

Cytoarchitectonics Based on a stepped reduction of the cell size and stain ability as well as on a parallel increase in cell density, three major divisions can be recognized: large-celled dorsal (BL D), medium-celled intermediate (BL I), and small-celled ventral (BL V). An extreme dorsolateral extension of the dorsal division of the BL nucleus, which appears in many coronal sections as seemingly separated from the rest of the cell mass of this nucleus, has been referred to as the dorsolateral (DL) part (de Olmos, 1990) of the BL nucleus, even though it was admitted that its cytoarchitectonic features were entirely similar to that of the main dorsal division. Ventrally a different situation can be appreciated where the larger size and denser disposition of the neuronal perikarya in the medial sectors of the BL V division justifies its subdivision into lateral (BL VL) and medial (BL VM) subparts. This latter subdivision probably corresponds to the amygdaloideum profundum ventrale pyramidale of Brockhaus (1938).

Fiberarchitectonics In both myelin- or silver-stained sections the BL nucleus is characterized by the presence of numerous small bundles of fibers, most of them running diagonally in a dorsalateral to ventromedial direction which provides the nucleus a radiate appearance (Fig. 22.7). These bundles of fibers become denser medially at the level of the BL I division of the nucleus. The background network of fine fibers present throughout the nucleus is, however, less dense than that in the La nucleus or, more particularly, in the BM nucleus, while being denser than that in the PL nucleus—a feature that helps in tracing the boundary between the BL V division and the latter nucleus. The DL division of the BL nucleus, though heavily encapsulated by thick bundles of medullated fibers, shows in its core solely the presence of very few thin

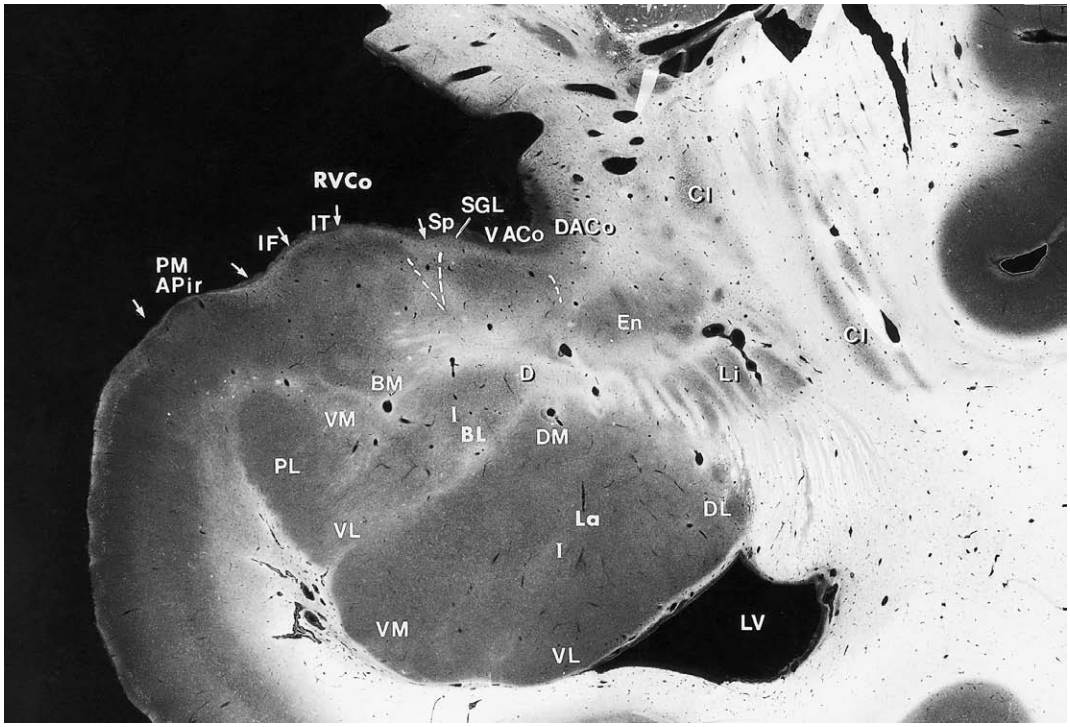

FIGURE 22.3 Low-power photomicrograph of the human amygdala at the level of the rostral pole of the ventral cortical amygdaloid nucleus (RVCo) showing its topographic relationships to the polar sectors of small-celled VL BM (Brockhaus' dense-celled division of his amygdalum profundum ventral). Already at this level the PM APir shows conspicuous development.

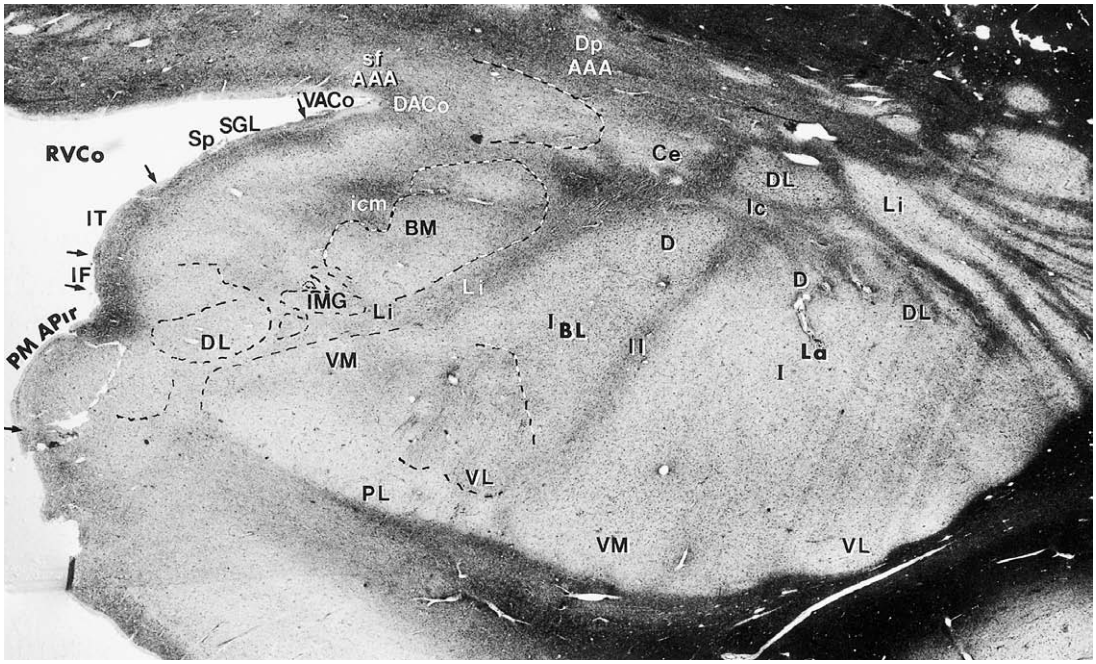

FIGURE 22.4 Low-power photomicrograph at the level of the rostralmost portion of the large-celled, dorsolateral division of the BL (DL BL). Individual subdivisions are clearly seen. Note the onset of the corridorlike bridge (SIsl) joining the Ce with the BSTL. A different method of transillumination was used by means of a microscope condenser and photographed directly with a reflex camera system.

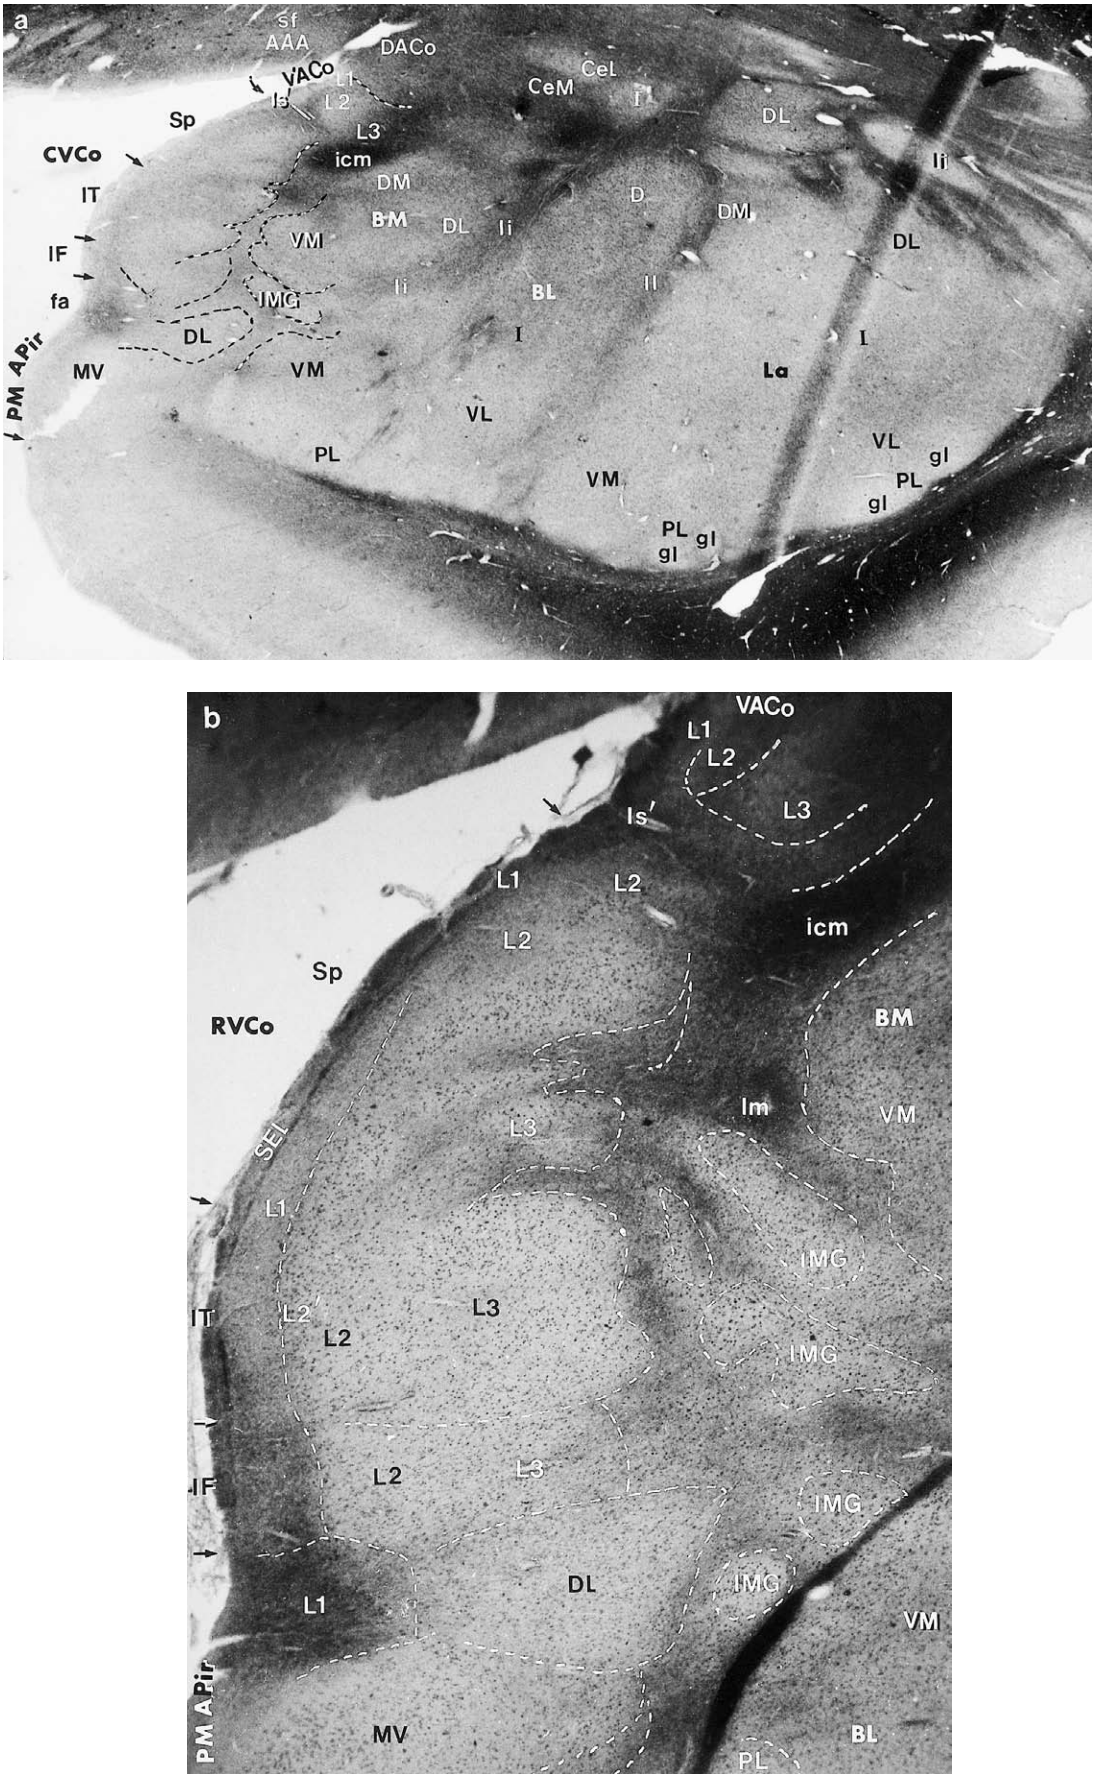

FIGURE 22.5 (a) Photomicrograph of a section slightly caudal to Figure 22.4 showing the subdivision of the VCo, the intramedullary grisea (IMG), the icm fiber system, as well as a more caudal segment of the SIsl as it fuses with the rostral pole of the Ce. (b) Medium-power photomicrograph providing a closer view of the intramedullary grisea (IMG) intervening between the BM and VCo. Note the lipofucsin-filled neurons in this amygdaloid region, and the clear boundaries that exist among the gray masses.

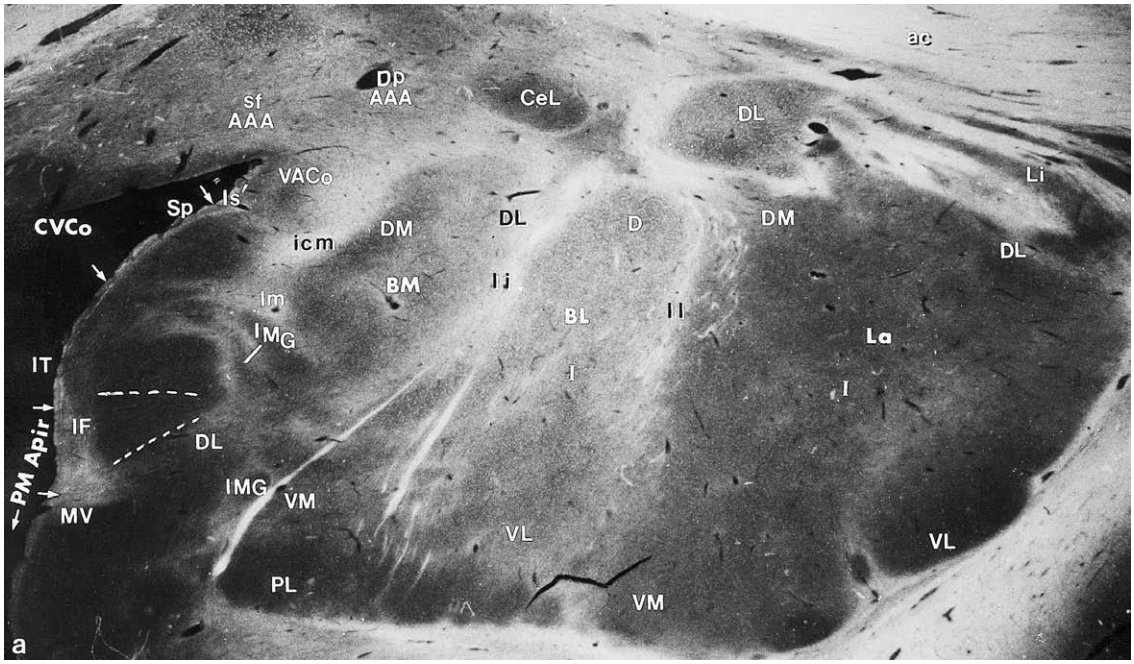

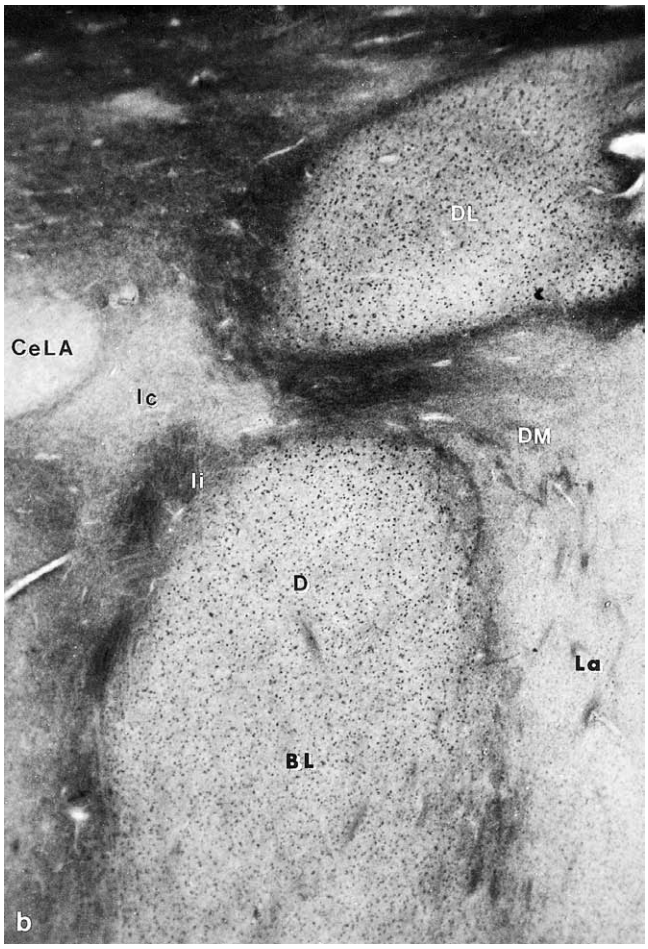

FIGURE 22.6 (a) Low-power photomicrograph at the level of the apical division of the central amygdaloid nucleus (CeLA) showing the clearly developed IMG intervening between the small-celled VM BM and the intermediate and inferior VCo medially, and the small-celled, ventromedial (VM) division of the BL laterally. The icm fiber system separates the large-celled DM BM from the ventral division of the ACo dorsomedially and the superior division of the VCo ventromedially. An intercalated mass (Ic) lies between the large-celled DL and D divisions of the BL laterally, and the Ce mediodorsally. (b) Medium-power magnification of the same section as in (a) but illuminated with the procedure indicated in Figure 22.4. It shows the different sizes of the lipofucsin deposits in the BL divisions and the small-celled, dorsomedial La. Lipofucsin deposits are absent in the intercalated masses (Ic) and in the CeLA.

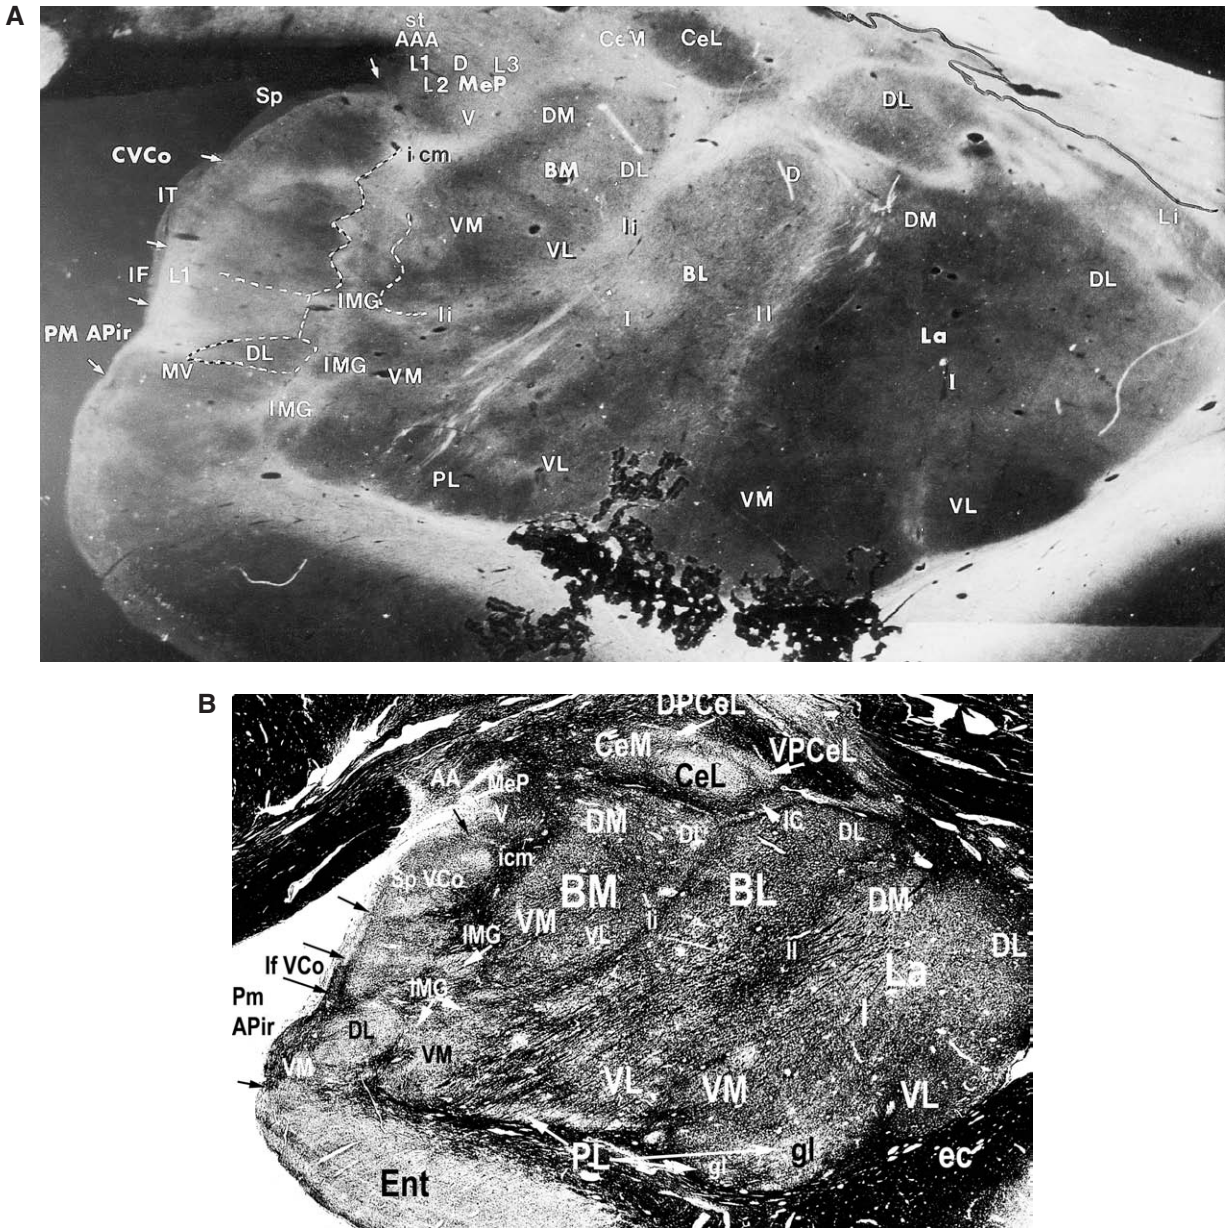

FIGURE 22.7 (a) Low-power photomicrograph of a transversal unstained section caudal to Figure 22.6 showing an almost vertical alignment of the intramedullary grisea (IMG) in the interface between the superficially located amygdaloid nuclei (IT CVCo, IF CVCo, DL PM APir, and MV PM APir on one side, and the medium-celled VM BM and small-celled VM BL and PL BL) on the other. A bigger IMG island lies between the VM BM and VM BL. (b) Low-power photomicropgraph of a transverse section taken at a plane just caudal to the that illustrated in figure 7a, which has been stained with a non-suppressive silver neurofibrillar stain. The image depicts a very close parallelism between the distribution pattern of optically dense medullated fibers seen in unstained sections with that provided by the silver stained material. The far more detailed demonstration provided by this latter procedure reinforces the parcellation proposed here for the human amygdala.

fiber bundles, a disposition that contrasts markedly with the radiated appearance in the rest of the nucleus. On the other hand, the dorsomedial tip of the BL VM subdivision shows a sharp drop in the number of radiating fiber bundles running through it that contrast markedly with their richness in the rest of the BL V division.

Chemoarchitectonics

Heavy Metals In Timm-Danscher's preparations of the marmoset monkey brain, the BL nucleus, like its other counterparts in the LBNC, shows a stepwise differential distribution of silver sulfide precipitate. Thus, while its dorsal sectors (DL D) show a comparatively poor reactivity, the middle sectors (BL I) display an

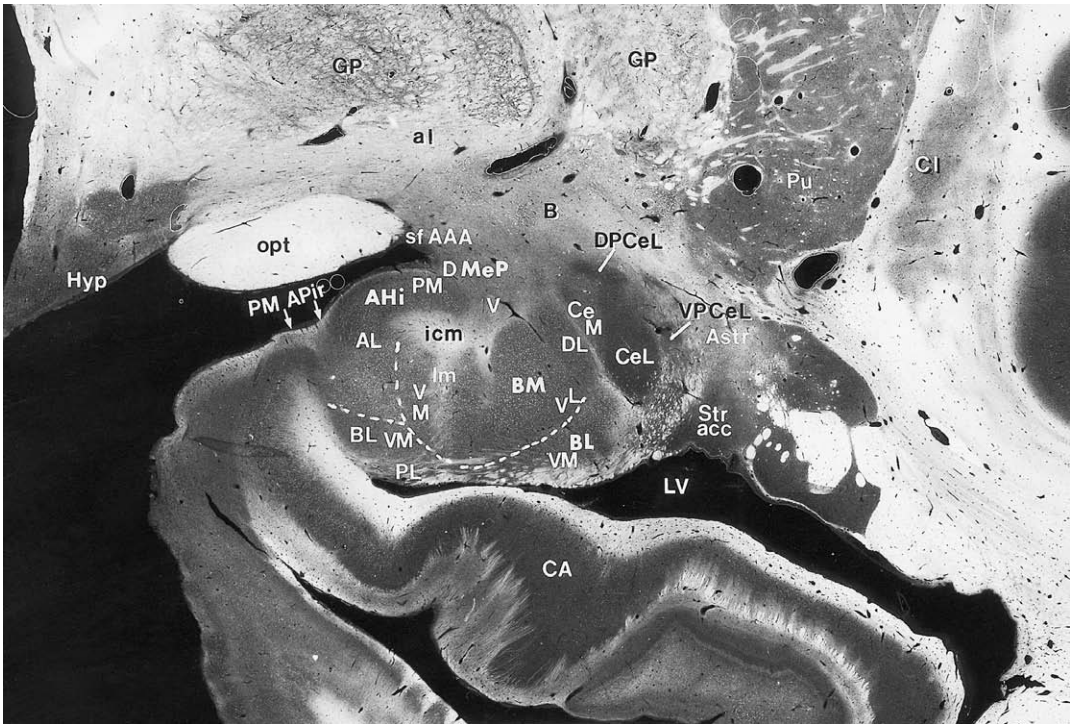

FIGURE 22.8 Low-power photograph at the caudal level of the amygdala showing the amygdalohippocampal-area (AHi) as well as some of the central amygdaloid nucleus subdivisions (Ce) and the relationship with the amygdalostriatal area. At this level the LA has disappeared and the BL is reduced to its small-celled VL and VM subdivisions which in turn are set apart by intervening portions of small-celled VL BM.

intermediate density and the ventral ones a heavy staining pattern that cannot be separated from that present in the PL nucleus (Fig. 22.23). Closer examination reveals that at difference with what happens in the La nucleus, most of the silver sulfide precipitate in the BL nucleus is distributed rather homogeneously throughout the nucleus but with patches of smaller density diffusely scattered in it. Rail rod-like images, although present here and there, are rather rare and difficult to locate within this generalized pattern of homogeneous distributed silver deposits and no Timm-Dancher-positive perikarya could be identified.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) This nucleus contains the most intensely stained AChE-positive neuropil in the amygdala with its intensity diminishing in a ventral direction (Nitecka and Narkiewicz, 1976; Svendsen and Bird, 1985; de Olmos, 1990; Darvesh *et al.*, 1998; Heimer *et al.*, 1999). There are only isolated AChE-containing neurons with fusiform or triangular-shaped perikarya representing approximately 1% of the total neuronal population.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Emre *et al.* (1993), in the human amygdala all nuclei contain ChAT-ir axons and punctate varicosities, but there are substantial regional variations in the density of these axons and *neuropil*. In the BL nucleus the density of varicosities are so dense that individual fibers cannot be identified. These varicosities may be interpreted as preterminal specializations, consistent evidence has been found by these authors to show that the amygdala contains intrinsic ChAT-ir neurons except for few aberrant perikarya belonging to the nucleus basalis of Meynert. This was confirmed by Lopez-Gimenez *et al.* (2001b), who could not find any ChAT mRNA in this nucleus or in any other amygdaloid nucleus.

Emre *et al.* (1993) have stated that the BL nucleus contains the highest density of ChAT-ir profiles and is sharply delineated from its neighboring nuclei for that reason. The high density of the ChAT-ir in this nucleus remains unchanged along the anteroposterior extent of the BL nucleus but such density decreased toward the transition from the BL to the basomedial nucleus (here the small-celled subdivisions of the BL nucleus plus the PL nucleus). In the deep division of their basomedial nucleus (here VL/VM BL subdivision) as in their superficial division (here the PL nucleus), there are high to moderate ChAT-ir profiles, and this picture does not vary in its anteroposterior extent. However, it should be pointed out that, together with the VCo

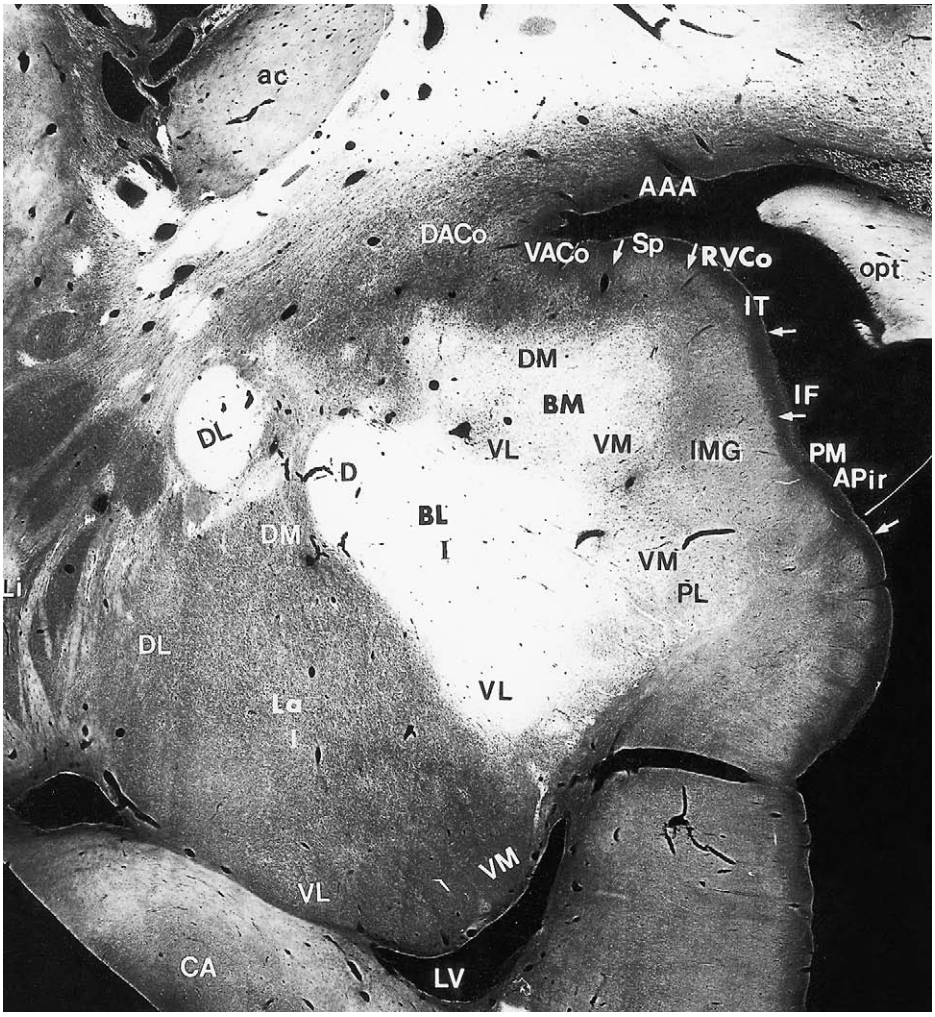

FIGURE 22.9 Low-power photomicrographs of transverse AChE-stained sections through the rostral third of the human amygdala showing the differential distribution of AChE activity in the amygdaloid nuclei. Same illumination system as in Figure 22.4.

nucleus and the BM nucleus, the small-celled VL/VM BL nucleus is ranked third in terms of the density of ChAT-ir fibers and varicosities.

In the macaque monkey, Amaral and Basset (1989) describe a picture very similar to the one present in the human amygdala, although, by recognizing a cytoarchitectonic different neuronal population in the interface between their classical magnocellular and parvicellular divisions of this nucleus, they have to introduce and fit their account to the new fact. Accordingly, their dorsally situated magnocellular division is said to contain an extremely dense and homogeneous amount of ChAT-ir fibers and terminals, while their intermediate subdivision bears ChAT fibers and terminals morphologically similar but that show a ChAT-ir density intermediate between that present in the dorsal magnocellular division and that existing in the ventral parvicellular division, which is substantially lower than in either of them.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Retrograde tracing experiments made in rats using tritiated D-aspartate indicate that a considerable number of the BL neurons could be the source of GLU/ASPergic projections to the nucleus accumbens and olfactory tubercle (Fuller *et al.*, 1987) and, even though in a very restricted manner, to the region of the paraventricular hypothalamic nucleus (Csáki *et al.*, 2000).

On the other hand, this nucleus seems to be the target of GLU/ASPergic afferent projections coming from cortical fields after injections of tritiated D-aspartate that involved the magnocellular and intermediate divisions of the BL nucleus. Among the cortical areas involved in these projections are neurons in the rostral two-thirds of the CA1 field of the hippocampus, in layers 5 and 6 of the entorhinal cortex, particularly its rostral olfactory division, and neurons in layers 3 and 5 of the insular cortex proper agranular (Ia), caudal

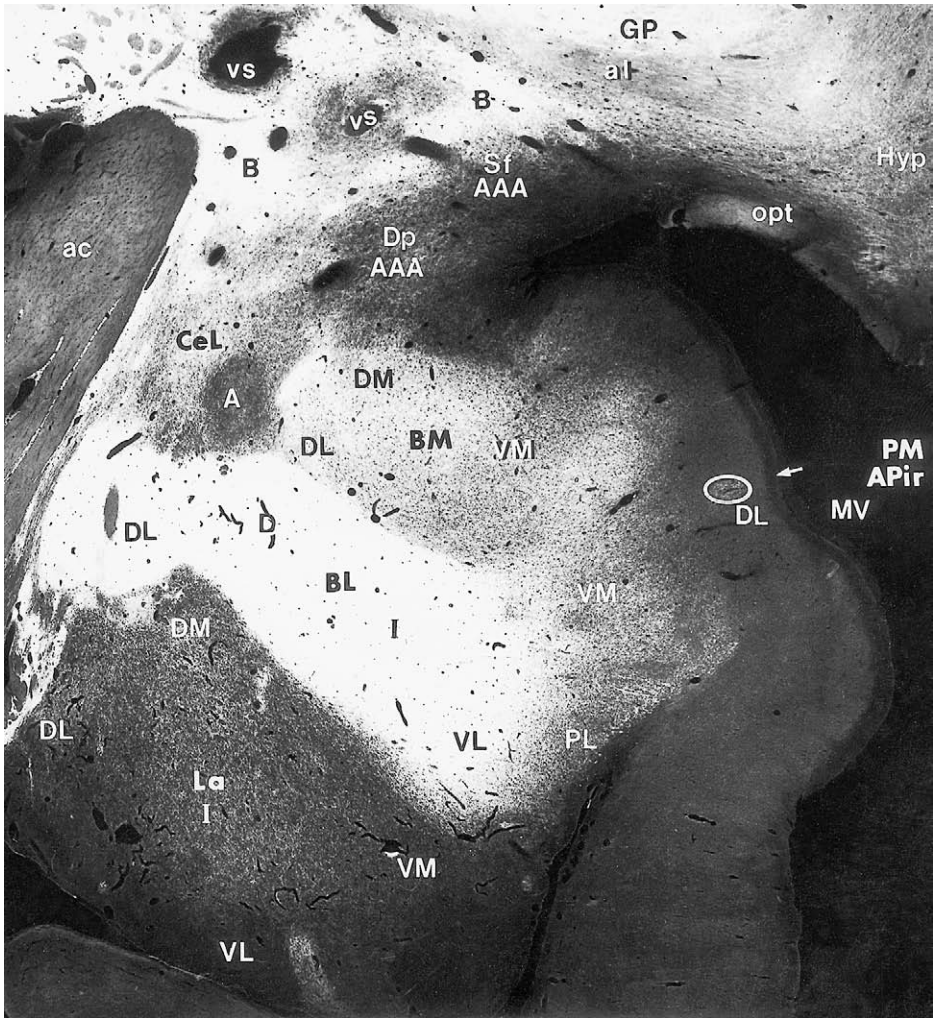

FIGURE 22.10 Low-power photomicrographs of transverse AChE-stained sections through the rostral third of the human amygdala showing the differential distribution of AChE activity in the amygdaloid nuclei. Same illumination system as in Figure 22.4.

portion of area 13a (14O), area 13 (13M and orbital periallocortex), cingulate areas 25 and 24, perirhinal areas 35 and 36, area TF and TH, etc. At the level of the amygdala itself, the most prominent intrinsic labeling with retrogradely transported tritiated D-aspartate occurs at the level of the PL nucleus neurons and not so markedly from the BST nucleus. From their schematic representation (Figs. 3 and 8A, B) it seems that the rostral and deep cell laminae of the AL AP-ir area (their periamygdaloid cortex sensu lato) contribute to the GLU/ASPergic neuropil in this nucleus.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), in the macaque monkey the basal nucleus (here the BL nucleus) has a slightly lower density of GABA-ir cells than the La and BM nuclei. The density of GABA-ir cell is similar in the magnocellular (here large-celled DL/D BL) and intermediate (here medium-celled I BL) divisions and slightly higher in the parvicellular (here, small-celled VL/VM BL). Type 1 cells are most common throughout the BL nucleus, and type 2 cells are present mainly in the intermediate and parvicellular divisions. Very few type 3 cells can be found throughout the BL nucleus. The density of GAD mRNA-labeled cells is slightly lower in the BL nucleus than in the La and BM nuclei. Consistently with all this, the density of GABA-ir fibers and terminals in the BL nucleus is lower than in the La nucleus. Within the BL nucleus, a slightly higher density of GABA-ir fibers and terminals is present in the magnocellular and intermediate divisions than in the parvicellular division. A characteristic feature of the magnocellular division is the presence of numerous pericellular baskets surrounding non-ir large cell bodies.

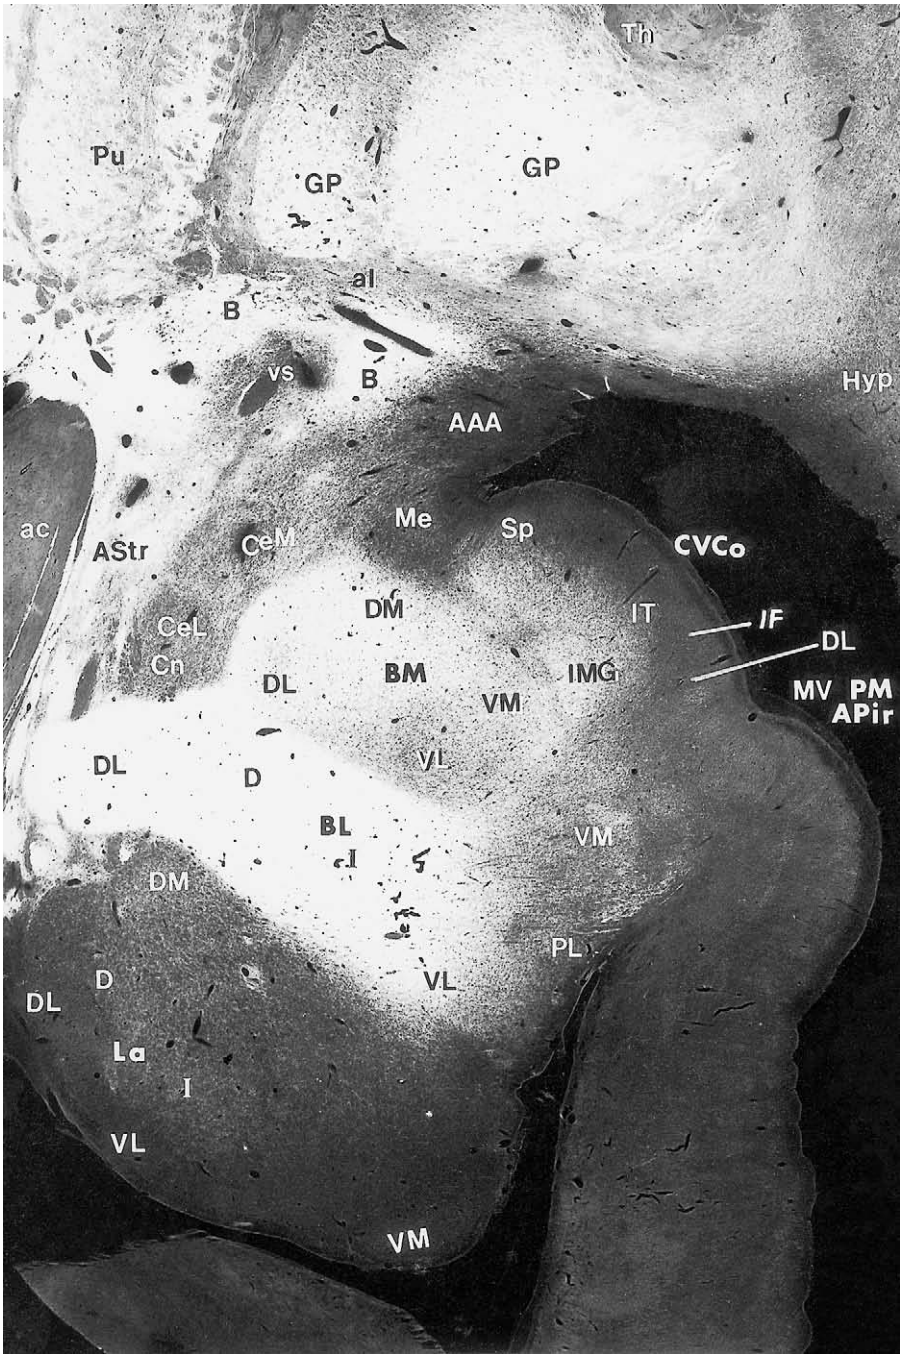

FIGURE 22.11 Low-power photomicrographs of transverse AChE-stained sections through the rostral third of the human amygdala showing the differential distribution of AChE activity in the amygdaloid nuclei. Same illumination system as in Figure 22.4.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey, the basal nucleus (here the BL nucleus) shows light DBH-ir in its magnocellular division (here the large-celled DL/D BL subdivision), and moderate ir in its parvicellular division (here the small-celled VL/VM BL subdivision), the latter appearing to fuse medially with the cortical transitional area. Note by the reviewer: It is possible that the parvicellular division of BL in the squirrel monkey, such as depicted by these latter authors, may also include the PL nucleus.

DOPAMINE TRANSPORTER (DAT) In the macaque monkey, Freedman and Shi (2001) have reported the presence of modest amounts of DAT-ir in the basal

FIGURE 22.12 High-power photomicrograph of a Nissl-stained section showing the smaller and more densely packed cells in the La as compared with the BL. Interposed between the La and BL is a dense group of very fine intercalated cells (Ic).

magnocellular amygdaloid nucleus, and they stress the fact that when DAT is present, outside striatum a network of very fine fibers of modest density is formed. Sadikot and Parent (1990) report that the basal nucleus (i.e., the BL nucleus) shows intranuclear gradients with dense TH-ir varicosities in the lateral aspect of the parvicellular division (here the VL/VM subdivisions of the BL nucleus) and moderate terminal density dorsally in its magnocellular division (here the DL/D of the BL nucleus).

SEROTONIN (5-HT) According to Freedman and Shi (2001), in the macaque monkey, there are relatively heavy concentrations of 5-HT-ir in the basal amygdaloid nucleus (here the BL nucleus).

After Sadikot and Parent (1990), in the squirrel monkey, the basal nucleus shows a gradient of 5-HT-ir ranging from moderate in the magnocellular division to dense in the lateral aspect of the parvicellular division (here the VL/VM BL subdivision). A patch of light 5-HT-ir is seen in the medial aspect of this division.

TYROSINE HYDROXYLASE (TH) According to Pearson (1990), the human BL nucleus contains a moderate amount of TH-ir axons and innervation that seems to diminish in density anteriorly.

Sadikot and Parent (1990) report that in the squirrel monkey the basal nucleus shows intranuclear gradients of TH-ir with denser TH-ir terminal varicosities in the lateral aspect of its parvicellular division and moderate TH-ir terminal density dorsally in its magnocellular division. A patch of light TH-ir is seen in the medial aspect of the parvicellular basal nucleus.

NEUROPEPTIDES

CHOLECYSTOKININ (CCK) The number of CCK mRNA-containing cell bodies in the BL nucleus seems to be rather modest (Savasta *et al.*, 1990).

CHROMOGRANIN B According to Marksteiner *et al.* (1999), the human BL nucleus contains a high-density PE-11-like ir that consists of varicose fibers and mixed-size varicosities. No PE-11-like ir neurons are present.

CORTICOTROPHIN-RELEASING FACTOR (CRF) Although the human BL presents only a sparse populations of small CRF-ir bipolar cells, the CRF-ir-containing fibers were highly conspicuous in this nucleus but not as dense as in BM (Powers *et al.*, 1987).

ENKEPHALIN (ENK) According to Piorio *et al.* (1990), in the human BL nucleus, as in the rest of the LBNC, only lightly stained delicate networks of varicose fibers are obscured.

GALANIN (GAL) According to Kordower *et al.* (1992), in the macaque monkey amygdala this member of the LBNC, like all of its remaining components,

does not contain GAL-ir cell bodies and few if any GAL-ir fibers.

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), in the human amygdala, NPY-ir fibers and cells are more numerous in all nuclei of the LBNC than in the medial superficial nuclei including Ce, Me, and VCo nuclei. On the other hand, as in other members of the LBNC, the NPY-ir perikarya appear to concentrate in the dorsal large-celled sectors of the BL nucleus, while the NPY-ir fibers appear highest in the ventral small-celled VL/VM subdivisions (i.e., their ventral *parvicellulare* subdivision of the nucleus profundus amygdalae intermedius).

According to McDonald *et al.* (1995), in the macaque monkey, the NPY-ir neurons resembled SOM-ir neurons in all nuclei of the LBNC, which is consistent with evidence for extensive colocalization of SOM-ir and NPY-ir. These "double" peptidergic neurons fall within two categories already mentioned to be present in the nuclei of the LBNC, i.e., spiny and spiny-sparse. (For more details, the reader is referred to the original paper by these authors.) As in the human amygdala fiber, labeling is most dense in the parvicellular basal nucleus, while it is much lighter in the magnocellular division though it still contains numerous NPY-ir fibers.

NEUROTENSIN (NT) Mai *et al.* (1987) reported that the human BL nucleus contains a much smaller density of NT-ir fibers than the corticomedial group of amygdaloid nuclei. According to Benzing *et al.* (1992), the large-celled BL nucleus (equivalent to DL/D BL and I BL of the present account) as a whole displays moderate densities of NT-ir, with the dorsal large-celled subdivisions (DL/D BL) containing a network of relatively short fine-beaded fibers and scattered dot-like puncta. In addition to the existence of a rostral-to-caudal gradient of increasing concentration of NT-ir, the fiber plexuses in the BL nucleus also show a dorsoventral gradient being densest in DL/D BL. By contrast, the NT-ir in their basal *parvicellulare* nucleus (equivalent to VL/VM BL of the present account) is described as being more dense than in DL/D-I BL and consisting of a network of fine and coarse fibers, with the fine ones strongly outnumbering the coarse ones.

SECRETONEURIN (SCR) The BL nucleus shows rather poor if any SCR-ir either in the neuropil or in perikarya of DL/D and I BL subnuclei, although what could be some expression of its presence can be found in the small-celled subdivisions of BL (see figure of Marksteiner *et al.*, 1995).

SOMATOSTATIN (SOM) In the human brain, Mufson *et al.* (1985) reported the presence of SOM-ir neurons in the BL nucleus (i.e., their laterobasal nucleus), but they did not provide further detail on the distribution pattern of cells and fibers within the nucleus.

According to Amaral *et al.* (1989), the density of SOM-ir cells is relatively low in the monkey BL nucleus, showing quite even distribution throughout the whole nucleus and varying sizes and shapes. By contrast, the density of SOM-ir fibers and terminals in the monkey BL nucleus follows a dorsoventral gradient, with their large-celled dorsal division showing the lowest level in the amygdala, the medium-celled intermediate division having a somewhat higher concentration, and the small-celled ventral division containing a fairly dense ir. According to McDonald *et al.* (1995), the BL nucleus, like the other amygdaloid nuclei, shows a moderate number of SOM-ir cell bodies (still more numerous than the NPY-ir cells). Since SOM-ir and NPY-ir colocalizes in significant numbers of neurons in this and other amygdaloid nucleus, this information should not be ignored. As can be inferred from these data, the density of SOM-ir fibers in the monkey BL nucleus parallels that of the NPY-ir fibers, although one has to keep in mind that SOM-ir neurons are always more numerous than NPY-ir neurons.

SUBSTANCE P (SP) According to Piorio *et al.* (1990), the BL nucleus, like in the rest of the LBNC, except their dorsal magnocellular part of the accessory basal nucleus (here DM/CM BM) contains few scattered SP-ir neurons together with branching fibers and punctate material.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), the human basal nucleus, i.e., the present BL nucleus, contains both BDNF-ir neurons and fibers, although showing a moderate staining intensity and rather modest density in number which contrast markedly with the much higher BDNF-ir in the neighboring Ce nucleus.

ENZYMES

ANGIOTENSIN-CONVERTING ENZYME (ACE) Moderate levels of binding for this enzyme are displayed by all the subdivisions, large celled and small celled, of the BL nucleus (Chai *et al.*, 1990), which contrast with the lower levels of binding shown by the other components of the LBNC.

BUTYRYLCHOLINESTERASE (BUCHE) The BL nucleus contains many BuChE-positive neurons being more numerous dorsally than ventrally. These neurons have round, fusiform, or triangular perikaria that give rise to numerous dendrites. According to Darvesh *et al.* (1998), approximately 10% of the neuronal population in the *BL* nucleus are BuChE.

NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) As in other members of the basolateral nuclear group, the BL nucleus contains NADPH-d but with the particularity that here the concentration of this enzyme reaches its greatest expression involving neuronal perikarya, fibers, and terminals (Simms and Williams, 1990; Brady *et al.*, 1992). However, its general distribution in the nucleus is not homogeneous but follows a dorsoventral gradient attaining its maximal concentration at the level of the small-celled subdivisions of the BL nucleus, which sets these sectors apart from surrounding areas. The staining pattern in the human BL nucleus is very similar to that reported for a New World monkey, the *Saimiri sciureus* or squirrel monkey (Brady *et al.*, 1992).

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, the BL nucleus (i.e., their basal nucleus) contains a moderate density of P450 AROM mRNA-labeled cells. Close examination of their illustrations indicates the existence of two separate labeled zones: one rostrally situated involving lateral sectors of the D and I subdivisions of the BL nucleus, and a caudal one that shifts toward the medial sectors of both subdivisions.

CALCIUM-BINDING PROTEINS

CALBINDIN-D28K (CAL) According to Sorvari *et al.* (1996b), the density of CAL-ir neurons in the DL/D (their magnocellular division) subdivision of the BL nucleus varies from low to moderate. The highest density of CAL-ir neurons was observed in the VL/VM subdivisions (their parvicellular division) of the BL nucleus. The I BL subdivision appears to contain higher density of neurons than the DL/D subdivision. The neurons are small and belong to mainly type 1 and type 2 categories. Characteristic of the I BL subnucleus is the presence of many large type 2 and type 3 cells, in addition to the smaller type 1 neurons. Lightly stained, pyramidal-shaped, immunopositive neurons are found only occasionally. The CAL-ir dendrites in the BL nucleus show a different appearance than those in the La nucleus. While the dendrites in this latter nucleus are thin and straight, the dendrites in the I BL and VL/VM subnuclei are thick and multibranched. In the VL/VM subdivision, the CAL-ir dendrites appear oriented in a dorsal-to-ventral direction and frequently extended to the PL nucleus. According to these authors, the intensity of neuropil CAL labeling in the BL nucleus was slightly higher than in the La and BMl nuclei, which helped define the borders between these areas. The I BL subnucleus of the BL nucleus appears to contain a substantially higher density of CAL-ir bundles than the VL/VM and DL/D subnuclei of the BL nucleus.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the common feature for all divisions of their basal nucleus (here BL nucleus) is the presence of small-type CR-ir cells. On the other hand, the overall density of CR-ir neurons and the proportion of the three neuronal types they recognize varies in the different divisions. In their magnocellular division (here DL/D) the density of CR-ir neurons is said to be low and to be composed almost exclusively of small type 1 cells. In their intermediate division (here I BL), this type of neuron still is predominant but some type 3 cells are also reported. Characteristic of I BL is said to be the presence of very large type 2 cells, the largest CR-ir in the amygdaloid complex. The density of the CR-ir neuronal population in I BL as compared with the overall density of these cells in the amygdaloid complex is moderate. Moreover, the density of the CR-ir cells in their parvicellular division (here VL/VM) is lower than in IBL, and its CR-ir neuronal population consisted mainly of small type 1 cells. Some large type 2 cells and some small type 3 cells are present.

The intensity of the staining of CR-ir fibers, terminals, and neuropil is said to vary also in different divisions of the nucleus with I BL showing a higher density than DL/D BL or VL/VM BL. Compared with its neighboring laterobasal nuclear masses, the intensity of the fiber and neuropil staining in BL is lower than in the La nucleus but higher than in the BM nucleus.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), the BL nucleus has more PAV-ir cells in its dorsal large-celled sectors than the intermediate and ventral small-celled subdivisions. The most common type of PAV-containing cell is the one constituted by neurons showing an angular and multipolar perikarya of variable size (their type 2 PAV-ir neurons). Some cells with stellate or spherical somata (their type 1 PAV-ir neurons) were detected particularly at the level of the intermediate subdivision of the BL nucleus. The BL nucleus also contains a high density of PAV-ir fibers that, as it happens in the La nucleus, follows a dorsoventral gradient though decreasing quite sharply at the border between the IBL and VLBM, with the latter and its medial counterpart, the VMBL subnucleus, displaying one of the lowest PAV-ir in the amygdala.

OTHER PROTEINS

DOPAMINE- AND ADENOSINE 3′,5′-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-1) According to Barbas *et al.* (1998), in the macaque monkey, there are fewer and less densely labeled neurons in the BLl nucleus than in the VCo, BMl, La, or Ce nuclei for I-l, and even fewer for DARPP-32.

The few and weakly stained DARPP-32-ir neurons can be found in its ventrolateral (VL BL) and, to a lesser extent, in its ventromedial sectors (VM BL). In contrast, I-l-ir neurons are more widely distributed in the VM sector of the nucleus, which abuts the BM nucleus. The ventrolateral zone of BL also contains I-l-ir neurons and, in a few sections, some can be noted in its central zone where the nucleus is narrow.

DOPAMINE TRANSPORTER (DAT) According to Ciliax *et al.* (1999), the human BL nucleus has the highest density of DAT-containing varicose axons, with a decreasing gradient from dorsomedial to ventrolateral regions providing a distinct boundary with both BM and La nuclei.

On the other hand, in the macaque monkey BL nucleus the number of DAT-ir fibers is modest, forming a very fine network (Freedman and Shi, 2001).

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, the BL nucleus is the most intensely stained nucleus of the primate amygdala. All divisions of the La nucleus express LAMP-ir, but the intensity of the ir differs among the various divisions and along the rostrocaudal extent of the nucleus. At the rostral pole, the BL nucleus consists of a single entity that displays very weak LAMP-ir. At slightly more caudal levels, a weak LAMP-ir occurs in the I BL and small-celled subdivisions of the BL nucleus but not in the large-celled division. At the midamygdaloid levels, the LAMP-ir is intense in the small-celled division, moderate in the I BL, and weak in the large-celled division. In the caudal one-third of the BL nucleus the LAMP-ir is weaker than at midamygdaloid levels. The magnocellular and intermediate divisions of the BL nucleus display a rather diffuse and moderate LAMP-ir.

SMI32 NEUROFILAMENT PROTEIN (SMI32-R) According to the Petrides *et al.* (2000) atlas on the distribution of the SMI32 neurofilament protein in the macaque monkey, this protein would be practically absent from most of the BL nucleus except at rostral levels where some SMI32-ir can be localized in the dorsal and intermediate subdivisions of this nucleus.

RECEPTORS

ADRENERGIC RECEPTORS

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the basal nucleus shows a low number of [^{3}H]RAU binding sites, being RAU indicative of this type of receptor.

ADRENORECEPTOR β According to Flügge *et al.* (1994), in the tree shrew, the majority of the monoamine nonsertoninergic receptors present in the basal nucleus are β-adrenoceptors.

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988), the basal accessory nucleus in humans (here the BM nucleus) contains intermediate levels of BNZ-R.

ESTROGEN RECEPTOR α (ER-α) ER-α can be detected in this nucleus (Blurton-Jones *et al.*, 1999). Österlund *et al.* (2000) confirm these findings by detecting a low amount of ER-α mRNA–labeled nuclei in the large-celled D BL nucleus, a labeling not detected in monkeys.

GABA A RECEPTOR (GABA A-R) According to McDonald and Mascagni (1996), in the macaque monkey, the density of GABA A-R in the BL nucleus (i.e., their basal nucleus) is rather weak in both its large-celled and small-celled sectors.

OPIOID RECEPTOR (OR) According to Daunais *et al.* (2001), within the macaque monkey BL nucleus, different patterns of μ receptor binding were readily apparent in their magnocellular (here DL/D) and parvicellular (here VL/VM) portions of this nucleus. The concentration of binding sites is greatest in the VL/VM subnuclei, especially medially and at more caudal levels. Binding was considerably less intense in the intermediate division (I BL) and sparsest in the DL/D subnuclei.

SEROTONINERGIC RECEPTORS (5-HT-R)

5-HT$_{1A}$ RECEPTOR (5-HT$_{1A}$-R) According to Flügge *et al.* (1994), in the tree shrew, the basal nucleus is densely labeled by [^{3}H]DPAT, a specific agonist of the 5-HT$_{1A}$-R.

5-HT$_{2A}$ RECEPTOR (5-HT$_{2A}$-R) According to Lopez-Gimenez *et al.* (2001a), although the magnocellular DL and D sectors of the BL nucleus express mRNA for the 5-HT$_{2A}$-R, its density was rather low.

5-HT$_{2C}$ RECEPTOR (5-HT$_{2C}$-R) Based on an illustration presented by Lopez-Gimenez *et al.* (2001b), it seems that the BL nucleus as a whole does not contain this type of receptor.

VASOPRESSIN RECEPTOR (AVP-R) According to Loup *et al.* (1991), the dorsolateral part of the basal amygdaloid nucleus (here the BL nucleus) displays a weak AVP binding capacity.

Basomedial Amygdaloid Nucleus (BM)

This nucleus is one of the major outputs for projections to the hippocampal as well as to the

entorhinal and perirhinal cortices (see below). Since the hippocampal formation is strongly associated with memory and the amygdala has been shown to be involved in emotional memory (Halgreen, 1992), and since neurons containing estrogen receptors are heavily present in this nucleus, it is possible that the BM nucleus has a significant role in this function (Österlund *et al.*, 2000).

Topographical Landmarks The BM amygdaloid nucleus [BM in plates 22–32 (0.0–13.3 mm) of Mai *et al.*'s *Atlas of the Human Brain*, 1997] (Figs. 22.7b, 22.1c,d, 22.3–22.6a; 22.7a, 22. 23b, and 22.8–22.11) is a fairly oval gray mass that appears slightly caudal to the rostral pole of BL and extends posteriorly almost to the caudal end of the amygdaloid complex. Throughout much of its extent, the BM lies under the semilunar gyrus, separated from its surface by the stratified grisea of the VCo rostrally and the AHi caudally. The medial medullary lamina intervenes between the BM and the cortical-like divisions of the superficial amygdala. Another stratum of fibers, the intermediary medullary lamina, separates the BM from the BL, both laterally and ventrally. BM is overlaid with the ventral divisions of ACo rostrally and Me caudally, being separated from them by more or less diffusely arranged fibers, constituting branches of a larger fiber system. Dorsolaterally, the BM is separated from the Ce by the dorsomedial medullary lamina (longitudinal association bundle according to Gloor, 1997). The rostral end of the nucleus is marked not only by a clear change in the cytoarchitectonic arrangement where it borders with the AAA dorsally and with the preamygdalar sector of the endopiriform nucleus rostrally, but also by a sharp densification of the fiber plexus that separates BM from these two other gray formations. This is better appreciated in horizontal and sagittal sections of the amygdaloid region.

Cytoarchitectonics In cell preparations, the BM nucleus, like the other members of the LBNC, shows a gradual reduction in the size of its cells and a densification of its neuronal population, the largest element being located in the dorsomedial aspect of the nucleus and the smallest in the ventrolateral one. The glial population also shows a reduction in its density parallel with the reduction in the size of the neurons while density of the fiber plexuses in the nucleus follows a reverse pattern.

On cytoarchitectonic grounds, the BM can be divided into four major subnuclei: dorsomedial large-celled (BMDM), ventromedial medium-celled (BMVM), dorsolateral mixed-celled (BMDL), and ventrolateral small-celled (BMVL). To these (main) four subdivisions, a fifth less conspicuous one has to be added: the caudomedial dense-celled subnucleus (BMCM). However, many authors have chosen to blend them into two large medial (magnocellular) and lateral (parvicellular) subnuclei (Svendsen and Bird, 1985; Sorvari *et al.*, 1995, 1996a, b).

The dorsomedial division of the BM nucleus is composed in great part of gross pyramidal-like neurons similar to those in the dorsal large-celled part of the BL nucleus, showing a looser arrangement, darker staining, and smaller size than the latter. Smaller, thinner, pyramidal-like, round, or oval neurons are also present in the dorsolateral BM nucleus. Glial cells are evenly distributed, and satellite cells are rather scarce compared with the dorsal BL.

The dorsolateral division of the BM nucleus is located in the dorsolateral aspect of the BM nucleus, varying as much in length as in shape. Neurons are smaller and thinner than in the dorsomedial BM nucleus.

The ventromedial division of the BM nucleus is in the ventral and rostral aspects of the BM and is made up of smaller, lighter staining, more delicately outlined neurons also showing greater variations in shape and a looser arrangement than those in other subdivisions of the BM. It contains pyramid-like neurons, together with multiangular or spindle-shaped ones.

The ventrolateral division of the BM nucleus is in the ventrolateral corner of the BM nucleus and is composed of smaller and more closely packed pyramid-like cells, together with slender, spindle-shaped neurons. This subnucleus stretches the whole length of the BM and, contrary to the rest of the BM subdivisions, the rostral polar part of this subnucleus contains a relatively rich satellite cell population [Brockhaus' 1938) dense-celled BM].

The caudomedial division of the BM nucleus is located in the medial most aspect of the caudal one third of the BM nucleus, lying ventrally and medially to the caudomedial radiation of the intermediate (icm) stratum of fibers, being separated by the latter and by the medullary lamina (lm) from the AHi transition area, the caudal division of the VCo, and the posteromedial APir area. At levels at which fibers from the stria terminalis (st) join both the lm and the icm, the caudomedial division of the BM nucleus appears to be separated from the rest of the BM nucleus by a narrow, relatively poor cell band that joins with these fibers. The nerve cells in the caudomedial division of the BM nucleus are somewhat smaller and more closely packed than in the dorsomedial division of the BM nucleus. The pyramid-like neurons are also lighter staining and slender, sometimes showing a triangular outline.

Fibroarchitectonics In myelin preparations the fiber network in the BM nucleus shows a denser arrangement than in the BL nucleus. This is probably

why in dark-field illuminated unstained frozen sections (see Figs. 22.1–22.6a; 22.7a; 22.8) the former nucleus is denser. The myelin pattern in the BM nucleus shows some regional variations, being somewhat denser at the level of the dorsomedial division of the BM nucleus but definitely richer in the polar ventrolateral division of the BM nucleus. In the ventromedial divisions of the BM nucleus the myelin is substantially less dense than in the rest of the BM nucleus. The fiber network here is also much looser. In the caudal aspect of the BM, small bundles of fibers pass through the ventromedial division of the BM nucleus and display a fan-shaped distribution in the more medial aspect of the caudomedial BM. Thus, the dorsomedial and dorsolateral divisions of the BM nucleus show a less dense fiber network than in its ventromedial division, constituted mostly by fine to moderately thick single fibers lying on top of a faintly stained ground plexus of very fine fibers. Other single running fibers cut vertically or obliquely to the main fiber network. The great majority of the obliquely oriented fibers reach to or come from the capsular fiber system constituted by the icm and the lm, which intercalates between the BM and the deep layers of the superficial cortical-like amygdaloid grisea (VCo nucleus and the AHi, and posteromedial APir transitions area), and from Me nucleus medially, and by intermediate medullary lamina, which intervenes between the BM and the BL laterally, dorsally, and rostrally. Fibers detach from or enter the thick fiber capsule (i.e., the dorsomedial medullary lamella) that separates this part of the BM nucleus from the Ce nucleus, the AAA area, and the intercalated masses embedded in it. Ventrally, a sharp densification of the fiber plexus coincides with the cytoarchitectonic border between these subdivisions and the ventromedial division of the BM nucleus.

In neurofibrillar preparations (see Fig. 7b) these subdivisions appear to be denser in fibers than both the dorsomedial and dorsolateral divisions of the BM nucleus. It is crossed by small bundles of fine fibers oriented in a dorsomedial-to-ventrolateral direction. These fiber bundles are derived from the intermediate medullary lamina in the boundary with the dorsal subdivisions of the BM nucleus. A ground plexus of fine fibers enmeshes the perikarya of the neurons of this subdivision. Although the general picture is dominated by the obliquely running fibers, there are others, though fewer, coursing at a slight right angle.

Chemoarchitectonics

Heavy Metals In Timm-Danscher's preparations of the New World monkeys (squirrel and marmoset) the BM nucleus shows a stepwise increase of the density of the silver sulfide precipitate (Fig. 22.23b), which is expressed in the following ascending order according to a densitometric evaluation made at the level of its main subdivisions in these primates: DM, DL, VL, and VM. Accordingly, the DM BM large-celled subdivision would contain the weakest density of zinc-containing neuropil while the VM small-celled one, the highest, with the remaining sectors of the nucleus displaying moderate to dense deposits of silver sulfide. As in the BL nucleus, the silver precipitate shows a rather homogeneous distribution and the neuronal perikarya remains unstained.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) According to most authors, the BM nucleus contains a moderately stained (Figs. 22.9–22.11) AChE-positive neuropil with few AChE-containing fusiform or triangular neurons (Nitecka and Narkiewicz, 1976; Svendsen and Bird, 1985; de Olmos, 1990; Sims and Williams, 1990). According to Nitecka and Narkiewicz (1976), the AChE activity in their basal medial nucleus (here BM) is, as previously mentioned, moderately intense, but apart from that they recognize two areas of activity that fuse without clearly defined boundaries: a superomedial part (here DM BM) part of the nucleus which displays moderate AChE activity, and an inferior one (here VM/VL) with a weaker enzyme reaction. They also consider that the BM nucleus, like other amygdaloid nuclei, shows a rather diffuse though uneven AChE activity with no cellular involvement. Like these authors, Svendsen and Bird (1985) consider that the BM nucleus (i.e., their basal accessory nucleus) shows medial and lateral differences in staining with the lateral region showing the greatest AChE activity.

Benzing *et al.* (1992), on the basis of AChE stained sections, found that the dorsomedial divisions of the BM nucleus (i.e., their Abm) is the next most densely stained amygdaloid griseum after the BL nucleus (i.e., their Bmg nucleus). The VM BL (i.e., their Abp nucleus) like the BM nucleus (their Abm), was darkly stained and thus was readily differentiated from their ventrally adjacent and more lightly stained Bpv. According to Nakamura *et al.* (1992), this nucleus contained numerous AChE-positive axons, although fewer than in the basal nucleus.

According to Sorvari *et al.* (1995), the magnocellular division of their basal accessory nucleus has a moderate intensity of AChE staining compared to the parvicellular division, where the staining intensity is lower. A similar pattern of AChE staining in La has also been reported by others (Sims and Williams, 1990; Emre *et al.*, 1993; Sorvari *et al.* 1995).

CHOLINE ACETYLTRANSFERASE (CHAT) According to Emre *et al.* (1993), both divisions of the BM nucleus

(i.e., their AB nucleus), lateral (Abl) and medial (Abm), display moderate densities of ChAT-ir varicosities and fibers. Although thin fibers with varicosities predominated, there are also occasional thick nonvaricose fibers. The density of ChAT-ir was not uniform within the BM nucleus, and patches of slightly more intense staining are present. At anterior and midamygdaloid levels, dense collections of ChAT-ir fibers can be seen located at the junction of BM, VCo (i.e., their cortical nucleus Co) and VM BL, which, according to them, would correspond to intercalated masses (their Fig. 8a, IC), but here they are interpreted to correspond to the intramedullary grisea (IMG). Examination of their images also shows further differences in the density of the ChAT-ir plexuses in the BM nucleus so that its lateroventral one-third is clearly poorer than the rest of it, while the dorsomedial sector shows a higher density. According to Lopez-Gimenez *et al.* (2001), no ChAT mRNA could be observed in this nucleus. Together with the small-celled VL/VM BL nucleus and with the VCo nucleus, the BM nucleus ranks third concerning the density of ChAT-ir fibers and varicosities.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Experimental retrograde tracing data obtained in rats by use of tritiated D-aspartate indicate that a considerable number of the BM nucleus neurons give rise to GLU/ASPergic projections to all the members of the ventral striatum (Acb, Tu and IPAC) and to the ventral pallidum (Fuller *et al.*, 1987), or to the paraventricular hypothalamic nucleus or immediate surroundings (Csáki *et al.*, 2000).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Agustine (1993), in the macaque monkey, their basal accessory nucleus, like the other members of the LBNC, exhibit moderate levels of GABA-ir with some regional variations. These GABA-ir neurons represent a rather small neuronal subpopulation that is outnumbered by that constituted by non-ir pyramidal neurons. This GABA-ir neuronal subpopulation is accompanied by numerous GABA-ir puncta distributed in the neuropil and seems to represent axon terminals since they appear encapsulating the perikarya and apical dendrites of non-ir neurons. As in the other members of the LBNC, in the BM nucleus there is a pronounced tendency for the GABA-ir neurons to form clusters or be aligned in rows surrounding areas devoid of GABA-ir. In the same manner as for other members of the LBNC, the GABA-ir neurons in the BM nucleus are morphologically heterogeneous with most GABA-ir cells showing a round or oval soma that are smaller than those of the non-ir neurons. Usually they show only the initial segment of their apical dendrites, dendrites that are sparsely spined, and, for that reason, corresponding morphologically to non-pyramidal neurons (class II and III).

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), the squirrel monkey accessory basal nucleus shows very light DBH-ir terminal labeling in its magnocellular division and light DBH-ir in its parvicellular and "superficial" (?) divisions.

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew, the BM nucleus, i.e., their nucleus basalis accessorius, which they do not include in their Table 1, would contain at least a similar amount of HA-ir fibers as other members of the LBNC, i.e., a fairly dense innervation.

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey, the basal accessory nucleus shows a dense population of 5-HT-ir axonal varicosities in its magnocellular portion with a mild rostrocaudal gradient of decreasing density. The parvicellular and "superficial" (?) divisions show very light 5-HT-ir labeling, with some fibers of passage crossing the basal and cortical nuclei.

THYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey the accessory basal nucleus (here BM) displays a striking paucity of TH-ir terminal labeling appearing in the one that is present in the form of preterminal fibers en route to the parvicellular basal nucleus and to the cortical transition area (here PM APir).

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Retrograde tracing experiments made in rats using tritiated D-aspartate indicates that a considerable number of the BM neurons give rise to GLU/ASPergic projections to the ventral pallidum and in a lesser degree to the nucleus accumbens (Fuller *et al.*, 1987).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), in the macaque monkey, all divisions of the basal accessory nucleus (here the BM nucleus) have a relatively high density of GABA-ir cells, most of them of type 1, though type 2 cells are also present. Cells expressing GAD mRNA are evenly distributed throughout the nucleus. Their density is

higher than in the BL nucleus but lower than in the adjacent VCo nucleus. The AB/BM nucleus has a medium-density GABA-ir neuropil with slightly higher density of GABA-ir fibers and terminals in the VM division.

NEUROPEPTIDES

COCAINE- AND AMPHETAMINE-REGULATED TRANSCRIPT (CART) The presence of a moderate CART mRNA signal has been reported for this nucleus (Hurd and Fagergren, 2000).

CHOLECYSTOKININ (CCK) The density of CCK mRNA-labeled cells in the BM nucleus is the highest after that in the La nucleus (Savasta *et al.*, 1990).

CHROMOGRANIN B According to Marksteiner *et al.* (1999), the human BM nucleus contains a high-density PE-11-like ir which consisted of varicose fibers and mixed-size varicosities. No PE-11-like ir neurons are present.

CORTICOTROPIN-RELEASING FACTOR (CRF) According to Powers *et al.* (1987), in the basolateral nuclear group there is a sparse populations of small, corticotropin-releasing factor immunoreactive (CRF-ir) bipolar cells, approximately 20 µm in length. In normal individuals CRF-ir axons, predominantly straight, thin, and unbranched, were present throughout the amygdala and were most conspicuous in the lateral and basolateral nuclei. However, according to their schematic representations these CRF-ir fibers will have a more homogeneous distribution in BM than in La, BL, or PL nuclei, although it seems that these fibers are more numerous in the middle sectors of the BM nucleus.

CORTICOTROPIN-LIKE INTERMEDIATE LOBE PEPTIDE (CLPI) Zaphiropoulos *et al.* (1991) reported that the highest accumulation of CLPI-ir fibers, varicosities and terminals present in the amygdaloid body take place at the level of the three major divisions of the basolateral amygdaloidal complex, i.e., La, BL, BM. In contrast, no CPLI-ir cell bodies were detected at any level of the amygdala.

ENKEPHALIN (ENK) According to Pioro *et al.* (1990), SP-ir neurons are clustered in their dorsal magnocellular part of the accessory basal nucleus (here DM/CM BM), but they are few and scattered in the rest of the amygdala.

GALANIN (GAL) According to Kordower *et al.* (1992), in the macaque monkey, amygdala this member of the LBNC, like all of its remaining components contains no GAL-ir cell bodies and few if any GAL-ir fibers.

NEUROKININ B (NKB) According to Chawla *et al.* (1997), the BM nucleus contains NKB-ir neurons that are scattered throughout the nucleus.

NEUROPETIDE Y (NPY) According to Walter *et al.* (1990), in the human amygdala, their nucleus profundus amygdalae mediale (here the BM nucleus), as in other members of the LBNC, the NPY-ir cells appeared to be concentrated in the dorsal (large-celled) regions whereas the reverse would be true concerning the distributions of NPY-ir fibers and terminals. Furthermore, according to Unger and Lange (1992), close to 90% of the NPY-ir neurons are also positive for NADPH-d.

NEUROTENSIN (NT) When the schematic drawings presented by Mai *et al.* (1987) are carefully examined, it becomes evident that the dorsomedial sectors of the BM nucleus (i.e., their nucleus amygdaloideus profundus, pars medialis) contains moderate amounts of NT-ir whereas ventrolateral sectors contain low levels. No NT-ir cell bodies were mapped by them, in agreement with Benzing *et al.* (1992), who reported that the BM nucleus (i.e., their basal accessory nucleus) contains collectively very little NT-ir with only few scattered fine- and coarse-beaded fibers expressing NT-ir. Apparently in their material there were no differences in density of NT-ir between their magnocellular (*my* DM/CM/DL subdivisions) and parvicellular (*my* VL/VM BM) divisions of their basal accessory nucleus. However, in a few cases a slight increase in NT-ir was observed in the extreme anterior aspect of the BM nucleus. This region likely represented a transition area between the posterior end of the AAA and the anterior BM; thus, the NT-ir fibers present here would likely be a caudal extension of the AAA rather than the BM proper.

SOMATOSTATIN (SOM) In the human brain, Mufson *et al.* (1981, 1988) reported the presence of SOM-ir neurons in the BM nucleus (i.e., their accessory basal nucleus) but did not provide further detail on the distribution pattern of cells and fibers within the nucleus. Bouras *et al.* (1987), in turn, reported rather low densities of cell bodies ir for somatostatin (SOM-ir) and low to medium concentrations of SOM-ir fibers and terminals at the level of all the subdivisions of the amygdaloid body. On the other hand, Unger and Lange (1992) established that close to 90% of the SOM-ir neurons are also positive for NADPH-d.

According to Amaral and Basset (1989) in the macaque monkey, their basal accessory nucleus (here

BM) shows a complementarity of SOM-ir fibers and cell body. SOM-ir fibers and terminals are very dense at the rostral parvicellular pole and continue caudally in the parvicellular sector of the nucleus where they seems to attain the highest density in the amygdala. Although the so-called accessory basal nucleus also contains SOM-ir cells, their density is not very high. While fibers and terminal labeling is quite low in the magnocellular division of the basal accessory nucleus, the density of SOM-ir cells is much higher than in the parvicellular division. This SOM-ir neuronal population is rather heterogeneous in shape and size. By contrast in the above-described picture, McDonald *et al.* (1995) describe a similar distribution.

SUBSTANCE P (SP) According to Piorio (1990), as in the remaining nuclei of the LBNC no SP-ir cells can be found, but a lightly stained delicate network of varicose SP-ir fibers can. However, Chawla *et al.* (1997) described the presence of scattered SP-ir neurons in the human amygdala.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), the human basal accessory nucleus, i.e., the present BM nucleus, contains both BDNF-ir neurons and fibers, although showing a moderate staining intensity and rather modest density in number, which contrasts markedly with the much higher BDNF-ir in the neighboring Ce nucleus.

ENZYMES

ANGIOTENSIN CONVERTING ENZYME (ACE) According to Chai *et al.* (1990), the BM nucleus (i.e., their basal accessory nucleus) displays lower levels of ACE binding than its counterpart, the BL nucleus.

BUTYRYLCHOLINESTERASE (BUCHE) This nucleus contains numerous BuChE-positive neurons that are of small size with round, fusiform, or triangular profiles. Some have several branching processes. The size of the BuChE-positive elements remains the same no matter its topographical location (Darvesch *et al.*, 1998).

NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) According to Unger and Lange (1992), except for the relatively small AAA, in all nuclei of the amygdala there were numerous, relatively homogeneously distributed NADPH-d-positive cells and, concomitantly, a dense network of NADPH-d fibers that was distributed throughout the whole gray complex (see also Brady *et al.*, 1992). These NADPH-d-positive neurons were similar in all subregions, i.e., showing predominantly medium-sized cells sending out extended bipolar or multipolar dendritic branches. These authors also found that more than 90% of the SOM-ir and NPY-ir neurons are also NADPH-d positive.

With regard to the presence of a dense NADPH-d-positive neuropil in the BM nucleus, Sims and Williams (1990), in contrast to the above-cited report, found that the NADPH-d activity is nil in the neuropil of their dorsal large celled subdivision of the accessory basal nucleus (i.e., the DM/CM/DL BM), whereas it is characteristically positive in that of the ventral small-celled subdivision of the same nucleus (i.e., VM/VL BM), with only few scattered Golgi-like cells showing NADPH-d positivity.

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, the BM nucleus (i.e., their basal accessory nucleus) contains very high density of P450 AROM mRNA containing cells. A close examination of their illustrations would indicate that the P450 AROM mRNA labeling is concentrated in the large-celled subdivision of the BM nucleus in rostral parts of the nucleus, but more caudally (Figs. 5B–D) the labeling shifts principally to the dorsolateral sector of BM and, but in a much lesser degree, to the ventral sectors of this nucleus, i.e., to places in the BM where the cell population is predominantly of the small celled.

PROTEINS

CALCIUM-BINDING PROTEINS

CALBINDIN (CAL) According to Sorvari *et al.* (1996b), the density of CAL-ir cells in the BM nucleus (their basal accessory nucleus) is high compared to other amygdaloid nuclei, particularly in the caudal portion of the large-celled dorsomedial subdivision (i.e., their magnocellular division). The small-celled DL and VL subdivisions and the medium-celled VM subdivision have slightly lower density of immunoreactive neurons than the DL. Most of the neurons in the DM and DL/VL parvicellular divisions were small type 1 neurons, although numerous type 2 and some type 3 cells were also observed. A few lightly stained pyramidal-shaped neurons have been also observed.

The highest density of CAL-positive fibers can be found in the VM BM. The density of CAL-ir neuropil in the BM nucleus is low. The DL/VL contained a moderate density of CAL-positive bundles. A slightly smaller number of bundles was found in the DM and VM subnuclei.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the most common CR-ir neurons in their basal accessory nucleus (here BM nucleus) are small type 1 and 3 cells. They also found in their magnocellular division

(approximately DM/CM here) numerous type 2 CR-ir neurons. Their parvicellular division (approximately VL/VM here) contains a slightly higher density of CR-ir neurons than the previously described subdivision, but its lateral rim (VL BM?) was reported to contain fewer of these immunoreactive neurons. Their ventromedial subdivision (here IMG) is said to contain a moderate number of type 1 CR-ir neurons. On the other hand, the BM nucleus seems to contain the lowest fiber and neuropil staining in the human amygdaloid complex. Interestingly, the ventral part of the small-celled BM displays a moderate level of staining.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1996c), the density of PAV-ir cells in this nucleus was lower than that in the magnocellular (here DL/D BL) and intermediate BL (here I BL).The largest number of PAV-ir cells could be found in their magnocellular subdivision (here DM/CM) of BM. All three types of cells were observed in moderate numbers, although the density of type 1 and type 2 cells was higher than that of type 3 cells.

As in other nuclei of the human and monkey amygdala, all of the PAV-positive neurons in BM belong to the aspiny or, in rare occasions, to the sparsely spiny categories (Pitkänen and Amaral, 1993; a, b), displaying spherical (type 1, 33%), angular, multipolar (type 2, 28%), and fusiform (type 3, 21%) shapes. The distribution of the PAV-positive cells was not uniform, showing a rostrocaudally decreasing gradient in their number.

Other Proteins

CALPASTATIN (CALPT) According to Mouatt-Prigent *et al.* (2000), large CALPT-ir neurons are present especially in the basal accessory nucleus (here the BM nucleus). A high proportion of these neurons are bipolar and strongly immunostained. They are surrounded by a dense plexus of CALPT-ir fibers and puncta very probably corresponding to nerve terminals.

DOPAMINE- AND ADENOSINE 3′,5′-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-1) According to Barbas *et al.* (1998), in the macaque monkey, the distribution of neurons DARPP-32-ir and I-1-ir is similar, though not identical, in the BM nucleus. For both phosphoproteins most ir neurons can be found in the medial half of the nucleus. However, I-1-ir neurons extended more ventrally and laterally than the DARPP-32-ir elements, suggesting only partial overlap in the two populations. The dorsolateral sector of the BM nucleus is relatively sparse in immunoreactive neurons, and those that can be detected are weakly labeled.

DOPAMINE TRANSPORTER (DAT) According to Ciliax *et al.* (1999), the BM nucleus has markedly fewer DAT-containing varicose axons than BL, a feature that helps its differentiation from this latter.

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, overall the BM nucleus stains much less intensely than does the adjoining BL nucleus. Rostrally, the BM nucleus is faintly LAMP-ir with only scattered ir punctate material in its small-celled division. More caudally, LAMP-ir is weak in the large-celled division, moderate in the small-celled one, and intense in the superficial division, this latter probably representing one of the large accumulations of intramedullary grisea of the present account. At its most caudal level, the BM nucleus shows a diffuse and moderate LAMP-ir.

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low-magnification atlas on the distribution of this protein in the macaque brain published by Petrides *et al.* (2000), it is evident that the dorsal large-celled BM nucleus contains SMI32-ir while the ventral small-celled division seems to be relatively devoid of SMI32-ir.

RECEPTORS

BENZODIAZEPINE RECEPTOR (BZD) The BM nucleus apart from showing, together with La and PL BL, the highest concentrations of BZR in the amygdala, also shows anteroposterior variations in their density, so that the highest concentrations of BZD-R appear in the rostral sectors of the nucleus (Niehoff and Whitehouse, 1983). The existence of very high concentrations of BZR at the level of this nucleus in humans was confirmed by Zezula *et al.* (1988).

Cholinergic Receptors

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), the human basal accessory nucleus (here the BM nucleus) contains one of the highest densities of mACh-R which belong predominantly to subtype 1 neuron. On the other hand, according to Smiley *et al.* (1999), the amygdala as a whole contains a low density of m2-ir neurons.

NICOTINIC RECEPTOR (NACH-R) No source of data is available to the present writer regarding the distribution of this type of receptors in the primate amygdala.

Monoamine Receptors

ADRENORECEPTORS α_1 According to Flügge *et al.* (1994), in the tree shrew, at mediorostral levels of the amygdala, the basal accessory nucleus (here BM) reveals

high numbers of [^{3}H]prazosin (α_1-adrenoreceptor antagonist) binding sites.

ADRENORECEPTORS α_2 According to Flügge *et al.* (1994), in the tree shrew, at mediorostral levels of the amygdala, the basal accessory nucleus (here BM) contains low numbers of [^{3}H]rauwolscine (α_2-adrenoreceptor antagonist).

ADRENORECEPTORS β_1 According to Flügge *et al.* (1994), in the tree shrew, the majority of the monoamine nonsertoninergic receptors present in the basal accessory nucleus (here BM) are adrenoreceptors of the beta 1 type.

SEROTONINERGIC RECEPTOR (5-HT-R)

5-HT$_{1A}$ RECEPTOR (5-HT$_{1A}$-R) According to Flügge *et al.* (1994), in the tree shrew, the basal accessory nucleus is strongly labeled by [^{3}H]DPAT, a specific agonist of 5-HT$_{1A}$-R.

5-HT$_{2C}$ RECEPTOR (5HT$_{2C}$-R) According to Lopez-Gimenez *et al.* (2001), high levels of 5-HT$_{2C}$-R mRNA are found in their basal accessory nucleus (i.e., the BM nucleus).

STEROID RECEPTORS

ESTROGEN RECEPTOR α (ER-α) According to Blurton-Jones *et al.* (1999), their accessory basal nucleus (here BM nucleus) displayed a large number of ER-α-labeled nuclei. According to Österlund *et al.* (2000), in both human and monkey brains, the mediodorsal part of both divisions (magnocellular and parvicellular) of the accessory basal nucleus (here the DM/MC/Mc VM nucleus) contain moderate amounts of ER-α-labeled nuclei.

OPIOID RECEPTOR (O-R) Daunais *et al.* (2001) divided the accessory basal nucleus (here the BM nucleus) into parvicellular (here VL/VM) and magnocellular divisions (here DM/CM), but found [^{3}H]DAMGO binding relatively uniform throughout these two subdivisions. They clearly noted an evident higher density of binding in what they called ventromedial subdivision (probably IMG, here), located along the medial border of the accessory basal nucleus.

SOMATOSTATIN RECEPTOR (SOM-R) According to Reubi *et al.* (1986), the BM nucleus contains a moderate amount of SOM-ir, which is lower than that present in the large-celled BL nucleus.

Neuropathology According to Kromer Vogt *et al.* (1990), the most pronounced density of neurofibrillar tangles (NTG), which are present in Alzheimers patients, are found in BM nucleus (i.e., their basal accessory nucleus) and cortical nuclei. According to Unger and Lange (1992), this nucleus, together with the corticomedial amygdala, shows the most dense accumulation of neuritic plaques (NP) in the amygdala of Alzheimer's patients. By contrast, this nucleus shows slight changes in patients suffering neuronal ceroid lipofuscinosis (Braak and Braak, 1987).

Paralaminar Amygdaloid Nucleus (PL)

For the sake of a greater conformity with the amygdaloid nomenclature more commonly used, I have decided to abandon the terminology I once used (paralaminar BL; de Olmos, 1990) for designating this part of the LBNC, not only because such naming implies that PL is a part of BL, as originally proposed by Crosby and Humphrey (1941) [i.e., their superficial part of the pars medialis (small-celled) of the basal nucleus], but because such implication conflicts with the cytoarchitectonic, chemoarchitectonic, and connectional data favoring segregation of these grisea.

Topographical Landmarks This nucleus (PL in Plates 28–30 (8.0–0.7 mm of Mai *et al.*'s *Atlas of the Human Brain*) (Figs. 22.1c,d; 22.2; 22.3; 22.4; 22.5a; 22.6a; 22.7a; 22.8–22.11; 22.3–22.6a; 22.7a,b; 22.8–22.10) lies superficially to the ventral small-celled sectors of both BL medially and La laterally. In sagittal sections it is possible to appreciate that this nucleus constitutes an incomplete dorsally opened shell around the rostral, ventral, and caudal borders of the nuclear mass formed by La, VL BL, and VM BL reaching farther dorsally in its rostral pole than in its caudal one.

Cytoarchitectonics On both topographic and cytoarchitectonic grounds, the PL nucleus can be divided into a larger and well-defined medial part, and a smaller lateral part, which, because of its insular arrangement, has been named the pars glomerularis by Brockhaus (1940), a name that is retained here. This part of the PL nucleus, which covers the ventromedial aspect of the La nucleus from the rostral pole to the more caudal sectors of the amygdala, tends to form cell strands and shell-shaped islands which, when the LBNC extends posteriorly for some distance into the roof of the lateral ventricle, lies immediately below the ventricle but never surfaces into it. The medial PL or PL nucleus proper, on the other hand, covers the ventral aspects of the two small-celled parts of the BL nucleus, i.e., the ventromedial and ventrolateral subdivisions (VM BL and VL BL), throughout their rostrocaudal extent as can be easily appreciated in sagittal sections. The cells of this sector of PL are smaller and more densely packed and hyperchromic than those

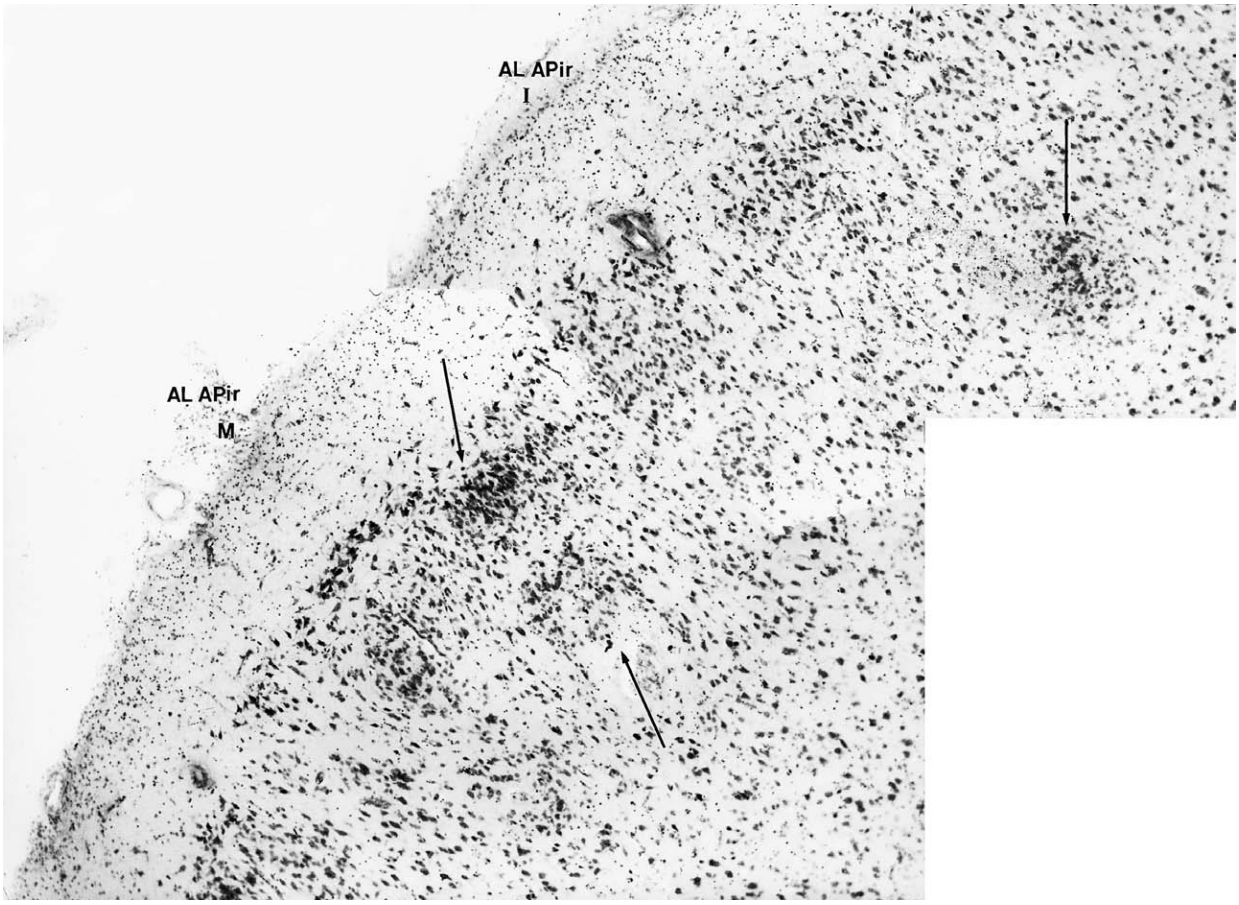

FIGURE 22.13 Medium-power photomontage of a Nissl-stained section through the anterolateral division (AL) of the amygdalopiriform area (Apir) showing the island of granule cells characterizing this transitional allocortical area. Arrows point to the islands of granule cells

in the neighboring small-celled BL nucleus, providing the division with a granular appearance. On the basis of cellular arrangement as well as differences in cell type, the medial PL division can be subdivided into anterior and posterior subparts. The anterior subpart (Brockhaus' amygdaloideum profundum ventrale supergrannulare) shows a tendency to break up into islands of different sizes, usually ovoid in shape (see also Brockhaus, 1940; Hilpert, 1928; Sanides, 1957b). The posterior subpart (Brockhaus' amygdaloideum profundum ventrale grannulare) presents, by contrast, a more compacted arrangement.

Finally, a characteristically cytoarchitectonic feature in PL, particularly appreciable in Nissl-stained sections, is the presence, along its whole extent, of numerous sharply delineated and deep staining nuclei resembling the naked nuclei of oligodendroglia cells that partially overlap the neuronal groups that constitute the nucleus. These naked nuclei tend to invade the deep layers of the amygdalopiriform transition area. It is interesting to point out that in a collection of macaque monkey brains at my disposition, this arrangement can be also found, whereas it is consistently absent in the squirrel monkey amygdala (unpublished observations).

According to Braak and Braak (1983), PL presents a characteristic pigmentation in aldehyde-stained sections different from that found in the other gray components of the LBNC, and which is due to the predominant presence in PL of small spiny neurons that store only moderate amounts of pigment granules. PL also contains pigment-laden aspiny or sparsely spiny neurons reminiscent of cortical stellate cells, and in addition sparsely pigmented small neurons that resemble morphologically similar neurons present in layer IV of the neocortex.

It should also be mentioned that, according to the embryological studies of several authors (Brockhaus, 1940; Humphrey, 1968, 1972; Mikami, 1952), PL is the last to be identifiable during the ontogenetic development of the amygdaloid nuclei. In addition to it, quantitative allometric studies by Stephan and Andy (1977) indicate that, among the various subdivisions of

the amygdala, PL is the most progressive structure. See Mueller and O'Rahilly (this volume).

Fibroarchitectonics In fiber preparations (Fig. 22.7b) the PL nucleus appears to have a less rich fiber network than that present in its companion nuclei of the LBNC, the La and BL nuclei, except in its island-like or glomerular-like (PL gl) sectors where the cell aggregations conforming them appear surrounded by relatively dense septa of fibers. The continuity of the lamina-like medial division of the PL nucleus is interrupted by small bundles of thin fibers traversing it almost perpendicularly to the temporal white matter running along its ventral surface.

Chemoarchitectonics

Heavy Metals In Timm-Danscher´s preparation of the marmoset and squirrel monkey brains (Fig. 22.23), the territory that is probably homologous to the PL nucleus in humans shows in most of its extent a dense silver sulfide precipitate similar to that described for its neighboring companions of the LBNC, except in some of the laterally located islands described above and the more medial sectors of the medial division of PL where the reactivity is apparently higher. As it happens with other amygdaloid nuclei showing a positive Timm-Dancher´s reaction, neuronal perikarya in the PL nucleus are negatively stained.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) According to Darvesh *et al.*'s (1998) histochemical data, the human PL (Figs. 22.9–22.11) would stand last concerning the AChE stainability as compared with the other nuclei of the LBNC. There are only isolated AChE-positive neurons in this nucleus with fusiform or triangular profiles, constituting less than 1% of the total neuronal population in this nucleus. With regard to the density of the AChE reaction at the level of this nucleus, Sorvari *et al.* (1995) claim that PL is slightly more intensely stained than the VL/VM BL nucleus (i.e., their parvicellular basal nucleus).

According to Amaral and Basset (1989), in the macaque brain, AChE preparations of the PL nucleus show a moderate pattern of fibrous staining similar to that present in their parvicellular basal nucleus (here small-celled VL/VM BL subnucleus). No AChE-positive cells can be detected in the PL nucleus. On the other hand, Flügge *et al.* (1994) reported that in the tree shrew the PL nucleus displays AChE reactivity from moderate to intense.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Amaral and Basset (1989), in the macaque brain, the distribution of ChAT-ir fibers and terminals is very similar to that seen in the parvicellular basal nucleus (here VL/VM BL subnucleus) consisting of a thin plexus of ChAT-ir fibers and terminals.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) According to Amaral and Insausti (1992), in the macaque monkey, injections of tritiated D-aspartate in the basal and lateral amygdaloid nuclei labeled a significant number of neurons along the whole PL nucleus, providing argument that the nucleus would be a source of glutamatergic intraamygdaloid projections to the above-mentioned nuclei.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Augustine (1993) and Pitkänen and Amaral (1994), in the macaque monkey PL nucleus, there is a marked reduction in the number of GABA-ir cells as compared with their density in the small-celled VL/VM BL nucleus, with most of the cells being type 1. This is also true for the labeling with GAD mRNA. The GABA-ir neuropil is also quite low in density.

MONOAMINE MARKERS

DOPAMINE β-HYDROXYLASE (DBH) From my own observations, at least in the squirrel monkey, DBH-ir fibers and terminals can be seen in this nucleus.

NEUROPEPTIDES

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), within the human amygdala the NPY-ir appear highest in the PL nucleus (i.e., the ventral parvicellular subdivisions of their nucleus profundus amygdalae ventralis).

According to McDonald (1995), in the macaque monkey PL nucleus, as in other components of the LBNC, the NPY-ir are numerous and the NPY-ir fiber plexus is dense. Likewise, the NPY-ir neuronal population in the PL nucleus includes spiny and spiny-sparse cells and many of them colocalize SOM-ir. The density of this plexus may be related to the fact that the NPY-ir spiny-sparse neurons are with all probability class II neurons possessing very dense local axonal arborizations.

NEUROTENSIN (NT) According to Benzing *et al.* (1990), the NT-ir in the human amygdaloid nucleus consists of a network of varicose fibers interspersed among a dense plexus of dot-like puncta. Although the density of the NT-ir in the PL nucleus is classified as high, as in the centromedial nuclei, it is, however, quite distinct.

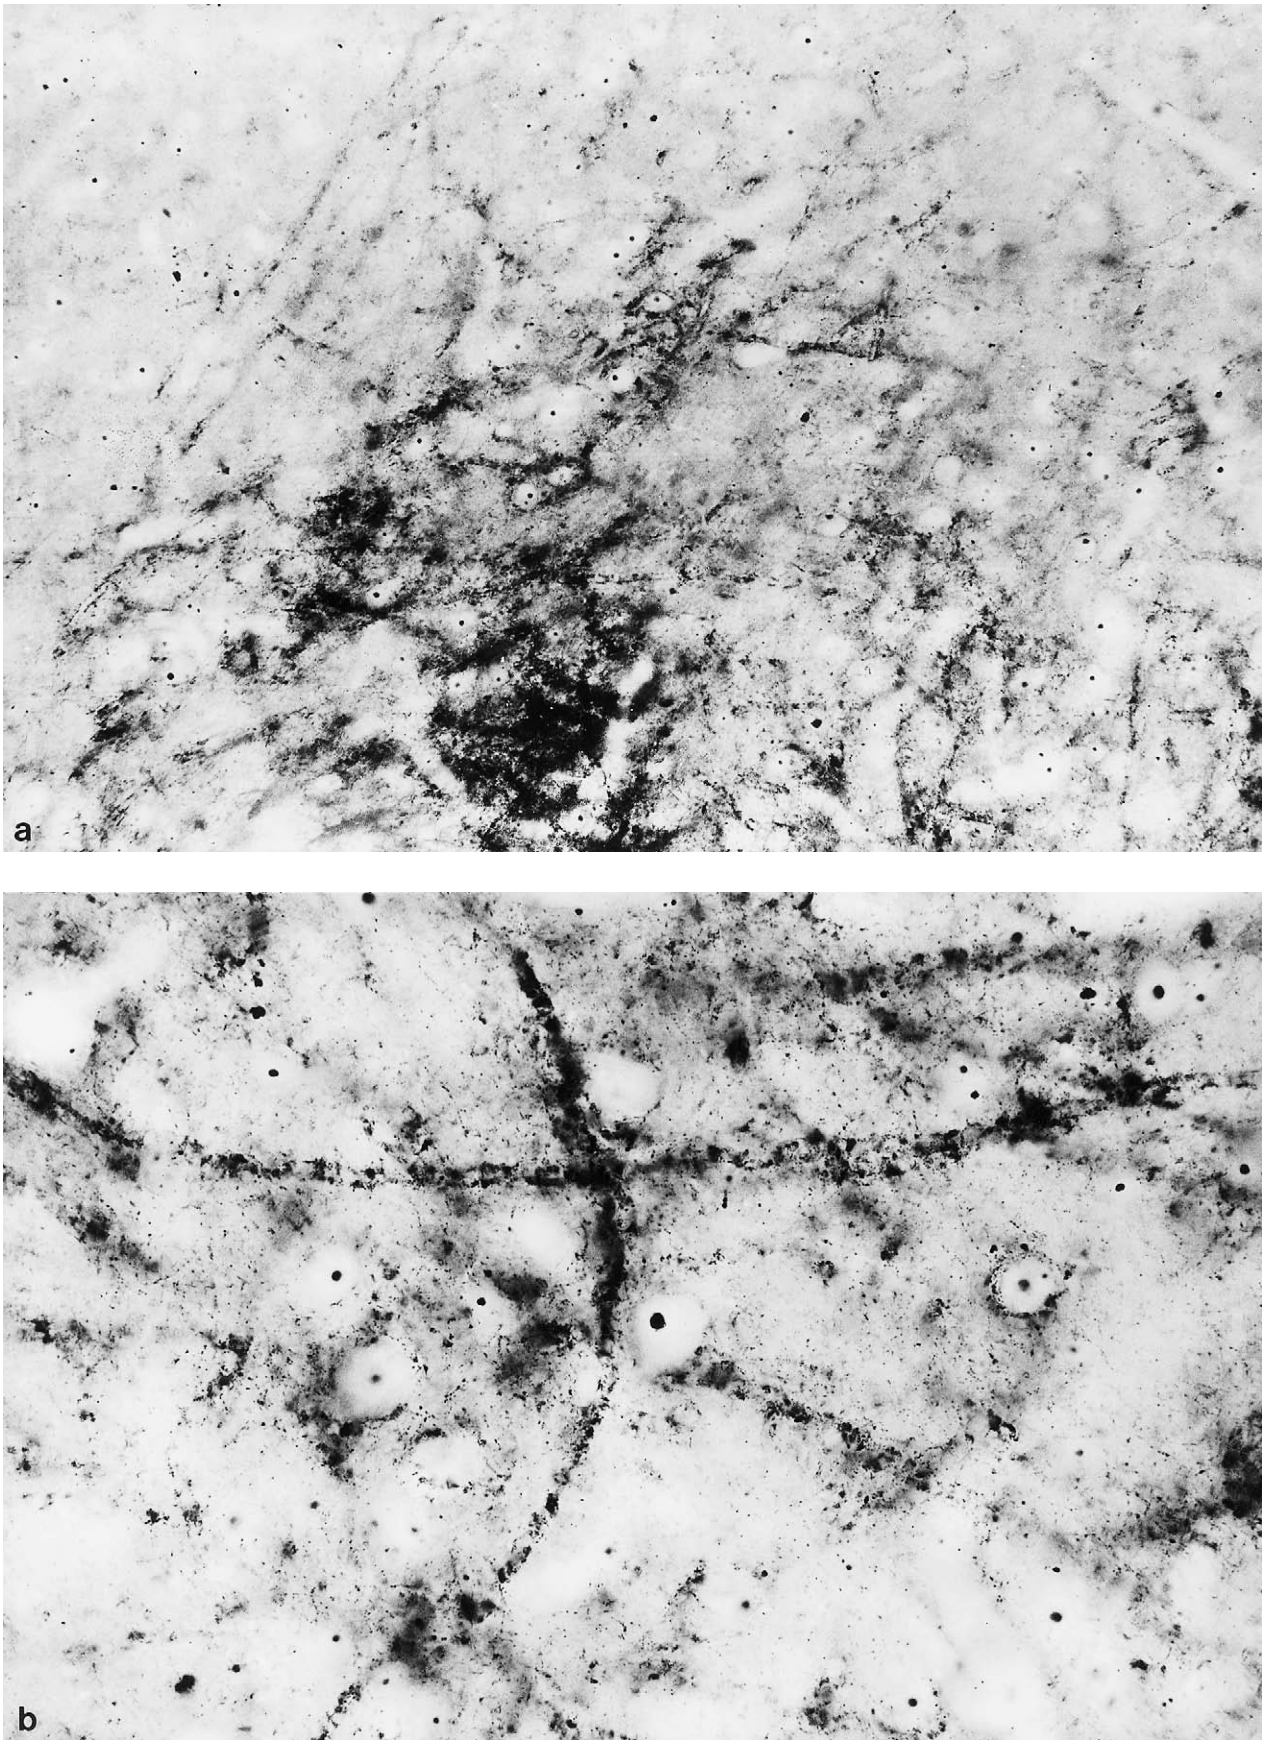

FIGURE 22.14 (a and b) Medium- and high-power photomicrographs of a cupric-silver stained coronal section through the sublenticular substantia innominata (SIsl) from a normal macaque monkey brain to show the heavily impregnated bistranded argyrophilic neuropil present at the level of the dorsal anterior division of this sector of the extended amygdala.

SOMATOSTATIN (SOM) In the monkey the PL is described as containing a fairly dense plexus of SOM-ir fibers and terminals that are similar in staining to that in the small-celled VL/VM BL nucleus. This nucleus is also described as containing numerous SOM-ir cell bodies especially at caudal levels of the amygdala (Amaral *et al.*, 1989). In McDonald *et al.* (1995) mapping of the localization of SOM-ir neurons also containing NPY can be seen to be more abundant in the medial subdivision of this nucleus while being more diffusely distributed in the lateral sector.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human brain, all amygdaloid nuclei show BDNF-ir neurons and fibers, from which it can be inferred that PL nucleus is included though it is not specifically mentioned by the authors. Close examination of their minimally magnified Figure 4A suggests that this is so.

ENZYMES

BUTYRYLCHOLINESTERASE (BUCHE) According to Darvesh *et al.* (1998), in the human amygdala, the PL nucleus contains BuChE-positive neurons that are morphologically similar to the neurons in the BL nucleus, i.e., they are round, fusiform, or triangular in profile with many branching processes. Approximately, 6% of the neurons in the PL nucleus contain BuChE and none of them contains pigment.

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), the PL nucleus contains one of the lowest densities of CAB-ir neurons in the human amygdaloid complex. Most of the CAB-ir neurons were small type 1 cells. A few small type 2 cells can be also found. The CAB-ir neurons are scattered around the PL nucleus and are mainly located outside the cell clusters, typical of this nucleus as seen in Nissl-stained preparations.

The density of the CAB-ir axons in the paralaminar nucleus is also low. In the medial part of the paralaminar nucleus, the few CAB-ir axons are located outside the neuronal clusters found in Nissl preparations. Some thick dendrites emanating from the CAB-ir somas located in the small-celled divisions of the BL nucleus (i.e., their parvicellular basal nucleus) extend to the PL nucleus. The intensity of the neuropil staining is similar to that in the BL nucleus. The lateral part of the PL nucleus located ventral to the La nucleus had more intense neuropil staining than this latter. Typical of the PL nucleus are thin, tortuous, and branched axonal plexuses. Such plexus are often observed near the soma of an CAB-ir type 1 neuron, which may have given rise to it. No CAB-ir bundles are observed in the PL nucleus.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the PL nucleus contains the lowest density of CR-ir neurons in the human amygdaloid complex. A few CR-ir neurons are mostly located in the medial half of the PL nucleus. The CR-ir neurons are mainly small type 1 cells that seem to avoid the cell clusters that typify the nucleus in cell preparations. In the medial half of the PL nucleus the intensity of the CR-ir fiber and neuropil staining is similar to that found in the VL/VM BL (i.e., their parvicellular basal nucleus). Fibers are typically oriented dorsal to ventral and they tend to avoid the above-mentioned cell clusters**.** In the lateral part of the PL nucleus, CR-ir fibers and neuropil resemble that in the previously described medial division—a feature that facilitates its separation from the La CR-ir due to its denser staining.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), only occasional PAV-ir cells can be found in the PL nucleus, and a low density of PAV-ir fibers and terminals. In the PL nucleus as well as in the border against the BL nucleus, the PAV-ir terminals form a small plexus enclosing several non-PAV-ir perikarya.

OTHER PROTEINS

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996) in the macaque amygdala, the PL nucleus is devoid of LAMP-ir rostrally but shows moderate to intense staining at midamygdaloid levels. More caudally the moderate to intense LAMP-ir in the PL nucleus is continuous with the ir present in the I BL nucleus.

SMI32 NEUROFILAMENT PROTEIN (SMI32) From the low-magnification atlas published by Petrides *et al.* (2000), it seems that the PL nucleus, except for its most rostral extent where it borders rostrodorsally with the La and BL nuclei, does not contain any SMI32-ir. However, this rostral most sector of the PL seems to give one of the strongest positive signals on the amygdaloid complex.

RECEPTORS

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988), the granular nucleus (here the PL nucleus) contains very high concentrations of BNZ-R.

CCK RECEPTORS (CCK-R) CCK binding in macaque amygdala showed marked variation among nuclear subdivisions with laterally, ventrally, and medially placed nuclei more heavily labeled than those located

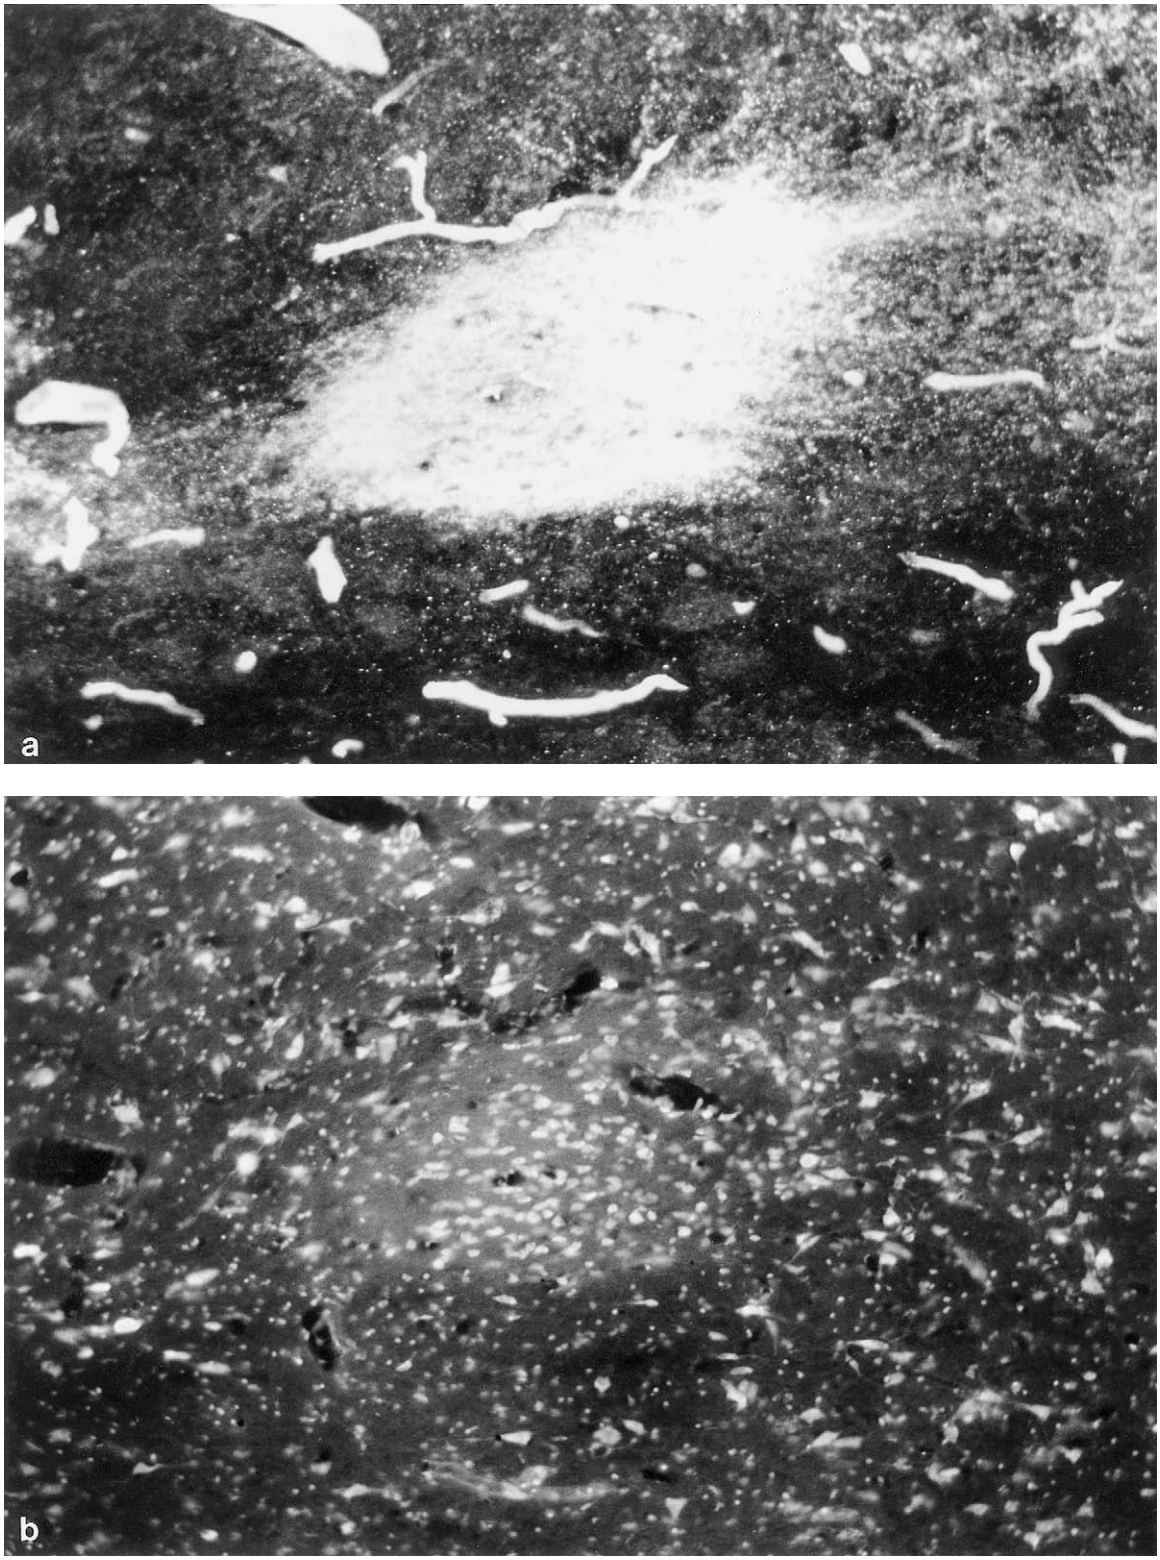

FIGURE 22.15 (a) Medium-power photomicrograph of a Timm's coronal section through the rostralmost extension of the dorsal anterior division of the sublenticular substantia innominata from a squirrel monkey brain. The very dense metal deposits are confined almost entirely to the small-celled neuronal island that is surrounded by the larger cells of the magnocellular basal forebrain complex (MCBFC). (b) The same section counterstained with ethidium bromide (micrograph courtesy of George Alheid).

more centrally and dorsally in the amygdaloid complex. Thus, the most prominent labeling was found over the endopiriform, cortical, mediobasal, and lateral nuclei, and in the parvicellular accessory basal nucleus. The magnitude of binding in the lateral and mediobasal nuclei showed parallels with cell density, i.e., the superficial or paralamellar portion of the mediobasal nucleus, characterized by small and densely packed cells (Crosby and Humphrey, 1941), was more densely labeled than the large-celled, deeper aspects of this nucleus.

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al*. (1987), the human granular nucleus (here the PL nucleus) contains one of the highest densities of mACh-R, which belong predominantly to subtype 1.

NICOTINIC RECEPTOR (NACH-R) This type of receptor as labeled by [^{3}H]ACh or [3H]nicotine, shows very low concentrations in all nuclei of the rat amygdaloid complex (Rainbow *et al*., 1984; Clarke *et al*., 1985).

MONOAMINERGIC RECEPTORS

ADRENORECEPTOR α_1 According to Flügge *et al*. (1994), in the tree shrew, the paralaminar nucleus forms a continuous band with the strongly labeled [^{32}H]PRA, an antagonist of this type of adrenoreceptor.

OPIOID RECEPTOR (OR) According to Daunais *et al*. (2001), the heaviest concentration of [3H]DAMGO binding sites in the amygdala was found in the PL nucleus. The distribution in this nucleus closely resembles the pattern reported for the small-celled VL and VM subdivisions of BL, in which the entire rostrocaudal extent was densely labeled.

Amygdaloclaustral Transition Area (ACA)

Topographical Landmarks According to Macchi (195l), the amygdaloclaustral transition area (ACA) (Fig. 22.1a) [caudodorsomedial part of PACl in plate 24 (2.7 mm) in Mai *et al*.'s (1997) *Atlas of the Human Brain*] is formed by islands of amygdaloid cells which constitute, together with the claustrum proper and the endopiriform nucleus, what he called the intercalated area. By contrast, many authors have considered this cell group either as part of the endopiriform nucleus [or claustrum preamygdaleum of Brockhaus (l938) or directly assigned to anterior amygdaloid area (see below)]. Actually, the ACA area is a well-circumscribed region made up of a rather homogeneous neuronal population located in the rostral portion of the amygdala, which as Macchi rightly thought is intercalated between the preamygdalar endopiriform nucleus rostrodorsally and laterally, and the lateral amygdaloid nucleus, ventrocaudally and medially, facing the temporal division of the piriform cortex and ACo nucleus in rostrocaudal succession. Groups of intercalated cells surround the nucleus dorsally, caudally, and ventrally, constituting a feature that assists its identification.

The topographical relationships of ACA coincide quite approximately with that given for the group Sorvari *et al*. (1995) labeled as anterior amygdaloid area, although in my material a direct topographical relationship with BL could not be as clearly seen. Furthermore, the cell population in ACA is not loosely packed but instead shows a far more coherent cell packing than that of AAA as here defined.

Cytoarchitectonics and Fiberarchitectonics It is composed predominantly of medium to large, rounded, darkly stained neurons surrounded by a rather scarce glial cell population, which contrasts markedly with the extremely rich glial framework in the neighboring preamygdalar endopiriform nucleus and the claustrum limitans. Groups of intercalated cells surround the nucleus dorsally, caudally, and ventrally. In fiber preparations its identification is facilitated by the rich fiber framework that surrounds this nucleus. Groups of intercalated cells surround the nucleus dorsally, caudally, and ventrally, constituting a feature that assists identification.

Chemoarchitectonics

Cholinergic Markers

ACETYLCHOLINESTERASE (ACHE) According to Amaral and Basset (1989), in the macaque monkey the ACA transition area (i.e., their anterior amygdaloid area) has a meager level of staining for AChE and can be distinguished by the large number of lightly to moderately stained AChE neurons that it contains. This can be confirmed in the Fig. 51 of the atlas of the rhesus monkey brain by Paxinos *et al*. (2000), in which the ACA transition area (i.e., their ventral endopiriform nucleus) appears wedged between the deep division of the AAA medially, the extended amygdala dorsally, and the La and BL nuclei ventrally. The area shows a very slightly higher content of AChE fibers than all of them, being bounded dorsally by the capsule of AChE positive fibers that encapsulates the extended amygdala, while ventrally AChE-rich ICMs mark the boundary with the nuclei of the LBNC.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Amaral and Basset (1989), in the macaque monkey, the ACA transition area (i.e., their

anterior amygdaloid area) has a meager level of ChAT-ir consisting of a fine network of ChAT fibers.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) No primate bibliographical data on the subject are available to the present writer.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), in the macaque monkey, in their anterior amygdaloid area (i.e., the present ACA), the number of cells that are GABA-ir or that contain GAD mRNA is about equal to that observed in the deep amygdaloid nuclei. The GABA-ir neuropil staining of this field is also similar to that in the deep amygdaloid nuclei.

NEUROPEPTIDES

NEUROPEPTIDE Y (NPY) Although no direct reference to this structure is made by McDonald *et al.* (1995) in their description of the distributions of NPY-ir in the macaque monkey amygdala, in their Fig. 1B, and under the name of dorsal anterior amygdaloid nucleus, this ACA area is depicted as containing a moderate number of NPY-ir cells.

SOMATOTASTIN (SOM) According to Amaral *et al.* (1989), their anterior amygdaloid area (here the amygdaloclaustral transition area) demonstrated a low to moderate density of SOM-ir fibers and terminals and scattered labeled cells. They also speak about a certain similarity with the medial division of the central amygdaloid nucleus.

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), their anterior amygdaloid area, which most probably corresponds to the present definition of ACA, contains a moderate density of CAB-ir neurons which correspond to their small type 1 and 2 cells. This territory also contains a moderate intensity of CAB-ir fibers and neuropil staining. The intensity of staining was slightly higher than in the surrounding areas, which helped them indicate the boundaries of the anterior amygdaloid area. No CAB-ir bundles of fibers are present here.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the density of CR-ir neurons in the amygdaloid territory, which they termed the anterior amygdaloid area, is high, with the majority of cells corresponding to the their type 1 and small type 2 cells. The fiber and neuropil CR-ir is also dense.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), in the region they termed the anterior amygdaloid area, the density of PAV-ir cells and fibers is low, and only an occasional small neuron can be detected.

OTHER PROTEINS

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low-magnification atlas on the distribution of this protein in the macaque brain published by Petrides *et al.* (2000), it seems that this controversial nucleus does not contain any SMI32-ir.

Extended Amygdala (EXA)

Recent evidence supports the view held by Johnston (1923) that the bed nucleus of the stria terminalis (BST) and the central (Ce) and medial (Me) amygdaloid nuclei constitute an anatomical entity (e.g., de Olmos and Ingram, 1972; Holstege *et al.*, 1985; Price *et al.*, 1987), a concept that now has gained general acceptance (Alheid and Heimer, 1988; Grove, 1988a, b; Moga *el al.*, 1989; Gomez and Winans-Newman, 1992). Today's notion, however, expands that originally proposed concept by this pioneering worker, who conceived the continuity between the aforementioned structures as occurring only by way of gray matter accompanying the stria terminalis along its supra-, post-, and infra-capsular courses, bridging between these amygdaloid nuclei and their own paraseptal expansion. Based on cytoarchitecture, histochemistry, and hodology, the present expanded conception tells us that the anatomical entity formed by the BST, Ce, and Me should be added to the sublenticular portion of the so-called substantia innominata, now named the sublenticular extended amygdala (SLEA), and the interstitial nucleus of the posterior limb of the anterior commissure (IPAC). The extensive gray complex thus formed can be divided into two major subdivisions: one consisting of the medial bed nucleus of the stria terminalis (BSTM), medial division of the sublenticular extended amygdala (SLEAM) and the rostral Me amygdaloid nucleus; and one with the lateral bed nucleus of the stria terminalis (BSTL), the central division of the sublenticular extended amygdala (SLEACn), and the Ce amygdaloid nucleus (de Olmos *et al.*, 1985; Groove, 1988a, b; Moga *et al.*, 1989; de Alheid *et al.*, 1995; de Olmos and Heimer, 1999; Heimer *et al.*, 1999; Winans, 1999). This elaborate conceptualization of this part of the basal forebrain is derived from several lines of evidence, the earliest being provided by differential staining of the granular argyrophilic neuropil and neurons in cupric silver preparations of normal unlesioned brains (de Olmos, 1969, 1972). Subsequently, evidence was produced by

the backfilling of the neuronal continuum involving the Ce, the anterodorsal Slsl, and the BST after injections of retrograde tracers into the dorsal medulla and by placing fluorescent tracers into the accessory olfactory bulb. This results in the retrograde labeling of the neurons forming the continuum, stretching from the anterodorsal Me nucleus through the medial division of the sublenticular extended amygdala and the large-celled lateral part of the BSTM (de Olmos *et al.,* 1985). Evidence in favor of this hypothesis is discussed below and has been presented in several recent reports (de Olmos *et al.,* 1972, 1985; Holstege *et al.,* 1985; Hopkins and Holstege, 1978; Alheid and Heimer, 1988; Grove, 1988a, b; Moga *et al.,* 1989; Gomez and Winans-Newman, 1992; Alheid *et al.,* 1995; de Olmos and Heimer, 1999; Heimer *et al.,* 1999). Alheid and Heimer (1988), in their thorough morphological and functional analysis of the basal forebrain, coined the term extended amygdala in order to formalize very briefly the incorporation of the BST and the so-called substantia innominata into the amygdaloid complex.

Central Extended Amygdala (CExA)

Paraseptal Components of the Central Extended Amygdala From information that can be gathered from the wealth of data that will be discussed in the context of the present chapter, the classical segregation of the neuronal population of the bed nucleus of the stria terminalis into medial and lateral divisions continues to fit not only the recent cytoarchitectonic, hodological, and chemoarchitectonic information presently available, but also to the physiological and behavioral findings of most recent data. This conceptual advance has been possible largely due to the contribution made by tract tracing with modern procedures and, more particularly, to the hodological relationships between the amygdaloid nuclei and the BST nuclei. Although such contribution has played a key role in re-enforcing the soundness of the medial-to-lateral segregation, it is especially the striking similarities, morphological or otherwise, existing between the lateral group of BSTL nuclei and their counterparts in the central amygdala that justify their inclusion as a part of the central extended amygdala and, as a consequence, to be considered as its paraseptal components.

The following section describes the cytoarchitectonic features of the four subdivisions identified within the lateral division of the bed nucleus of the stria terminalis by using both classical neurohistological procedures applied to transverse, horizontal, and sagittal frozen sections, and nontraditional methods such as transillumination and the application of most recent histochemical and immunohistochemical staining procedures.

The Bed Nucleus of the Stria terminalis (BST)

Topographical Landmarks In the human brain the bed nucleus of the stria terminalis (BST) is a lengthy structure that stretches rostrally from the amygdaloid body to the paraseptal pericommissural region (Figs. 22.1b–22.26b). On topographical grounds the BST can be divided into intra-amygdaloid, supracapsular, and paraseptal sectors. In all mammals, including humans, the paraseptal sector undoubtedly constitutes the main part of the nucleus. It forms an elongated, irregularly shaped pyramid, with its basis over the anterior commissure and the preoptic region and its apical end resting on the dorsolateral aspect of the thalamus. This section lies caudal to the nucleus accumbens, immediately ventrolateral to the anterior horn of the lateral ventricle, caudoventrolateral to the lateral septal nucleus, lateral to the anterior pillars of the fornix, medial to the internal capsule, and rostral to the stria medullaris thalami. It also completely encircles the anterior commissure just before its crossing of the midline. On this basis, pre-, supra-, infra-, and postcommissural sections can be distinguished (Figs. 22.16–22.18, 22.24b, 22.23, 22.26a). Moreover, in their cytoarchitectonic studies of the human septal region, Andy and Stephan (1968) recognized three parts: anterior, internal, and external, the former two being small celled and the latter large celled. These gross divisions were also recognized by Brockhaus (1942a,b), who used different names for them in his cell studies of the hypothalamus and the striatum, and by Strenge *et al.* (1977) in their pigmentoarchitectonic analysis of the whole BST. Although the idea of such a division has held quite well, the markedly heterogeneous population of the BST itself suggests the possibility of further subdivisions. This has already been disclosed in rats with the application of classical histochemical techniques but has been reaffirmed by the introduction of immunohistochemical procedures for demonstrating neuropeptides and other neurotransmitters or neuromodulators. This has received additional support from the hodological information provided by fluorescent retrograde tracers and their combined use with the immunochemical procedures. Since most of this vast array of information comes from studies in the rat, it remains to be seen to what extent these results can be fully extrapolated to the human brain. However, close scrutiny of the literature and my own observations of human and monkey material indicate that several, but not all, of the major subdivisions of the paraseptal BST described for the rat brain are also present in the brains of these higher mammals. Consequently, I have

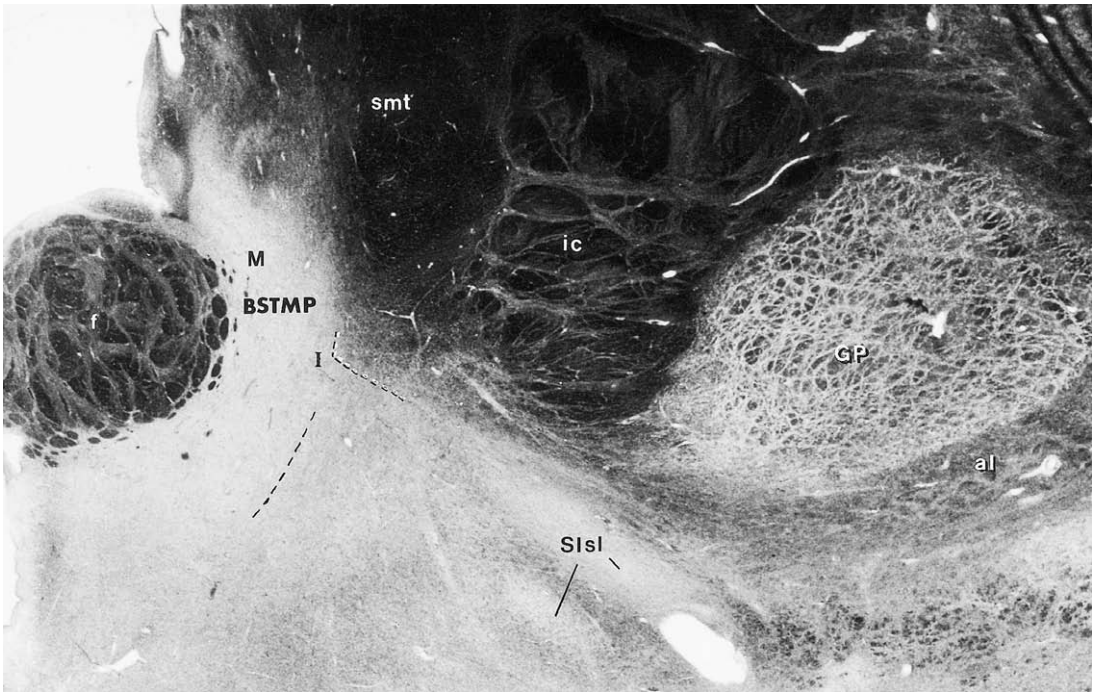

FIGURE 22.16 Low-power photomicrograph of a transverse section through the caudal portion of the BST in its preoptic extension. Note one of the junction bridges between the BST and SIsl. Such continuities have been demonstrated in human brain by immunohistochemical procedures for several neuropeptides (Som, CCK, LENK).

identified not only the two classical major divisions, the lateral (BSTL) and medial (BSTM) but also anterior- and posterior-derived subdivisions, in agreement with the morpho- and neurogenetic findings made by Bayer and Altman (l987) in the rat. In consequence, I include anteromedial, dorsolateral, and juxtacapsular BST subdivisions on the supracommissural plane; a ventral lateral BST subdivision on the infracommissural plane; and medial posterior and lateral posterior BST subdivisions on the postcommissural plane. As in the rat, the posterior medial BST subdivision can be further subdivided into small-celled medial, medium-celled intermediate, and large-celled lateral gray columns. By contrast, in Nissl sections of human brains, I was not able to identify with certainty the presence of a ventral BST subdivision on the medial infracommissural region of the human telencephalon, at least with the cytological characteristics the rat ventral BST presents (see below), nor could I detect a commissural division, whereas the intermediate division seems to be reduced to a thin lamina of scattered large neurons interposed between the intermediate and medial BST.

The Lateral Division of the Bed Nucleus of the Stria Terminalis (BSTL)

Cytoarchitectonic Characterization In cell preparations the BSTL is characterized by its heterogeneous neuronal population and its apparent division into fractions, or island-like cell aggregations, contributing to the difficulty of its analysis. This is partially circumvented by the fact that the island-like formations show a rather scarce population of glial cells and a lack of any particular orientation of the neurons that form them. Such a disposition contrasts with the greater density of the glial cell component in other subdivisions of the BSTL and with the consistent alignment of their neurons with the incoming fibers of the stria terminalis. Another feature worth mentioning here is the presence of small islands made up of tightly packed granular-like neurons [Sanides' (1957) insulae terminalaes] sprinkled at the level of the juxtacapsular and intermediate sectors of the BSTL. Finally, with the exception of its dorsal part, the BSTL contains large to very large neurons displaying different degrees of chromophilia, which are loosely dispersed singly or in clusters. Neurons displaying hyperchromatic staining probably correspond to the diffuse or interstitial component of the MCBPC (Hedreen *et al*., 1984; Mesulam and Geula, 1988; Saper and Chelimsky, 1984; Saper, 1990), whereas the relatively hypochromatic ones presumably represent vestigial elements of the intermediate BST as described in the rodent brain (de Olmos *et al*., 1985).

The dorsal subdivision of the BSTL division (BSTLD) is the largest of the cell aggregates forming

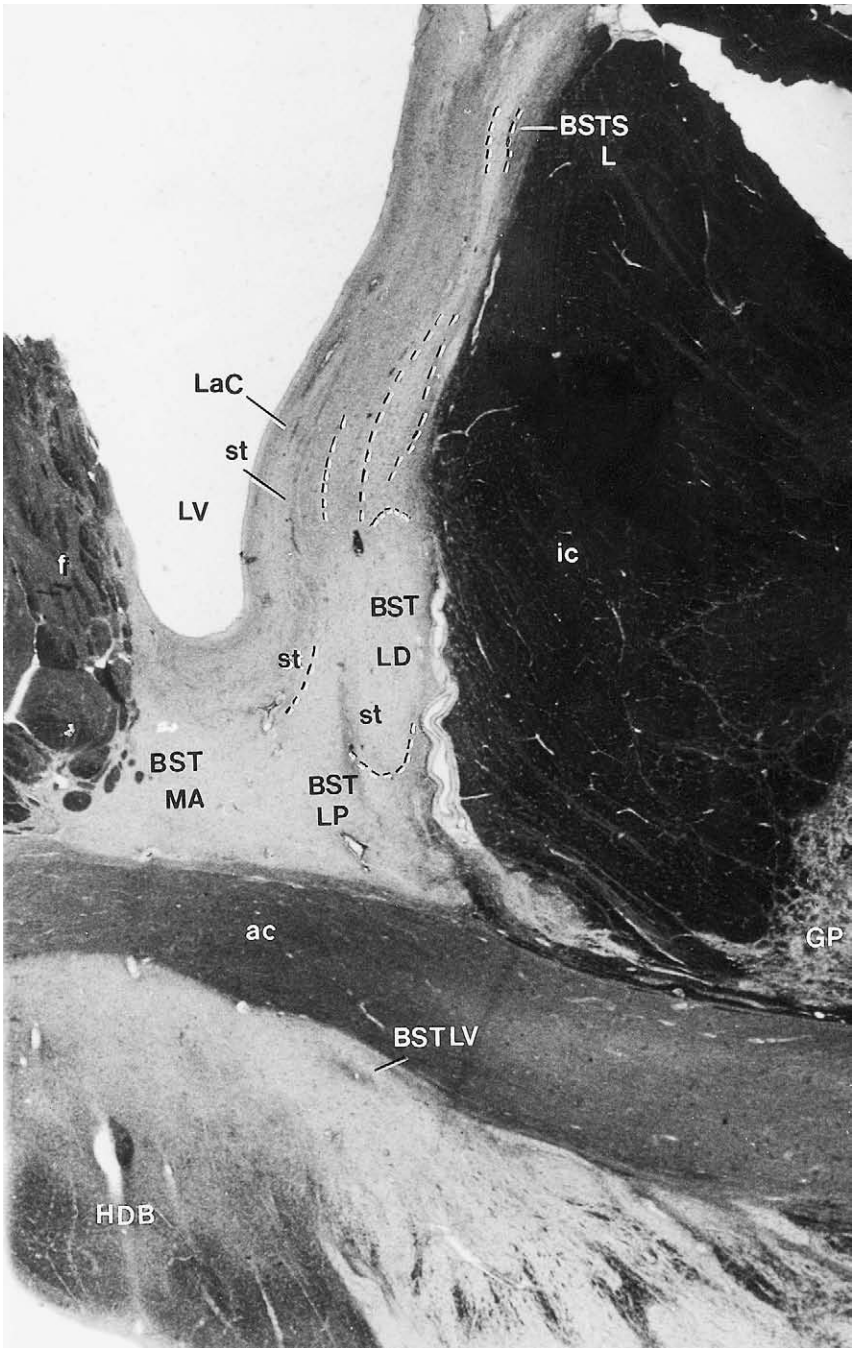

FIGURE 22.17 Low-power photomicrograph of a coronal section through the anterior commissure (ac) decussation showing the bed nucleus of the stria terminalis (BST) in its paraseptal expansion. The picture shows the supracapsular extension of this nucleus.

the supracommissural BST, stretching from the rostral end of the BST to a plane passing slightly caudal to the decussation of the anterior commissure. In transverse sections this subdivision of the BST appears composed of a number of cell islands or clusters, the largest of which is located centrally and dorsally within the supracommissural BST and adopts an elongated oval outline (Figs. 22.17, 22.22a, 22.23a, 22.24). The other, smaller islands appear rounded or semirounded. However, examination of sagittal and horizontal sections reveals that a majority of these islands are continuous with the main body of the dorsal subdivision. At its anteromedial border, the latter is separated from the ependermal lining of the lateral ventricle by a

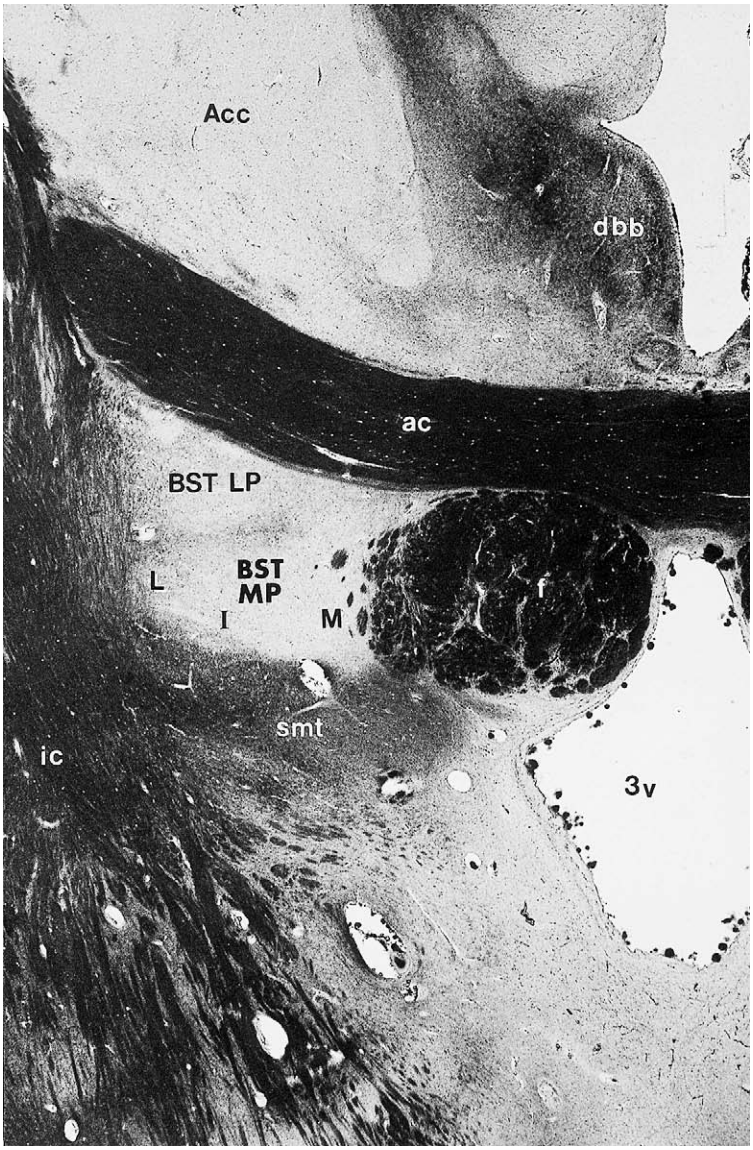

FIGURE 22.18 Low-power photomicrograph of a Weigert-stained horizontal section showing the topographical relationship between the various subdivisions of the posterior part of the medial BST. the nucleus appears completely enclosed by four great fiber systems (ac, f, ic, smt).

broad subependermal glial layer, the lamina cornea (Fig. 22.17). A narrow, sparsely celled zone separates the dorsal BST, rostrally and dorsally, from the striatum. Laterally, a caudoventral extension of the striatum and the juxtacapsular subdivision of BSTL intervenes between the BSTLD and the internal capsule (Figs. 22.22a, 22.23, 22.24a, 22.25). Caudally, medially, and ventrally the posterior subdivisions of BSTL replace the dorsal subdivision. In the interface between these two subdivisions of the BST appear occasional, very small islands of very small neurons, some made up of Sanides' (1957) gamma 1 cells (Figs. 22. 19a and 22.24) and, more often, of gamma 2 cells (Fig. 22.19b). Surrounding the main body of the BSTLD as well as its "peninsula-like" extensions there is a narrow, sparsely celled zone that is particularly clear in horizontal sections. On account of this feature it is reasonable to distinguish a central core and capsular subdivision in the BSTLD (Figs. 22.22a, 22.24a, and 22.25a).

In cell preparations, some cytological features facilitate identification of the BSTLD. These is a translucent background consequent to a poverty of glial cell nuclei, and a random orientation of the rather loosely packed medium-sized neuronal population of the central subdivision (Fig. 22.20). Within its capsular subdivision, cells are predominantly oriented parallel to

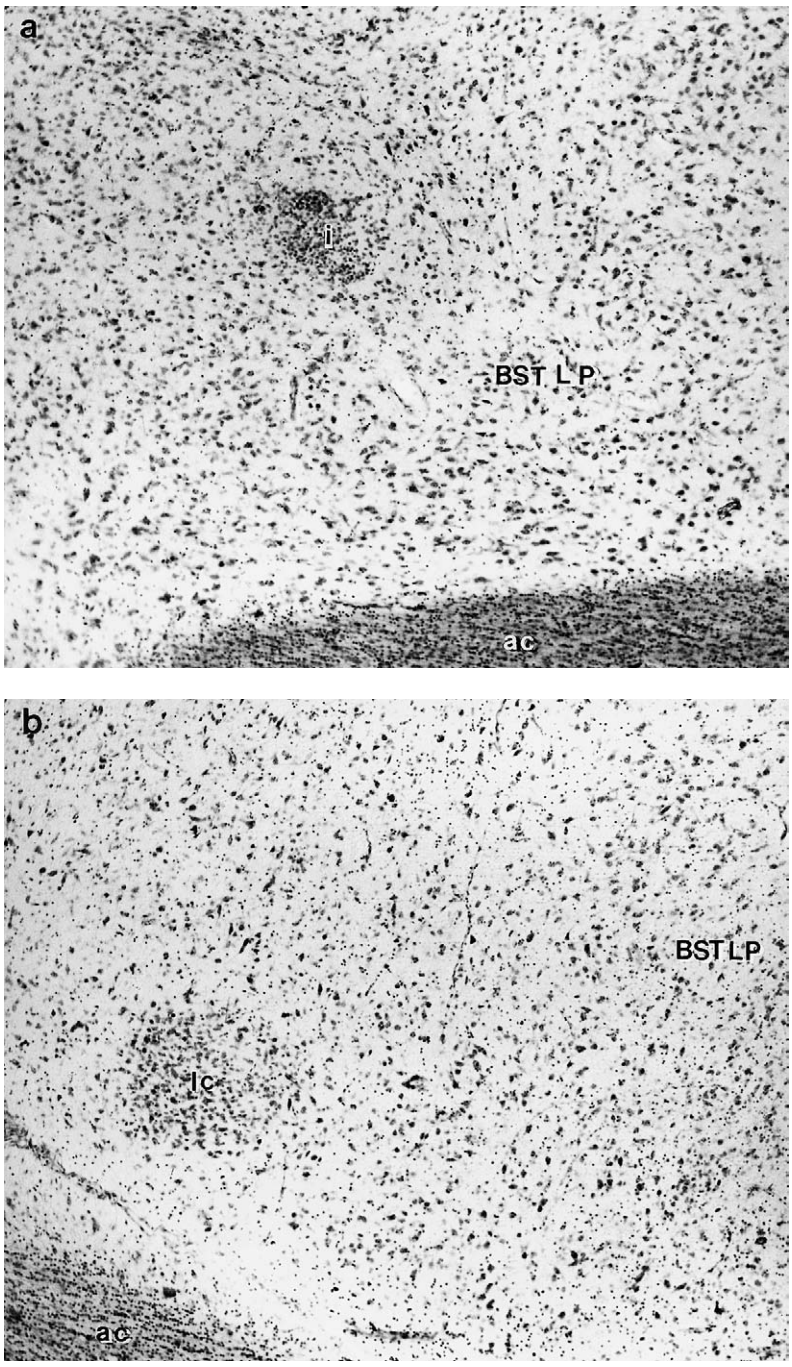

FIGURE 22.19 Photomicrographs of transverse Nissl-stained sections of the BST at the level of the anterior commissure (ac) decussation to show the neuronal clusters present in this nucleus. (a) Neuronal aggregate similar to the γ^1-cell islands (i) described by Sanides (1957). (b) Cell clusters reminiscent of intercalated masses (Ic) referred to as γ^2 islands by Sanides.

the contours of the BSTLD and tend to be larger and with a predominance of spindle-shaped neurons. Such an arrangement is better appreciated in sections processed for the immunohistochemical staining of neuropeptides (Bennett-Clarke and Joseph, 1986; Gaspar *et al.*, 1987; Martin *et al.*, 1988).

The posterior subdivision of the BSTL division (BSTLP) (Figs. 22.17, 22.19, 22.22a, and 22.23–22.26) extends ventrally, caudally, and medially to its dorsal counterpart until it meets the dorsally to ventrally coursing fibers of the stria terminalis. In doing so, it merges with the ventral subdivision of the BSTL just

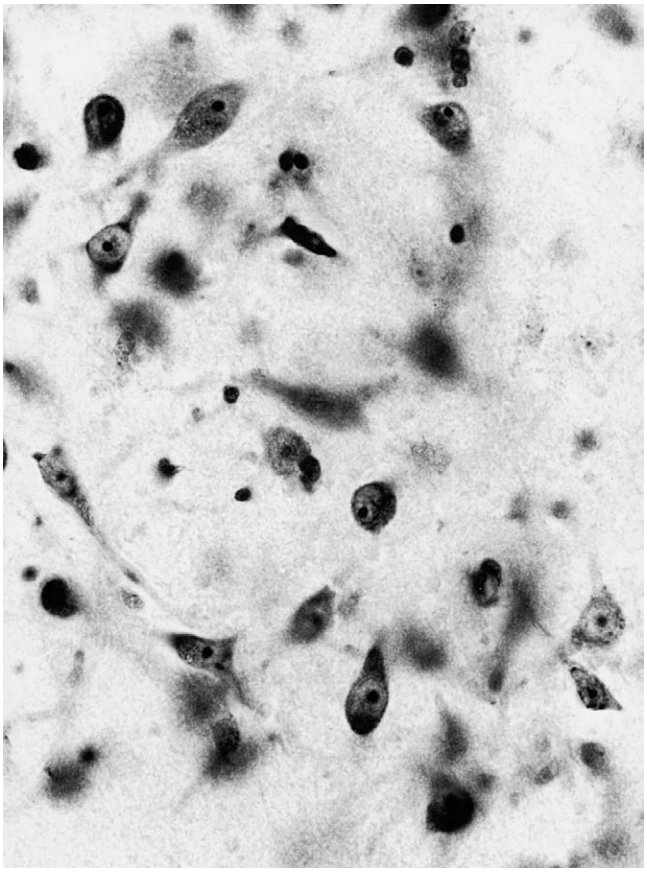

FIGURE 22.20 High-magnification photomicrograph of a Nissl-stained section showing the type of neurons present in BSTLD. Note the transparency of the background and the reduced number of glial nuclei characteristic of this division.

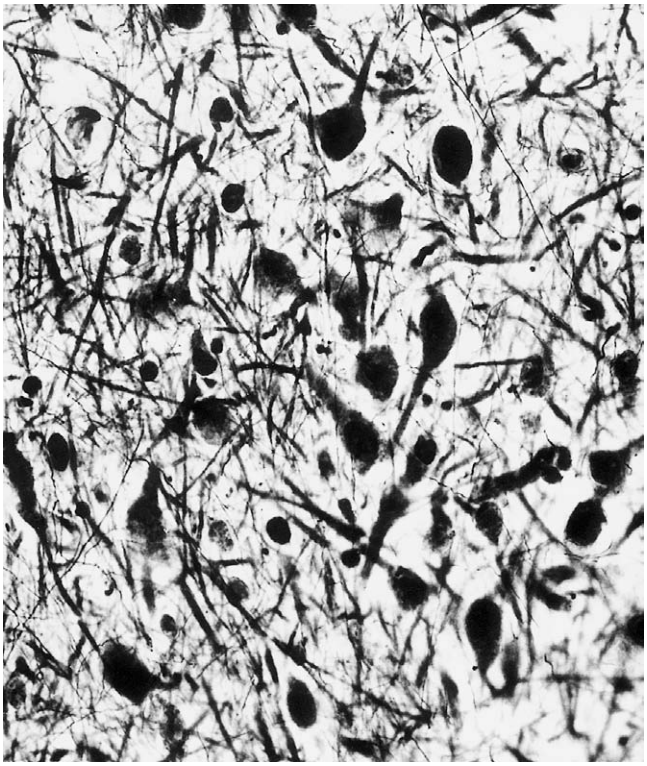

FIGURE 22.21 High-magnification photomicrograph of neurons in BSTLD of human brain using a modified Glees silver method, which demonstrates the dendritic processes of the leptodendritic neurons.

caudal to the decussating anterior commissure and fuses with the more rostral extent of the dorsal anterior division of the sublenticular substantia innominata (Fig. 22.26a). Along its supra- and postcommissural extent, the BSTLP is flanked by the previously mentioned rounded granular interface islands. The continuity of the former structure is occasionally interrupted by these islands (Figs. 22.19 and 22.24b). In contrast with the other subdivisions of BSTL, the BSTLP can be followed continuously to its merger with the supracapsular division of the BST nucleus. Cytoarchitectonically, neurons in the BSTLP can be differentiated from those on their dorsal counterpart by their smaller size, more slender profile, and the preferential dorsoventral orientation of their longer axes. Also, contrary to the BSTLD, the BSTLP can be characterized by its rather rich content of glial cell nuclei.

The juxtacapsular subdivision of the BSTL division (JXC) (Figs. 22.22a, 22.23, 22.24a, and 22.25) can be found in the supracommissural sector of the BST lying interposed between the internal capsule laterally and the dorsal and posterior subdivisions of the BSTL division medially. Anteriorly, it is bounded by the ventrocaudal extension of the caudate nucleus, while posteriorly it is eventually replaced by the most caudal extent of the posterior BSTL. Ventrally, the juxtacapsular BSTL borders with supracommissurally located granular and parvicellular interface (Sanides' gamma types 1 and 2, respectively). In cell preparations, the JXC appears to be made up of slender columns of neurons that are smaller, more darkly staining, and more densely packed than those in the remaining subdivisions of BSTL. Scattered among the core elements there are thin, triangular or spindle-shaped neurons showing a somewhat better defined tigroid substance. However, these medium-sized-to-large cells are considerably smaller than the large-celled neuronal component of the neighboring striatum or the singly lying ectopic neurons bordering the medial aspect of the internal capsule which belong to the MCBFC. As in the posterior BST, the JXC is also rich in glial cell nuclei, and the greater majority of its neurons are oriented in a dorsal-to-ventral direction, parallel to the medial border of the internal capsule. Here and there,

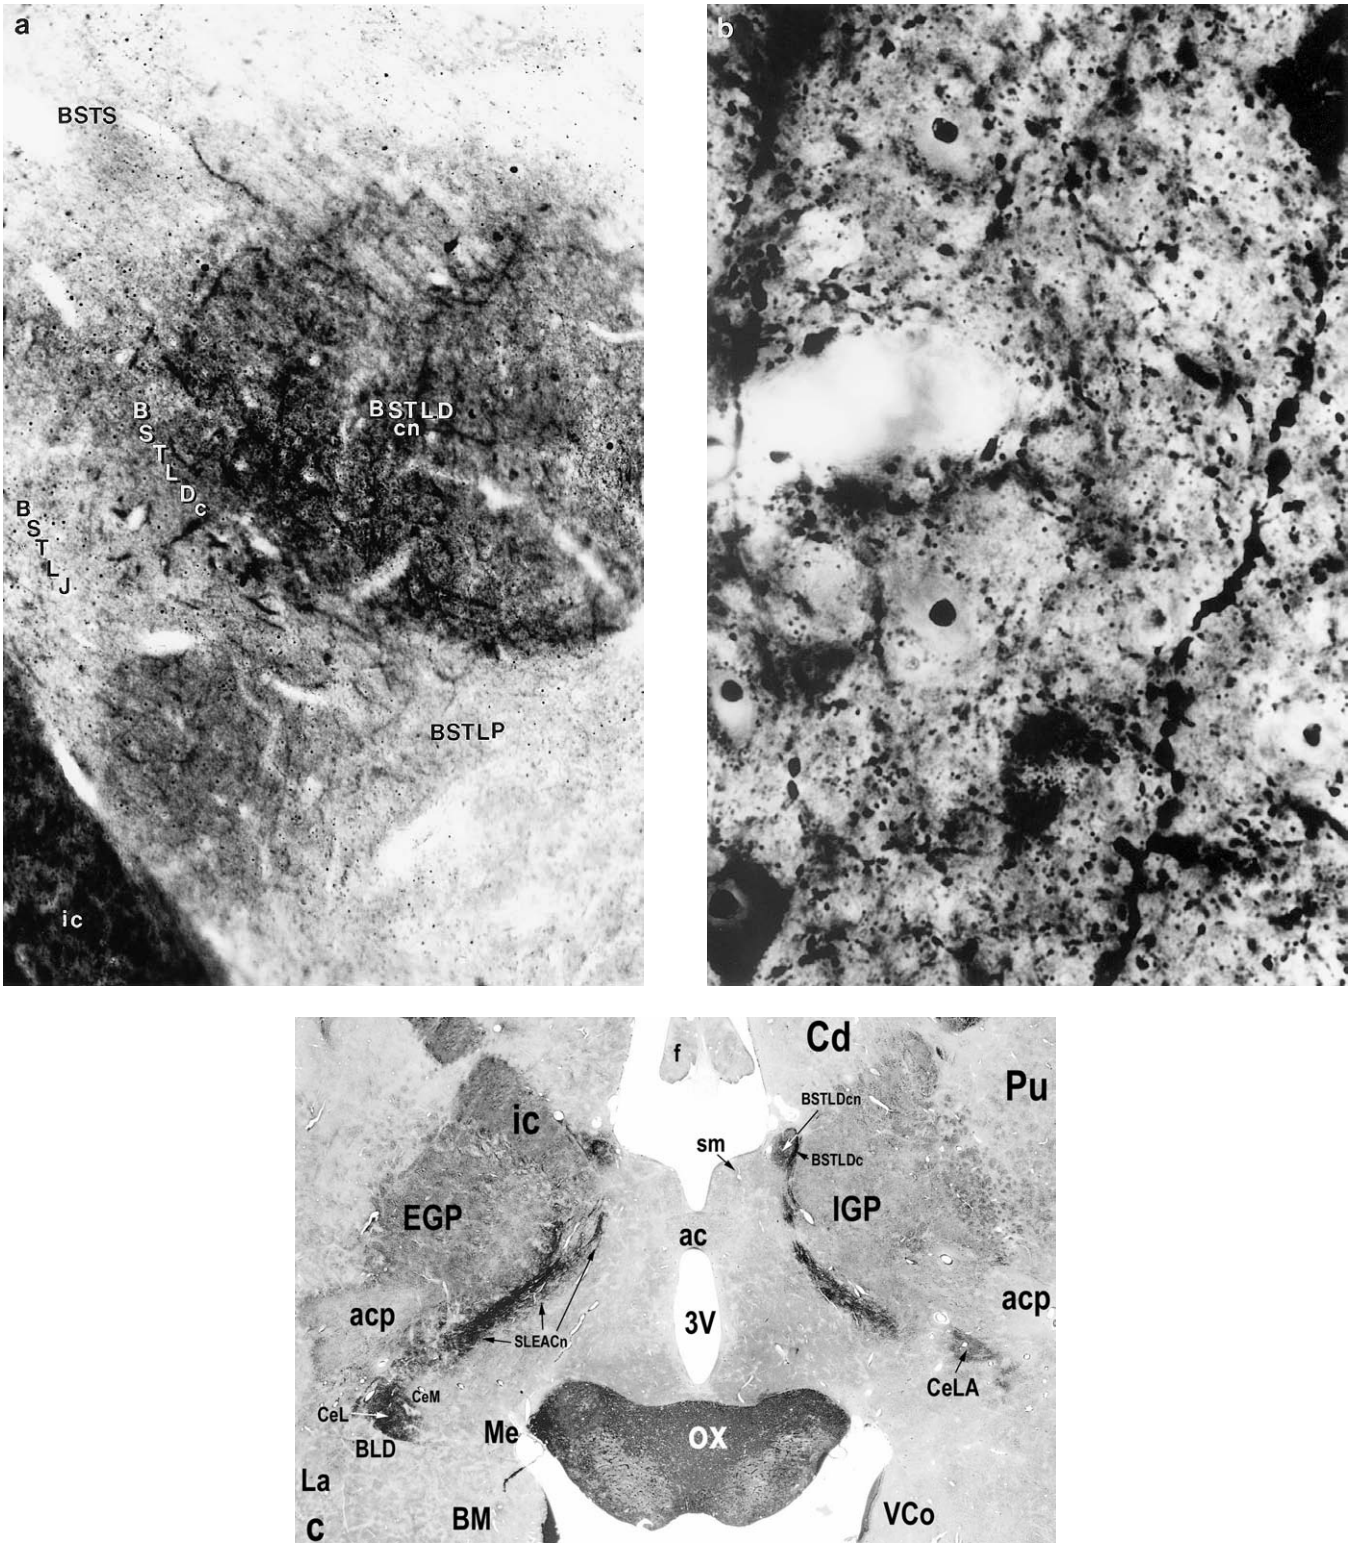

FIGURE 22.22 Medium-, high- and low power photomicrographs of cupric silver stained sections through the supra-commissural sector of the bed nucleus of the stria terminalis from a normal macaque to show in the first two illustrations the bi-stranded (a) and granular beaded (a and b) neuropil present at this level. At high power (b) it is possible to see at the level of the BSTLDcn the additional presence of rounded granular argyrophilic neurons which in general are not present in other divisions of the paraseptal BST nucleus except for few isolated slender spindle shaped neurons in its more medial and posterior sectors. Transverse sections in the squirrel monkey (c) stained with the same histological procedure allows to see even at low power and in just a single section the continuum conformed by the granular argyrophilic neuriopil which stretches from the lateral division of the central amygdaloid nucleus (CeL) through dorsal sublenticular sector of the basal forebrain until it reaches and invades the dorsolateral division (BSTLD) of the BST nucleus. Note that the members of the MEXA remain unstained, while the posterior division of the BSTL nucleus and the medial division of the Ce nucleus though positively stained too, it requires high magnification to be appreciated.

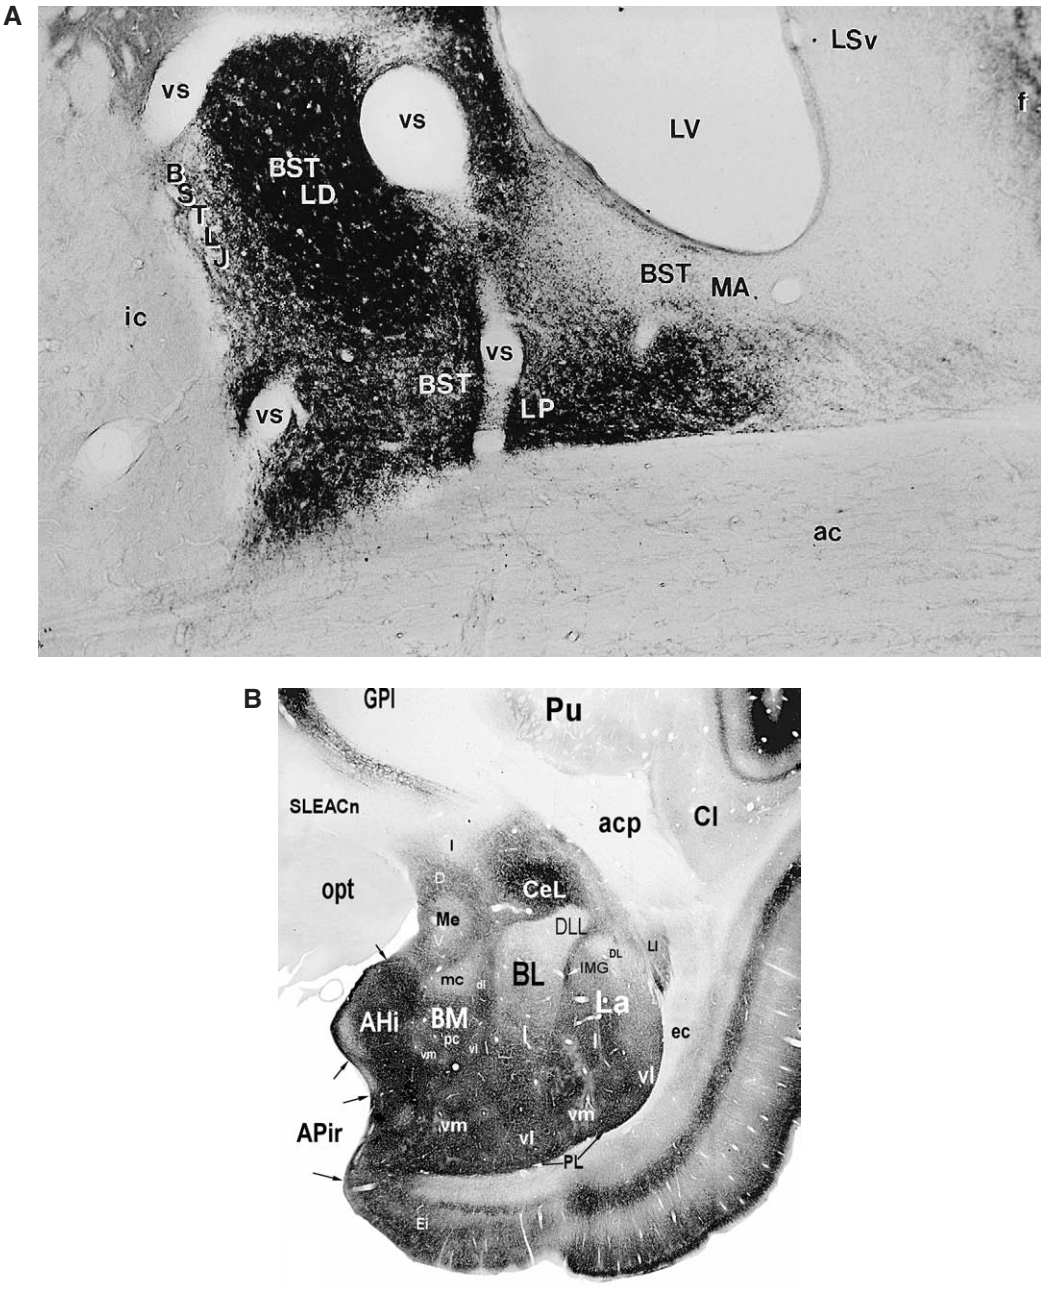

FIGURE 22.23 (a) Timm-stained coronal section (medium-low magnification) of the marmoset monkey BST at the level of the anterior commissural decussation to show the different intensity of silver selenite precipitate in the various divisions of the supracommissural sector of the nucleus (courtesy of George Alheid). (b) Low-power microphotograph of a Timm's stained transverse section through the squirrel monkey brain at a plane quite similar to that seen in Fig. 22.22c which shows that the silver sulphide precipitate in the CeL nucleus streaches through the central SLEA in direction to its final distribution in the BSTLD division of the BST nucleus as shown in Fig. 22.23a.

the continuity of the JXC is interrupted by the presence of very small granular and parvicellular interface islands (Sanides' gamma type 1 and type 2, respectively).

The ventral subdivision of the BSTL division (BSTLV) (Figs. 22.17, 22.22c and 22.26) in the human brain, as compared with the presumably homologous cell group in nonhuman primates, appears to be rather reduced in extent. In frontal sections it occupies a relatively narrow irregular triangular area below the anterior commissure close to the angle formed by the

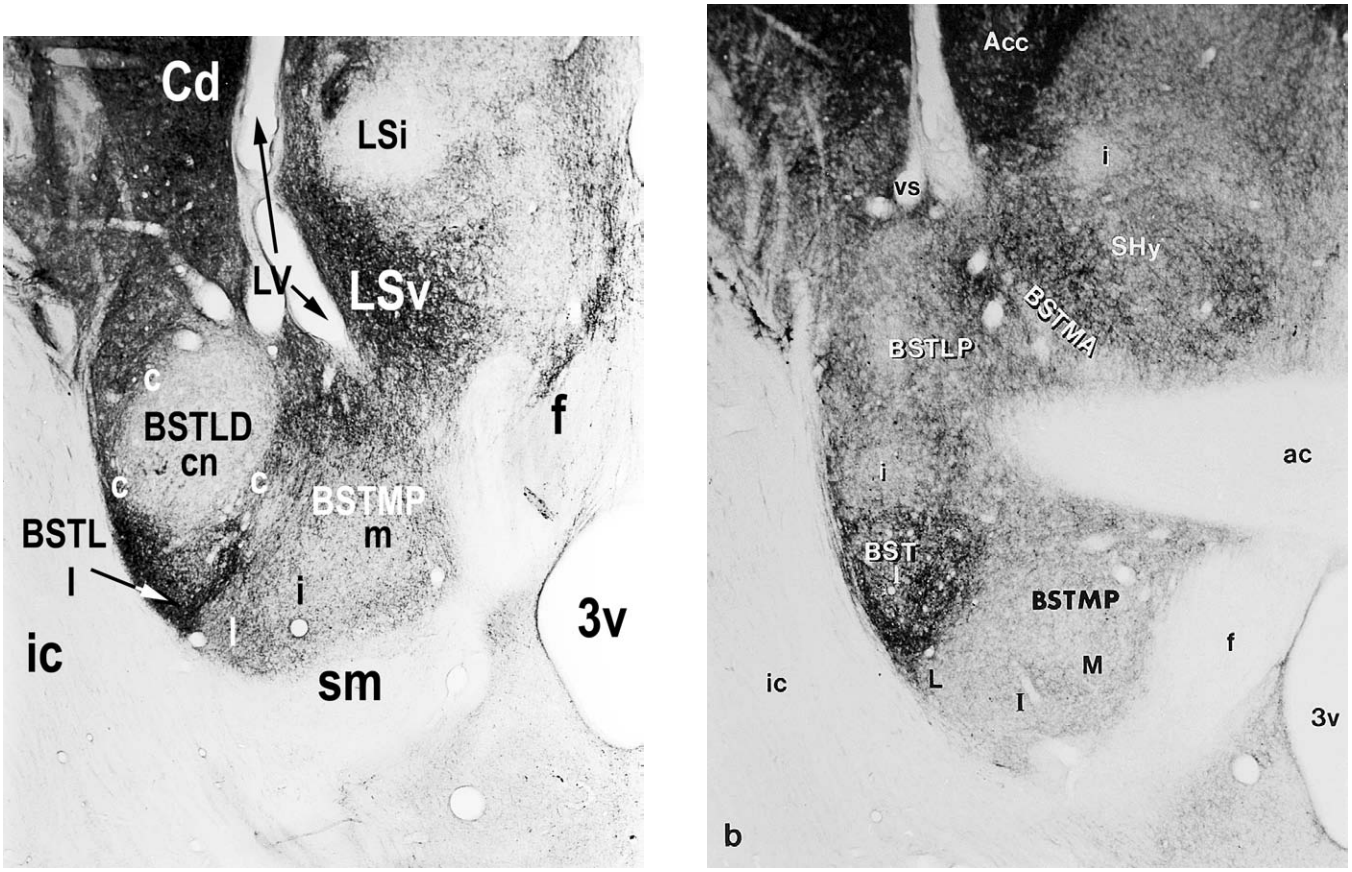

FIGURE 22.24 (a) Medium-power photomicrograph of an horizontal immunostained section from a squirrel monkey brain used for the demonstration of distribution of Substance P (SP) immunoreactivity at the supracomisural level of the BST nucleus. This plane of sectioning like the one that follows below, allows to appreciate the columnar arrangement of the SP-positive and SP-non-positive neuronal pools and neuropil existent on this paraseptal member of the Extended Amygdala. (b) Medium-power photomicrograph of an horizontal immunostained section from a squirrel monkey brain for the demonstration of the Substance P (SP) immunoreactivity present at the level of the anterior commissure crossing of the midline in the same monkey brain which allows to strengthen the columnar arrangement suggested by a sequence of serial sections not shown here.

latter and infracommissural coursing bundles detached from the internal capsule (Fig. 22.17). Caudally the BSTLV merges with the posterior division dorsally and with the dorsal anterior division of the sublenticular substantia innominata ventrolaterally (Figs. 22.22c and 22.26), while rostrally and medially it is replaced by the bed nucleus of the anterior commissure. In cell preparations, the BSTLV is made up of a loosely packed mixture of small to medium-sized neurons that are round to oval or spindle shaped, and by somewhat larger, more scattered, and more densely stained multiangular neurons. This last cell type, however, is smaller and more lightly staining than that in the neighboring ventral pallidum (laterally) or the lateral preoptic area (ventrally). The general orientation of neuronal population in the BSTLV tends to change from a horizontal direction rostrally to an oblique dorsomedial to ventrolateral one caudally. Along its rostrocaudal extent, the BSTLV is almost constantly flanked laterally by parvicellular interface islands (Sanides type 2).

Chemoarchitectonics

CUPRIC SILVER METHOD (CU–AG) In cupric silver–stained sections from normal marmoset, squirrel, and macaque brains, the dorsal and ventral divisions of the BSTL division and, to a much lesser degree, its posterior division (BSTLP) displays a typical argyrophilia in their neuropil (Figs. 22.22a–c). As will described for the Ce nucleus, this appears "granular" or in a "bistranded" arrangement, the former pattern being confined to the central subdivision of the BSTLD (Fig. 22.22), whereas the bistranded pattern can be observed at the level of the capsular subdivision of the BSTLD, and at the BSTLP and BSLTV. Together with

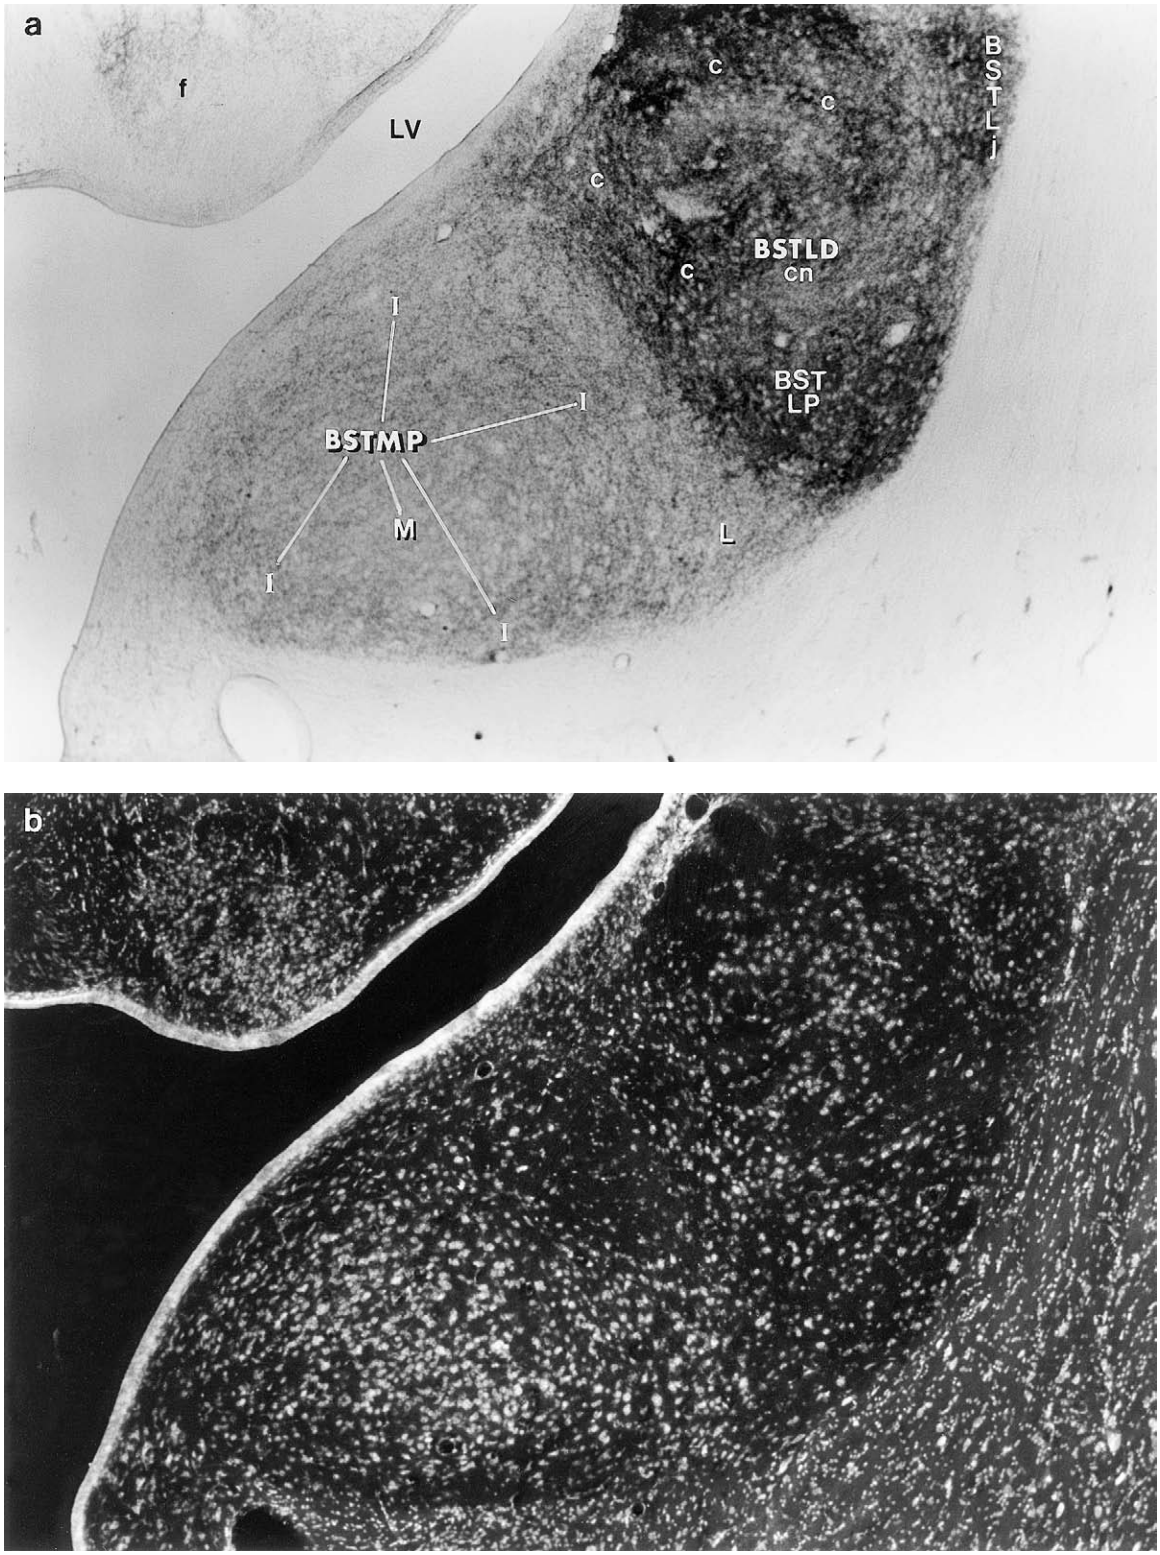

FIGURE 22.25 (a) Medium-power photomicrograph of a Timm's horizontal section through the supracommissural bed nucleus of the stria terminalis from a squirrel monkey brain, showing the differential distribution of heavy metals in the different divisions of the nucleus. The same section counterstained with ethidium bromide is shown in (b).

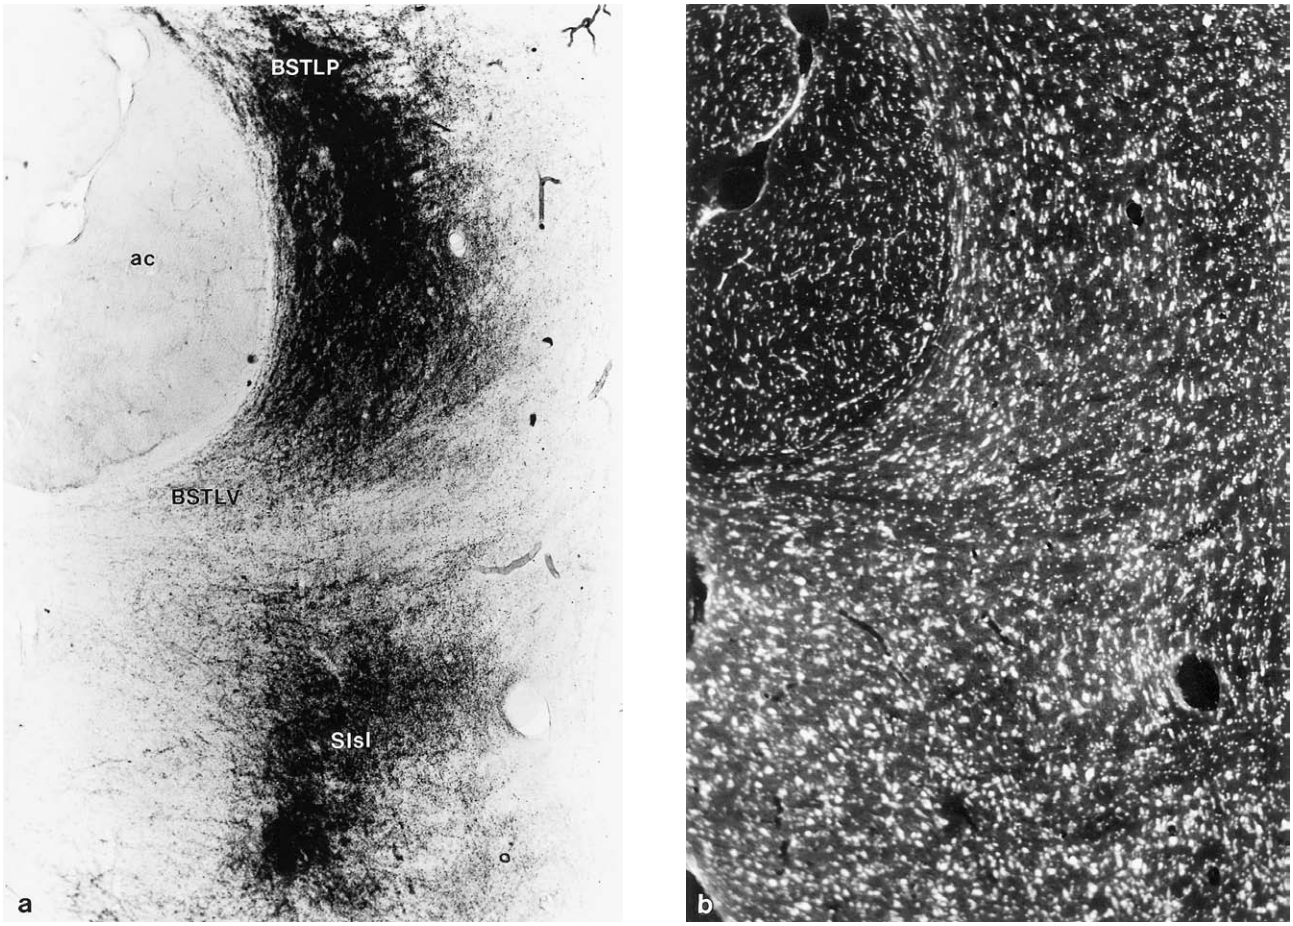

FIGURE 22.26 (a) Medium-power photomicrograph of a Timm-stained sagittal section through the retrocommissural sectors of the bed nucleus of the stria terminalis from a squirrel monkey brains, showing the nearly continuous metal deposits within the ventral and posterior parts of the lateral divisions of this nucleus and the DA SIsl. (b) The same section counterstained with ethidium bromide indicates that most of the metal deposits coincide with the location of the small- to medium-celled neuronal population in this nuclear complex. Note the almost complete lack of deposits in the neighboring larger-celled structures.

granular impregnation of its neuropil, the central subdivision of the BSTLD contains granular argyrophilic neurons displaying the same morphological features as those to be described for the central subdivision of the CeL division of the Ce nucleus (Fig. 22.22b). Both staining patterns can also be identified, although in discontinuous fashion, along the large-celled lateral column of the supracapsular BST.

HEAVY METALS It is unfortunate that until recently it has not been possible to obtain normal human material stained for the above-described silver procedure or with the Timm-Danscher procedure for heavy metals, for reasons that I will discuss here based on information provided by monkey material. Thus, in Timm-Danscher (1981) stained transverse sections of the amygdala of macaque, squirrel, and marmoset monkeys, the central subdivision of the BSTL division shows very dense silver deposits that are greater than in any other member of the group (Fig. 22.25a). Furthermore, a very strong reaction, though not as strong, covers all the space left laterally and ventrally to the dense core (Figs. 22.23 and 25.25a), which would correspond to the BSTLP subdivision of the BSTL nucleus. This precipitate also fills a very narrow representative of the BSTLV laterally just below of the anterior commissure decussation (not shown).

In Part 3 of the Heimer *et al.* "The Primate Nervous System" (1997), their Fig. 22C and D shows quite clearly the distribution of silver deposits, a product of the selenite reaction with heavy metals that occurs in axon terminals of presumably zinc containing glutamatergic pathways with most probable source in cortical regions, mostly of the allo-, periallo-, or proisocortical

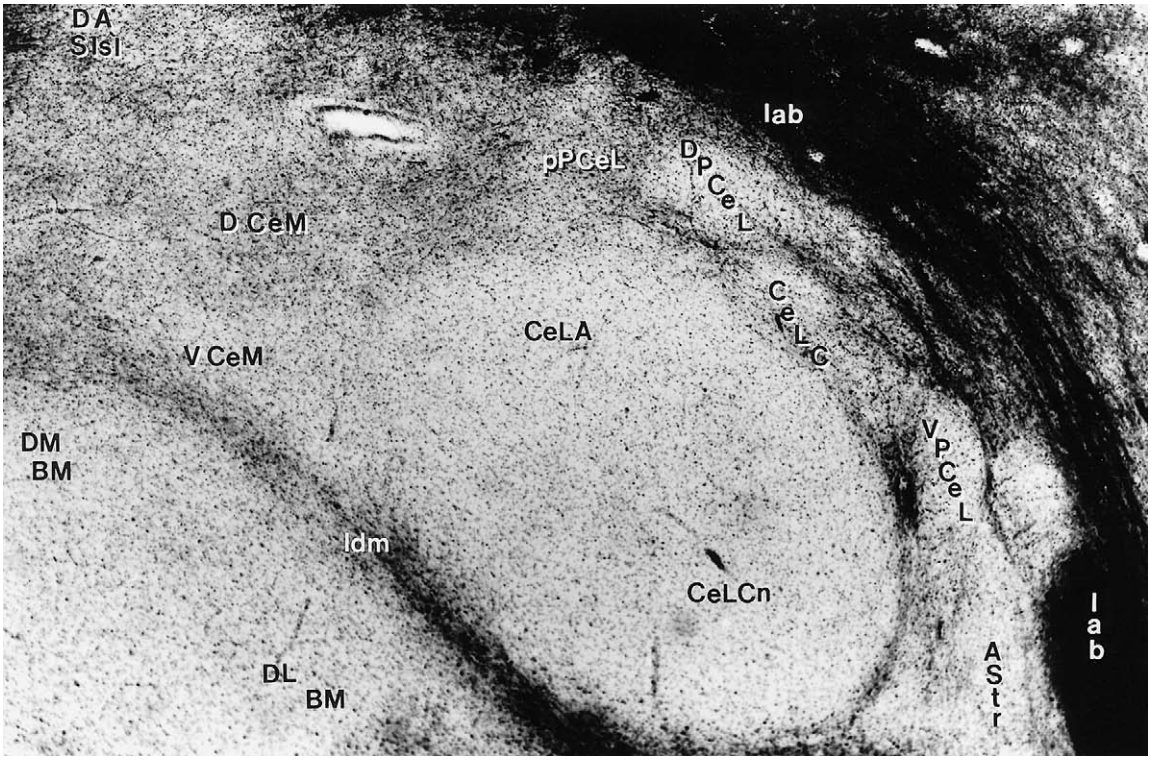

FIGURE 22.27 Medium-power photomicrograph of a Weigert-stained coronal section through the central amygdaloid nucleus from a human brain to show the different divisions of this nucleus.

type which are known to send projections to this particular sector of the rat brain (for reviews, see Olmos, 1985; Amaral *et al.*, 1992; McDonald *et al.*, 1999). In more posterior levels, it is possible to appreciate a direct continuation of the metal deposits present in these two subdivisions of the BSTL up to their continuation in the SLEA ventrally or in the supracapsular component of the BST nucleus dorsally. Such silver deposits correspond to those occurring at the level of the central amygdaloid nucleus, in this way forming a perfect ring around the internal capsule.

In unpublished rat experiments with iontophoretic injections of Na selenite in the area of the Ce/SLEACn carried out in collaboration with C. A. Beltramino in our laboratory, it was possible to establish the source of these zinc-laden projections from the temporal sector of the piriform cortex, the amygdalopiriform cortex, the lateral entorhinal cortex, the agranular insular cortex, etc., as well as from other amygdaloid nuclei, such as the posterolateral amygdaloid nucleus, posterior basolateral nucleus, ventral basolateral nucleus, and both divisions anterior and posterior of the basomedial amygdaloid nucleus. Since the presence of zinc in axons terminals has been associated with that of glutamate, it is probable that all of the above-listed structures, which are known by other tracing procedures to be a source of afferents to the extended amygdala, would be the right candidates for the glutamatergic innervation of the SLEACn and, therefore, of the whole extended amygdala.

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) In AChE-stained sections the BSTL presents a rather heterogeneous staining picture, where along with places in which the staining is strongly positive, as in its JCX, there are other places where the AChE activity is practically nil, as in the capsular subdivision of the BSTLD division, to moderate to strong in some of the oval-shaped cell clusters representing its central subdivision.

In the monkey material placed at my disposition (macaque, squirrel, and marmoset), the AChE staining pattern at the level of the BSTL division of the BST nucleus is somewhat complementary to that which can be observed in Timm-Danscher-stained section; that is to say that while the core shows a lighter staining, the capsule and the surrounding BSTLP and the BSTLV subdivisions show a heavier staining although the AChE reactivity in the capsular region and in the JCX appears much stronger.

MONOAMINERGIC MARKERS

DOPAMINE β-HYDROXYLASE (DBH) According to Gaspar *et al.* (1985), in the septal area in humans, the BSTL nucleus is sparsely innervated by DBH-ir fibers. In the macaque monkey the heaviest concentration of DBH lies in the BSTLV subnucleus while moderate amounts are also present in the BSTLD and BSTLP subdivisions (Freedman and Shi, 2001).

DOPAMINE TRANSPORTER (DAT) According to Freedman and Shi (2001), in the macaque monkey, the concentration of DAT throughout the EXA is generally far lower than in the striatum. Moderate amounts of DAT-ir fibers are present in the BSTLD and JXC subnuclei of the BSTL division. However, the JXC subnucleus shows somewhat higher DAT-ir than its neighboring BSTL subnuclei.

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew (*Tupaia belangeri*), HA-ir fibers collected in dense bundles are seen at the level of the BST nucleus where they distribute forming a very dense plexus that reaches the highest density.

SEROTONIN (5-HT) According to Freedman and Shi (2001), in the macaque monkey, the heaviest concentration of 5-HT-ir fibers in the BST nucleus is in its BSTLD and BSTLV subnuclei with levels comparable to that found in the striatum. A moderate to heavy density of these fibers is also present in the JXC. In the heavily labeled BSTLD, multiple small puncta 5-HT-ir structures with relatively few fibers are present as is a diffuse background staining that is higher than structures without specific labeling.

SEROTONIN TRANSPORTER (SERT) According to Freedman and Shi (2001), in the macaque monkey, the distribution of the SerT in the BSTL largely parallels that of the 5-HT. SerT-ir fibers are present in moderate to heavy concentration in the BSTLD, BSTLV, and JXC subnuclei.

TYROSINE HYDROXYLASE (TH) Gaspar *et al.* (1985) demonstrated that within the human BST nucleus, the distribution of the TH-ir fibers adopts a topographical disposition that is complementary of that of the DBH-ir ones. Within the BSTL division of these paraseptal griseum, the TH-ir fibers show a patchy distribution, with densely innervated ovoidal areas neighboring others more lightly innervated. These dense TH-ir clusters are frequently aligned along the lateral edge of the BST nucleus or surrounding the dorsal and ventral aspects of the decussating anterior commissure. Within these clusters, fine dot-like varicose fibers are most abundant and frequently form basket-like pericellular arrangements. A rostrocaudal decreasing gradient of TH-ir terminals can also be observed, particularly caudally to the anterior commissure. Finally, a close correspondence seems to exist between these patches of TH-ir terminals and the intensely AChE stained islands present in the BST nucleus. In a later report in which a topographical analysis was made to determine the relationships between the TH-ir and the peptidergic innervation of the BST nucleus, Gaspar *et al.* (1987) arrived at the conclusion that there is an overlap between fields containing the characteristic dopaminergic pericellular baskets and the clusters of dense SOM-ir fibers and perikarya. However, Lesur *et al.* (1989), performing a similar analysis concluded that the aminergic and peptidergic inputs do not converge on the same neuronal components since none of the TH-ir pericellular baskets colocalized with SOM-ir or ENK-ir, even though TH-ir, ENK-ir, and SOM-ir profiles overlap coincidentally with the patchy cell organization present in the BSTL nucleus. Although TH-ir basket-like formations frequently surrounded SOM-ir perikarya, they did it more often on nonlabeled cell bodies. Finally, they found that in the infracommissural portion of the BST nucleus, TH-ir axons of smooth nonvaricose type not only are concentrated in its ventrolateral sector (i.e., the BSTLV subdivision), but tended to have the same orientation as the peridendritic plexuses.

On the other hand, in the macaque monkey, Freedman and Shi (2001) described that TH-ir fibers are most dense in the BSTLD and BSTLV subnuclei, with their concentration approaching that of the striatum, although the density decreases at the most caudal level.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Injections of tritiated aspartate in the BL nucleus of the macaque monkey amygdala produce the retrograde labeling at the level of the BST nucleus (Amaral and Insausti, 1992). Furthermore, in the rat, injections of tritiated D-aspartate in the ventral pallidum caused the retrograde labeling of a moderate number of cells in lateral and ventral aspect of BST (Fuller *et al.*, 1987), and also after similar of injections in the area of the paraventricular hypothalamic nucleus (Csáki *et al.*, 2000). These results favor of the existence of a subpopulation of glutamatergic neuron within this component of the CExA. These data also favor the concept of the extended amygdala, as it can be gathered from the fact that the Ce nucleus, but more particularly its medial division, also contributes to the putative glutamatergic innervation of the above-listed structures.

INHIBITORY AMINO ACIDS

γ-Aminobutyric Acid (GABA) According to Heimer *et al.* (1999), the BSTLD subdivision of the human BST nucleus contains significant concentrations of GAD as is shown in their illustrations (Figs. 6 and 13B), while the remaining sectors contain somewhat less dense concentrations.

NEUROPEPTIDES

Calcitonin Gene–Related Peptide (CGRP) According to De Lacalle and Saper (2000), in the human brain, the presence at the level of the BST nucleus of specific patterns of CGRP-ir innervation seems to be closely related to the subnuclear subdivisions of this nucleus. Although scattered CGRP-ir fibers and terminals can be found throughout the whole BST complex, the most prominent innervation involves the supracommissural BSTL division excepting its anterior portion (BSTA). On the other hand, the BSTLP subdivisions is rather loosely innervated by CGRP-ir fibers. Islands of Sanides γ cells are surrounded by dense bundle of CGRP-ir fibers. The most characteristic feature of the CGRP-ir innervation of the BST nucleus are the dense baskets of peridendritic and perisomatic CGRP-ir that outlines the contour of non-ir neuronal somata. No CGRP-ir cell bodies are detectable in the BST nucleus.

Cocaine- and Amphetamine-Regulated Transcript (CART) According to Hurd and Fagergren (2000), the human BST nucleus shows a moderate CART mRNA expression. Although no statement is made about the specific localization of this peptide, from the illustrations presented by them (Figs. 2B and 5), it seems that the strongest signals occur in the whole BSTL division.

Chromogranin B According to Marksteiner *et al.* (1999), in the human brain peptide PE-11-like ir can be found in the BST nucleus in high densities in the medial, lateral, and ventral parts of this nucleus. In the lateral part, a core of PE-11-like ir perikaria is surrounded by PE-11-like ir wooly-like fibers with intensely stained varicosities.

Corticotropin-Releasing factor (CRF) In the human amygdaloid complex, dense accumulation of CRF-ir fibers, with large varicosities, and terminals has been reported in almost all amygdaloid nuclei (Power *et al.*, 1987; Zaphiropoulos *et al.*, 1991). In the BST nucleus, a few fusiform lightly CRF-ir neurons are present (Powers *et al.*, 1987).

Dynorphin (DYN) The presence of fibers displaying DYN-ir has been detected (Haber and Watson, 1985) at the intersection between the internal capsule and the anterior commissure. After crossing the former fiber system, the fibers enter into the BST, forming a thin stratum that covers the medial surface of the internal capsule.

Enkephalin (ENK) According to Gaspar *et al.* (1987), only few ENK-ir perikarya are present in the BST nucleus. The peptidergic axons are always small, forming peridendritic terminal plexuses that give the appearance of thick granular or tubular fibers or strands, named "wooly fibers" by Haber and Nauta (1983). Following a pattern of nonoverlap of the same target, few of these ENK-ir fibers also label pericellular SOM-ir baskets. However, Lesur *et al.* (1989) were unable to determine if there is some colocalization in these circumstances. They also found that the ENK-ir plexuses are much more numerous than SOM-ir ones, that there are no basket-like formations within the cell clusters, and that while a few ENK-ir peridendritic plexuses can be detected, they are grouped in the lateral-most sector border near the internal capsule. With reference to the distribution of ENK-ir cell bodies, their location seemed not to follow any particular pattern within or outside the cell patches. According to these authors, their central division (here BSTLD) is delimited by ENK fibers that encircles it forming a shell (i.e., the present capsular subdivision of the BSTL subnucleus) of densely labeled ENK-ir peridendritic plexuses but with a moderate innervation of the central core (the central subdivision of the BSTLD subnucleus). The bulk of the ENK-ir basket-like pericellular formation seem to be concentrated in the BSTLD. Finally, according to these authors, very rare SOM-ir perikarya or pericellular basket formations can be detected in the BSTLV division of the BST nucleus that are characterized by very dense SOM-ir peridendritic plexuses of granular type. Many of them can be followed for long distances in a lateroventral direction toward the so-called substantia innominata.

According to Kaufmann *et al.* (1997), the woolly-like and varicose ENK-ir fibers are predominantly present in the BSTLP subdivision of BSTL nucleus. At infracommissural levels, just behind the crossing of the anterior commissure, ENK-ir can be detected ventromedially to the internal capsule and the ventral pallidum (Martin *et al.*, 1991). In this ventral part of the BST, i.e., the present BSTLV subnucleus, the ENK-ir consists of woolly-like fibers. From here woolly-like ENK-ir fibers extend laterally to the sublenticular substantia innominata, though to a lesser degree than the SECR-ir.

Haber and Watson (1985) described the presence in the macaque monkey forebrain of distinct clusters of

ENK-positive woolly fibers that invade the supracommissural BST nucleus. In this sector of the BST a dense swirl of these fibers encapsulates and to a lesser degree permeates BSTLD (ovoid) subnucleus, which contains numerous ENK-positive cell bodies.

GALANIN (GAL) According to Kordower *et al.* (1992) in the cebus monkey, numerous GAL-ir perikarya are seen throughout the BST with a preponderance of neurons in the anterior aspect of this nucleus. At this level the GAL-ir neurons are preferentially located in the medial (BSTMA), dorsolateral (BSTLD), and ventrolateral (BSTLV) subdivisions of the BST, as well as within the caudal temporal portion of the stria terminalis (BSTSl).

NEUROKININ B (NKB) Practically no SP-ir is present at the level of the BSTLD (ovoid nucleus), and very little in other sectors of the BST (Haber and Watson, 1985; Chawla *et al.*, 1997). By contrast, the presence of numerous small, oval-to-round, NKB-containing neurons were found in the BST. The illustrations (Fig. 3A–C) presented by Chawla *et al.* (1997) indicate that most of the NKB-containing neurons are more concentrated in the medial than in the lateral sectors of BST, and more in supracommissural than in infracommissural position.

NEUROPEPTIDE Y (NPY) According to Gaspar *et al.* (1987), the NPY-ir innervation of the human BST nucleus is essentially restricted to the lateral part of the nucleus, forming an elongated zone close to the internal capsule (i.e., BSTLD) and a smaller field medially close to the pillars of the fornix. NPY-ir perikarya are small to medium-sized, scarce, and almost exclusively located in the BSTL division in both supra- and infracommissural sectors. Ventrocaudally the NPY-ir fiber and terminal network can be seen to extend to the preoptic area and the substantia innominata. Comparison of SOM-ir and NPY-ir patterns demonstrates partly overlapping and partly complementary patterns of both peptidergic innervations. Thus, the central or dorsal SOM-ir clusters seem to contain only small amounts of NPY-ir fibers and practically no colocalization of these neuropeptides, whereas the lateral, caudal, and medial fields contain only moderate amounts of both peptides and only a few double-labeled neurons.

According to Walter *et al.* (1990), the supracommissural portion of the human BST nucleus contains bipolar NPY-ir cell bodies, are located exclusively along the boundary of the internal capsule (i.e., the BSTL division) and preferentially oriented ventrodorsally. NPY-ir fibers occur with no particular orientation. A column of very high fiber density lying laterally at the border of the internal capsule (here BSTLP division) is distinct from an intermediate zone of considerably less NPY-ir, corresponding to Brockhaus' (1942a) nucleus subcaudatus (here the BSTLD subnucleus). Moreover, they maintain that the subcommissural region (BSTLV) of the BST nucleus appears as a ventral extension of the BSTLP supracommissural, and contains both NPY-ir fibers and pericaria. This contingent seems to eventually join those in the basal telencephalon.

On the other hand, according to Bons *et al.* (1990), in the BST nucleus of the microcebus murinus (primate, lemurian), the NPY-ir axons form a dense plexus surrounding the anterior commissure and fornix. However, in contraposition to what has been described above, the NPY-ir perikarya seems to be predominantly located near the border of the lateral ventricle (i.e., BSTM).

NEUROTENSIN (NT) According to Mai *et al.* (1987), within the telencephalic regions studied, the BST nucleus that is close to the anterior commissure contains NT-ir cell groups. In this nucleus most of the NT-ir neurons accumulate laterally at the medial border of the internal capsule, i.e., the BSTL division. These authors establish likewise that the most conspicuous accumulation of NT-ir fibers within subcortical telencephalic structures occurs around the head of the anterior commissure, predominantly the septal area and the BST nucleus.

PREPROTACHYKININ A Intense PPT-A mRNA hybridization signals have been reported to be present in some neurons of the bed nucleus of stria terminalis. PPT-A mRNA-expressing cells also were scattered throughout the substantia innominata (sublenticular extended amygdala). Silver grains were seen predominantly over the medium-sized and small neurons, and not over the large neurons, within this area. No positive PPT-A hybridization signals were detected in the ventral pallidum or the globus pallidus, except in a few subjects under very long exposure time, and even then the signal was barely higher than the background.

SECRETONEURIN (SECR) According to Marksteiner *et al.* (1992) and Kaufmann *et al.* (1997), within the human supracommissural BSTL, its central core (BSTLD) shows the highest density of SECR-ir which contains perisomatic SECR-ir surrounding SECR-ir and non-SECR-ir oval-shaped neurons. This oval core appears in turn surrounded by SECR-ir woolly-like and SECR-ir varicose fibers. This SECR-ir is partially coexistent with ENK-ir and CAB-ir profiles but not with SP-ir ones. The posterior part of BSTL, i.e., the

present BSTLP, which shows a much less dense SECR-ir pattern, contains both SECR-ir varicose fibers and SECR-ir woolly-like fibers (type II) oriented dorsoventrally with an arrangement similar to that presented by ENK-ir profiles.

At infracommissural levels, just behind the crossing of the anterior commissure, SECR-ir can be detected ventromedially to the internal capsule and the ventral pallidum. In this ventral part of the BSTL division of the BST nucleus (here the BSTLV subdivision), the SECR-ir consists of a very high density of woolly-like fibers. From here a dense network of SECR-ir woolly-like type II fibers extends laterally into the sublenticular subtantia innominata, i.e., the present CSLEA.

SOMATOSTATIN (SOM) Mufson *et al.* (1988) and Bennet-Clarke and Joseph (1986) were the first group of researchers to describe the presence of SOM-ir neurons in the human BST nucleus, and they stress the tendency of SOM-ir fibers to form island-like clusters, which they were also able to detect at the level of the so-called substantia innominata. On the other hand, Gaspar *et al.* (1987) described the BST nucleus as the structure that contains the highest density SOM-ir innervation. SOM-ir perikarya and fibers were said to be present throughout the entire nucleus but were more densely grouped within oval or round clusters or fields forming a mosaic-like pattern. In the rostral BST nucleus, the clusters appear distributed in both the infra- (BSTLV) and supracommissural sectors of the nucleus, occupying the central and dorsal field (BSTLD). Caudally to the anterior commissure, the dense SOM-ir fields tend to be restricted to the ventral part of the BST nucleus and to small dorsal zones close to the stria terminalis. The clusters display dense packing of round or fusiform medium-sized SOM-ir perikarya, and also contain varicose fibers, isolated varicosities, and SOM-ir woolly-like fibers. A relatively large number of pericellular arrangements can also be seen, particularly in the BSTLV. Outside the clusters, in the lateral, caudal, and medial fields of the BST nucleus, SOM-ir perikarya and fine varicose fibers are far more scattered. Finally, the so-called SOM-ir woolly-like fibers,which are highly characteristic for this nucleus, become particularly abundant ventrally (BSTLV).

In a later report by Mufson *et al.* (1988), which extended their previously published preliminary data, they not only confirmed that the BST nucleus constitutes the forebrain area containing the heaviest concentration of SOM-ir perikarya, nerve fiber, and terminals, but more importantly they provided additional documentation in favor of the existence of a SOM-ir pathway connecting these SOM-ir with that in the Ce nucleus via the ansa peduncularis/ventral amygdalofuga1/sublenticular substantia innominata system of fibers and neurons.

Lesur *et al.* (1989) took another approach and reached the conclusion that aminergic and peptidergic inputs do not converge on the same neuronal components, so that none of the pericellular baskets formed by TH-ir fibers contained SOM-ir (or ENK), whereas a few SOM-ir pericellular baskets also contained ENK-ir profiles. SOM-ir woolly-like fibers were also found in continuity with pericellular baskets. Furthermore, according to these authors, very rare SOM-ir perikarya or pericellular basket formations can be detected in the BSTLV division of the BST nucleus that are characterized by very dense SOM-ir peridendritic plexuses of granular type. Many can be followed for long distances in a lateroventral direction toward the so-called substantia innominata.

In the macaque monkey, Amaral *et al.* (1989) found that the SOM-ir has much of the same appearance as that in the Ce nucleus. According to them, SOM-ir fiber and terminal are present in the lateral division of the nucleus where they tend to be substantially denser than in the medial division, a distribution pattern that coincides with that in the human BST. As happens in the Ce nucleus, dense clusters of SOM-ir neurons appear located in the lateral part of the BST, but are concentrated in the dorsolateral portion at the rostral pole of the nucleus.

There is a very important point here, since there are profound sexual behavioral consequences. These are related to the dimorphic difference in the peptidergic organization of the central BSTLD subdivision of the BSTL. According to recent studies in humans, it has been established quite firmly that SOM-ir neurons are more numerous in males than females (Kruijver *et al.*, 2000), which is consistent with the fact that this nucleus is larger in males (39%) than in females (Zhou *et al.*, 1995; Kruijver *et al.*, 2000; Chung *et al.*, 2002).

SUBSTANCE P (SP) According to Kaufmann *et al.* (1997), only a few single fibers can be detected at the level of the supracommissural BSTL, particularly in BSTLP. At infracommissural levels, just behind the crossing of the anterior commissure, where high SECR-ir can be detected ventromedially to the internal capsule and the ventral pallidum, no SP-ir could be detected.

VASOINTESTINAL PEPTIDE (VIP) According to Martin *et al.* (1991a), both in the human and monkey BST nucleus, VIP-ir fibers and terminals are heavily concentrated in the BSTLDcn (see also Chung *et al.*, 2002), This VIP-ir can also be followed in the rostral substantia innominata and anterior commissure region,

conditions that are strikingly demonstrated in the Heimer *et al.* (1999) illustrations. On the other hand, Martin *et al.* (1991a) were unable to identify VIP-ir perikarya in any sector of the two major divisions of the extended amygdala. It has been demonstrated (Chung *et al.*, 2002) that, as happens with the SOM-ir, there is dimorphic distribution of this peptide at the level of the BSTLDcn (larger VIP-ir area in human males than females), and this deserves as much special attention as that dedicated to the SOM-ir in view of their behavioral implications (Chung *et al.*, 2002) (see above).

NEUROTROPHINS

Brain-Derived Neurotrophic Factor (BDNF) According to Murer *et al.* (1999), in the human BST nucleus, BDNF-ir fibers form a dense and strongly ir plexus where several non stained neuronal cell bodies are completely enveloped by BDNF-ir terminals boutons and fibers. Furthermore, it can be inferred from their Fig. 3A that both supra- (BSTLP/BSTLD) and infracommissural (BSTLV) representatives of the lateral BST nucleus contain BDNF-ir.

CALCIUM-BINDING PROTEINS

Calbindin (CAB) According to Kaufmann *et al.* (1997), in the supracommissural BSTL, CAB-ir coexists with ENK-ir and SECR-ir but not with SP-ir. For the rat, Celio *et al.* (1990) provide a rather succinct description according to which the CAB-ir staining pattern is very similar to that of the lateral septum consisting of the presence of a myriad of small cells embedded in a rich CAB-ir fiber and terminal matrix. According to these authors, the medial division of the BST posesses a denser distribution than the lateral.

Calretinin (CR) No information concerning the distribution of this protein within the paraseptal components of the extended amygdala in humans or nonhuman primates is available at present. However, even though extrapolation from one mammalian specie to another is always a risk, the present writer considers it to be beneficial for the reader and for a greater consistency of this section to describe some observations made on material immunostained for this protein in transverse and sagittal section of the rat and guinea pig basal telencephalon. According to the information provided by this material, the rat lateral bed nucleus of the stria terminalis shows a lightly CR-ir core surrounded by a rich CR-ir background composed of fine granular CR-ir profiles enmeshing both scattered CR-ir perikarya and non-ir cell bodies. The more lightly CR-ir stained ovoidal core corresponds to the BSTLD subdivision of the rat BST nucleus, which appears more or less encapsulated ventrally, medially, dorsocaudally, and caudally by groups of more densely packed CR-ir cell bodies. The regions corresponding to the BSTLP and BSTLV subdivisions also show a rich CR-ir neuropil in which CR-ir cell bodies are distributed in a scattered manner. CR-ir fibers and scattered CR-ir cell bodies can be traced along the course of the stria terminalis, with most of them located in the BSTSl sector of the BSTS division of the BST nucleus. It goes without saying that the distribution of cells and fibers in the central amygdaloid nucleus conforms very closely to that seen in the lateral BST nucleus.

Parvalbumin (PAV) According to the schematic mapping illustrated by Celio *et al.* (1990), in the rat, the PAV-ir is nil in the BST nucleus.

OTHER PROTEINS

Calpastatin (CALPT) Although this division of the BST nucleus is not mentioned or listed among the telencephalic structures that show CALT-ir, examination of the Moutt-Prigent *et al.* (2000) Fig. 2A reveals that, at the level of the BSTL, an irregularly oval cluster of CALP-ir appears surrounded by a non-ir capsule, and below it another probable CALPT-ir formation that topographically corresponds to the BSTLP subdivision. Such property would support the fact that in the Ce nucleus its counterpart in the temporal lobe is also CALPT-ir stainable.

Limbic System–Associated Membrane Protein (LAMP) According to Côté *et al.* (1996) in the macaque amygdala, the LAMP-ir present in the dorsal part of the sublenticular substantia innominata, i.e., the SLEAC of the present account, becomes continuous with the LAMP-ir present in the BSTL division. This LAMP-ir is predominantly expressed in the dorsal subdivision of the extended amygdala (CExA), which extends in the form of strands from the Ce nucleus ventrolaterally to the dorsal part of the BST nucleus dorsomedially. According to these authors, the LAMP-rich dorsal continuum avoids the intensely CAB-ir basal forebrain magnocellular neurons, including the nucleus basalis of Meynert.

ENZYMES

P450 Aromatase The large number of cells expressing P450 aromatase mRNA in the BST (and in its amygdaloid counterparts) make it probable that testosterone (T) acts in large part through the aromatase pathway in these brain regions. These same regions have been also found to exhibit high levels of ER-α and ER-β, suggesting that locally formed estrogen

can act on cells in the immediate vicinity through ER-mediated mechanisms. Studies in other species have also demonstrated that a majority of neurons in the BST and its amygdaloid counterparts contain P450 aromatase and estrogen receptors (see Roselli *et al.*, 2001).

RECEPTORS

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), there is high concentration of mACh-R in the human BST nucleus, which presents densely labeled patches especially near the internal capsule and which is enriched in m_1 subtype. From their illustrations (Fig. 5A, B) it can be inferred that the most dense activity takes place in the BSTLD and JCX subnuclei of the BSTL, whereas lower labeling occurs at the level of the BSTLP and BSTLV subnuclei.

GALANIN RECEPTOR (GAL-R) According to Kohler and Chan Palay (1990), within the human telencephalon, high densities of [^{125}I]GAL-R are found in the BST nucleus.

GLUTAMATE RECEPTOR (GLUR) According to Ginsberg *et al.* (1995), in the macaque monkey, the laterodorsal subnucleus of the bed nucleus of the stria terminalis (here BSTLD), contain a high density of GluR 2/3-ir neurons and a lower density of GluR1-ir neurons but express minimal GluR4.

OPIOID RECEPTOR (OR) Both [^{3}H]DAMGO binding and DAMGO-stimulated G proteins were expressed in high densities in the medial portions of the bed nucleus, but moderately in the lateral cytoarchitecturally defined subdivisions (Daunais *et al.*, 2001).

OXYTOCIN RECEPTOR (OTR) For the human BSTL, Loup *et al.* (1991) made no mention of the presence of this type of receptor. However, according to Wilson *et al.* (1999), while a high level of oxytocin (OT) binding could be found in the Ce nucleus and associated BSTLD, the binding density was lower in the MeA nucleus and in the BSTMA. These authors also found that although the OT binding was the greatest in the nuclei of the CExA, the excitatory responses to OT did not match it, being greater in the MexA. However, it is important for the hypothesis of the EXA that the relative expression of OT binding sites and the patterns of response reflect these associations within the extended amygdala.

VASOPRESSIN RECEPTOR (AVP) According to Loup *et al.* (1991), in the human BST nucleus, the lateral and lateroventral divisions show inconsistent weak AVP binding.

Sublenticular Components of the Central Extended Amygdala (SLEAC)

Central Division of the Sublenticular Extended Amygdala (SLEACn)

Topographical Landmarks Basically, the SLEACn can be defined as the griseum that connects the BSTL division of the bed nucleus of the stria terminalis with the Ce amygdaloid nucleus (Figs. 22.14a,b, 22.15a,b, 22.16, 22.22c, 22.26b) [BSTCV in Plate 24 (2.7 mm) in Mai *et al.* (1997), *Atlas of the Human Brain*; EA (extended amygdala) in Plates/Figs. 50–55 (Interaural 18.30–16.05 mm) of Paxinos *et al.* (2000), *The Rhesus Monkey Brain in Stereotaxic Coordinates*]. At a closer look, the SLEACn appears constituted by cell columns corresponding to the dorsal (BSTLD), posterior (BSTLP), and ventral (BSTLV) parts of the lateral division of the BST nucleus, which become located in a sublenticular corridor that crosses the classically denominated substantia innominata while accompanying the ventral amygdalofugal pathways in their passage through these regions of the basal telencephalon. By doing so, these cell columns come to constitute in a broad way their bed nucleus. Along this route, they come to occupy what some authors (Martin *et al.*, 1991; Marksteiner *et al.*, 1993; Kaufman *et al.*, 1997) have denominated the anterodorsal and posterodorsal sectors of the so-called substantia innominata before meeting the Ce nucleus.

Cytoarchitectonics The neurons that form these bridges are loosely packed, medium sized, fusiform to triangular shaped, and more elongated than those in the SLEAM (Fig. 22.15b). Another feature that helps to identify them is that these sublenticular columns are eventually surrounded by magnocellular neurons at the point where the intermediate division of the basal nucleus of Meynert comes to be subdivided into intermediodorsal and intermedioventral parts. Groups of small, granule-like, tightly packed, and darkly stained neurons (parvicellular interface islands or Sanides' type 2 cells) are also found in the sublenticular sector of the so-called substantia innominata. These types of cells may be linked to the striatum (Heimer *et al.*, 1999) in which case they should not be considered to form part of any of the divisions of SLEA.

While in the macaque and squirrel monkeys the BSTL divisions of the BST nucleus and Ce amygdaloid nucleus appear to continue in each other as uninterrupted cell columns extending along the course of the stria terminalis dorsally and through the so-called substantia innominata ventrally (de Olmos, 1990; Martin *et al.*, 1991), this pattern does not seem to hold for

the human brain since the gray columns that connect them are more or less dislocated, particularly in the sublenticular sector of the EXA, probably by reason of their interruption by dense fibers of passage.

Freedman and Shi (2001), on the basis of their immunohistochemical tracing of the monaminergic innervation of the extended amygdala, concluded that the dorsal part of the substantia innominata appears similar to the medial subnucleus of the Ce amygdaloid nucleus, though they also stressed the existence of a more heterogeneous cell population in the SLEACn. Such apparent heterogeneity was considered to be probably due to the interdigitation of the true SLEACn cell constituents with other basal telencephalic with more or less diffusely arranged cell subpopulations.

As here defined SLEACn encloses Martin *et al.*'s (1991) anterodorsal (SIad) and posterodorsal (SIpd) branches of their sublenticular (BSTSL) division of the BST (see also Marksteiner *et al.*, 1993; Kaufman *et al.*, 1997).

Chemoarchitecture

CUPRIC SILVER STAIN (CU-AG) One of the intriguing staining properties of the SLEACn (Figs. 22.14a,b, 22.22, 22.26a) along with the Ce nucleus and the BSTL division of the BST nucleus is the specific manner in which silver impregnates to what I have called the granular argyrophilic neuropil and neurons. This application of the Cu-Ag procedure (de Olmos, 1981; de Olmos *et al.*, 1994) to normal brain tissue of many mammalian species, such as zariguella or South American opossum, armadillo, rat, rabbit, guinea pig, cat, dog, and Old (macaques) and New World (squirrel and marmoset) monkeys with this suppressive silver impregnation method (which does not allow the staining of normal fibers or matter whether myelinated or unmyelinated, or most normal neurons in the brain), consistently shows this specific reaction.

While few argyrophilic cell bodies can be detected in a lateral branch of this peculiar system of granular preterminal fibers that courses rostrally very close to the basal surface of the posterior limb of the anterior commissure (IPAC?, see below), another medially directed branch of greater size and density, which comes to occupy the sublenticular region (i.e., SLEACn), only shows peridendritic and perisomatic argyrophilic granules. High-magnification examination reveals that these images correspond to the terminal boutons issued by very thin argyrophilic preterminal fibers detectable just at the limit of the optical microscope resolution. This argyrophilic profile surrounds otherwise negatively stained dendrites and slender, fusiform perikarya of medium-sized neurons, and they never seem to get into contact of any kind with the large unstained cell bodies of the basal nucleus of Meynert. As can be appreciated, this staining pattern closely resembles that described for the many neuropeptides present in the same area.

NEUROTRANSMITTERS

Cholinergic Markers

ACETYLCHOLINESTERASE (AChE) In AChE preparations many of the interrupted columns and channels of the SLEACn appear to be far less reactive than the nearby MCBFC and the neuropil that surrounds them. Some authors have shown a granular, moderately AChE-positive neuropil that enmeshes AChE-negative neurons (see Perry *et al.*, 1984) bearing morphological characteristics seen in the BSTL division of the BST nucleus and of the Ce nucleus.

CHOLINE ACETYLTRANSFERASE (ChAT) No human or nonhuman primate information on this important point is available at present.

Excitatory Amino Acids

GLUTAMATE (GLU) No human or non-human primate information about this important point is available at present.

Inhibitory Amino Acids

γ-AMINOBUTYRIC ACID (GABA) According to Pitkanen and Amaral (1994), in the macaque monkey, this region of the brain presents insurmountable difficulties for identifying which are the true representatives of the continuum even if GABA-ir fibers can be identified in the region of the ventral amygdalofugal pathway.

MONOAMINE MARKERS

Dopamine-β-Hydroxylase (DBH) Sadikot and Parent (1990) report that in the squirrel monkey DBH-ir fibers enter the amygdala via the ansa lenticularis/ventral amygdaloid bundle that derive from DBH-ir fascicles running in the ventrolateral hypothalamus. The DBH-ir in the substantia innominata is light rostrally and increases progressively to moderate levels caudally.

Histamine (HA) According to Airaksinen *et al.* (1989), in the tree shrew the HA-ir fibers spread in the amygdaloid complex as a dense network including in this manner the SLEACn (see their Fig. 3G).

Phenylethanolamine-N-methyltransferase (PNMT) (Adrenaline/Epinephrine) According to Sadikot and Parent (1990), in the squirrel monkey, few PNMT-ir fibers are present in the ansa lenticularis/ventral amygdalofugal bundle. No further data are given.

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey, 5-HT-ir fibers arrive from via the medial forebrain bundle in the lateral hypothalamus to reach the amygdala via the ansa peduncularis/ventral amygdaloid bundle in the sublenticular substantia innominata. These latter contains a large number of nonvaricose and varicose 5-HT-ir fibers showing profuse terminal arborizations.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey, the TH-ir fibers in their route toward their amygdaloid targets travel in the ansa peduncularis/ventral amygdalofugal pathway fiber system, which run in the sublenticular substantia innominata to turn ventrally toward the amygdala. Within this fiber system, fine TH-ir fibers, regularly spaced ovoid varicosities are interrupted by thicker, nonvaricose terminal fibers. Varicose and non-varicose TH-ir fibers cross the substantia innominata, with their number increasing in a rostrocaudal axis of this structure.

NEUROPEPTIDES

CALCITONIN GENE–RELATED PEPTIDE (CGRP) De Lacalle and Saper (2000), in the human brain, report the presence of a bundle of CGRP-ir fibers bridging between the Ce nucleus and the BST nucleus that crosses the so-called substantia innominata in a mediolateral and dorsoventral progression.

CHROMOGRANIN B According to Marksteiner *et al.* (1999), the sublenticular part of the so-called substantia innominata contained the highest density of PE-11-like ir. In the dorsal part of the substantia innominata and in the transition zone to the amygdala the PE-11-like ir is mainly composed of woolly-like fibers.

CHOLECYSTOKININ (CCK) According to Martin *et al.* (1991), who worked with human tissue, their sublenticular BST division (here the SLEACn) of the BST-amygdala continuum contains long, linear or curvilinear dendrites of non-ir neurons that are covered with CCK-ir boutons. These boutons are predominantly present on proximal dendrites and perikaryal surfaces of the nonreactive large, triangular, and fusiform neurons that build up this continuum.

CORTICOTROPIN RELEASING FACTOR (CRF) In the human amygdaloid complex, a dense accumulation of CRF-ir fibers, with large varicosities, and terminals has been reported to be present in almost all amygdaloid nuclei (Powers *et al.*, 1987; Zaphiropoulos *et al.*, 1991). This statement may be extendable to the so-called substantia innominata (Zaphiropolous *et al.*, 1991)

ENKEPHALIN (ENK) In the human brain, Haber and Watson (1985) described ENK-ir fibers of the so-called woolly type. Such fibers extend medially and laterally from a position beneath the ansa peduncularis, and from there they continue as a prominent group that curves around the lateral side of the Ce nucleus. Lesur *et al.* (1987), in turn, reported the presence of "islands" of very dense ENK-ir characterized by the presence of numerous ENK-ir plexuses of granular type, and propose the possibility that these peptidergic "islands" may represent a continuation of the BST nucleus ENK-ir with that of the amygdaloid nuclei via the sublenticular substantia innominata. Martin *et al.* (1991) reported likewise the presence of ENK-ir peridendritic and perisomatic fiber formations which they described either as ribbon-like structures, or as woolly-like, or as tubules as a characteristic of ENK-ir arrangement in the anterodorsal and posterodorsal SLSI (here SLEACn) (see also Haber and Watson, 1985; Mai *et al.*, 1986; Kaufmann *et al.*, 1997). In addition, they reported that peridendritic woolly-like type II fibers as well as ENK-ir varicose fibers extend from the ENK-ir lateral infracommissural BST (i.e., BSTLV) into their anterodorsal sublenticular substantia innominata (i.e., SLEACn). At more caudal levels, these ENK-ir profiles curve medially and ventromedially to the internal segment of the globus pallidus to get into the area of the ansa peduncularis and into the postero-dorsal substantia innominata (i.e., still SLEACn) to eventually reach the dorsal aspect of the amygdaloid body, closely imitating the distribution pattern of the SECR-ir (see below).

DYNORPHIN (DYN) According to Haber and Watson (1985), the human subtlenticular region contains only few DYN-ir fibers.

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented in the cebus monkey amygdala (Kordower *et al.* 1992), this member of the CExA, like other components of this gray continuum, does not contain GAL-ir cell bodies but seems to contain small amounts of GAL-ir fibers, which are depicted in continuity with those at the level of the Ce nucleus, ventrolaterally and caudally. However, the pattern changes dramatically at the level of its paraseptal expansion, i.e., the BSTL division.

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), in the human brain, the area corresponding to the sublenticular extended amygdala contains fibers running in a uniform orientation parallel to the pial surface ventral to, and rarely within, magnocellular complex of the basal forebrain. Occasional NPY-ir

perikarya appear that seem to merge with NPY cells in the ventral part of the putamen accompanied by NPY-ir fibers. By comparison, McDonald *et al.* (1995) could not see NPY-ir peridendritic axonal configurations in the macaque monkey.

NEUROTENSIN (NT) According to Mai *et al.* (1987), NT-ir fibers forming the AA area are continuous with the claustrum striatale and the pedunculus lentiformis as well as with the sublenticular region, including the so-called substantia innominata. Some of the full picture concerning the distribution of NT-ir fibers in this region of the telencephalon form without doubt to the NT-ir component of the extended amygdala described by Martin *et al.* (1991), who described the existence of NT-ir peridendritic and perisomatic profiles which were considered to be characteristic in the anterodorsal and posterodorsal SLSI (here SLEACn).

PROSOMATOSTATIN-DERIVED PEPTIDE (PSDP) According to Bouras *et al.* (1987), the human substantia innominata contains moderate amounts of both PSDP-ir cell bodies and fibers.

SECRETONEURIN (SECR) According to Kaufmann *et al.* (1997), from the lateral infracommissural BST (i.e., the BSTLV) SECR-ir peridendritic woolly-like type II fibers as well as SECR-ir varicose fibers extend into the sublenticular substantia innominata (i.e., SLEACn). More caudally, these SECR-ir profiles curved medially and ventromedially to the internal segment of the globus pallidus to get into the area of the ansa peduncularis where they appear distributed in two areas separated by the large CAB-ir neurons of the nucleus of Meynert, neurons that do not express SECR-ir. More laterally and caudally, prominent SECR-ir can be observed throughout the posterodorsal substantia innominata (i.e., still SLEACn). SECR-ir peridendritic woolly-like fibers extend ventrolaterally beneath the caudal aspect of the anterior commissure to eventually reach the dorsal aspect of the amygdaloid complex and join the SECR-ir in the Ce nucleus.

SOMATOSTATIN (SOM) According to Candy *et al.* (1985), Bennet-Clarke and Joseph (1986), Lesur *et al.* (1987), Mufson *et al.* (1988), and Heimer *et al.* (1999) in the human brain, SOM-ir fibers and small fusiform, multipolar or bipolar SOM-ir perikarya can be seen to form island-like clusters, with some forming a continuous band up to the dorsolateral preoptic area, with SOM-ir processes present in every area containing SOM-ir perikaria. Gaspar *et al.* (1987) describe the SOM-ir woolly-like and other fine lone SOM-ir fibers coursing within the ansa peduncularis/ventral amygdalofugal pathway. Martin *et al.* (1991) confirmed these observations but also stressed the continuation of the BSTLV division of the BST into anterodorsal and posterodorsal sectors of the substantia innominata (here the SLEACn). They also found that this peptidergic sector of the substantia innominata is delineated by a dense band of overlapping immunoreactivity for several other neuropeptides.

Amaral *et al.* (1989), in the macaque monkey, specifically stressed the fact that the SOM-ir present in the Ce nucleus is continuous with the dense SOM-ir located in the so-called substantia innominata and BST nucleus, an observation that coincides with those of Mufson *et al.* (1988) in the human basal forebrain. They also remarked that this disposition parallels the projection of the Ce nucleus to the BST nucleus (see Fig.2B in Price and Amaral, 1981). These authors also pointed out the presence in this SOM-ir field within the sublenticular substantia innominata (i.e., the present SLEACn) of dense, fasciculated bundles of only slightly varicose SOM-ir fibers as well as large varicosities that formed single or double parallel profiles that, as in the Ce nucleus, outlined dendritic processes of non-ir neurons. Closely associated with them, Amaral and Prise (1988) also found patches of densely SOM-ir terminals. None of these latter seem to be associated with magnocellular neurons of the basal nucleus of Meynert, but rather with clusters of densely packed smaller neurons located within the sublenticular substantia innominata. Similar findings have been reported by McDonald *et al.* (1995).

According to Desjardin and Parent (1992), in the squirrel monkey, the areas corresponding to the EXA display a rather intense SOM-ir. In this New World primate, as in the macaque brain, within the SLEA groups of SOM-ir fibers form a dense bundle that course among the fibers of the ansa lenticularis, the inferior thalamic peduncle, and the adjoining BST nucleus. These fibers could be traced continuously within the so-called substantia innominata to the dorsal tier of the Ce nucleus. A large proportion of these fibers in the squirrel monkey brain are of the woolly-like type. It is interesting to point out that, according to these authors, in contrast to what happens with every component of the EXA, the entire pallidal complex in the squirrel monkey is largely devoid of SOM-ir.

SUBSTANCE P (SP) According to Haber and Watson (1985), in the humans sublenticular region, there are no SP-ir fibers.

VASOINTESTINAL PEPTIDE (VIP) Although Martin *et al.* (1991) have schematically mapped the presence of

this peptide in the sublenticular region of the BSTLD, the material illustrated with microphotographs by Heimer *et al.* (1999) provides a dramatic and convincing demonstration of the ventrolaterally directed VIP-ir continuum coming from the VIP-ir fibers and neuropil present in the BSTLD division of the BST nucleus to reach immediately after the SLEACn and later on the VIP-ir plexus in the central division of the Ce nucleus. This proof is especially significant given the fact that the VIP-ir is a specific marker for central extended amygdala since neither the BSTM division nor the Me or the SLEAM shows VIP-ir. The VIP-ir appears in these areas in the form of perisomatic and peridendritic profile.

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Kaufmann *et al.* (1997), CAB-ir profiles are not present at any level of the anterodorsal sublenticular substantia innominata, i.e., the present SLEACn. Sorvari *et al.* (1996b) described CAB-ir in the ventral amygdalofugal pathway.

RECEPTORS

GALANIN RECEPTOR (GAL-R) According to Kohler and Chan Palay (1990), in the human telencephalon, [^{125}I]-galanin binding occurs in the so-called substantia innominata in the form of patches separated by areas of low or no specific binding.

SEROTONINERGIC RECEPTORS (5-HT-R)

5-HT$_{2C}$ RECEPTOR (5-HT$_{2C}$-R) According to Lopez-Gimenez *et al.* (2001), the sublenticular extended amygdala constitutes one of the forebrain structures showing the strongest hybridization signal with probes for 5-HT$_{2C}$-R mRNA.

Interstitial Nucleus of the Posterior Limb of the Anterior Commissure (IPAC) In the rat brain IPAC has been well delineated as a result of normal and experimental studies carried out in this macrosmatic mammal by Alheid and colleagues (Alheid *et al.*, 1994, 1995; Alheid and Heimer, 1996, Alheid *et al.* 1998; Heimer *et al.*, 1997a, b; Veinante and Freund-Mercier, 1997). This anatomical entity includes an area along the posterior limb of the anterior commissure that is continuous with the caudomedial accumbens and shares the histochemistry and close connections with the central division of the extended amygdala. At present it is not possible to specify with any precision the homologous area of the primate or human brain. However, some histochemical data presented by Heimer *et al.* (1999) suggest that portions of the human ventral striatum that are close to the temporal limb of the anterior commissure are differentiated from the overlying striatum and stain in a similar fashion as the ventrally adjacent elements of the extended amygdala (see their Figs. 26A, B for SECR-ir and CCK-ir).

CUPRIC SILVER STAIN Examination of transverse sections of the macaque and squirrel monkey brains stained with the cupric silver technique show that argyrophilic neuropil and a few granularly silver-stained neurons appear below and very briefly in front of the temporal limb of the anterior commissure of what might be a very reduced representation of this structure in nonhuman primates. If this is so, one can expect that this small and so peculiarly argyrophilic region will share the immuhistochemical characteristics of the rest of the equally argyrophilic SLEACn. Finally, it should be pointed out that in nonprimate macrosmatic mammals larger than the rat, such as the guinea pig, the rabbit, and the cat, the region of the ventral striatum located around or near the external capsule displays a similar picture to that observed in the above-mentioned monkeys.

Supracapsular Components of the Extended Amygdala

The Supracapsular Division of the Bed Nucleus of the Stria Terminalis (BSTS) and the Stria Terminalis Bundle (st) The neurons of the BSTS division of the BST nucleus form a more or less continuous column of cells along the stria terminalis extending from the BST nucleus to the centromedial or supra-amygdaloid sector of the amygdaloid complex (Figs. 22.17 and 22.22a) [BST/st in Plates 30–48 (10.7–34.6 mm) in Mai *et al.*, *Atlas of the Human Brain*, in Plates/Figs. 57–88 in Paxinos *et al.* (1997), "The Rhesus Monkey Brain in Stereotaxic Coordinates"]. In the human brain, this division appears to be composed mainly of two discontinuous columns of cells (however, see Martin *et al.*, 1991): medial (BSTSM) and lateral (BSTSl).

The BSTS subdivision of the supracapsular BST nucleus consists of a column of cells that at the level of the anterior thalamic nuclei, lies just medioventral to the stria terminalis bundles and, more caudally, comes to lie directly within the bundles themselves, where it is represented by relatively few neuronal elements. In general, the BSTS column is made up of small, spindle-shaped neurons with their longer axis oriented parallel to the course of the bundle resembling very much those in the BSTM division of the BST nucleus.

The more laterally located and complex BSTSL subdivision initially becomes evident at the same level as the just described BSTS, but located dorsolateral to the stria terminalis and within the border of the caudate nucleus. It continues in this position until it reaches the amygdaloid expansion of the BST nucleus. In an

intermittent fashion but still along the whole stretch of the supracapsular BST, small granular (Sanides' gamma type I) and parvicellular (Sanides' gamma type II) cells accompany this lateral component of the BSTS division. The more externally located, more continuous, larger celled lateral cell column constituted by the BSTSL proper when compared with the BSTS subdivision appears to be composed of somewhat more ovoid medium-sized neurons intermingled with a few larger and darkly staining neuronal elements scattered along the subdivision. These neurons are morphologically similar to those described for the BSTLD subnucleus of the lateral division of the BST nucleus.

The BSTS division of the bed nucleus of the stria terminalis as here defined in humans seems to be equivalent to that utilized by Martin *et al.* (1997), although the BSTSL subdivision of the present account seems to include their dorsal (BSTSld) and posterior (BSTlpl) subdivisions. According to these authors, the first cited subdivision would be a continuation of the BSTLD subdivision of the paraseptal BST nucleus, and the second cited one to the BSTLP subdivision.

Chemoarchitectonics

HEAVY METALS In Timm-Dansher's preparations of marmoset and squirrel monkey brains, it is possible to see a direct continuation of metal deposits present in the BSTL nucleus with those in the lateral large-celled column of the BSTSCn, which can be followed up to their final reunions with similar deposits at the level Ce nucleus. This evidence speaks in favor of a supracapsular continuation of the extended amygdala.

CUPRIC SILVER STAIN In cupric silver–stained transverse sections of macaque, squirrel, and marmoset monkey brains, it is possible to identify along the suprathalamic course of the stria terminalis pocket of granular argyrophilic perikarya and neuropil more or less closely adjacent to the lateral side of the compact medial bundle of the stria terminalis near the ventricular surface. The same can be seen near the entrance of the stria terminalis into the amygdaloid complex. Other times the pockets of argyrophilic perikarya and neuropil are found laterally in the angle between the stria terminalis and the thalamic radiation of the internal capsule, or within thin wedge-like septa of gray matter interposed between lateral and medial bundles of the stria terminalis when this fiber system travels below the optic tract, etc. Although this distribution pattern sometimes resembles that described for some neuropeptides, such as the CCK or SOM, it seems that there is no entire coincidence.

NEUROTRANSMITTERS OR NEUROMODULATORS

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Gaspar *et al.* (1985), in the human basal telencephalon the DBH-ir fibers, together with TH-ir ones, participate in a contingent of catecholaminergic fibers coming from the medial zone of the medial forebrain bundle into the septal region located around the anterior commissure decussation from which level a caudally oriented bundle branched from them runs dorsally toward the stria terminalis forming a vertically oriented axonal bundle that follows the lateral border of the BST nucleus medially to the internal capsule vertically. From this position abundant DBH-ir fibers branch off to concentrate in the medial portion (BSTM) of the BST nucleus while innervating very scarcely its lateral portion (BSTL).

In the squirrel monkey, DBH-ir fibers have been detected in the intra-amygdaloid portion of the stria terminalis (Sadikot and Parent, 1990).

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew the stria terminalis contains a dense bundle of HA-ir fibers.

SEROTONIN (5-HT) In the squirrel monkey, 5-HT-ir fibers are present in the intra-amygdaloid portion of the stria terminalis (Sadikot and Parent, 1990).

TYROSINE HYDROXYLASE (TH) TH-ir fibers follow approximately the same course as DBH-ir fibers to become incorporated in the stria terminalis after innervating the BST nucleus in a complementary fashion with respect to that provided by the DBH-ir fibers, i.e., by innervating the lateral portion (BSTL) of the BST nucleus.

In the squirrel monkey, TH-ir fibers are present in the intra-amygdaloid portion of the stria terminalis (Sadikot and Parent, 1990).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), GABA-ir fibers could be observed along the entire course of the stria terminalis. Some of the fibers entered the medially adjacent extension of the BST nucleus and developed a dense network there.

NEUROPEPTIDES According to Martin *et al.* (1991), the gray matter constituting caudal extension of the BST nucleus that accompanies the stria terminalis dorsally, i.e., its supracapsular division, contains neurons that are similar to those present in the main

body of this nucleus, so that the BSTS has features of the BSTLD, BSTLP, and BSTM divisions.

CHOLECYSTOKININ (CCK) According to Martin *et al.* (1991), both dorsolateral and posterolateral divisions as well as the medial division of the baboon and green monkey contain CCK-ir varicose fibers and punctate material. Only in the baboon are CCK-ir bodies present in the lateroposterior and medial divisions of the BSTS.

CHROMOGRANIN B According to Marksteiner *et al.* (1999), the stria terminalis displayed a high density of PE-11-like ir fibers.

ENKEPHALIN (ENK) According to Martin *et al.* (1991), both dorsolateral and posterolateral divisions of the BSTS division material of the macaque, baboon, and green monkeys contain ENK-ir cell bodies as well as of ENK-ir varicose fibers, peridendritic, perisomatic, and punctate material.

GALANIN (GAL) According to Kordower *et al.* (1992), in the cebus monkey, temporal segments of the stria terminalis and occasional small GAL-ir neurons can be detected.

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), human stria terminalis exhibits NPY-ir fibers in low to moderate amounts. Occasionally, small NPY-ir perikarya can be noted in the vicinity of these fibers.

NEUROTENSIN (NT) According to Martin *et al.* (1991), both dorsolateral and posterolateral divisions of the BSTS division of the macaque, baboon, and green monkey contain NT-ir cell bodies as well as of NT-ir varicose fibers, peridendritic, perisomatic, and punctate material.

OXYTOCIN (OXT) According to Caffé *et al.* (1989), in the macaque brain, thick, smooth OXT-ir fibers are present in the stria terminalis with origin very presumably in the magnocellular paraventricular hypothalamic nucleus.

PROSOMATOSTATIN-DERIVED PEPTIDE (PSDP) Bouras *et al.* (1987), in the human brain, were able to detect a high density of PSDP-ir fibers in the stria terminalis.

SECRETONEURIN (SECR) According to Kaufmann *et al.* (1997), this part of the BST complex displayed a high density of SECR-ir varicose fibers and is partially confluent with that of the stria terminalis. This bundle displayed the highest density of this neuropeptide compared with that of other neuropeptide markers.

SOMATOSTATIN (SOM) According to Gaspar *et al.* (1987), while a majority of the so-called SOM-ir woolly fibers are oriented to the sublenticular region of the basal telencephalon, a few course along the stria terminalis. Martin *et al.* (1991) have reported the presence of SOM-ir cells in the laterodorsal BSTS division, as well as of SOM-ir varicose fibers, peridendritic, perisomatic, and punctate material in both laterodorsal and lateroposterior subdivisions of the BSTS of the macaque and green monkeys.

VASOINTESTINAL PEPTIDE (VIP) According to the report by Martin *et al.* (1991), VIP-ir fibers are present in the laterodorsal subdivision of the macaque BSTS division.

VASOPRESSIN (VP) According to Caffé *et al.* (1989), in the macaque brain very thick, smooth VP-ir fibers are present in the stria terminalis, presumably having their origin in the magnocellular paraventricular hypothalamic nucleus

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), the human stria terminalis contains CAB-ir fibers. However, they do not comment about the presence or absence of CAB-ir cell bodies.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the human stria terminalis contains CR-ir fibers; however, they do not comment about the presence or absence of CR-ir cell bodies. In observations made in rat material processed in my laboratory for immunochemical demonstration of CR-ir, the CR-ir fibers tend to run predominantly in the ventral component of this bundle, being stronger in the lateral division of this component than in the medial one. CR-ir perikarya can be detected forming a small cluster along the course of the ventrolateral ST. Interestingly, no CR-ir fibers or cells are present in the commissural component of the ST bundle, which goes along with the very poor presence of CR-ir cells in the LOT nucleus.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), in the human basal telencephalon, very few PAV-ir fibers can be found in the stria terminalis.

Temporal Lobe Components of the Central Extended Amygdala

Central Amygdaloid Nucleus (Ce) The Ce nucleus is the main output of the amygdala acting as an

integrator site that receives multimodal sensory information supplied by amygdaloid, paleo-, archi-, periallo- and neocortical structures, by the hypothalamus and thalamus, and by brain stem areas. As such, it is concerned with the elaboration of autonomic, endocrine, cardiovascular, immune, and behavioral functions, playing, for example, a crucial role in modulating cardiac changes associated with fear and anxiety, and with aggression. For this reason, it plays also a key role in fear-related responses, such as the increase of the arterial blood pressure and tachycardia that occurs in this type of behavior. It is also considered to be the main brain structure for conditioned fear-responses, accomplishing all of these functions through its direct and indirect efferent projections to thalamic, hypothalamic, brain stem, and even spinal cord effector centers.

Topographical Landmarks The Ce nucleus [Ce (plates 25–33, 4.0–14,6 mms in Mai *et al.* (1997) *Atlas of the Human Brain*] is the most deeply located amygdaloid nucleus seated in the angle formed by the BL and BM nuclei (Figs. 22.4, 22.5a, 22.6a,b, 22.7a,b, 22.8, 22.10, 22.11, 22.22c, 22.27). It extends within the posterior two-thirds of the amygdaloid complex, lying ventral to the base of the pallidum and putamen from which it is separated by numerous myelinated fiber bundles and by magnocellular neurons that are the caudal representatives of the diffuse and compact parts of the basal nucleus of Meynert (BC). The Ce extends until it reaches the posterior limit of the amygdala, though it remains separated from the ventricular wall by intra-amygdaloid fiber radiation of the stria terminalis together with the neurons that form their bed nucleus. The Ce nucleus is also bounded ventrally and laterally by dense fiber bundles [Broackhaus'(1938) lamellae dorsomedialis and dorsalateralis, respectively], although a less prominent fiber network surrounds the nucleus almost entirely forming a capsule. Rostrally the Ce nucleus is bordered dorsally by the SLEACn, with which it is continuous, and by the intermediate division of the nucleus basalis (BC). The Ce nucleus is also flanked laterally by the temporal limb of the anterior commissure (ac) and the amygdalostriatal transition area (AStr) by which it is partially replaced further caudally. As pointed out before ventrolaterally, the Ce nucleus is bounded by the DL subdivision of the BL nucleus and by intercalated cell islands of different size and shape, while ventrally the DM division of the BM nucleus provides the seat for this nucleus. Medially, the Ce nucleus is separated from the MeA nucleus by a narrow arm of the deep AAA that wedges between both nuclei. The rostral pole of the Ce abuts the deep AAA from which is separated by a thin but always present rostral extension of the capsular formation mentioned earlier. The existence of this fiber limit can be clearly seen in neurofibrillar preparations stained with nonsuppressive silver procedures. In this type of preparation it is possible to establish without doubt the existence of such limiting fiber barrier as well as the far less dense fiber network present in the Ce nucleus as compared with that seen in the deep AAA. Furthermore, in Nissl preparations, and contrary to the much insisted continuity of the Ce with the deep AAA, it is also easy to appreciate not only that the background staining in the Ce nucleus is more translucent than that in the deep AAA, but also that the glial population in this latter griseum is richer than in the Ce nucleus, a glioarchitectonic feature that very presumably reflects higher fiber density present in the deep AAA.

Just dorsal to the main mass of the Ce nucleus and even reaching beyond the rostral pole of it, neuronal islands appear that share some of the morphological characteristics of the Ce nucleus, such as chromophilic ground substance and light staining in both Nissl and Weigert preparations. These cell islands correspond to what Brockhaus (1938) labeled the "supraamygdala ventralis accessoria." In the present chapter they are called the paracapsular subdivision of the CeL (PC CeL). As pointed out in a previous version of this chapter, and accepted by other investigators (Martin *et al.*, 1991; Heimer *et al.*, 1999), these accessory formations may constitute peninsular extensions because they are attached to the main body by bridges of Ce tissue. Furthermore, these accessory formations, like the principal nucleus, are encircled by narrow capsular-like formation of cells and fibers that shares many of the morphological and chemical characteristics of the main capsular division of the Ce nucleus. It is important to add that similar disposition can be observed in the BSTL, supporting in this manner the principle of symmetry on which is based the morphological theory of the extended amygdala.

Cytoarchitectonics On the basis of its cytoarchitectonic arrangement, the Ce nucleus can be divided into two major divisions: medial (CeM) and lateral (CeL). Each one, in turn, can be subdivided into subnuclei: the former division into dorsal (D CeM) and ventral parts (V CeM), and the latter named division, which shows a far more complicated cell arrangement, into central (CeLCn), apical (CeLA), capsular (CeLC), paracapsular (PCeL), and periparacapsular (PPCeL) subdivisions.

The CeM, lies dorsomedially to the CeL subnucleus and is intercalated between this laterally, the deep AAA rostrally, the MeA nucleus medially, and the DM BM ventrally. CeM has a more heterogeneous

neuronal population made up of densely packed small and medium-sized neurons and, in general, contains a denser glial cell population than that in CeL. Furthermore, if differences in cell packing and topographic location are taken into account, the CeM division can be divided into dorsal (D CeM) and ventral (V CeM) subnuclei. While the neuronal population in the D CeM subnucleus is more densely arranged and the glial population richer than in the V CeM, this latter possesses a more loosely arranged and homogeneous cell composition.

Broadly speaking, the CeL division of the Ce is constituted by medium-sized, lightly stained cells, with those in the CeLCn being very similar in appearance to the cells in the BSTLDcn. These neurons show a well-defined round, fusiform, or triangular outline against a very typical translucent background in which very few glial cells can be observed, as compared with the glial population in surrounding structures. There are, however, some organizational differences in different sectors in several divisions of the CeL that justify its parcellation. Thus, the main body of CeL can be divided into a less extensive anterodorsally located apical part (CeLA) and a much larger central part (CeLCn) that lies posteroventrally to the former subdivision. Such subdivision results from a looser arrangement and orientation of the slightly larger and more darkly staining neurons in CeLCn subnucleus, but from the typically much sharper outline of their cell processes and perikarya. The neuronal population in the CeLA subnucleus is, on the other hand, more heterogeneous than that in the CeLCn subnucleus, in the sense that it contains a significanty larger number of pallidal-like neurons. On the basis of this and other morphological features to be dealt with later in this chapters, the CeLA subnucleus could be viewed as an extension of the capsular part of the CeL division.

The narrow neuron-poor and glial cell–rich CeLC is populated by loosely arranged, more darkly stained, usually fusiform neurons enmeshed in the fiber capsule that surrounds the CeLCn subnucleus, a disposition that is again very similar to that observed in the BSTLD. On topographical grounds, this subdivision of the CeL division can be parcelled into dorsal (D PCeLC), ventral (V PCeLC), and periparacapsular (P PCeLC) parts, although these latter two subdivisions may be continuous and constitute a structurally uniform sheet wrapping both the PCeL division and the dorsal and lateral aspects of the CeLCn. By contrast, the V PCeLC subdivision appears to be made of a more heterogeneous and larger-celled neuronal population. Peculiar to the capsular CeL is the orientation of its generally spindle-shaped neurons parallel to the locally predominant direction of the fiber fascicles in which they are enmeshed. Such features help to distinguish this division of the Ce nucleus from surrounding structures. (For further details, see de Olmos, 1990.)

The paracapsular sector (PCeL) of the Ce nucleus forms an irregularly shaped plate-like structure in which the central segment is, in general, thinner than its ends and discontinuous at times. It is this thinner portion that connects with or appears to be connected by cell bridges to the main body of the CeL division. The neurons in the paracapsular part are, in general, smaller and more densely packed than in the CeLCn and tend to be oriented parallel to the long axis of gray paracapsular formation to whose buildup they contribute. Like the rest of the CeL division, the PC CeL is poor in glial satellite cells and shows a translucent background staining.

On purely topographical grounds, the PCeL can be divided into dorsal (D PCeL) and ventral (V PCeL) parts. The D PCeL extends farther dorsally (and rostrally) and its ventral counterpart eventually becomes continuous with the SLEACn. The cells in this subdivision are regularly oval shaped with poorly outlined processes and weakly stained Nissl substance with a oval nucleus centrally located. The V PCeL is sharply delineated by the capsular formation that surrounds and separates it from the CeLCn, the AStr, and the ventral putamen.

Fibroarchitectonics In Weigert-stained sections or in neurofibrillar preparations (Fig. 22.27b), the CeM division can be distinguished from surrounding structures by the dense and random orientation of the fiber plexus present in it. Rostromedially and dorsally, the fiber plexus in the CeM division seems to merge into the deep AAA or in that related to the basal nucleus of Meynert. However, as pointed out at the beginning of this chapter, closer examination reveals that this division of the Ce nucleus is actually separated from the deep AAA by a thin fiber capsule barely visible in Weigert sections that becomes denser toward the BM nucleus. The D CeM subnucleus can be differentiated from the V CeM subnucleus by the greater density of its fiber plexuses.

The CeL division and its many subdivisions are more sharply defined in this type of preparation than in cell preparations. As was pointed out, the main body of the CeL division and its paracapsular extensions are easily recognized by their fiber-poor composition, which contrasts sharply with the richly fibered CeLC subdivision. Ventrally, however, this latter, which is poor in fibers, should not be mistaken for the dorsomedial medullary lamina that separates the Ce nucleus from the BM nucleus and in which are

embedded a few neuronal elements whose cytological characteristics are much like those in the CeM nucleus.

As here described, the Ce nucleus corresponds to the supra-amygdaleum profundum dorsale (sApd), supra-amygdaleum profundum ventrale (sApv), and supra-amygdaleum profundum ventrale accessorius (sApv acc) of Brockhaus (1938). The dorsolateral subdivision of the Ce nucleus by Sims and Williams (1990) probably corresponds to the PCeL subdivision of the present account; however, their ventrolateral subdivision seems to correspond to the AStr, and their interstitial subdivision most probably represents one of the intercalated nuclei that are always present around the Ce nucleus.

Chemoarchitectonics

CUPRIC SILVER STAIN In cupric silver–stained sections of macaque, squirrel, and marmoset monkey brains (Fig. 22.22c), silver deposits involve all divisions of the Ce nucleus, although such deposits assume different expressions according to the subdivision under examination. These silver precipitates, which occur in an otherwise normal tissue, display a granular and beaded appearance for which reason the name of granular argyrophilic neuropil was assigned. The central core of the Ce nucleus is characterized by its content of granular or punctate profiles that appear to represent mostly thickened terminals of granular argyrophilic axons. The diameter of argyrophilic axons is small and on most occasions the axons are not detected by the optical microscope. Embedded in this neuropil and having a tendency to be located ventrally and laterally within this part of the lateral Ce are granular argyrophilic neurons of rounded cell bodies with different degrees of argyrophilia. This argyrophilia is expressed by the accumulation of minute argyrophilic granules that almost fill their perikarya and that, on occasion, may also invade the proximal dendrites of these neurons and—more rarely—their axons (de Olmos, 1969; de Olmos *et al.*, 198l). These neurons are scattered throughout the core of the lateral paracapsular Ce, as well as in the rostral and caudal extensions of the central core and also involving the supracapsular–dorsolateral BST continuum or the SLEACn (see above). In the capsular lateral and apical lateral Ce, as well as the paracapsular extensions of the former, the argyrophilic profiles assume the ribbon-like or bistranded arrangement already described when dealing with the medial Ce. This argyrophilic pattern also extends beyond the boundaries of the just-mentioned subdivisions of the lateral Ce to continue into the supracapsular BST division caudally and into the SLEACn ventrolateral BST rostrally. Seldom are argyrophilic neurons seen in any of the subdivisions of the capsular lateral or apical lateral Ce.

HEAVY METALS In Timm-Dancher's-stained sections (see Fig. 22.23b) of macaque, squirrel, and marmoset monkey brains, the CeL division is densely impregnated with silver-sulfur granular deposits, while the CeM division shows a much lighter silver precipitate. Within CeL the staining is not homogeneously distributed but is denser on a medially located core (CeLCn) than on the lateral semiring (CeLC) that encloses the lateral and dorsal sides of the former. Interestingly, around the less densely stained semiring formation appears somewhat denser area suggesting a paracapsular division because of its more dense reaction. Adjacent sections stained for AChE show a point-to-point complementary staining pattern. Whatever the meaning of this histochemical heterogeneity, the point remains that this division of the Ce nucleus is most probably the target of zinc-containing pathways with source outside the nucleus. This reasoning is based on the fact that in rats microiontophoretic injections of sodium selenite in this Ce nucleus does not cause the labeling of the local neurons but occurs in neurons located in amygdaloid nuclei and in cortical structures known to have this nucleus as a target of their efferent projections (de Olmos and Beltramino, unpublished observations).

NEUROTRANSMITTERS

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) As pointed out by Gloor (1997), the various reports available in the literature concerning the presence in the Ce nucleus of cholinergic markers differ in detail, but there exists a general consensus that the neuropil of the Ce nucleus stains lightly and that some cells contain AChE (Nitecka and Narkiewicz, 1976; Sims and Williams, 1990). There are, however, some differences in the AChE reactivity within the Ce nucleus that deserve to be stressed, since this enzyme is more densely expressed in the CeM division than in the CeL division (Sorvari *et al.*, 1995; Heimer *et al.*, 1999). On the other hand, Darvesh *et al.* (1998) have claimed that they were not able to detect AChE-positive neurons in four of five brains, and in the only one that showed them, they were very few. Furthermore, the distribution pattern of the AChE activity within the CeL helps to distinguish the CeLCn subnucleus from the CeLC, being denser in the former and providing a clear picture of the more or less continuous AChE-negative sheet that encapsulates the CeLCn subnucleus (Benzing *et al.*, 1992; Heimer *et al.*, 1999).

In the macaque monkey brain AChE staining of the CeL division of the Ce nucleus is lighter than that of the CeM division. AChE staining in the CeL division is finer and slightly different in color than in other regions of the amygdala and there are few distinctly stained

fibers. The density of the staining is darker at caudal levels of the CeM division in which the AChE staining involved fiber and background. The dorsal half of the nucleus has higher levels of both types of staining. AChE-positive neuronal perikarya can frequently be detected adjacent to the fibers that surround the Ce nucleus as well as within the CeM division.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Emre *et al.* (1993), the Ce nucleus in humans has a clearly delimited oval CeL that is surrounded by a non-ir fiber bundle and a less well-delineated CeM that merges into neighboring structures, such as the so-called substantia innominata. The density of varicose ChAT-ir profiles is high within the CeL division and slightly less intense within the CeM division. The density is slightly higher and more patchy in the more posterior levels, especially in the CeL division. In overall ranking the CeL division is second only to the large-celled DL/D BL nucleus concerning the density of ChAT-ir fibers and varicosities.

Amaral and Basset (1989) report that in the macaque monkey the CeL division contains a moderate density of diffuse ChAT-ir that has a finely granular appearance. A thin plexus of fine-caliber ChAT-ir fibers are also visible. Superimposed on the diffuse ChAT-ir are small patches of more dense ir that appears to be condensation of ChAT-ir terminals. The overall staining of the CeL division increases at more caudal levels. The ChAT-ir in the CeM division of Ce consists primarily of relatively coarse ChAT-ir fibers that appear largely to be running through the nucleus. There is also a little of a fine ChAT-ir indicative of terminal labeling. Thus, in ChAT preparations the CeL division tends to have a darker appearance. ChAT-ir neurons are not seen within the boundaries of the Ce nucleus.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) In the rat, cells of the Ce nucleus have been said to contain a lesser amount of Glu/Asp than the nucleus of the laterobasal and superficial cortical amygdaloid formations (Ottersen *et al.*, 1986). However, experimental tracing data obtained by the use of tritiated D-aspartate indicate that a considerable number of the Ce neurons, mostly in its CeM, would be source of GLU/ASPergic projections to the ventral striatum (IPAC) and to the ventral pallidum (Fuller *et al.*, 1987), or to the paraventricular hypothalamic nucleus or immediate surroundings (Csáki *et al.*, 2000).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Augustine (1993), in the macaque monkey, the Ce nucleus in its lateral division displays a moderate to light GABA-ir which resembles that in the striatum, though the latter contains more intense GABA-ir. In the Ce nucleus, its medial neighbor, the MeA nucleus, contains a very dense array of GABA-ir puncta that appear to represent axon terminals whose density is greater than in the LBNC and that of most nuclei of the superficial pseudocortical amygdala while approximating that in the ACo nucleus. In both major divisions of the Ce nucleus it is possible to identify parallel rows of large GABA-ir puncta-encapsulating processes that appear to be dendrites. This type of image can be found more frequently in the lateral Ce nucleus than in the medial one. Finally, some encapsulated somata and dendritic processes exhibit light GABA-ir. The whole picture has been entirely confirmed in Pitkännen and Amaral's (1994) studies.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) (NORADRENALINE/NOREPINEPHRINE) The human forebrain regions that are innervated by the ascending norepinephrine-containing fibers display low to moderate concentrations of fine, varicose DBH-ir fibers, with sparse medium-sized, nonvaricose DBH-ir fibers intermixed. The most probable candidate as a source of the NET-containing fibers in the human forebrain appears to be the locus coeruleus (A6) (Basile *et al.*). On the other hand, according to Freedman and Shi (2001), in the macaque monkey, the concentration of DBH-ir fibers in the amygdaloid complex is generally lower than in the BSTLV subnucleus. Accordingly, there are moderate numbers of this type of fiber in the CeM division of this important member of the CExA.

In the squirrel monkey, both the CeM and CeL divisions of the Ce display moderately dense terminal DBH-ir with a slight decrease from medial to lateral (Sadikot and Parent, 1990).

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew (*Tupaia belangeri*), HA-ir fibers collected in dense bundles along the stria terminalis continue to the amygdaloid complex to spread as a dense and diffusely distributed network in the amygdala. At the level of the Ce nucleus this network reaches a high density.

PHENYLETHANOLAMINE-*N*-METHYLTRANSFERASE (PNMT) (ADRENALINE/EPINEPHRINE) According to Sadikot and Parent (1990), in the squirrel monkey, PNMT-ir occurs only in the Ce nucleus as a very sparse terminal labeling. These PNMT-ir fibers are likely to arise from a few PNMT-ir fibers within the ansa lenticularis/ventral amygdalofugal bundle, although direct continuity is difficult to establish.

SEROTONIN (5-HT) Within the macaque monkey amygdala, the heaviest concentration of 5-HT-ir fibers is found in the dorsal part of the rostral CeLC subnucleus and in the more caudal parts of the CeLCn subnucleus. These heavily labeled gray formations contain multiple small punctate 5-HT-ir structures with relatively few fibers and a diffuse background staining that was higher than in structures without specific ir. The CeM division of this nuclear component of the CExA contain only moderate amounts of 5-HT-ir fibers.

In the squirrel monkey, the CeM division of the Ce nucleus display very dense to dense 5-HT-ir terminal labeling with a mediolateral gradient of decreasing 5-HT-ir. The CeL division shows moderately dense 5-HT-ir, although its extreme caudolateral and dorsal aspects display dense 5-HT-ir (Sadikot and Parent, 1990).

TYROSINE HYDROXYLASE (TH) (DOPAMINE) According to Freedman and Shi (2001), in the macaque monkey amygdala, the highest densities of TH-ir fibers are found in the Ce nucleus, particularly in the rostrodorsal and caudal CeLC subnucleus and in the more caudal parts of the CeLCn subnucleus, while there are modest amounts of TH-ir fibers in the CeM division. In the squirrel monkey, the CeM division of the Ce nucleus displays very dense TH-ir terminals at its medial sector that diminish to dense TH-ir laterally. The CeL division of the Ce nucleus shows a medial to lateral gradient, varying from moderate ir medially to a dense one at its extreme lateral and dorsal portion.

NEUROPEPTIDES

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human amygdala, although BDNF-ir neurons and fibers are present in all amygdaloid nuclei, in the Ce nucleus they are only moderately represented by neurons displaying a rather strong staining. By contrast, BDNF-ir fibers form a very dense plexus within which some BDNF-ir neuronal cell bodies can be distinguished.

CALCITONIN GENE–RELATED PEPTIDE (CGRP) According to De La Calle and Saper (2000), in the human amygdala, the dorsal CeLC and CeLcn subdivisions of the Ce nucleus contain the densest concentration of CGRP-ir axons. At the rostral pole of the Ce nucleus there is an extremely dense CGRP-ir plexus that fills a distinct spherical region that corresponds to the CeL nucleus, which at caudal levels expands into the characteristic ovoid shape of the Ce nucleus. At these levels the CeM division of the Ce nucleus shows only a light to moderate plexus of CGRP-ir fibers that disperses throughout. Caudally and ventrally patches of CGRP-ir fibers bridge the Ce nucleus with the amygdalostriatal area.

CHROMOGRANIN B According to Marksteiner *et al.* (1999), the strongest intensity of PE-11-like ir is found in the Ce nucleus. This is the only amygdaloid nucleus that contains PE-11-like ir neuronal perikarya.

COCAINE- AND AMPHETAMINE-REGULATED TRANSCRIPT (CART) According to Hurd and Fagergren (2000), moderate CART mRNA signal can be demonstrated at the level of the Ce nucleus (primarily the anterior region).

CHOLECYSTOKININ (CCK) In the human brain, there is a concentration of CCK-ir puncta and varicose fibers in the central part of the CeL and a tendency for the labeling of peridendritic terminals to appear as tubular profiles, especially in the more dorsally located capsular part. CCK-ir varicose fibers and terminals, sometimes in typical peridendritic pattern, also characterize the para- and periparacapsular parts of the CeL division. In contrast, the Ce does not seem to contain CCK-ir neuronal perikarya (Heimer *et al.*, 1999), a negative finding that would agree with an apparent absence of CCK mRNA hybridization signal in this nucleus as can be inferred from its nonlisting among the amygdaloid nuclei showing it (Savasta *et al.*, 1990).

CORTICOTROPIN-RELEASING FACTOR (CRF) In the human amygdaloid complex, a dense accumulation of CRF-ir fibers with large varicosities and terminals has been reported in almost all amygdaloid nuclei (Power *et al.*, 1987; Zaphiropoulos *et al.*, 1991). This finding, together with the fact that the BST and the sublenticular substantia innominata (here SLEA) also contain a high density of CRF-containing fibers and terminals (Powers *et al.*, 1987; Zaphiropoulos *et al.*, 1991), speaks in favor of the existence of a similar distribution pattern in Ce. In contrast, the Ce nucleus seems to contain a rather sparse population of small bipolar CRF-ir neurons.

On the other hand, in rodents, the Ce nucleus has been shown to be the site of high concentrations of CRF-containing cell bodies that project to areas known to mediate endocrine, autonomic, and behavioral responses to stress. The presence of CRF–synthesizing neurons has been confirmed by the finding that, at least in rat brain, this nucleus is the place in the amygdala showing the maximal CRH mRNA expression; what

is of great significance is that this expression is significantly increased in response to stress (Hsu *et al.*, 1998).

DYNORPHIN (DYN) This endogenous opioid peptide, which in the rat is distributed in the neuropil of the Ce, seems to originate in part at least from DYN-containing neurons located in the lateral hypothalamic and perifornical areas of the hypothalamus (Zardetto-Smith *et al.*, 1985).

ENKEPHALIN (ENK) In the human amygdala, the ENK-ir is concentrated almost exclusively within the Ce, particularly in CeL (Pioro *et al.*, 1990). According to material presented by Heimer *et al.* (1999), the components of CeL division are characterized by strong or moderately strong ENK-ir. The central and apical parts of the CeL division contains a large number of ENK-ir puncta and varicose fibers in addition to some ENK-ir neuronal somata, whereas the capsular part (CeLC) is characterized by granular-type tubular profiles and puncta. The accessory parts of the Ce, i.e., the paracapsular and pericapsular subdivisions of the CeL, are surrounded by fiber-rich capsules characterized by tubular profiles in ENK-stained sections. CeM, on the other hand, shows a moderately strong reaction to ENK, which is similar to that present in the BSTLP. According to Sukhov *et al.* (1995), the human Ce contains a robust number of preproenkephalin (PENK) mRNA-containing neurons.

In the monkey ENK-ir fibers form a plexus of "woolly-like" fibers that surrounds the nucleus and extends into the substantia innominata (SLEAC) (Haber and Watson, 1985).

In the rat, the lateral division of the Ce nucleus, as in humans, also contains ENK-ir cells, and the administration of amphetamine in different experimental setups produced significant and synchronized changes in the c-fos mRNA expression both in ENK-ir cells of the CeL nucleus, and of its rostral extent, the BSLTLD (oval) nucleus (Day *et al.*, 2001).

It should be mentioned that in the rat, ENK-containing neurons located in the lateral and perifornical hypothalamic areas, though in rather scarce numbers contribute to ENKergic innervation of Ce (Zardetto-Smith *et al.*, 1985).

GALANIN (GAL) GAL-ir cell bodies are found mostly in the medial subdivision of the nucleus in the monkey (Köhler *et al.*, 1989a, b). However, according to mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992) in the macaque monkey amygdala, this member of the superficial amygdala, like its other components, would not contain GAL-ir cell bodies but seems to contain at least a small number of GAL-ir fibers.

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), in the human amygdala, the Ce nucleus shows a small number of cells in the lateral half of the CeL division.

According to McDonald *et al.* (1995), in the macaque monkey, the CeL division and the rostral CeM contains very few NPY-ir neurons, whereas moderate amounts of these type of neurons can be found in the caudal sectors of the CeM division. The NPY-ir cells in the Ce nucleus are small to medium sized with three to four sparsely branched dendrites. A distinct population of larger, richly spined NPY-ir neurons can be found around the dorsal, lateral, and ventral boundaries of the CeL division. These cells are endowed with three to four sparsely branched dendrites. It should be pointed out that all the NPY-ir cells in the Ce nucleus are also SOM-ir (McDonald *et al.*, 1995). Whether this also occurs in the human Ce nucleus is not known.

NEUROTENSIN (NT) Mai *et al.* (1987) describe the presence of NT-ir cell bodies in the transition zone between the LBNC (i.e., their amygdaloid body proper) and the anterocentromedial nuclear group (i.e., their supra-amygdaloid region) and in the Ce nucleus. They also reported that the strongest accumulation of NT-ir fibers and varicosities can be found in the corticomedial and anterocentromedial amygdala. According to Benzing *et al.* (1992), the Ce nucleus is densely NT-ir throughout its anteroposterior extent, although at caudal levels there is a greater density in the staining than at anterior levels. The CeM division, in turn, stains more intensely than the CeL, being one of the most intensely NT-ir structures in the whole amygdaloid complex. The NT-ir in the CeM division consists primarily of a dense matrix of puncta and interspersed fine-beaded fibers, and of numerous darkly staining bipolar and multipolar neurons randomly distributed throughout the nucleus. By contrast, the CeL division contains considerably less NT-ir than the medial one and appears encircled by a dense band of NT-ir fibers that is continuous with the NT-ir fiber plexus in the CeM division. The NT-ir neurons in the CeL division differ from those in the CeM division in that they consist of about equal numbers of multipolar, bipolar and unipolar, lightly or moderately stained cells, being more numerous in caudal levels of the division than anteriorly. Heimer *et al.* (1999) confirmed this description in general but also pointed out that the majority of the NT-ir neuronal perikarya are located in the CeM division rather than in the central part of the CeL division.

PROSOMATOSTATIN-DERIVED PEPTIDES (PSDP) According to Bouras *et al.* (1987), all of the nuclear divisions of the human amygdaloid complex contain PSDP-ir neurons as well as PSDP-ir fibers and terminals.

SECRETONEURIN (SECR) According to Kaufman *et al.* (1997), in the human amygdala the SECR-ir reaches particularly high levels of density, which stands out from the relatively SECR-ir poor LBNC. In the central subregion of the CeL division are numerous SECR-ir neurons that are very similar in size and shape to neurons in the central core of the BSTLD. Numerous SECR-ir and non-ir neurons are pericellularly stained. The CeLCn appears surrounded by SECR-ir granular, peridendritic, and perisomatic plexuses of the same type as those in the BSTLD and in the SLEAC. The CeM division displays a high density of SECR-ir varicose fibers with only scattered woolly-like fibers. The rostral part of the CeM divisions contains the most SECR-ir neurons.

SOMATOSTATIN (SOM) In humans, as in other primates and nonprimates, SOM-ir fibers and terminals are abundant in the Ce nucleus, though predominating in the CeL division. Some of these fibers can be followed directly into the so-called substantia innominata (here SLEAC) (Mai *et al.*, 1987; Mufson *et al.*, 1988).

In the monkey the Ce has been described as having the most distinctive pattern of SOM-ir, although the appearance of the fibers and terminals containing this neuropeptide varies with the type of antibody utilized. Irrespective of this fact, the lateral division (CeL) of the nucleus displays much denser fibers and terminals than the medial (CeM) one, and the soma and principal dendrites of several neurons appear heavily encrusted with large varicosities (Amaral *et al.*, 1989). Also, the majority of the SOM-ir neurons in Ce is located in the CeL (Amaral *et al.*, 1989; McDonald *et al.*, 1995) appearing tightly clustered in the ventromedial portion of the caudal pole of the nucleus. The cells were small and multipolar. It should be stressed again that many of the SOM-ir neurons in the CeM division are also ir for NPY (McDonald *et al.*, 1995). On the other hand, as pointed out by Amaral *et al.* (1989), a striking feature of the SOM-ir associated with the Ce nucleus is that the distinctive coarse varicose fiber staining is continuous with the dense SOM-ir detectable in substantia innominata (here SLEAC) and in the BSTL (Amaral *et al.*, 1989). Desjardins and Parent (1992) reported in the squirrel monkey amygdala that the medial and lateral divisions of the Ce nucleus are separated by a dense plexus of fine, vertically oriented, varicose, SOM-ir fibers. By contrast, the core of each division displayed a very light to light SOM-ir, whereas high SOM-ir occurs in the peripheral portion of this nuclear region. Overall, the Ce nucleus in the squirrel monkey seems to contain relatively few SOM-ir cell bodies.

SUBSTANCE P (SP) According to Mai *et al.* (1986), SP-ir fibers could be followed in the ventral amygdalofugal pathway and bands of punctate SP-ir are continuous with the supra- and periamygdaloid regions (here Ce, MeA, and AA). SP-ir is seen in scattered neuron branching fibers and punctate material throughout the human amygdala with no preference for the Ce nucleus. In the supra-amygdaloid area (here Ce), the substantia innominata (here SLEAC) contains rare SP-ir cell bodies (Pioro *et al.*, 1990). According to Heimer *et al.* (1999), CeL is lightly stained for SP as compared with the darker staining CeM.

TAKYKININS: NEUROKININ B (NKB) NKB is the predominant tachykinin in the Ce. Both NKB and SP neurons were scattered in the basomedial nucleus of the amygdala. More NKB neurons than SP neurons were observed in the BST and the Ce. Consequently, NKB is the predominant tachykinin in both the BST and Ce (Lucas *et al.*, 1992; Marksteiner *et al.*, 1992a). These data support the concept that these nuclei are part of a neuronal continuum extending through the substantia innominata (Alheid and Heimer, 1988; de Olmos, 1990; Martin *et al.*, 1991).

VASOINTESTINAL PEPTIDE (VIP) According to Heimer *et al.* (1999), VIP-ir, which is said to be an excellent marker of the central extended amygdala, is present in both CeLCn and CeLC as dense, fine granular, peridendritic, and perisomatic immunoreactivity.

VASOPRESSIN (VP) According to Sofroniev *et al.* (1981), in several primate species (tree shrew, macaque monkey), including human, it is possible to trace neurophysin/VP-ir fibers which distribute in the Ce nucleus via the stria terminalis from their source in the paraventricular hypothalamic nucleus. According to Caffé *et al.* (1989), in the macaque monkey, thick varicose VP-ir fibers are present in the MeA nucleus as well as in two types of VP-ir cell: one of ovoid shape that resembles the VP-ir cells in the BST nucleus is located at a level near to the hippocampal formation, and the other of multipolar appearance that resembles the VP-ir cells in the ventromedial BST nucleus and is present at more rostral levels of the MeA nucleus.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human CeAN

nucleus BDNF-ir fibers form a very dense plexus within which some BDNF-ir neuronal cell bodies can be distinguished.

Enzymes

ANGIOTENSIN CONVERTING ENZYME (ACE) According to Chai *et al.* (1990), the Ce nucleus in the human amygdala contains low binding levels for ACE as would also happen with other members of the CExA.

BUTYRYLCHOLINESTERASE (BuChE) It contains few BuChE-containing small to medium-sized fusiform neurons. Approximately 1% of the neuronal population of Ce expressed this enzyme (Darvesh *et al.*, 1998).

NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-d) The CeM division stains more intensely for NADPH-d than the CeL division, and there is a particularly intense staining for both the neuropil and the perikarya along the border with the BL and BM nuclei (Sims and Williams, 1990). In contrast, Brady *et al.* (1992) have stated that the NADPH-d–ir is minimal in the human Ce and squirrel monkey amygdala. These authors also described the existence of a pleomorphic population of NADPH-d-positive neurons that is divisible into two classes based on their staining characteristics: intensely or lightly stained neurons. In the macaque monkey, the Ce nucleus shows only a few NADPH-d-containing neurons and rather poor NADPH-d-containing fibers and neuropil (Pitkannen and Amaral, 1991b), which seems to concur with a similar finding in the squirrel monkey amygdala (Brady *et al.*, 1992).

Receptors

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988) the human Ce nucleus contains intermediate levels of BNZ-R.

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the central amygdaloid nucleus shows a high amount of [^{3}H]RAU binding sites, RAU being indicative of this type of receptor.

GALANIN RECEPTOR (GAL-R) According to Kohler and Chan Palay (1990), in the human amygdala primarily the Ce and MeA nuclei harbored significant amounts of specific [^{125}I]-galanin-R.

MUSCARINIC RECEPTOR (mACh-R) According to Cortés *et al.* (1987), there is an intermediate to low concentration of mACh-R in the human Ce nucleus which is of the m_1 type. On the other hand, according to Smiley *et al.* (1999), the amygdala as a whole contains a low density of mACh-ir neurons.

NICOTINIC RECEPTOR (nACh-R) Hybridization signals for the α_4 and β_2 subunits of this ionic excitatory receptor can be found in virtually all parts of the rat amygdala. However, the signals for these subunits in Ce are rather weak, while practically no signals can be found for the subunits α_2 and α_3 (Wada *et al.*, 1989).

STEROID RECEPTORS

Estrogen Receptor α (ER-α) According to Österlund *et al.* (1999), the central amygdaloid nucleus in human and monkey brains does not show any ER-α mRNA signal.

Estrogen Receptor β (ER-β) In the rat, areas that expressed the greatest density of ER-β-ir cells included, among others, the Ce nucleus, and it is highly probable that this receptor colocalizes with PAV-ir neurons present in it (Blurton-Jones and Tuszinski, 2002).

MU OPIOID RECEPTOR (ORμ) According to Mansour *et al.* (1988), the density of the opioid receptors in the monkey Ce is moderate with predominance of the mu type although some of them are of the delta type. Daunais *et al.* (2001) have reported that in the cynomolgus monkey by far the lowest concentrations of [^{3}H]DAMGO binding sites are found in the Ce where there is a uniformly low binding within the lateral and medial divisions of this nucleus regardless of the anterior–posterior level considered. Similar low levels of μ receptors in the Ce nucleus has also been observed in rhesus monkeys (Daunais and Porrino, unpublished observations). On the other hand, in striking contrast to very low levels of [^{3}H]DAMGO binding found in this nucleus, moderate levels of DAMGO-stimulated [^{35}S]GTPγS binding are found in it.

SEROTONINERGIC RECEPTOR (5-HT-R)

5-HT$_{2C}$ Receptor (5-HT$_{2C}$-R) According to Lopez-Gimenez *et al.* (2001), one of the strongest hybridization signals with probes for the 5-HT$_{2C}$-R that can be found in the basal forebrain is the Ce nucleus, which is one of the components of the extended amygdala.

The Medial Extended Amygdala (MExA)

The medial amygdaloid nucleus has been classically considered to be part of the superficial or olfactory group of amygdaloid nuclei (see Figs. 22.1c, 22.7a,b, 22.8, 22.11, 22.16, 22.16, 22.18, 22.23b, 22.24b, 22.25, 22.28). Today it is generally accepted that this nucleus

should be considered a part—a very important part indeed—of the "medial extended amygdala." The forebrain gray continuum which bridges this was once considered a superficial nucleus, with the deep located medial bed nucleus of the stria terminalis in the paraseptal telencephalon (de Olmos *et al.*, 1985; Alheid and Heimer, 1988; de Olmos, 1999; Martin *et al.*, 1991). Furthermore, because of its strategic position the medial amygdaloid nucleus receives, handles and transfers olfactory-related information (Meyer and Allison, 1949; Allison, 1954, Heimer *et al.*, 1977; Turner *et al.*, 1978; Price, 1990; Carmichael *et al.*, 1994), adding emotionally relevant olfactory information to the inputs that reach the medial caudal aspect of the shell of the accumbens nucleus, or the medial hypothalamus, among other important targets of medial amygdaloid nucleus efferent projections. As was briefly stated at the beginning of this introductory section, the concept of the extended amygdala implies that the bed nucleus of the stria terminalis and the centromedial nuclei of the amygdala are parts of a single structure whose continuity is maintained by more or less uninterrupted columns of neurons. The cellular bridges that do that extend dorsally among the fibers of the stria terminalis and ventrally through the posteroventral sectors of the so-called substantia innominata, accompanying the ventral amygdalofugal/ansa peduncularis pathway, a gray matter/fiber bridge that is termed in this account the medial sublenticular extended amygdala. Morphological evidence demonstrates that in the forebrain of humans and monkeys, similarly to what occurs in nonprimate macrosmatic mammals like the rat, there is a neuronal continuity between the BST and the amygdala (Mufson *et al.*, 1981, 1988; Amaral and Basset, 1989b; Lesur *et al.*, 1989; de Olmos, 1990; Martin *et al.*, 1991, Heimer *et al.*, 1999; etc.). However, the functional relevance of the amygdalosublenticulostrial continuum in primates remains under question, but by assuming that there is some analogy with other species, this complex griseum may play an important role regarding species-typical behaviors associated with reproduction, feeding, emotion, etc. In addition, the medial amygdaloid nucleus, together with its partners that form the medial extended amygdala continuum, may interact with the visceroendocrine and autonomic system by way of their reciprocal connections with hypothalamic and brain stem centers, but also with motor systems through its efferent projections to the ventral striatum and certain mesencephalic motor regions (Alheid *et al.*, 1995).

As has been done with the description of the central division of the extended amygdala, this section will start with the description of the paraseptal components of the MExA to be followed by that of the sublenticular and supracapsular bridges and, finally, its temporal lobe components. A reason for doing this is the fact that, as reported by Stephan and associates (Andy and Stephan, 1976, Stephan and Andy, 1977; Stephan *et al.*, 1987), the bed nucleus of the stria terminalis is a progressive structure in humans and nonhuman primates, whereas the medial amygdaloid nucleus seems to be a regressive griseum in the primate phylogeny and the central amygdaloid seems to have just maintained its morphological and functional properties without showing signs of regression or progression.

Paraseptal Components of the Medial Extended Amygdala The medial nucleus in rodents and other nonprimate macrosmatic mammals is considered to be not only a part but rather the main component of the "medial extended amygdala," i.e., the forebrain gray continuum that bridges the medial amygdaloid nucleus and medial bed nucleus of the stria terminalis (de Olmos *et al.*, 1985; Alheid and Heimer, 1988; de Olmos, 1999; Martin *et al.*, 1991). As such, the medial amygdaloid nucleus mediates olfactory-related information (Price, 1973; Turner *et al.*, 1978), adding emotionally relevant olfactory information to the inputs that reach the shell of the accumbens nucleus, one of the targets of the Me nucleus efferent projections. According to the concept of the extended amygdala, the BST and the centromedial nuclei of the amygdala are parts of a single structure whose continuity is maintained by more or less uninterrupted columns of neurons. The cellular bridges extend dorsally among the fibers of the stria terminalis and ventrally through the posteroventral sectors of the so-called substantia innominata, a bridge that in this account is termed the medial sublenticular extended amygdala. Morphological evidence demonstrates that in the forebrain of humans and monkeys, as in nonprimate mammals like the rat, there is neuronal continuity between the BST and the amygdala (Mufson *et al.*, 1988; Amaral and Basset, 1989b; de Olmos, 1990; Martin *et al.*, 1991; Heimer *et al.*, 1999, etc.). However, the functional relevance of the BST–amygdala continuum in primates remains largely speculative, but by analogy with other species (Kondo Y and Sachs BD.,2002) may be important in species-typical behaviors associated with reproduction, feeding, and so forth. The medial amygdaloid nucleus as the main member of the medial extended amygdala continuum interacts jointly with visceroendocrine and autonomic systems through its connections with hypothalamic and brain stem autonomic centers, and with motor systems through its connections with basal ganglia and mesencephalic motor regions (Alheid *et al.*, 1995).

Interestingly, in humans, amygdala lesions localized mainly in the medially situated nuclei blunt emotions but not fear (Narabayashi and Shima, 1980) and the posterior Me nucleus has been related mainly to sexual behaviors (Kondo Y and Sachs BD.,2002), but the relevance to primates is not clear. On the other hand, the medial amygdaloid nucleus, which is one of the amygdaloid nuclei richest in P450 aromatase, not only has intrinsic connections within the amygdala but also projects to several of the so-called limbic areas of the allocortical (paleo- and archicortex) and periallocortical types such as the piriform cortex, the hippocampal formation, and the entorhinal cortex, to the nucleus accumbens septi in the ventral striatum, and to the hypothalamus. Thus, locally formed estrogen may be able to regulate and influence many of the so-called limbic functions and related behaviors such as emotion processing, sexual and social behavior, memory, learning, and cognition. Finally, it should be pointed out that, although in subprimates like rodents and in New World squirrel monkeys sexually dimorphic differences in the neuronal composition of the medial amygdaloid nucleus has been reported (Nishizula and Arai, 1981, 1983; Mizukami *et al.*, 1983; Arimatsu *et al.*, 1981; Bubenik and Brown, 1973), very careful statistical analysis does not support the existence of such sexual dimorphism in the medial amygdaloid nucleus of humans (Murphy, 1986).

In the description that follows, each member of the medial extended amygdala will be thoroughly examined by taking into account only their cytoarchitectonic, fibroarchitectonic, and chemoarchitectonic properties, and reference to their afferent and/or efferent connections will be made only when they may contribute substantially to the understanding of the intrinsic cell organization of the concerned structures. By no means, the present writer is not ignoring the great importance of such hodological data; however, limitations of space have placed a limit on how far it is possible to go with the enormous amount of information that the writer has to handle in trying to be fair regarding the scientific contribution of fellow investigators in the field of the neuroanatomy.

But before dealing with further details concerning intrinsic anatomical and cytochemical organization of the medial extended amygdala, it is necessary to first describe the topographical relationship of the brain formation which hosts the paraseptal ends of both medial and central divisions of the extended amygdala, the bed nucleus of the stria terminalis.

Medial Division of the Bed Nucleus of the Stria Terminalis (BSTM) In the human brain this sector of the paraseptal region represents the rostral end of a intermitently interrupted ring-like gray continuum that is here termed the medial extended amygdala (MExA) [BSTM, BSTP, BSTPL in Plates/Figs.19–25 (–2.0–4.0 mm) of Mai *et al.* (1997), *Atlas of the Human Brain*; BST, BSTMA, BSTMP, BSTMPI, BSTMPM, BSTMPL in Plates/Figs.46–56 (interaural 20.10–15.60 mm) of Paxinos *et al.* (2000), *The Rhesus Monkey Brain in Stereotaxic Coordinates*. In this division it is possible to recognize two main subdivisions: anterior and posterior. This is in agreement with the neurogenetic findings of Bayer and Altmann (1987) in the rat.

The **anterior subdivision of the BSTM** (Figs. 22.17, 22.23, and 22.24b) [BSTM in plates 19 to 22 (-2.0-0,0mm) of Mai *et al.´s Atlas of the Human Brain*, 1997] in humans occupies a medial position in the supracommissural BST immediately ventral to the inferior angle of the lateral ventricle and ventromedial to the ventral expansion of the lamina cornea. At its rostral pole it is bounded by the lateral septal nucleus, while more caudally it is flanked by the postcommissural fornix, lying in the angle formed by this bundle and the decussating anterior commissure. Caudally, it is replaced by the more dense, small-celled medial subdivision of the posterior BSTM. In all preparations the anterior division of BSTM can be further divided into dorsolateral small-celled and ventromedial large-celled parts. While the lighter staining cells in the dorsolateral part tend to be oriented parallel to the incoming fibers of the stria terminalis, the more darkly staining cells in the ventromedial part show a more random arrangement. In addition, the dorsolateral part has a much richer content of glial cells than the ventromedial one. At times islands of granular (Sanides' gamma type 1) and parvicellular (Sanides' gamma type two) interface islands appear at the lateral boundary of the ventromedial subdivision of the anterior BSTM division.

In the human brain, like in other mammals, the **posterior division of the BSTM** (Figs. 22.16 and 22.18) [BSTP, BSTPL in plates 23 to 26 (1,3-5.4mm) of Mai *et al.´s Atlas of the Human Brain*, 1997] lies caudal to the decussating anterior commissure flanking the descending columns of the fornix, medially while being separated from the ventral thalamus by the stria medullaris thalami, caudally, and from the internal-capsule by posterior division of the BSTL, laterally. Caudoventrally, the BSTMP division becomes continuous with the medial preoptic region. Like its predecessor, the BSTM division can be further divided into three so to say vertically oriented cell ciolumns, medial small-celled, intermediate medium celled, and lateral large-celled subdivisions. **The small-celled medial subdivision** of the posterior BST (Figs. 22.16, 22.18, 22.23–22.25), as in other nonhuman primate and

nonprimate mammalian species (G. Alheid and J. S. de Olmos, unpublished observations; de Olmos *et al.*, 1985; Moga *et al.*, 1989); constitutes a comparatively narrow, dorsally to ventrally oriented cell column that makes its appearance at a transverse plane just behind the decussating anterior commissure and the medial-most coursing bundles within the main body of the stria terminalis. Dorsally, the medial aspect of the small-celled subdivision of the posterior medial BST is first bounded by the lateral ventricle and then flanked by fornix bundles ventrally. This column appears surrounded on all its other sides by the medium-celled intermediate portion of the posterior BSTM (Figs. 22.16, 22.18, 22.24, and 22.25). In Nissl preparations the medial subdivision of the posterior BSTM appears to be composed of small, relatively densely packed round to oval, well-staining neurons. Scattered among them can be observed larger triangular, darkly staining neurons. Ventrally, the medial posterior BSTM subdivision can be followed within the medial preoptic region without major modifications in its cell constitution, as can be judged from the Nissl material available for the author. Finally, thin and discontinuous aggregates of much larger and more darkly staining cells appear intercalated between this column and the immediately adjacent intermediate posterior BSTM subdivision.

The **medium celled intermediate subdivision** of the posterior BSTM (Figs. 22.16, 22.18, 22.24–22.25), like its small-celled medial neighbor (which it almost completely surrounds), constitutes a cell column that fills most of the postcommissural BST. In doing so it also extends more dorsally and ventrally than the small-celled medial column, while at the same time it compresses the larger celled lateral component of the posterior BST into a rather thin, broken lamina. Throughout the great part of its intradiencephalic course, this column lies just rostral to and adjoining the stria medullaris. At its ventral end, it separates from the stria medullaris, becoming rostral and ventral to the descending columns of the fornix, where it seems to merge with similar cell types belonging to the medial preoptic–anterior hypothalamic region.

The medium celled, intermediate subdivision of the posterior BSTM is composed of more loosely arranged and lightly staining medium-sized spindle and angular-shaped neurons. Although most neurons are seen with the thin larger axis oriented parallel to the incoming fibers of the stria terminalis, many additional types of neurons are oriented obliquely or perpendicularly to them. Furthermore, this subdivision of the posterior BSTM, in contrast with the medial ones, shows not only a lesser content of glial cell nuclei but undergoes modifications in the density of its neuronal population, which becomes greater in a ventral direction.

The large-celled lateral subdivision of the posterior BSTM (Figs. 22.16, 22.18, 22.24–22.25) in the human brain appears to be limited to the middle sectors (dorsoventrally) of the postcommissural BST. It is represented by a heterogeneous population of loosely arranged neurons, many of which are larger than the largest ones scattered in the other two subdivisions of the posterior BSTM but smaller than ectopic neurons of the MCBFC.

Chemoarchitectonics

CUPRIC SILVER STAIN (CU-AG) As it happens with its companions, the Me nucleus and the SLEAM, the BSTM division of the macaque, squirrel, or marmoset BST nucleus does not show a Cu-Ag staining pattern of the type present in all of the components of the central extended amygdala. However, like its temporal lobe counterpart, the Me nucleus (see below) contains isolated bipolar, slender, strongly argyrophilic neurons with a very scattered distribution. As will be discussed below for the Me nucleus, these neurons show a very similar morphological appearance to the LH-ir neurons and also coincide with them in their hypothalamic distribution.

HEAVY METALS In sections from squirrel monkey brain, the staining pattern in the BSTM division of the BST nucleus has a heterogeneous distribution (Fig. 22.23a, b; 22.24a, b; 22.25) showing at a same level areas of high precipitate and other of very low precipitate; however, with a tendency for the amall-celled medial subdivision to stain lighter than the medium-celled subdivision that surrounds it almost entirely though, as a whole, the density of the silver precipitate is lower than in the BSTLD subdivision of the paraseptal BST nucleus.

NEUROTRANSMITTERS

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) According to Heimer *et al.* (1999), most of the anterior and posterior division subsections of the medial division of the BST nucleus exhibit little AChE activity, especially dorsally (see Plates AChE 5-6 to 10, in Sakamoto *et al.*, 1999). In macaque brain (BST, BSTMA, BSTMP, BSTMI, BSTMPL) (Plates/Figs. 47, 49, 51, and 55 in Paxinos *et al.* (2000), *The Rhesus Monkey in Stereotaxic Coordinates* and in macaque monkey darkfield collection of low magnification microphotographic material put to my disposition by Drs. Heimer and Alheid, it is clear that the BSTM division in this nonhuman primate shows a lower density than the lateral one. Caudal patches of stronger AChE activity appear at the level of the medial subdivision (BSTMPm) of the posterior BSTM

division of the BST nucleus. It is also evident that the intermediate subdivision presents the lowest density of the three subdivisions identified in this posterior region of the BST nucleus.

Excitatory Amino Acids

GLUTAMATE/ASPARTATE (GLU/ASP) In the rat, injections of tritiated D-aspartate in the ventral pallidum caused the retrograde labeling of a moderate number of cells in the ventral subdivision of the BSTMA division of the BST nucleus and in the ventral sector of the lateral cell column of the BSTMP division of this nucleus (Fuller *et al.*, 1987). Furthermore, similar injections in the area of the paraventricular hypothalamic nucleus caused the retrograde labeling of neurons in the anterior (BSTMA) and ventral (BSTMV) subregions of the medial division of the BST nucleus (Csáki *et al.*, 2000). These results speak in favor of the existence of a subpopulation of glutamatergic neurons within this component of the medial extended amygdala. These data provide further support to the concept of the extended amygdala, as it can be inferred from the fact that in the same experiments Me nucleus also shows the presence of many [^{3}H]D-aspartate-labeled neurons, contributing this sector of the extended amygdala to the GLU/ASPergic innervation of pallidal and hypothalamic structures.

Inhibitory Amino Acids

γ-AMINOBUTYRIC ACID (GABA) Since in most regards the BSTM division of the bed nucleus of the stria terminalis as a component of the medial extended amygdala shares most of the chemoarchitectonic properties of its temporal lobe companion, the Me amygdaloid nucleus, one may be justified in extrapolating those properties to the BSTM.

Monoamine Markers

DOPAMINE-β-HYDROXYLASE (DBH) According to Gaspar *et al.* (1985), the human medial division of the BST contains abundant amounts of DBH-ir fibers. The terminal DBH-ir field in the BSTM division is continuous ventrally with that of the preoptic area and medially with that of the ventral lateral septal nucleus.

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew (*Tupaia belangeri*), HA-ir fibers collected in dense bundles are seen at the level of the BST nucleus where they distribute forming a very dense plexus that reaches the highest density. Their illustrations (Fig. 3F, G) suggest that the denser concentration of HA-ir fibers occurs in supra-, infra-, and postcommissural sectors of the medial division of the BST.

TYROSINE HYDROXYLASE (TH) According to Gaspar *et al.* (1985, 1987), the TH-ir innervation of the BST nucleus is complementary to that by DBH-ir fibers, with little if any for the medial sector, except for a patch of TH-ir fibers and terminals located near the wall of the lateral ventricle at the level of the decussation of the anterior commissure.

Neuropeptides

COCAINE- AND AMPHETAMINE-REGULATED TRANSCRIPT (CART) According to Hurd and Fagergreen (2000), the human BST nucleus shows a moderate CART mRNA expression. No statement is made about the specific localization of this peptide, nor it is possible to gather this information from the illustrations presented.

CHOLECYSTOKININ (CCK) Martin *et al.* (1991) were unable to detect CCK-ir cell bodies in the human BSTM, although some seem to be present in the baboon monkey. CCK-ir varicose fibers and puncta show moderate density.

CHROMOGRANIN B Although Marksteiner *et al.* (1999) include this division of the BST nucleus as displaying PE-11-like ir, no detail is added beyond this citation.

DYNORPHIN (DYN) According to Sukhov *et al.* (1995), in the human amygdala, a moderate amount of small preprodynorphin (PDYN) containing neurons arranged in peripheral islands accompany the main core of the nucleus as it traverses the rostrolateral hypothalamus toward the amygdala. However, their number is small.

ENKEPHALIN (ENK) According to Lesur *et al.* (1989), the ENK-ir innervation of the BSTM is unconspicuous, being made up of varicose fibers of a moderate density. In addition, this division of the BST nucleus does not contain ENK-ir perikarya, a fact that was confirmed by Martin *et al.* (1991). By contrast, after Shukov *et al.* (1995), in the human basal telencephalon, there is abundant preproenkephalin (PENK) containing neurons at the level of the BST. Their illustrations indicate that the majority are located dorsally, ventrally, and caudally to the crossing of the anterior commissure, corresponding to BSTMA, BSTMV, and BSTI subdivisions of the BST nucleus. However, according to Kaufmann *et al.* (1997), confirming in part Gaspar *et al.*'s (1985, 1987) observations, the human medial BST does not contain ENK-fibers. In the material examined by Heimer and associates (1999), the ENK-ir is modest or very light in the anterior subregion of the

BSTM division, a pattern that is not maintained posteriorly where it becomes quite heterogeneous.

GONADOTROPHIN-RELEASING HORMONE–ASSOCIATED PEPTIDE (GAP) According to Song *et al.* (1987), in macaque and baboons, a few round or fusiform bipolar GAP-ir cells are found in the BST nucleus together with a similar scarcity of GAP-ir fibers.

GALANIN (GAL) Martin *et al.* (1991) detected few GAL-ir somata in the BSTM division of the human BST nucleus, but GAL-ir beaded fibers and puncta appeared prominent. According to Kordower *et al.* (1992) in the cebus monkey, numerous GAL-ir perikarya are seen throughout the BST, with a preponderance of neurons in the anterior aspect of this nucleus. At this level the GAL-ir neurons are preferentially located in the medial (BSTMA), dorsolateral (BSTLD), and ventrolateral (BSTLV) subdivisions of the BST, as well as in the caudal temporal portion of the stria terminalis (BSTSl).

Mufson *et al.* (1993) reported that the GAL-ir profiles appeared as either thin beaded or thick coarse fibers within the BST of apes (gorilla, chimpanzee, and gibbons). In addition, a small number of GAL-positive parvicellular neurons could also be detected in this region, and GAL-ir fibers appeared to coalesce within the territory of the so-called substantia innominata to form a major GALergic pathway that travels through this region en route to the hypothalamus, bed nucleus of the stria terminalis, and vertical limb of the diagonal band just as it has been described in the human telencephalon (Mufson, 1993). Within the BST, the similar distribution patterns of cell bodies and fiber staining are evident.

NEUROKININ B (NKB) Small, oval to round NKB-containing neurons were numerous in the BST nucleus. Examination of the illustrations (Figs. 3A–C) presented by Chawla *et al.* (1997) reveals that most NKB-containing neurons appear to be concentrated more in the medial than in the lateral sectors of BST, and more predominant on supracommissural than in the infracommissural ones.

NEUROPEPTIDE Y (NPY) According to Gaspar *et al.* (1987), innervation by NPY is essentially restricted to the lateral BST nucleus although in close proximity to the pillar of the fornix. NPY-ir is apparent in a small field of axons and terminals. NPY-ir perikarya are almost exclusively located in the lateral BST nucleus. On the other hand, and although the BSTM division of the human BST nucleus is not specifically mentioned in Walter *et al.*'s (1990) mapping of the NPY-ir distribution in this epencephalic structure, their Fig. 1c shows that both supracommissural and infracommissural sectors of the BSTM division contain NPY-ir profiles.

By comparison, Bons *et al.* (1990) reported that in the BST nucleus of the microcebus murinus (primate, lemurian), NPY-ir axons form a dense plexus surrounding the anterior commissure and fornix. Apart from that, NPY-ir perikarya could be visualized especially near the border of the lateral ventricle (BSTM), which does not seem to be the case in humans.

NEUROTENSIN (NT) Martin *et al.* (1991) were unable to detect NT-ir cell bodies in the BSTM division of the human BST nucleus, but a few could be detected in the macaque monkey.

OXYTOCIN (OXT) According to Caffé *et al.* (1989), in the macaque monkey, the BST nucleus contains OXT-ir fibers although their presence is not as dense as that in the cortical nucleus. No mention is made about the presence of OTX-ir cell bodies, although in their schematic representation of the distribution of OXT-ir cell bodies in Fig. 2, cells of this type are depicted close to the fornix pillars in an area that may belong to the medial cell column of the BSTMP division. This does not seem to be the case in the BST nucleus of the common marmoset where scattered OXT-ir neurons are present in the medial subdivisions of the anterior and posterior divisions (Wang *et al.*, 1997).

SECRETONEURIN (SECR) According to Marksteiner *et al.* (1993) and Kaufmann *et al.* (1997), the BSTM division contains a high density of SECR-ir varicosities and varicose fibers, which sometimes form pericellular arrangements, but only scattered peridendritic woolly-like type 2 fibers. This picture does not seem to vary with sex or age.

SOMATOSTATIN (SOM) According to Gaspar *et al.* (1985, 1987), in the human BSTM division, SOM-ir fibers and cell bodies are more diversely distributed than in the lateral division. Bennet-Clarke and Joseph (1986) partially confirmed the previous report by describing that SOM-ir perikarya not only are scattered throughout the BST nucleus but also invade the bed nucleus of the anterior commissure that is adjacent to the ventral border of the commissure, and that SOM-ir processes are seen in every area of the BST nucleus containing SOM-ir perikarya. By contrast, Martin *et al.* (1991) were unable to detect SOM-ir cell bodies in the BSTM division of the human BST nucleus or in that of several nonhuman primates.

SUBSTANCE P (SP) Martin *et al.* (1991) traced a continuum of SP-ir puncta and varicose fibers to the

BSTMA subdivision of the human BST nucleus, also detecting a few SP-ir cell bodies. Kaufmann *et al.* (1997), confirmed these findings but also stressed that the BSTM division as a whole contained only moderate densities of SP-ir when compared to the very high levels of SECR-ir present there. Heimer and associates' (Heimer *et al.*, 1999; Sakamoto *et al.*, 1999) human material shows that, while the SP-ir in the posterior sub-region of the BSTM division is somewhat heterogeneous, these SP-ir gradually increases in strength in the anterior part of the medial bed nucleus [see Plates SP5–SP9 in Sakamoto *et al.* (1999)].

VASOPRESSIN (VP) According to Fliers *et al.* (1986), in the human BST nucleus, few bipolar VP-ir cells can be identified, but not so in its amygdaloid companion, the Me nucleus. After their results, the bipolar VP-ir cells located in the rostral BST nucleus appear to be smaller than those of the magnocellular supraoptic and paraventricular hypothalamic nuclei. However, on more caudal levels, many VP-ir neurons can be found that show magnocellular features. Interestingly, the highest incidence of VP-ir fibers in the limbic system is found in the BST and BAC nuclei, but also in a very reduced number of telencephalic nuclei. Finally, there is no evidence of sex differences concerning the richness of the VP-ir innervation.

Caffé *et al.* (1989), working with macaque monkey brains, reported the existence in their BST nucleus of a VP-ir innervation pattern that seems to represent an extension from that present in the preoptic area, although with an increased density in the former. In addition, a very dense plexus of thick, highly varicose VP fibers appears to be confined to what they call the "BST nucleus proper," a well-defined cell aggregation located in the supracommissural part of the BST nucleus. Very probably this cell group corresponds to the BSTLD subnucleus of the present parcellation. Furthermore, they could determine that these types of VP-ir fibers are also found ventral to the anterior commissure corresponding most probably in location to the BSTLV subnucleus.

Medially to their BST nucleus proper and just adjacent to the lateral ventricle, a few ovoid bipolar VP-ir neurons could be identified (i.e., in the area corresponding to the medial subdivision of the BSTMP division). In addition, a moderate number of multipolar VP-ir cells exhibiting many short dendrites are also found in the ventromedial part of BST (i.e., the BSTMV subdivision).

On the other hand, Wang *et al.* (1997) studying the common marmoset (*Callithrix jacchus*) found a distribution pattern of VP-ir fibers and cells that closely imitated the distribution pattern of VIP-ir cells reported for the human brain, i.e., with VP-ir somata that remain confined to the supracommissural sector of both anterior and posterior subregions of the BSTM division, and with no VP-ir cell present in the Me nucleus. However, at variance with the human pattern, the subpopulation of VP-ir neurons presents in this animal dimorphic differences with respect to the number of VP-ir cells in the male versus the female BST.

VASOINTESTINAL PEPTIDE (VIP) According to Martin *et al.* (1991), in nonhuman primates, such as the macaque monkey among others examined, VIP-ir puncta and varicose fibers that are present in the dorsomedial nucleus accumbens extend caudally to merge with a similar disposition in the BSTMA subregion (their BSTA) and in the bed nucleus of the anterior commissure (BAC). No evidence for the existence of VIP-ir cell bodies in the BSTM division was found.

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human BST nucleus, BDNF-ir fibers form a dense and strongly ir plexus where several nonstained neuronal cell bodies are completely enveloped by BDNF-ir terminals boutons and fibers. Isolated BDNF-ir neurons are rarely found in a region localized between the ventricular wall, the caudate nucleus, and the septum/BST region. It is a problem that the presented illustration (Fig. 3G) corresponds only to a sector within the BSTMA subnucleus according to the present parcellation of the EXA. Also from their Fig.3A it can be inferred that both supra- and infracommissural regions of the medial BSTM division of the BST nucleus contain BDNF-ir.

ENZYMES

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey, the BST nucleus contains P450 AROM with the heaviest labelling occurring in the medial anterior (BSTMA) and medial posterior (BSTMP) BST subnuclei, areas that have strong reciprocal connections with the hypothalamus and amygdala. Even though these authors reported scattered labelling in the substantia innominata, these data also speak in favor of the existence of a medial extended amygdala, since the Me nucleus also contains high concentrations of this enzyme.

CALCIUM-BINDING PROTEINS Since there is a paucity of data in the literature concerning the distribution of these types of proteins in the human or monkey BST nucleus, and since immunohistochemical information

from my own laboratory indicates that the rat BST nucleus presents staining patterns for these proteins that closely match that seen in the rat central and medial amygdaloid nuclei, these data will be given here to provide an approximate picture of what can happen in this nucleus in primates.

CALRETININ (CR) Examination of rat material processed immunohistochemically for the demonstration of this calcium-binding protein reveals a significant presence of a subpopulation of CR-ir neurons enmeshed in a dense CR-ir neuropil in both anterior and ventral subdivisions of the BSTMA subdivision of the BST nucleus as well as the intermediate medium-celled column of the BSTMP subdivision of this nucleus. This information acquires relevance when considering that in the rat both anterodorsal and anteroventral subnucleus of the Me nucleus contains an equally significant subpopulation of CR-ir neurons and that in experiments carried out in rats utilizing a double-labeling procedure (Krzywkowski *et al.*, 1995) it has been possible to determine that CR-ir neurons of both components of the medial extended amygdala send projections to the ventromedial hypothalamic nucleus. Such results fit very well to the theory of the extended amygdala.

RECEPTORS

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), there is a high concentration of mACh-R in the human BST nucleus. However, from their illustrations (Fig. 5A, B) it can be inferred that the densest activity takes place in the BSTLD and JCX subnuclei of the BSTL while lower labeling occurs at the level of the BSTM.

GLUTAMATE IONOTROPIC RECEPTOR (GLUR) According to Ginsberg *et al.* (1995), in the macaque monkey, the BSTM contains a high density of GluR2/3-ir neurons and a lower density of GluR1-ir neurons but expresses minimal GluR4 immunoreactivity.

ANDROGEN RECEPTOR (AR) According to two groups of researchers (Resko *et al.*, 2000; Roselli *et al.*, 2001), in the adult male macaque monkey, only moderate amounts of neurons expressing AR mRNAs appear to be present in the BSTMA and BSTMP. In contrast, these sectors of the BST appear to contain very high densities of strongly labeled aromatase-containing neurons. This distribution and labeling pattern coincides with those reported for the other end of the MExA, the Me nucleus. By contrast, a few aromatase-containing cells and no AR containing cells could be detected in the SLEA.

OXYTOCIN RECEPTOR (OT-R) Although Loup *et al.* (1991) made no mention of the presence of OT-R in the medial division of the BST nucleus, their Fig. 5 shows heavy OT binding in a sector of the human paraseptal region that, despite being considered to represent a dorsal part of the lateral septal nucleus (which they label as LSD), by all present criteria for the organization of the human basal telencephalon, should be assigned as the BSTMA division of the BST nucleus [see corresponding level in Plate/Fig. 22 of Mai *et al.*, 1997 *Atlas*]. It deserves to be mentioned that Wilson *et al.* (1999) found in rats that whereas the OT binding density is lower in the Me nucleus and in the BSTMA than in CExA representatives, the excitatory response to OT was greater in these representatives of the MExA than in the CExA. Nevertheless, what is important for the hypothesis of the EXA is that the relative expression of OT binding sites and the patterns of response reflect these associations within the extended amygdala.

STEROID RECEPTORS

ESTROGENIC RECEPTOR (ER)

Estrogen Receptor α (ER-α) According to Österlund *et al.* (2000), the medial division of the BST nucleus shows low ER-α mRNA in human and monkey brain.

Medial Division of the Sublenticular Extended Amygdala (SLEAM) This medial component of the SLEA extends from the BSTMPL, passing into the ventral sectors of the so-called sublenticular SI and eventually fusing with the superficial division of AAA rostrally and Me caudally. The cells that form this more ventral column, despite sharing most of the cytological characteristics seen in more dorsal sectors of the SLEA, show a rounder shape, in some parts arc-like. Coursing through the so-called substantia innominata, some ectopic elements detached from neighboring basal telencephalic structures and invade this structure, partly modifying its cytoarchitectonic characteristics.

Although the medial nucleus of the amygdala (Me) is cytologically similar to the medial division of the bed nucleus of the stria terminalis, the sublenticular cell bridges that connect them are by no means clearly identifiable in Nissl preparations. Some help is provided by the fact that this division of the sublenticular extended amygdala, like both the medial amygdaloid nucleus and the posterior division of the bed nucleus with which the medial sublenticular is continuous, are richer in their glial cell population than the representatives of the central sublenticular limb of the extended amygdala. Other neighboring neuronal populations not related to either continuum also share this cytoarchitectonic trait. The same can be said concerning

the morphological features of the cells that form this continuum: lightly staining, medium to small sized, slender, generally fusiform, and preferentially roughly transverse orientation of their cell body long axis. This allows us to distinguish them from the large, strongly staining cells that form the magnocellular gray complex of the basal telencephalon whose main representative is the basal nucleus of Meynert. SLEAM is not clearly distinguishable from its companion central limb of the SLEA or from other similar-looking cells belonging to other nearby gray formations, such as those in the ventral pallidum rostrally or the lateral preoptic region medially. Adhering to this difficulties is the fact that the region where this continuum extends is traversed by numerous fiber systems that disrupt the continuum into islands of varying size. This may also occur because of their adaptation to many variations in position and physical compression they undergo during early stages of their ontogenetic development. Although not all of these factors in the rat play this negative role as in higher mammals for the identification of the medial continuum, even in this relatively simple brain dissection of this component does not come easily. It is only with the help of a histochemical procedure such as the Timm-Dansher staining for heavy metals or the experimental application of retrograde tracing procedures that it has been possible to unravel the existence of this continuum (de Olmos *et al.*, 1985; Grover *et al.*, 1988a, b); neither procedure can be applied to the study of the human SLEA. At this point it should be pointed out that Martin *et al.* (1991) rightly emphasized that immunohistochemical procedures that were well suited for the demonstration of the SLEACn division did help in the delineation of the medial continuum (their anteroventral and posteroventral SLSI). However, as has been reported by Heimer *et al.* (1999), human brain sections stained for both CCK and NT (see their Figs. 27A, B) provide evidence of partly interrupted NT-ir/SOM-ir sublenticular columns close to the ventral brain surface. Another good marker of this medial continuum is the antibody for the demonstration of secretoneurin (Marksteiner *et al.*, 1993; Kaufmann *et al.*, 1997; Heimer *et al.*, 1999). This antibody was demonstrated to be very useful in immunostaining the extended amygdala in the sense that it labels both its central and medial divisions while leaving practically unstained the rest of the amygdaloid nuclei. However, it presents the disadvantage of also labeling the ventromedial parts of the striopallidal system, especially in places of the basal epencephalon where these adjoin the extended amygdala. However, the fact remains that both ends of the medial extended continuum, the BSTM division of the BST nucleus and the Me amygdaloid nuclei, are densely SECR-ir labeled (for a more detailed discussion, see Heimer *et al.*, 1999).

As here defined SLEAM corresponds to the Martin *et al.* (1991) and Kaufman *et al.* (1997) anteroventral subdivision (SIav) of their sublenticular BST, while their posteroventral subdivision corresponds to the amygdaloid sector or temporal end of the MExA, i.e., the superficial division of the AAA or the anterior division of the Me nucleus. Freedman and Shi (2001), on the basis of their immunohistochemical tracing of the monaminergic innervation of the extended amygdala, concluded that the ventral part of the substantia innominata (here the SLEAM division) appears similar to the medial subnucleus of the Ce nucleus, though stressing the greater density of the AChE staining in the formerly cited component of the EXA. As in the case of the SLEACn, this apparently greater heterogeneity of the SLEAM may be due to a similar interdigitation with elements detached form the main core of non-EXA telencephalic structures.

Chemoarchitecture

CUPRIC SILVER (CU–AG) Like the other members of the medial extended amygdala, the SLEAM does not show the Cu-Ag staining pattern that is present along the extent of the central extended amygdala, nor it has been possible to detect isolated argyrophilic cells of the type sometimes present in the Me nucleus or the BSTM division of the BST nucleus.

HEAVY METALS In sections stained by the Timm-Danscher method (Danscher, 1981) for heavy metals obtained from squirrel or marmoset brain, close examination reveals that the pattern of silver precipitate in the sublenticular region has two expressions. One of these is in the form of a dorsal, very dense column of thick silver selenite precipitate that detaches clearly from the dorsomedial aspect of the Ce nucleus. This column can be followed just ventral to the globus pallidus and internal capsule until it joins an equally densely stained region in the lateral posterior and ventral subdivisions of the BST nucleus. Another more or less compact and densely stained column apparently departs from the dorsomedial aspect of the Me amygdaloid nucleus and superficial AAA area to extend medially and dorsally until it reaches a comparatively similar weak-stained region in the lateroventral aspect of the posterolateral subdivision of the medial BST nucleus.

NEUROTRANSMITTERS

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) In the macaque brain [EA Plates/Figs. 51 and 55 in Paxinos *et al.* (2000),

The Rhesus Monkey in Stereotaxic Coordinates], and in macaque monkey darkfield collection of low-magnification microphotographic material generously provided to the author by Drs. Heimer and Alheid, it is clear that this sector of the monkey basal telencephalon shows a lower AChE activity than surrounding structures.

CHOLINE ACETYLTRANSFERASE (ChAT) No human or nonhuman primate data are available about the presence or absence of this enzyme in this sector of the SLEA.

EXCITATORY AMINO ACIDS

GLUTAMATE (GLU) No human or nonhuman primate data are available about the presence or not of this neurotransmitter in this sector of the SLEA; however, it is justifiable to assume that this sector of the SLEAM might imitate its representative in the temporal lobe, i.e., the Me nucleus, in containing subpopulation of GABA-ir neurons and its corresponding GABA-ir neuropil.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) No data available for the author from the literature are cited.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Freedman and Shi (2001), there are moderate amounts of DBH-ir fibers in the ventral part of the so-called substantia innominata (here, SLEAM).

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew the HA-ir fibers spread in the amygdaloid complex as a dense network including in this manner the SLEAM (see their Fig. 3G).

NEUROPEPTIDES

CORTICOTROPIN-RELEASING FACTOR (CRF) In the human amygdaloid complex, a dense accumulation of CRF-ir fibers, with large varicosities and terminals, has been reported to be present in almost all amygdaloid nuclei (Power *et al.*, 1987; Zaphiropoulos *et al.*, 1991). This statement may be extensible to the substantia innominata and more particular to this division, according to the mapping made for this region by Zaphiropolous *et al.* (1991).

CHOLECYTOKININ (CCK) Although according to Martin *et al.* (1991), the data provided by their human and nonhuman primate material did not provide evidence for a participation of CCK-ir neurons. Heimer *et al.* (1997), in contrast, found unmistakable evidence for the existence CCK-ir fibers and terminals in this region of the human extended amygdala continuum.

ENKEPHALIN (ENK) According to Martin *et al.* (1991), the data provided by their human and nonhuman primate material did not provide evidences for a participation of ENK-ir neurons or ENK-ir fibers and terminals in this part of the extended amygdala continuum.

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992) in the cebus monkey amygdala, this member of the MExA, like the other amygdaloid components of it, would not contain GAL-ir cell bodies, though it may contain small amounts of GAL-ir fibers. Instead, this pattern is shown to change dramatically toward the paraseptal expansion of the posteroventral continuum, i.e., the present SLEAM.

NEUROKININ B (NKB) Small to round NKB mRNA-containing neurons are numerous in the BST, which contrasts with the small number of SP-ir cells present there. NKB mRNA is also identifiable in small neurons scattered from the BST to the amygdala. These NKB neurons are occasionally seen aligned in small groups along fiber bundles (Chawla *et al.*, 1997).

NEUROTENSIN (NT) According to Heimer *et al.* (1999) evidence for the existence of the SLEAm is provided by partly interrupted sublenticular columns close to the ventral brain surface. This NT-ir islands contain NT-ir fibers and terminals as well as the typical medium-sized fusiform neuronal cell bodies that are part of a string of NT-ir islands that rostromedially form a continuous arch in apparent continuity with the posterolateral part of the BSTM division of the bed nucleus of the stria terminalis.

SECRETONEURIN (SECR) According to Kaufmann *et al.* (1997), in the human brain, their anteroventral and posteroventral parts of the so-called substantia innominata (here SLEAM) exhibit SECR-ir although such activity resided mainly in varicose fibers, not participating in the type of axonal peridendritic formation sometimes called woolly fibers.

SOMATOSTATIN (SOM) According to Martin *et al.* (1991), the data provided by their human and nonhuman primate material did not provide evidence for a participation of SOM-ir neurons or SOM-ir fibers and terminals in this part of the extended amygdala continuum.

SUBSTANCE P (SP) According to Martin *et al.* (1991), the data provided by their human and nonhuman primate material did not provide evidence for a participation of SP-ir neurons or SP-ir fibers and terminals in this part of the extended amygdala continuum.

VASOPRESSIN (VP) According to Caffé *et al.* (1989) in the macaque monkey, there is moderate innervation by thick varicose and thin beaded fibers. These fibers form a continuum with those in the BST nucleus and the amygdala.

ENZYMES

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, scattered cells containing P450 AROM mRNA could be detected at the level of the substantia innominata.

CALCIUM-BINDING PROTEINS

CALRETININ (CR) In rat material processed in my laboratory for the immunostaining of this calcium-binding protein, it is possible to see that columns of CR-ir neurons and neuropil bridge sublenticularly the anterodorsal subdivision of the Me nucleus with the intermediate subdivision of the BSTMP division of the BST nucleus. Since in the human brain the medial amygdaloid nucleus shows, as will be described below, a rich CR-ir neuronal population that is enmeshed in a very dense CR-ir network of fibers and terminals, it is justifiable to assume that a CR-ir medial continuum of neurons and fibers is present in the human brain.

OTHER PROTEINS

SEROTONIN TRANSPORTER (SERT) According to Freedman and Shi (2001), in the macaque ventral substantia innominata (here SLEAM), there are moderate to high amounts of SerT-ir fibers. Unlike serotonin labeling, fibers as varicosities are well defined and tend not to have much diffuse background labeling.

RECEPTORS

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), there is an intermediate to low concentration of mACh-R in the so-called substantia innominata in the human telencephalon, which is of the m_1 subtype.

SEROTONINERGIC RECEPTORS (5-HT-R)

5-HT_{2C} RECEPTOR (5-HT_{2C}-R) According to Lopez-Gimenez *et al.* (2001), the sublenticular extended amygdala constitutes one of the forebrain structures showing the strongest hybridization signal with probes for 5-HT_{2C}-R mRNA.

STEROID RECEPTORS

ANDROGENIC RECEPTOR (AR) Although not mentioned in a report about testosterone action in the brain of the female macaque brains by Rees *et al.* (1986), their mapping (Fig. 1 A–D) indicates that at least this division of SLEA contains scattered [^{3}H]testosterone-labeled nuclei.

ESTROGENIC RECEPTORS (ER)

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), both in human and monkey brains, the ER-α transcript is widely distributed in neurons of the amygdala but predominantly in the more medial nuclei throughout the entire rostral to caudal continuum of the amygdaloid complex.

The Temporal Lobe Components of the Medial Extended Amygdala

Medial Amygdaloid Nucleus (Me)

Topographical Landmarks The medial amygdaloid nucleus (see Figs. 22.1c,d, 22.7, 22.8, 22.22c, 22.23b, 22.28, 22.29) [Me in Plates 26–33 (5.4–14.6 mm) of Mai *et al.* (1997), *Atlas of the Human Brain*; and Me in Plates/Figs. 49–65 (interaural 18.75–11.55 mm) in Paxinos *et al.* (2000) *The Rhesus Monkey Brain in Stereotaxic Coordinates*], which is continuous dorsomedially with the caudal superficial AAA, is an elongated mass of gray matter located in the superficial portion of the dorsomedial amygdala stretching throughout the caudal two-thirds of the amygdaloid complex. In coronally cut sections passing through the level of its main body, the Me nucleus shows a crescent-like shape whereas in sagittal sections cut along its main longitudinal axis, the nucleus appears as a very regular columnar formation. At its rostral one-third, the Me nucleus is located adjacent to the notch formed by the entorhinal sulcus, but near its caudal pole Me occupies only the ventral bank of this sulcus and eventually is displaced from that position by the amygdalohippocampal transition area (AHi) that wedges between this gray formation and the medial division of Ce. Along its extent Me borders ventrally, in successive sequence, with the caudal superior subdivision of the ventral cortical nucleus (CSpVCo) and the rostrodorsal pole of the posteromedial division of the amygdalohippocampal area (PM AHi); dorsolaterally, the narrow extension of the deep AAA wedges between Me and the medial division of Ce. Throughout most of its rostral to caudal extent Me is filled by a relatively dense stratum of fibers forming Brockhaus' (1938) intermediate central fiber masses (icm), which surround the nucleus dorsally, laterally, and, partly, ventrally. At its rostral pole this fiber system fades out coincidentally with the replacement of the Me nucleus by the ACo nucleus. Rostrally and ventrally, a small, round neuronal

griseum, probably representing the caudal-most end of the ventral subdivision of the ACo nucleus or the posterior part of the so-called nucleus of the lateral olfactory tract of some authors, intervenes between the Me nucleus and the superior subdivision of the VCo.

Cytoarchitectonics As with other superficial amygdaloid grisea, there is a tendency for the neurons of the Me nucleus to form layers, especially superficially, allowing the identification of a cell-poor molecular layer (L1), a superficial dense cell layer (L2), and a deep layer (L3) with somewhat less densely distributed neurons. On the basis of purely morphological criteria the Me can be divided into two major divisions: anterior (MeA) and posterior (MeP). The MeP division, in turn, can be further divided into dorsal (D MeP) and ventral subnuclei (V MeP). The MeA nucleus borders rostrally with the ACo nucleus, the superficial amygdaloid griseum which it replaces caudally until it is replaced by the dorsal subdivision of the MeP subnucleus. The latter stretches until it reaches the onset of the extra-amygdaloid portion of the stria terminalis at the posterior end of the amygdala. It is the V MeP subnucleus that is separated from the amygdalohippocampal transition area by a capsule of fibers detached from the medial medullary lamina whose density varies but that always intervenes between these two gray formations.

The MeA division (see Figs. 22.7 and 22.8), in contrast with MeP, still shows a rather wide molecular layer (L1) although not as wide as that in ACo. As in this latter nucleus, it is invaded, though in a very scattered fashion, by small, slender neurons of varying conformation and stainability. Deep to the molecular layer, the main cell layers, superficial (L2) and deep (L3), are clearly segregated from L1 and form a relatively homogeneous cell mass, although the neurons located in the superficial two-thirds show a tendency to lie more closely packed. Furthermore, the more deeply lying cells tend to be slightly larger and more darkly stained than the more superficially located ones. The neuronal population in the MeA division is rather heterogeneous being made up of pyramidal, multiangular, round, and spindle-shaped cells of different sizes, but still smaller than those in the neighboring Sp VCo, and more compactly and regularly arranged than those in AAA. The MeA can be differentiated from the rostral immediate neighbor, the ACo, by the greater cell density of L2, and a concomitant rarefaction of its deeper lying neuronal population as well as by the narrowing of its L1.

In the MeP division, its ventral subdivision (V MeP) occupies the most dorsal segment of the ventral bank of the entorhinal sulcus shortly before the optic tract meets its now narrow fundus. It is constituted by a rather narrow cell aggregate encapsulated ventromedially and laterally by the fiber septum which branches off from the intermediate caudomedial fiber masses (icm) described by Brockhaus (1938). It shows a well-defined superficial cell layer (L2) composed of medium-sized, darkly staining neurons that in more caudal sectors of the V MeP subnucleus tend to become more densely arranged toward the deep aspect of this griseum. The deep layer (L3) in the V MeP is even more densely populated and narrower than L2, containing a more darkly staining neuronal somata displaying no particular orientation. Finally, the deep aspect of the molecular layer (L1) of the V MeP appears invaded by small cells showing the same distribution pattern and general morphological features as those in L1 of the MeA division.

Dorsally the V MeP subnucleus merges with its dorsal counterpart (D MeP). This subnucleus lies for most of its extent immediately adjacent to the optic tract's lateroventral facet, intercalated between the V MeP subnucleus and the Sf AA. It contains a more homogeneous neuronal population of slightly larger, more densely packed, and darker staining neurons than the V MeP subnucleus. Its superficial cell layer (L2) contains slender radially oriented, oval to spindle-shaped neurons more densely packed than those in L3. The latter contains a more heterogeneous population of darkly staining neurons showing no particular orientation. Finally,the D MeP possess a richer glial population than its ventral counterpart.

No less important than the cell composition and arrangement as a means of delineating the different components of this member of the MEXA is its fibroarchitectonic arrangement. Thus, the MeA division shows a moderately rich plexus of randomly oriented myelinated fibers that become denser in its more superficial layers. This pattern changes dramatically at the level of the MeP division. Here the density of the myelinated fiber plexus increases sharply in both subnuclei of the MeP division but showing variations regarding its predominant orientation. Consequently, whereas the plexus of myelinated fibers in the D MeP subnucleus is dominated by transversely coursing fibers, the medullated fiber plexus in the PV subnucleus is made up of more randomly oriented fibers with some predominance of ventrodorsally coursing fibers radiating from the Brockhaus (1938) ism fiber masses. Furthermore, the presence of short bundles of densely myelinated fibers intercalated between the superficial cell layer an the lateral margin of the optic tract also marks the difference between both subnuclei of the MeP division. Corroborating the above-described myeloarchitectonic arrangement, neurofibrillar preparations

display a similar arrangement but with a far denser disposition.

As pointed out by Heimer *et al.* (1999), although the heterogeneous population of small to medium-sized, relatively lightly stained neurons and a significant number of glial cells in the Me is reminiscent of the situation in parts of the BSTM, it is not yet possible to closely correlate the various parts of the Me nucleus and the BSTM on the basis of cytoarchitectonics alone. Furthermore, the generally weak reaction for AChE, and ENK added to the stronger reaction for SP is consistent with the overall concept of the MExA, which is based in the premise of a general correspondence between the Me nucleus and the BSTM. As will be seen below, even more convincing evidence supporting the above-mentioned premise comes from the examination of human material stained for CCK, NT, and SECR.

Chemoarchitectonics

HEAVY METALS In sections of both squirrel and marmoset monkeys stained with the Timm-Danscher method, the medial amygdaloid nucleus shows a heterogeneous pattern of staining that varies both in the dorsoventral axis of the nucleus and in the anteroposterior one. As a whole, the density of the silver selenide deposits in this nucleus is significantly lower than in its ventral neighbor, the VCo nucleus, or its more laterally located component of the central extended amygdala, the Ce nucleus.

CUPRIC SILVER STAIN (CU-AG) In Cu-Ag-stained sections of macaque and squirrel monkeys brain the Me nucleus does not show an argyrophilic staining pattern like that obtainable in all members of the central extended amygdala. However, in the squirrel monkey material it was possible to detect the presence of isolated bipolar granular argyrophilic neurons of fusiform shape, with very slender perikarya that appear scattered along the medial surface and in the whole extent of the Me, ACo nuclei, and the superficial division of the AAA area, oriented mostly parallel to the brain surface. Neurons of the same morphological characteristics could be detected at the level of the BSTM division. Interestingly, argyrophilic neurons with exactly the same appearance as those just described are also present in the subfornical organ, the organum vasculosum laminae terminalis, the medial preoptic area, the infundibular arcuate nucleus, the ventral premammillary nucleus, and even the area of the interpeduncular nucleus just behind the mammillary bodies. On some occasions it was possible to follow one of their very thin processes for some distance. If one looks for similar images, the closest are those presented by LH-RH-ir neurons.

NEUROTRANSMITTERS AND NEUROMODULATORS

Cholinergic Markers

ACETYLCHOLINESTERASE (AChE) Me contains a lightly AChE stained neuropil and a few isolated AChE-containing neurons (Darvesh *et al.*, 1998; Sorvari *et al.*, 1995; Heimer *et al.*, 1999). Amaral and Basset (1989) have shown that in the macaque monkey the Me nucleus together with the ACo nucleus contains the lowest density of AChE-positive fibers. In contrast with these low levels of AChE activity, both nuclei, but more particularly the Me nucleus, contain large numbers of AChE positive neurons.

CHOLINE ACETYLTRANSFERASE (ChAT) According to Emre *et al.* (1993), the Me nucleus in humans has the lowest density of ChAT-ir profiles of all amygdaloid nuclei. Only a few ChAT-ir varicose axons are present in this nucleus. In agreement with this, Amaral and Basset (1989) found that in the macaque monkey amygdala, the medial amygdaloid nucleus can be distinguished by its extremely low ChAT-ir fibers and terminals, yielding in this nucleus the lowest density of this type of fiber in any amygdaloid areas.

Excitatory Amino Acids

GLUTAMATE (GLU/ASP) Retrograde tracing experiments made in rats using tritiated D-aspartate indicate that a considerable number of Me neurons, mostly the anterodorsal division, are a source of GLU/ASPergic projections to both the laterocaudal ventral striatum (IPAC?) and the ventral pallidum (Fuller *et al.*, 1987), as well as to the paraventricular hypothalamic nucleus or immediate surroundings (Csáki *et al.*, 2000).

Inhibitory Amino Acids

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Augustine (1993), in the macaque monkey the Me nucleus, despite containing some GABA-ir neurons, mostly contains non-ir neurons. Pitkännen and Amaral (1994) consider that in this nucleus the distribution pattern of the GABA-ir is very similar to that of the ACo nucleus and, therefore, confirmed the McDonald and Augustine data concerning the low numbers of GABA-ir cells present in Me. However, they found that the density of GAD mRNA-labeled neurons is very high. At anterior levels the cells are preferentially located in the superficial portion of L2 and in the deep portion of L3. In the caudal portions of the Me the labeled cells are more homogeneously distributed throughout L2 and L3.

The neuropil GABA-ir levels are among the highest in the monkey amygdaloid complex. Pericellular baskets in L2 are more prominent than in the ACo

nucleus. Finally, a bundle of dense GABA-ir fibers lies located immediately lateral to this nucleus.

Monoamine Markers

DOPAMINE-β-HYDROXYLASE (DBH) According to Freedman and Shi (2001), in the macaque monkey there are moderate amounts of DBH in the Me. In the squirrel monkey, the Me nucleus (plus ACo) shows moderate to dense DBH-ir at its caudal portion (the Me nucleus proper), but the DBH-ir becomes much lighter at its rostral-most portion (the ACo nucleus) (Sadikot and Parent, 1990).

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew (*Tupaia belangeri*), HA-ir fibers collected in dense bundles along the stria terminalis continue to the amygdaloid complex to spread as a dense and diffusely distributed network within the amygdala. At the level of the Me nucleus this network reaches a high density (4 in a scale of 0–5).

SEROTONIN (5-HT) According to Freedman and Shi (2001), in the macaque monkey, there are moderate amounts of 5-HT-ir in the Me nucleus. In the squirrel monkey, the Me nucleus shows light 5-HT-ir terminal labeling (Sadikot and Parent, 1990).

TYROSINE HYDROXYLASE (TH) According to Freedman and Shi (2001), there are moderate concentrations of TH-ir fibers in the rostral part of the Me nucleus. In the squirrel monkey, the TH-ir terminal labeling is light to absent in the Me nucleus (Sadikot and Parent, 1990).

Neuropeptides

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human amygdala, BDNF-ir neurons and fibers are present in all amygdaloid nuclei. No specific data are given concerning Me.

CHROMOGRANIN B According to Marksteiner *et al.* (1999), in the human brain, the Me nucleus displays a moderate density of PE-11-like ir. However, from their illustrations it seems that the most caudal part of the Me nucleus according the present parcellation contains a high density of this neuropeptide. Such ir is exclusively due to fibers and neuropil but not to cell bodies since only the Ce nucleus within the whole amygdaloid complex would contain them.

COCAINE- AND AMPHETAMINE-REGULATED TRANSCRIPT (CART) According to Hurd and Fagergren (2000), the highest CART mRNA expression can be found in the Me nucleus.

CORTICOTROPIN-RELEASING FACTOR (CRF) In the human amygdaloid complex a dense accumulation of CRF-ir fibers, with large varicosities, and terminals can be found in almost all amygdaloid nuclei. This finding, together with the fact that the bed nucleus of the stria terminalis and the sublenticular substantia innominata (here SLEA) contain a high density of CRF-containing fibers and terminals (Zaphiropoulos *et al.*, 1991), speaks in favor of the existence of a similar distribution pattern in Me.

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992), in the macaque monkey amygdala, this member of the superficial amygdala, like its other components, does not contain GAL-ir cell bodies but seems to contain at least a small number GAL-ir fibers.

GONADOTROPHIN-RELEASING HORMONE–ASSOCIATED PEPTIDE (GAP) According to Song *et al.* (1987), in macaque and baboon, a few GAP-ir fibers can be detected in the Me A nucleus.

LUTEINIZING HORMONE–RELEASING FACTOR (LHRF) According to Silverman *et al.* (1982), in the brain of macaque monkeys, a group of LHRF-ir round perikarya showing a short segment of their processes are situated in the Me nucleus. However, these cells seem to be rare.

NEUROPEPTIDE Y (NPY) According to McDonald *et al.* (1995), in the macaque monkey the highest densities of NPY-ir neurons are found in the Me nucleus. It is interesting that large globular uni- or multipolar NPY-ir neurons are also present in the Me nucleus of the lemur microcebus marinus (Bons *et al.*, 1990).

NEUROTENSIN (NT) Mai *et al.* (1987) stated that the Me nucleus together with the cortical nucleus and the so-called supra-amygdaloid areas (i.e., the Ce and AAA nuclei) contain the strongest accumulation of NT-ir fibers. This statement was confirmed by Benzing *et al.* (1992), who found that the Me nucleus contains a dense NT-ir that is distributed evenly across the anteroposterior extent of the nucleus. Most of the NT-ir is confined to dot-like puncta although many fine- and a few coarse-beaded fibers are present. In addition to the NT-ir fibers, numerous darkly stained bipolar neurons are distributed throughout the nucleus, but they are preferentially located in the deep (lateral) portions of the nucleus. As can be inferred from the illustrations and mapping of the amygdaloid nuclei presented by these authors, their anterior amygdaloid area (Fig. 1, AAA) not only comprises the AAA as here

defined but also the ACo, while their mapping of the medial amygdaloid nucleus (Fig. 1, Me) coincides approximately with the Me nucleus as defined here. It is interesting to point out differences in the density of the NT-ir shown between AAA and their Me (Figs. 3C and 4C, respectively), with the AAA stained least of the subnuclei of the centromedial group. Furthermore, according to Heimer *et al.* (1999), the NT-ir fibers and terminals intermingle with NT-ir perikarya and form a continuous column from the Me nucleus through the AAA and further medially to the NT-ir islands in the sublenticular region of the basal forebrain.

OXYTOCIN (OXT) According to Fliers *et al.* (1986), in the human Me nucleus, very few OXT-ir fibers and no OXT-ir cells are present. No mention of the presence of this type of fiber in the macaque Me nucleus is made by Caffé *et al.* (1989), while, according to Wang *et al.* (1997), in the common marmoset monkey amygdala a few OXT-ir cells are present in the dorsal aspect of the Me nucleus. In this latter animal, no sex difference seems to exist concerning the number of OXT-ir cells or the density of the OXT-ir innervation.

SOMATOSTATIN (SOM) In the macaque monkey the Me nucleus has been described as containing one of the most dense plexuses of SOM-ir fibers and terminals distributed throughout all layers of the nucleus, clearly demarcating the limits of the nucleus. The nucleus also contains numerous SOM-ir cells located in both the compact layer II and the more loosely organized layer III. The SOM-ir cells tend to be small, round, and similar in appearance to those located in ACo (Amaral *et al.*, 1989). In the squirrel monkey amygdala, Desjardins and Parent (1992) were able to detect SOM-ir beaded fibers coursing along the lateral side of the optic tract before reaching the Me nucleus, where they also found a very dense SOM-ir plexus. No SOM-ir-labeled cell bodies could be found in this nucleus. They also call attention to the fact that the ventral pallidum and other pallidal structures in this New World monkey are almost entirely devoid of SOM-ir.

SUBSTANCE P (SP) According to Bouras *et al.* (1986), in the human amygdaloid complex few medium-sized SP-ir cells can be seen in its dorsomedial sectors, particularly in the medial nucleus.

VASOPRESSIN (VP) According to Sofroniev *et al.* (1981), in several primate species, including humans, it is possible to trace VP-ir fibers that run laterally over the optic tract from their source in the medial hypothalamus—presumably from VP-ir neurons in the suprachiasmatic nucleus—to the Me nucleus, which appears densely innervated. By contrast, Fliers *et al.* (1986) found few VP-ir fibers and no VP-ir cells in the human Me nucleus. In harmony with this, in the common marmoset monkey, no VP-ir fibers or cells are present in the Me nucleus (Wang *et al.*, 1997).

ENZYMES

ANGIOTENSIN-CONVERTING ENZYME (ACE) Like other members of the superficial amygdala, the Me nucleus shows low labeling levels for this enzyme, sharing this rather negative attribute with the stria terminalis and its bed (Chai *et al.*, 1990). This contrasts markedly with high binding levels shown by every division of the pallidum, a structure with which some authors have proposed the Me should be compared.

BUTYRYLCHOLINESTERASE (BUCHE) The Me nucleus contains a few small to medium-sized triangular BuChE-positive neurons. Processes of some of these cells were also stained. Approximately 5% of the neurons were BuChE-positive and were found predominantly in the medial portion of the nucleus (Darvesh *et al.*, 1998). There was a slightly stained AChE-positive neuropil in this nucleus, with only isolated AChE-positive neurons.

NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) Except for the AAA, a dense network of NADPH-d-ir fibers has been reported to be present throughout the remaining amygdaloid nuclei, conjointly with a rather homogeneous distribution of NADPH-d-ir cells. According to Brady *et al.* (1992), the Me nucleus shows a moderate NADPH-d activity in both human and squirrel monkey amygdala. Furthermore, these cells are said to be similar in all subregions, and there is an almost complete overlap between NADPH-d and SOM- or NPY-containing neurons (Unger and Lange, 1992).

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, the Me nucleus contains a very high density of P450 AROM mRNA-labeled cells. Examination of their illustrations (Fig. 5) would indicate a strong labeling in the rostral amygdala (Fig. 5A), which corresponds to both dorsal and ventral subdivisions of ACo of the present parcellation.

P450 AROM mRNA expression has been found to be extensively distributed throughout the extended amygdala in the primate brain. In particular, P450 AROM mRNA is concentrated in the ventral division (the present MExA) composed of the medial components of BST, the ventral SI (the present SLEAM), and Me, where lower densities of AR-containing cells have been detected. The relative abundance of P450 AROM mRNA compared with ARE mRNA within this circuitry

in nonhuman primates suggests that the aromatization pathway plays a major role in mediating testosterone actions on BST and amygdala neurons. Furthermore, the expression of P450 AROM, ARE, as well as ER mRNA (Österlund *et al.*, 2000) has been reported to be low in the primate amygdala areas related to fear. The highest levels of P450 AROM, were detected in the BM, posteromedial AHi, and posterior Me. Estrogen receptor mRNA was reported to be abundant in all of these regions (Österlund *et al.*, 2000), whereas ARE mRNA expression was found predominantly in the If VCo.

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), like the D ACo nucleus, the Me nucleus shows a high density of CAB-ir neurons in layer 2 and also in layer 3 (Fig. 3). However, layer 1, contained only a few neurons. At the caudal level, lamination of the CAB-ir neurons became less obvious. All three morphological cell types described by these authors are found in the Me nucleus, with the majority of the neurons being of the medium-sized type 2 cells. As in the D ACo nucleus, there were small, lightly stained cells in which only the proximal portions of the dendrites can be followed. The staining of the fibers and neuropil is similar in intensity to that in the D ACo nucleus.

The highest intensity of fibers and neuropil staining occurs in layer 2, followed by layer 3. The intense neuropil staining helped Sorvari *et al.* (1996b) to distinguish the Me nucleus from the neighboring nuclei, such as from the BM and PM AHi. As in the D ACo nucleus, no CAB-ir bundles of fibers can be observed in this nucleus.

CALRETININ (CR) According to Sorvari *et al.* (1996a), the Me nucleus contains considerablely fewer CR-ir cells than the D ACo nucleus. However, as in the D ACo nucleus, these cells are small and darkly staining, displaying all of the features of their type 1 cells with only the proximal part of their dendrites being stained. More lightly stained cells can be found scattered among the very darkly staining neuropil. The CR-ir in the Me nucleus is considerably higher than in the surrounding areas such as the BM nucleus and the PM AHi.

PARVALBUMIN (PAV) The human Me nucleus contains only a few small PAV-ir neurons with no visible dendrites or only short ones. Cells can be found mainly in layers 2 and 3. Furthermore, the density of PAV-ir fibers and terminals is very low, being distributed diffusely in all three layers. No basket-like or cartridges are found here (Sorvari *et al.*, 1995).

OTHER PROTEINS

DOPAMINE- AND ADENOSINE 3′,5′-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-L) According to Barbas *et al.* (1998), in the macaque monkey, the Me nucleus contains very few lightly stained DARPP-32-ir and I-l-ir neurons.

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, the caudal half of the medial amygdaloid nucleus, i.e., the Me nucleus of the present account, is weakly LAMP-ir. This is particularly obvious in the most superficial aspect of the nucleus.

PALLADIN (PALL) In the Me nucleus the pattern of distribution of the Pall-ir puncta is similar to that observed in the striatum (Hwang *et al.*, 2001). Most of the palladin was colocalized (60%), with synaptophysin in puncta distributed throughout the nucleus. It should be stressed that the Pall expression in the globus pallidus is one of the weakest in the forebrain, which contrasts with its very dense concentration in the Me nucleus, where it reaches the same level as that in the striatum. This protein is predominantly present in the excitatory synapses and is consistently present in glutamatergic ones (Hwang *et al.*, 2001).

SEROTONIN TRANSPORTER (SERT) According to Freedman and Shi (2001), in the macaque monkey moderate to heavy amounts of SerT-ir fibers are present in the Me nucleus.

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low-magnification atlas on the distribution of this protein in the macaque brain published by Petrides *et al.* (2000), it is evident that the Me nucleus is practically devoid of SMI32-ir. This is in marked contrast to the high labeling occurring in the ventral pallidum, a structure with which this Me nucleus has been proposed as equivalent.

RECEPTORS

ADRENERGIC RECEPTORS

ADRENORECEPTOR α_1 According to Flügge *et al.* (1994), in the tree shrew, the medial nucleus show moderate levels of [^{3}H]PRA binding, an α-adrenoreceptor antagonist indicative of the presence of this type of adrenoreceptors.

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the central nucleus shows a high density of [^{3}H]RAU binding sites, RAU being indicative of the presence of this type of receptor.

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988), the Me nucleus contains intermediate levels of BNZ-R.

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTORS (MACH-R) According to Cortés *et al.* (1987), the human Me nucleus presents one of the lowest concentrations of mACh-R. On the other hand, according to Smiley *et al.* (1999), the amygdala as a whole contains a low density of m_2-ir neurons.

SEROTONINERGIC RECEPTORS (5-HT-R)

5-HT_{1A} RECEPTOR (5-HT_{1A}-R) According to Flügge *et al.* (1994), in the tree shrew, the Me nucleus is faintly labeled by [^{3}H]DPAT, a specific agonist of the 5-HT_{1A}-R.

5-HT_{2C} RECEPTOR ($5HT_{2C}$-R) According to Lopez-Gimenez *et al.* (2001), one of the strongest hybridization signals with probes for the 5-HT_{2C}-R can be found in the basal forebrain of the Me nucleus, one of the components of the extended amygdala. It is interesting to point out that the pallidal grisea show no signal for this receptor.

STEROID RECEPTORS

ANDROGEN RECEPTOR (AR) In contrast with its high density of aromatase-containing neurons, the number of neurons AR mRNA containing neurons is modest (Roselli *et al.*, 2001).

ESTROGENIC RECEPTORS

Estrogen Receptor α (ER-α) According to Österlund *et al.* (1999), both in humans and in monkeys, the Me nucleus displays low ER-α mRNA but still compares well with the lack of this type of hybridization signal in the globus pallidus. It should be pointed out that the medial division of the bed nucleus of the stria terminalis, like the Me nucleus, shows low ER-α mRNA.

Estrogen Receptor β (ER-β) In the rat brain, areas that express the greatest density of ER-β-ir cells include, among others, the Me nucleus. Occasional ER-β/PAV-ir cells could be detected in this nucleus (Blurton-Jones and Tuszinski, 2002).

Anterior Amygdaloid Area (AAA)

Topographical Landmarks [AA in Plates/Figs. 23–27 (1.3–6.7 mm) of Mai *et al.* (1997), *Atlas of the Human Brain*]

According to the ontogenetic and phylogenetic literature so far available with respect to the basal forebrain territory bearing this name in the brains of nonprimate mammals, the AAA of the higher primates would be represented by the ill-defined area located at the cephalic pole of the amygdala, which, according to Crosby and Humphrey (1941), has differentiated into specific nuclear masses. As such, this territory comprises the heterogeneous transitional griseum that at the level of the rostral and rostrodorsal aspects of the amygdala fills the space lying just lateral and caudal to the horizontal limb of the anterior commissure. The griseum stretches caudomedially to the preamygdalar endopiriform nucleus (En) so as to even reach levels close to the exit of the stria terminalis where it is partly replaced by the Ce and the Me amygdaloid nuclei (see Figs. 22.1d, 22.4–22.11). For much of its rostrocaudal extent, it occupies the dorsal lip and superior part of the fundus of the sulcus hemisphericus (endorhinal sulcus), but it also fills the space intervening between the superficial nuclei of the amygdala (ACo and Me), the amygdaloclaustral transition area (ACA), and the medial division of Ce, successively.

Cytoarchitectonics The AAA, as in other mammals, can be divided into superficial (Figs. 22.4–22.7 and 22.10) (ventral) and deep (dorsal) parts or sectors. The superficial AAA is characterized by the presence in its molecular layer of a rich population of glial cells and a well-defined subpial granular layer, as well as the presence, in the inner half of this layer, of a scattered population of small, multiangular neurons. The feature is also found further caudally at the level of the ACo and allows individualization from other superficially lying structures. The cell layer proper shows no stratification and is composed of superficially, mostly lightly stained, spindle-shaped neurons mixed with many fewer large triangular neurons. This latter type of neuron becomes more numerous toward the depth of the AAA where the superficial sector blends gradually with the deep one. Medially and dorsally the AAA becomes continuous with cell corridors of the medial SLEA.

Fibroarchitectonics Apart from stretching for a longer distance than its superficial counterpart, the main characteristic of the deep AAA is the richness of the fiber network present in it, which is formed by a mixture of both fibers of passage and intrinsic axons. Embedded in this dense network lies a morphologically heterogeneous neuronal population in which, again, predominates cells of small and medium size but with a greater presence of bigger and more chromophilic multiangular neurons. However, these latter cells do not share the morphological characteristics of the nearby magnocellular grisea like the basal nucleus of Meynert (BC). All of these typifying features can be better appreciated in nonsuppressive silver-stained sections where the density of the fiber plexus found

in the AAA is not matched by that in any other amygdaloid structure. This observation is confirmed by computer-based semiquantitative densitometric analysis of amygdaloid tissue treated in this manner. Such fiber arrangements, added to the fact that even the biggest neurons in the AAA do not match the size or deep stainability of the neurons composing the so-called preamygdalar endopiriform nucleus (En), or of those making up the ACA, or their greater cell compactness, greatly contribute to differentiating AAA from both of them.

Golgi-Stained Sections At this point it should be stressed that in Golgi studies in the cat brain by Hall (1972) and Kamal and Tömbol (1975), the amygdaloid region that in this mammal shares most of the morphological features that have been applied here for defining the human AAA was found to contain a neuronal pool composed mainly by small or medium-sized projecting neurons displaying ovoid, fusiform, or multiangular perikarya that were provided with three to six richly arborized primary dendrites endowed with a moderate number of dendritic spines, with one of them giving origin to a long projecting axon. In the cat, as in other mammalian species, AAA also contains, but in lesser number, large triangular or multiangular neurons provided with beaded irregular dendritic trees and possessing long projecting axons. According to Kamal and Tömböl, these neurons appeared scattered in the superior half of the AAA. On the basis of their material these authors also described the presence in the cat AAA of fusiform cells typical of what they called the substantia innominata, as well as the existence of small neurons of the Golgi type I resembling those found in La and the so-called cortical amygdala (Hall, 1972). On the other hand, McDonald (1992) working with Golgi impregnated section of rat amygdala, arrived at the conclusion that the medium sized cells in the deep AAA, the substantia innominata (here SLEA), the Me, and the medial subdivision of Ce are similar.

The above description of AAA coincides with that given by Croby and Humphrey (1940), de Olmos (1990), Barbas and de Olmos (1990), Sims and Williams (1990), Benzing *et al.* (1992), Mai *et al.* (1997), and Heimer *et al.* (1999) for the human brain, and with the accounts or mappings of AAA in the monkey brain by Lauer (1945) and by Paxinos *et al.* (2000). Benzing *et al.* (1992), on the other hand, includes as part of AAA the amygdaloid region that here is considered to represent ACo nucleus. Furthermore, there is also a close correspondence of the present account with that reported by Brockhaus (1938) for his area perisupra-amygdalae dorsalis (psAd) and, by the same token, with that of the Koikegamis collaborators (Mikami, 1952a, b; Sasagawa, 1960a, b) on studies done on the brains of humans, chimpanzees, macaques, and New World monkeys. However, it should be pointed out that many of the authors who have described the AAA in humans or in monkeys do not concur with the above definition. While some of them consider that the preamygdalar endopiriform nucleus should be included in or simply homologized with AAA (Gloor, 1997, for humans; J imenez Castellanos, 1949 for the macaque monkey), others confine AAA to a well circumscribed griseum made up of darkly stained neurons that are somewhat smaller and paler than those in the endopiriform nucleus or in the neighboring claustrum [Sorvari *et al.* (1995, 1996) in humans; Amaral and Basset (1989), Amaral *et al.* (1992), and Pitkänen and Amaral (1993) in macaque monkeys]. The mappings and descriptions of their putative anterior amygdaloid area coincide almost entirely with what is here called the ACA (see Heimer *et al.*, 1999 for further details).

Chemoarchitectonics Because of the existing differences in terminology, it is far from clear to which point some of the histochemical and immunohistochemical findings reported by some authors concerning what they define as AAA can be applied to the amygdaloid territory defined here as such. Therefore, they will only be cited to the extent that, through examination of the illustrations presented, they seem to fit the morphological and topographical parameters that guide the present account.

HEAVY METALS/ZINC In Timm Na/selenite–stained section through the squirrel monkey brain, AAA shows homogeneous moderate to weak granular silver deposits that contrast markedly with their virtual absence in the neighboring interstitial nuclei of the horizontal limb of the diagonal band of Broca (HDB) or of the Meynert CB. This staining seems to be continuous with similarly dense silver deposits found along the cell corridors that form medial SLEA. However, it should be stressed that the density of the silver deposits are very weak in comparison with those occurring along the CExA or at both expanded ends (Me and BSTM) of the MexA. The AAA silver deposits probably are representative of terminal boutons belonging to axons coming from more caudally located zinc-rich glutamatergic neuronal somata. Similar observations could also be made in brains of Tamarin monkeys (Heimer *et al.*, 1999).

NEUROTRANSMITTERS

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) According to the present author´ own material, this region is rather

poor in AChE activity, with AAA showing a weaker content of this enzyme than Dp AAA, a result that coincides with those reported by other authors (Svendsen and Bird, 1985; Simms and Williams, 1990; Benzing *et al.*, 1992).Weak AChE activity can be detected in the perikarya of spindle-shaped neurons that are oriented parallel to the brain surface at the level of AAsf, while a stronger reactivity can be seen in some much larger, polymorphic neurons that probably represent ectopic elements of the BC.

CHOLINE ACETYLTRANSFERAE (CHAT) In the human brain the AAA seems to contain only a moderate to low level of ChAT-ir fibers (Emre *et al.*, 1993). ChAT stained a section of the macaque brain (Amaral and Basset, 1989), i.e., an area corresponding approximately to what Barbas and de Olmos (1990) describe as the AAA.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey, the AAA area displays very light and moderate DBH-ir.

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey, the AAA area shows a light density of 5-HT-ir terminals.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey, the classical AAA area displays a light density of terminal TH-ir varicosities, with preterminal fibers of passage seen en route to temporal lobe areas rostral and lateral to the amygdala.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Augustine (1993), in the macaque monkey, the AAA area would contain a subpopulation of GABA-ir neurons that varies in size and shape. Most cells are ovoid and the neuropil exhibits moderate levels of GABA-ir.

NEUROPEPTIDES

CHOLECYSTOKININ (CCK) Heimer *et al.*'s (1999) examination of the immunostained material for the demonstration of CCK shows quite clearly that AAA not only displays a moderate to heavy CCK-ir in its neuropil but also contains a few scattered CCK-ir neurons. At present it is not possible to establish if these neurons only provide for the local CCK innervation or if they also participate in the CCK pathway that courses medially toward the preoptic-hypothalamic region [see Heimer *et al.*'s (1999) Fig. 27A].

CHROMOGRANIN B Although not mentioned by Marksteiner *et al.* (1999), examination of their illustrations (Fig. 3b and c) shows that the human AAA area (not recognized as such in their Fig. 3B) contains moderate PE-11-like ir.

CORTICOTROPIN-RELEASING FACTOR (CRF) In the human amygdaloid complex, a dense accumulation of CRF-ir fibers, with large varicosities, and terminals has been reported in almost all amygdaloid nuclei (Power *et al.*, 1987; Zaphiropoulos *et al.*, 1991).

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992), in the macaque monkey amygdala, this member of the superficial amygdala, like its other components, does not contain GAL-ir cell bodies but seems to contain at least a small amount GAL-ir fibers.

NEUROTENSIN (NT) NT-immunoreactive cell bodies have been reported to be located in the transition area between the amygdaloid body proper and the supra-amygdaloid region of the human brain, including in this manner the region defined here as AAA. They are randomly scattered throughout the AAA and they are predominantly multipolar in shape although bipolar and unipolar neurons were observed as well. This transition area also contains one of the strongest accumulations of NT-ir fibers and these are continuous with those located in the substriatal claustrum, the lentiform peduncle, and the sublenticular region of the substantia innominata. However, the density of the NT-ir fiber plexus at the level of AAA, though greater than in some of its neighbors (i.e., the endopiriform, basolateral, and lateral nuclei), was less than in the centromedial group ((Mai *et al.*, 1987; Benzing *et al.*, 1992). Material available to me confirms these observations (see Heimer *et al.*, 1999). The AAA contains a light matrix of NT-ir fine-beaded fibers, dot-like puncta, and a small number of NT-ir neurons.

SECRETONEURIN (SECR) As illustrated by Heimer *et al.* (1999) [Figs. 28A] this rostral representative of the SLEAM show in human a strong SECR-ir which is higher in its superficial division. Such ir is a high as in the Me nucleus but lesser than that in the neighbor Ce nucleus. In the Tamarin monkey a similar picture can be appreciated [Fig. 20B, C and D of Heimer *et al.*, 1999].

SOMATOSTATIN (SOM) According to Mufson *et al.* (1988), in the human amygdala, the AAA area contains SOM-ir perikarya. On the basis of the illustrations

(Figs. 2A–F) presented by Amaral *et al.* (1989) on the distribution of SOM-ir in the macaque monkey amygdala, it seems that after the present parcellation is considered to represent the AAA area, containing high amounts of this neuropeptide though in lesser concentration than its neighboring ACo, MeA, and ACA nuclei. On the same basis it seems that the superficial sector of the AAA area contains higher amount of SOM-ir than the deep one this is particularly marked in the more caudal sectors of this amygdaloid undifferentiated area, where SOM-ir radiations seem to have as target the hypothalamic region.

SUBSTANCE P (SP) According Mai *et al.* (1986), SP-ir fibers could be followed along the ventral amygdalofugal pathway, and a band of punctate SP-ir within the sublenticular areas could be followed up to the supra- and periamygdaloid regions, including the AAA.

ENZYMES

ANGIOTENSIN-CONVERTING ENZYME (ACE) According to Chai *et al.* (1990), the AAA area displays low binding levels for this enzyme.

NICOTINAMIDE ADENINE NUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) The human AAA shows no or at most a rather poor NADPH-d immunoreactivity. (Sims and Williams, 1990; Unger and Lange, 1992).

CALCIUM-BINDING PROTEINS

CALRETININ (CR) According to Sorvari *et al.* (1996), mapping of the CR-containing neurons in the human amygdala (see their Figs. 1B, 2B, 3, 4B, and 5), AAA, i.e., the field covered by black points that has been depicted outside the line-encircled amygdaloid nuclei, seems to contain a lower density of this type of cell than its immediate neighbors, the ACo and MeA nuclei, but an equivalent concentration to that depicted for the CeM division of the Ce nucleus. Furthermore, although they did not label the sector they assigned to their version of the AAA area, they claimed that this sector contained a high amount of lightly stained CR-ir cells.

PARVALBUMIN(PAV) In the immunohistochemical maps of PAV-containing neurons built for the human amygdala by Sorvari *et al.* (1995; Figs. 1B, 3B, 5B), as in the case of those reconstructed by Pitkänen and Amaral (1993; Figs. 3A) for the macaque monkey amygdala, it is apparent that the density of the PAV-ir cells in AAA area, as here defined, matches quite closely that found in other two members of the EXA, the MeA nucleus and the CeM division of the Ce nucleus. This subpopulation of GABA-producing inhibitory cells has a rather poor representation in this part of the amygdala. By contrast with this pattern, the PAV-ir neuropil in the AAA area appears to be better developed, particularly in the more rostral aspects of this undifferentiated territory.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human brain, all of the amygdaloid nuclei contain BDNF-ir neurons and fibers. However, from their Fig. 4A it is possible to infer that the density of the BDNF-ir is moderate in the AAA area as compared with that of the inferior subdivision of the VCo nucleus or that of the Ce nucleus, whereas it is comparable to that of the ACo nucleus according to the present parcellation of the amygdaloid complex in humans.

OTHER PROTEINS

DOPAMINE- AND ADENOSINE-3,5-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-L) According to Barbas *et al.* (1998), in the macaque monkey, very few DARP-32-ir or I-1-ir neurons can be found in the AAA area.

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, the AAA area is devoid of LAMP-ir.

NEUROFILAMENT PROTEIN SMI32 (SMI32) In the macaque brain, this region does not seem to contain any SMI32-ir (Petrides *et al.*, 2000), going along with what occurs with other members of the MExA.

RECEPTORS

ADRENERGIC RECEPTORS

ADRENORECEPTOR α_1 According to Flügge *et al.* (1994), in the tree shrew, the AAA area shows moderate levels of [^{3}H]PRA binding, an α-adrenoreceptor antagonist indicative of the presence of this type of adrenoreceptor.

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the AAA area has a low number of [^{3}H]RAU binding sites, RAU being indicative of this type of receptor.

CHOLECYSTOKININ RECEPTOR (CCK-R) According to Kritzer *et al.* (1988), in contrast with the rest of the superficially located amygdaloid grisea, the AAA area of the macaque monkey shows minimal CCK binding.

μ OPIOID RECEPTOR (ORμ) According to Daunais *et al.* (2001), low to moderate concentrations of [^{3}H]DAMGO binding sites could be measured in the AAA area. Furthermore, the distribution of mu-stimulated [^{35}S]GTPγS binding also corresponds to the anatomical distribution of [^{3}H]DAMGO sites in the AAA area.

SEROTONIN RECEPTORS

5-HT$_{1A}$ RECEPTOR (5-HT$_{1A}$-R) According to Flügge *et al.* (1994), in the tree shrew, the ventral part of the AAA area is moderately labeled by [^{3}H]DPAT, a specific agonist of the 5-HT$_{1A}$-R.

STEROID RECEPTORS

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), in the human and monkey AAA area, no ER-α mRNA hybridization signal can be detected.

Superficial Cortical-like Secondary Olfactory Amygdala

In a detailed review of the rat amygdaloid gray complex, de Olmos *et al.* (1985) pointed out that the most characteristic feature of the "olfactory" nuclear group of the amygdala is that each member receives direct input not only from the mitral cells in the main olfactory bulb but from the whole primary olfactory cortex (including the prepiriform cortex, or eupaleocortex, and anterior olfactory or transitional entorhinal periarchicortex). In addition to the above olfactory projections, the olfactory amygdala receives important input from the interstitial nucleus of the horizontal limb of the diagonal band, a well-established source of cholinergic and GABA-ergic projections, the locus coeruleus (norepinephrine), and the raphe nuclei (serotonin). On the other hand, efferent projections from the olfactory amygdala reach back to the primary olfactory cortex and the fundus striati.

Within the amygdaloid complex itself, the olfactory amygdala, either into or though some of its members, projects heavily to MExA or CExA while it restricts its projections to the most ventral member of the LBNC, the ventral basolateral amygdaloid nucleus, which may be the homolog of the amygdaloclaustral transition area (ACA) of the nonhuman primate amygdala. On these grounds the olfactory amygdala could relay olfactory information to all these gray formations. With this in mind, it should be stressed that although many of the structures listed above may undergo regressive changes during the phylogenetic evolution leading to humans, some others seem to have remained unchanged and still others have even undergone some progression (Andy and Stephan, 1976; Stephan, 1975; Stephan and Andy, 1977; Stephan *et al.*, 1987).

As previously done by Alheid *et al.* (1995) for the rat amygdala, the term "cortical-like" is applied here for heuristic reasons and does not imply a strict equivalence with cortical structures. Even so, this subject is controversial and may need more attention than can be provided here. However, until this subject is fully resolved, what deserves consideration is the fact that, at least in the rat, for most of the "olfactory" superficial amygdaloid nuclei the earliest cells that appear developmentally are in the most superficial layers (Bayer, 1980b). This is in contrast to the prepiriform cortex, and the cortex in general, in which deep layers develop first, with superficial layer developing later (Angevine, 1965; Sidman and Angevine, 1961; Bayer, 1980, 1986). For this reason it has been argued that the "olfactory" amygdaloid nuclei should be considered subcortical zones**.** It is in this context that the term ventral cortical nucleus (VCo) was used by us in previous chapters about the human (de Olmos 1990, Heimer *et al.*, 1999) and macaque monkey (Barbas and de Olmos, 1990) amygdala, i.e., for the amygdaloid superficial structures identified as the "periamygdaloid cortex" in the amygdala of rats, monkeys, and humans by Price and coworkers (Krettek and Price, 1977; Price *et al.*, 1987; Amaral *et al.*, 1989; 1992; Pitkänen and Amaral, 1991-1994; Sorvari *et al.*, 1996–1998). In this context it may have especial meaning, concerning the existence of the so-called nucleus of the lateral olfactory tract in primates. In the rat, a macrosmatic animal in which the existence of such a nucleus is accepted without discussion, the cells in this structure follow a deep to superficial developmental sequence (Bayer, 1980) typical of cortical areas.

In a previous chapter on the human amygdala (de Olmos, 1990), the present writer applied to the human amygdala the same classificatory criterion used for the rat brain (de Olmos *et al.*, 1985). That is to say, the anterior amygdaloid area, the anterior, ventral, and posterior cortical amygdaloid nuclei, together with the amygdalopiriform transition area were grouped together as belonging to the olfactory amygdala. Although a nucleus of the lateral olfactory tract was included as part of that group, its existence as such was firmly questioned. For that reason, and in spite of controversy, in this chapter the cell group identified as such by other authors will be taken into account only when needed and always in the context of the ventral cortical nucleus parcellation. Furthermore, because connectional information derived from non primate mammals would favor the existence intimate hodological relationships between the amygdalohippocampal area on one side and the proper olfactory amygdaloid nuclei, as well as with primary olfactory cortex, on the other, it seems appropiate to incorporate

this superficial transitional cortical-like gray formation to the superficial cortical-like group of nuclei and therefore described in the same section. Furthermore, since histochemical information has become available that reinforces the arguments put against the existence of a so-called 'posterior cortical amygdaloid nucleus' in the caudal part of the superficial amygdala by Heimer and colleagues, and since that evidence suggests its inclusion as part of the amygdalohippocampal transition area, in the section that follows the description of the olfactory amygdaloid nuclei, the above-mentioned cells groups will not be recognized as entities by their own. On the other hand, as it has been already discussed in the section concerned with the medial extended amygdala, there are convincing histochemical, immunohistochemical, morphofunctional, and behavioral data for viewing the anterior amygdaloid area and the medial amygdaloid nucleus as temporal end of the medial extended amygdala. Since there is no clear evidence that both structures receive afferents from the olfactory bulb (for a thorough discussion, see Heimer *et al.*, 1999), these two anatomical entities will be treated together with the other members of this gray continuum.

Anterior Cortical Amygdaloid Nucleus (ACo)

Topographical Landmarks The ACo nucleus (Figs. 22.3–5, 22.6a, 22.7a, and 22.8) is located in the rostral half of the amygdala bordering the piriform cortex (Pir) rostrally, the Me nucleus caudally, and the superior subdivision of the VCo nucleus ventrally, from which it is separated by a superficial extension of the icm. In so doing, it extends rostrocaudally from the level of the APir claustrocortex and of the insular and temporal divisions of the piriform cortex, to a transverse plane passing through the rostral pole of the dorsolateral large-celled division of the BL nucleus and the rostral-most tip of the inferior horn of the lateral ventricle, at which level it is replaced by MeA nucleus. Throughout its extent ACo lies in the immediate vicinity of the fundus and the lower lip of the sulcus hemisphericus, being bound by the ventral cortical nucleus (VCo) ventromedially, by the BM nucleus ventrolaterally, from which is separated by the medial medullary lamina and by the AAA laterally and dorsally. When compared with other divisions of the olfactory amygdala, the ACo nucleus stands apart by displaying a sharp widening of the cell-poor layer that separates it from the brain surface and which can be considered a molecular layer (L1). Such widening starts at the border with Me caudally and attains its peak at the border zone with the piriform allocortex and particularly at the bottom of the sulcus hemisphericus. As in the superficial division of the AAA, it is characteristically bound at the outer border of the molecular layer by a prominent granular subpial layer and shows a richer glial cell population than the more caudal and ventral superficial amygdaloid nuclei.

Cytoarchitectonics On topographical and cytoarchitectonic grounds, the ACo nucleus can be divided into dorsal and ventral parts. The dorsal division of the anterior cortical nucleus (D ACo) occupies the fundus of the sulcus hemisphericus and therefore shows a wide molecular layer (L1) that also contains the rich glial cell population and a sharply marked subpial granular layer (described above). It is made up of small, lightly staining, loosely arranged neurons, among which predominate those of fusiform shape, whereas the less numerous pyramid-like neurons are slightly larger and more darkly staining. In the D ACo division the superficial and deep neurons practically form a gray continuum without any distinct boundary among them, constituting, in consequence, a homogeneous field.

The ventral division of the anterior cortical nucleus (V ACo) occupies that part of the lower lip of the sulcus hemisphericus that stretches from the dorsolateral border of the VCo nucleus to the beginning of the fundus of this sulcus. 1t appears caudally to the D ACo nucleus behind the lateral subdivision of the AL APir from which it is separated by a cell-poor zone [Brockhaus' (1938) 1" bundle] and stretches just beyond the boundary between the D ACo nucleus and the anterior division of the Me nucleus. Fibers detached from Brockhaus' (1938) intermediate caudomedial fiber masses (icm) surround the nucleus ventrally and medially. Those medially located form a relatively loose fiber septum that separates the V ACo nucleus from its ventromedially adjacent neighbor, the superior subdivision of the R VCo nucleus. Like its dorsal counterpart, the V ACo division possesses a well-defined subpial granular (glial) layer, but this and its L1 are substantially less wide than in the dorsal subdivision.

In Nissl preparations, the V ACo division appears more structured than its dorsal counterpart and presents a more clearly defined stratification. Within its molecular layer, small invading neurons, such as those seen in the D ACo division, are still present though in a more scattered fashion. This is in sharp contrast with the total absence of such cells in the neighboring VCo nucleus. Its superficial cell layer is made up of more loosely packed and darkly staining neurons than those in the D ACo division and tend to become clustered. Although these neurons present a variety of body shapes, they are slender and more

angular than those in the dorsal ACo nucleus but less so than in the adjacent VCo nucleus. The deep cell layer is made up of larger, more loosely arranged, predominantly pyramidal-shaped neurons showing a tendency to form scattered, loosely packed clusters.

Fibroarchitectonics In Weigert preparations, the D ACo division can easily be differentiated from its ventral counterpart by the presence of much denser plexuses of mostly transversely coursing fibers that are quite homogeneously distributed throughout this subdivision, although they are somewhat richer within its molecular (L1) and deep cell (L2–3) layers. However, the greatest difference occurs with respect to the fiber content in the superficial cell layer where the fiber plexuses in the V ACo division are far less dense than in its dorsal counterpart, and are composed of mostly randomly oriented fibers.

As here described and mapped, the ACo nucleus corresponds to the anterior portion of Crosby and Humphrey's (1940) medial nucleus, to Brockhaus' (1938) area perisupra-amygdalae intermedialis and ventralis, Stephan's (1975) area medialis as a division of this subregion periamygdalaris anteromedialis, the dorsal cortical nucleus of Gloor (1997), and the anterior part of the V ACo division plus the superficial part of AAAS in Plates/Figs. 46–48 (interaural 20.10–19.20 mm) of Paxinos *et al.* (2000) *The Rhesus Monkey Brain in Stereotaxic Coordinates*]. When comparing the present parcellation of the human cortical nucleus with that of the macaque monkey proposed by Price *et al.* (1987), Amaral and Basset (1989), and Amaral *et al.* (1989), it is clear that the former authors when describing the ACo nucleus did not differentiate it from the rest of the ventral subdivision that appears in the Paxinos *et al.* (2000) atlas of the rhesus monkey (Plate/Fig. 46), even if in Fig. 4 of Amaral and Basset's paper it is possible to appreciate the occurrence of a clear bending in the surface of the ACo nucleus that takes place a little before the border with the so-called nucleus of the lateral olfactory. Furthermore, in my estimation, the so-called 'nucleus of the lateral olfactory tract' (NLOT), according to Sorvary *et al.* (1996a, b), seems to involve both the ventral division of the ACo nucleus and the rostral intermediate and superior subdivisions of the VCo nucleus of the human amygdala, whereas in the monkey the representative of this nucleus (Pitkänen and Amaral, 1993a,b) seems to be confined to what Barbas and de Olmos (1990) termed the superior subdivision of the VCo nucleus. It is interesting that Price (1990) and Price *et al.* (1987) confine the extension of this nucleus in both human and monkey brain to a very small group of densely packed, darkly staining cells that lie in the interface between the ventral division of the ACo nucleus and the superior subdivision of the VCo nucleus. I have been able to detect this group of cells in my human and macaque monkey preparations, but I do not assign the homology with the NLOT of macrosmatic mammals.

Chemoarchitectonics

Heavy Metals In Timm-Danscher-stained sections from Old (macaque) and New World (squirrel, marmoset) monkeys, the ACo nucleus, together with the Me nucleus and the AAA area, shows low to moderate metal content as compared with other amygdaloid nuclei.

Neurotransmitters

CHOLINERGIC MARKERS The ACo has the very lowest levels of cholinergic markers in the amygdala, which helps to distinguish it from rostrally located piriform cortex that has moderate levels of AChE and ChAT staining (Amaral *et al.*, 1992).

ACETYLCHOLINESTERASE (AChE) In AChE sections from human brains, the ACo appears poorly stained, although a closer examination reveals a slightly higher activity than in the MeA nucleus.

According to Amaral and Basset (1989), in the macaque monkey, the ACo nucleus, like the MeA nucleus, can be distinguished by the extremely low level of AChE-positive fibers and terminals but, by contrast, contains a large number of AChE-positive neurons.

CHOLINE ACETYLTRANSFERASE (CHAT) Emre *et al.* (1993), in their description of the distribution of ChAT-ir in the human amygdala, do not mention the existence of an anterior cortical nucleus. Rather, they seem to include within the boundaries of their putative medial amygdaloid nucleus the present ACo nucleus. Therefore, this latter appears to share the low ChAT-ir displayed by the rest of the MeA nucleus. In comparing this with that described by Amaral and Basset (1989) in the macaque monkey, it is evident that in this non-human primate the ACo nucleus, like the MeA nucleus, displays an extremely low level of ChAT-ir fibers and terminals, although the level is somewhat higher than in the latter.

EXCITATORY AMINO ACIDS

GLUTAMATE (GLU) Retrograde tracing experiments in rats using tritiated D-aspartate indicate that a number of the ACo neurons would be a source of GLU/ASPergic projections to both the laterocaudal ventral striatum (IPAC) and the ventral pallidum (Fuller *et al.*, 1987).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) Although McDonald and Augustine (1993) reported that the ACo nucleus has a GABA-ir equivalent to that in the centromedial amygdaloid nuclei, their illustration in Fig. 1 seems to correspond rather to the more rostral portions of the MeA nucleus. By contrast, Pitkänen and Amaral (1994) have found that their ACo nucleus has one of the lowest densities of GABA-ir cells in the amygdala, most of them being of type 1 and located in L2 and L3. They are ovoid or spherical without visible processes. The density of GAD mRNA-labeled cells is one of the highest in the amygdala and consequently clearly higher than that of the GABA-ir cells. The density of the GABA-ir neuropil is quite high, and many of the GABA-ir fibers and varicosities in L2 formed basket-like plexuses around non-ir somata.

NEUROPEPTIDES

CHROMOGRANIN B Although Marksteiner *et al.* (1999) did not recognize this nucleus in their account of the distribution of this neuropeptide, a close examination of their illustrations (Fig. 3) indicates that they had included ACo as a part of their medial amygdaloid nucleus. If this observation is applied, then ACo will contain a moderate amount of PE-11-like ir.

CORTICOTROPIN-RELEASING FACTOR (CRF) According to Basset *et al.* (1992), in the macaque monkey, the density of CRF-ir fibers in the superficial and the so-called cortical regions of the amygdala seems to be light to moderate in relation to that observable in the Ce and La amygdaloid nuclei. The highest density of this type of fibers is seen in the MeA and ACo nuclei, with those in L1a showing the same appearance than in the molecular layer of the piriform cortex, i.e., darkly CRP-ir fibers on a more uniform background. Deeper in these nuclei the density of the CRF fibers decreases and a few CRF-ir small cell bodies with their dendritic processes can be seen.

NEUROPEPTIDE Y (NPY) In their mapping of the distribution of NPY in the human telencephalon, Walter *et al.* (1990) do not mention this nucleus. However, since they depict the Me nucleus as including within it the present ACo nucleus it can be inferred that it is devoid of NPY-ir fibers or cells. On the other hand, these authors stated that "labeled cells and fibers were more numerous in the nuclei amygdalae profundi of Brockhaus or the basolateral group in contrast with the nuclei corticali, medialis and centralis"—a comparison that implies the presence, though scarce, of this neuropeptide in some neurons of the superficially located nuclei.

In complete contrast with this picture, according to McDonald *et al.* (1995), in the macaque monkey, their ACo nucleus (probably equivalent to the dorsal division of the human ACo) is one of the amygdaloid nuclei showing the highest number of NPY-ir neurons. Although some NPY-ir neurons are found in L1, the vast majority are located in the deeper cellular layers. The perikarya and dendritic morphology of the NPY-ir neurons is essentially identical to that of the spine-sparse class seen in the LBNC. Furthermore, these peptidergic neurons are roughly the same size as the non-NPY-ir cells that form its pool of principal neurons.

The NPY-ir neurons in L1 possess dendrites that are oriented parallel to the pial surface, whereas many of the peptidergic neurons in the deep layers have their dendrites oriented to the pial surface.

NEUROTENSIN (NT) According to Benzing *et al.* (1992) mapping of the human amygdala, the ACo nucleus would be included within what these authors consider to be the human AAA area. According to such criterion, the ACo nucleus would share with the AAA area the type of NT-ir distribution pattern. Consequently, the NT-ir in the ACo nucleus would be prominent enough to differentiate it from neighboring nuclei, such as the endopiriform nucleus, and the BM and BL nuclei, but less dense than that in the temporal representatives of the MExA, the MeA and Ce nuclei. This NT-ir is represented mostly by a light matrix of fine-beaded NTR-ir fibers, dot-like puncta, and a small number of NT-ir multipolar perikarya that are randomly scattered throughout the nucleus.

SOMATOSTATIN (SOM) In the macaque monkey, this amygdaloid nucleus shows the highest number of SOM-ir neurons (McDonald *et al.*, 1995). When the ACo emerges from the caudal end of the piriform cortex, the density of SOM-ir fibers and terminals decreases slightly and preferentially involves L1. By contrast, the number of SOM-ir neurons increases, and they appear to be distributed more diffusely throughout all layers of ACo (Amaral *et al.*, 1989).

In the sector of the monkey V ACo that the above-mentioned authors have labeled as the NOLT there is no prominent SOM-ir and, much like the adjacent rostral APir, SOM-ir fibers are seen in L1 of this formation. Numerous SOM-ir neurons can be observed deep to this subdivision of the ACo nucleus (Amaral *et al.*, 1989).

VASOPRESSIN (VP) According to Caffé *et al.* (1989), in the macaque monkey, dense accumulations of VP-ir fibers are found in the cortical nucleus, which,

according to the present amygdaloid parcellation, includes among others the ACo nucleus.

Neurotrophins

Brain-derived neurotrophic factor (BDNF) According to Murer *et al.* (1999), in the human brain all of the amygdaloid nuclei contain BDNF-ir neurons and fibers. However, from their Fig. 4A it is possible to infer that the density of the BDNF-ir in the ACo nucleus is moderate in comparison with that of the inferior subdivision of the VCo nucleus or that of the Ce nucleus, while it is comparable to that of the AAA according to the present parcellation of the amygdaloid complex in humans.

Calcium-Binding Proteins

Calbindin (CAB) According to Sorvari *et al.* (1996b), there are virtually no CAB-ir neurons in layer 1 of their ACo nucleus, which corresponds to the present D ACo division. However, L2 contains a high density of CAB-ir neurons. In L3, the neuronal density is slightly lower than in L2. In L2 and L3, the cells are mostly medium sized or small type 2 cells with short dendrites. A few type 3 and type 1 cells can also be observed. In addition, there are numerous lightly stained small neurons that resembled type 1 and type 2 cells. Because of the intense neuropil labeling, the dendritic morphology of these neurons cannot be determined with certainty.

The above-mentioned authors consider L1 in the sector of the present V ACo division to represent the nucleus of the lateral olfactory tract; it contains a low density of CAB-ir neurons. L2 and L3 contain moderate densities of neurons. In layer 2, the small, darkly stained type 1 and 2 CAB-ir neurons form clusters corresponding to the cellular clusters in cell preparations. In L3, the density of diffusely scattered CAB-ir neurons is high. Characteristic of the CAB-ir neurons in this division would be their variable morphology, which ranged from small, darkly stained type 1 cells to large, lightly stained type 2 and 3 cells.

L2 contained the highest intensity of CAB-ir fibers. In L3, the intensity of CAB-ir is said to be lower than in L2, and L1 contains only a few CAB-ir fibers oriented perpendicular to the pial surface. While the CAB-ir of the neuropil is high in all three layers, it is highest in L2. A low density of CAB-ir fiber bundles can be observed in L2 and L3.

Calretinin (CR) According to Sorvari *et al.* (1996a), the density of CR-ir neurons in their ACo nucleus, here the D ACo division, is one of the highest in the human amygdala, with these neurons being mostly small and lightly staining and corresponding to their types 1 and 3 cells with only the proximal part of their dendrites being stained. The CR-ir cells are densely packed in L2 and L3, whereas L1 contains only a few neurons. The neuropil density in this division of the ACo nucleus is similar to that of the MeA nucleus reaching such high levels that it is not possible to distinguish individual fibers and terminals.

On the other hand, the cell aggregates they consider to be the human representative of the nucleus of the lateral olfactory tract of lower mammals that here is included as a part of the V ACo division, is said to contain a large number of small type 1 and some type 3 CR-ir neurons. The density of the CR-ir cells is higher in those places where there are higher concentrations of cells (L2) while they are more diffusely scattered in those with lesser aggregations. In contrast with what happens in the D ACo division, the density of CR-ir fibers and terminals is moderate but staining is as intense as in the MeA nucleus.

Parvalbumin (PAV) According to Sorvari *et al.* (1995), the very few PAV-ir cells that can be detected in their ACo nucleus, here the D ACo division, are small type 1 and 2 neurons with short dendritic processes located mainly in layers 1 and 2. The density of PAV-ir fibers is also very low with total absence of basket-like terminal plexuses or cartridges. On the other hand, their so-called nucleus of the lateral olfactory tract, which here is included as part of ACo or, better, its ventral division (V ACo), is described as containing a moderate number of type 2 and some type 1 PAV-ir cells. The location of most of these corresponds to cell clusters and columns in layers 2 and 3. The distribution of PAV-ir fibers and terminals also corresponds to the location of neuronal clusters in L2, while in L1 the fibers run perpendicularly to the pial surface and in L3 the PAV-ir fibers are diffusely scattered.

Other Proteins

Dopamine- and adenosine-3′,5′-monophosphate (cAMP)–Regulated Phosphoprotein of M, 32 kDa (DARPP-32) and Phosphatase Inhibitor 1 (I-1) Since the sector corresponding to the ACo nucleus in the macaque amygdala has been included by Barbas *et al.* (1998) within what they define as the medial amygdaloid nucleus, one should conclude, by taking into account their mapping of the distribution of this protein and their photomicrographs (e.g., Fig. 3A), that the presence of this protein here is negligible as in the Me nucleus itself.

Limbic System–Associated Membrane Protein (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, the anterior half of their medial

amygdaloid nucleus and their ACo nucleus as well as their nucleus of the lateral olfactory tract, i.e., the two formerly cited entities representing together the main dorsal divisions of the ACo nucleus of the present account, and the remaining one the ventral division of the present ACo nucleus, all of them, are totally devoid of LAMP-ir.

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low magnification atlas on the distribution of this protein in the macaque brain published by Petrides *et al.* (2000), that part of their Me nucleus (fig.27, section 567) that includes the ACo nucleus according to Price *et al.* (1987) is negatively stained for this protein.

RECEPTORS

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), the human ACo nucleus shows low signals of ER-α mRNA.

NEUROKININ-1 RECEPTOR (NK-1R) According to Mileusnic *et al.* (1999), in the human amygdala, the density of NK-ir shows the highest expression at the level of ACo nucleus and in the AHi area, but no mention is made of other superficial amygdaloid nuclei.

Ventral Cortical Amygdaloid Nucleus (VCo) and Nucleus of the Lateral Olfactory Tract (LOT)

Topographical Landmarks The VCo nucleus [ACoV plus part of PCo in Plates 24 to 28 (2.7–9.3 mm) in Mai *et al.* (1997), *Atlas of the Human Brain*; BAOT plus VCo in Plates/Figs. 46–57 (interaural 20.10–15.15 nn) in Paxinos *et al.* (2000), *The Rhesus Monkey Brain in Stereotaxic Coordinates*], i.e., the periamygdaloid cortex, PAC, of some authors (see below), constitutes the main component of the superficial amygdala (Figs. 22.1c,d; 22.3–22.6a; 22.7a–22.11; 22.22c). This heterogeneous group occupies most of the semilunar gyrus (SEL) and, in clear contrast with other components of the superficial group that lie rostrally and dorsally to it (the ACo nucleus and the AAA area), its superficial pyramidal cell layer appears clearly separated from the brain surface by a relatively cell-free molecular layer of varying wideness. This molecular layer is rich in transversally oriented fibers running parallel to the brain surface as can be easily appreciated in non-suppressive silver-stained sections.

Cytoarchitectonics and Fibroarchitectonics On the basis of cyto- and fibroarchitectonic criteria, it is possible to divide VCo into two major divisions, **rostral (RVCo)** and **caudal (CVCo)**, the latter being the larger of the two. Either division is, in turn, susceptible to further division into superior, intermediate, and inferior subnuclei, the laterodorsally located ones being less extensive and narrower than those forming the upper wall and the lip of the amygdaloid fissure and the adjacent convexity of the semilunar gyrus medioventrally.

All of these divisions have been basically visualized at least in part by different authors (see below), and they can be clearly seen in frozen sections under darkfield illumination or by projecting them onto a panatomic photographic paper with a photographic enlarger. These renditions are possible on account of the existence of heavily myelinated fiber systems forming septa between each of the subdivisions of the VCo nucleus mentioned above and by building fiber plexuses of different density that provide diverse degrees of transparency. This occurs particularly at the level of the inferior divisions, both caudal and rostral, of the VCo nucleus (Fig. 22.7b), differentiating them in their whole extent from the intermediate ones dorsally and from the dorsolateral and medioventral subdivisions of the posteromedial APir area. Such parcellation can also be detected in Nissl preparations and in neurofibrillar silver- or Weigert-stained sections appropriately oriented.

Irrespective of the type of staining procedure used, the two major divisions of the VCo nucleus, rostral and caudal, can be differentiated by some simple morphological features. These include the thinness of the dorsolateral sectors of the rostral VCo division, which, together with a gradual thickening in a ventromedial direction, provides this sector an inverted comma-like shape in transverse sections. These features contrast markedly with the rather abrupt thickening of every subdivision of the caudal VCo, imparting to the whole caudal VCo division a semioval shape. Furthermore, Nissl preparations reveal a much more organized arrangement of the neuronal elements in the caudal than in the rostral division. This increased organization has prompted some investigators to define this region as cortical, a definition that is inconsistent with ontogenetic data (Bayer, 1980). The rostral and caudal VCo exhibit some common cytoarchitectonic characteristics. For example, they have a relatively narrow but well-delineated superficial cell layer, followed by a deeper one less clearly delineated, particularly at its deepest boundary. The presence of cell islands (here called intramedullary grisea, IMG) (Figs. 22.4 and 22.7b), which are intercalated between the VCo nucleus and the deep amygdaloid nuclei, provides guidance concerning the point of separation.

Other morphological features shared by the two main divisions of the VCo nucleus are: (l) a relatively

narrow molecular layer overlaid by a rather thin granular subpial layer; (2) loosely arranged neurons in the superficial cell layer showing typical features, such as slenderness, pyramidal or spindle shape, and long, thin dendritic processes resembling the fork-shaped cells in the piriform cortex; and (3) the fact that the continuity of the deep cell layer is interrupted by cell-poor, wedge-like, elongated, narrow spaces.

In fiber preparations these spaces are occupied by fiber septa irradiating from the deeper dorsolateral to ventromedial fiber capsule that constitutes the medial medullary lamellae (Fig. 22.7b). On occasion, these fiber septa are accompanied by neurons that seem to be related to the intramedullary griseum system (IMG) rather than the VCo nucleus.

However, the rostral and caudal subdivisions of the VCo nucleus present several cyto- and fibroarchiteconic features which allow their distinction from each other as it will be appreciated from the following account.

As mentioned before, the **rostral VCo division** (RVCo in 22.3 and 22.4) con be is less clearly stratified than its caudal counterpart and like this latter it can be divided into superior, intermediate and inferior parts.

The **superior rostral VCo** (Sp RVCo in Figs. 22.3 and 22.4) abuts rostrally and laterally with the lateral subdivision of the anterolateral APir area and, more caudally, the ventral ACo nucleus, from both of which it is separated by a wide, superficially located cell gap. It is the thinnest of all of the VCo subdivisions, constituting the tail of the inverted comma-like rostral VCo divisions. In spite of this, the superficial cellular layer features a thin additional sublayer (L2′) made up of darkly staining, scattered, pyramidal and spindle-shaped neurons. The main axes of these neurons are oriented parallel to the brain surface. This accessory superficial cell layer, which is separated from L2 by a cell-free narrow interval, appears to be continuous, with a band of cells showing the same general features but located in a thin band perpendicular and medially adjacent to the cell gap mentioned above. Whether this group is the putative "nucleus of the lateral olfactory tract" of some authors could not be established with certainty. The main superficial cell layer of rostral VCo division is made up instead of lighter staining neurons, with their apical dendrites directed perpendicular to the brain surface. The deeper cellular layer (L3) lies separated from L2 by an ill-defined narrow space with few cells. Neurons here are somewhat smaller than those at the center of L3 but also made up of large, isolated polymorphic cells. Immediately deep to L3 lies a cell-free area corresponding to the intermediate caudomedial fiber system (icm) coursing between the superior rostral VCo subdivision and the large-celled dorsomedial division of the BM nucleus.

In fiber preparations the molecular layer (Ll) of the former, particularly near its rostral end, is rather wide compared with that of its more ventrally located counterpart, the intermediate rostral VCo subdivision. The superior rostral VCo subdivision is filled with tangentially running fibers whose richness diminishes toward this subdivision. The cell layers appear to be poorer in fiber content but more so L2. The **intermediate subdivision** of the rostral VCo nucleus (It RVCo in Figs. 22.3, 22.4, and 22.9) presents a superficial cell layer made up of more chaotically arranged pyramidal cells, although it blends without any transition with L2 in the superior rostral VCo nucleus. This layer in the intermediate rostral VCo subdivision widens gradually in a ventromedial direction to stop just beside L2 in the inferior rostral VCo subdivision. The superficial line of the latter lies more deeply than that of the superficial cellular layer in the intermediate rostral VCo subdivision. As a result, the molecular layer in the inferior rostral VCo subfield is wider than in any other VCo subfields, except its counterpart in the inferior caudal VCo subdivision. As in the more dorsally located superior subdivision of the rostral VCo nucleus, the deep cellular layer in the intermediate rostral VCo subarea is rather poorly celled, but not as much as in the former subnucleus. Cell islands deep to the intermediate subdivision are a feature that helps to identify this portion of the VCo nucleus.

These cell islands are made up of darker staining, more densely packed neurons whose main cell axes are oriented in the same direction as the fiber systems that surround them. This can be seen in fiber preparations but is also suggested by the myelin density pattern in unstained sections. These are most probably intramedullary grisea (IMG) which tend to be located around the ventromedial aspects of the neighboring BM nucleus (Figs. 22.5a and 22.6a).

In fiber preparations the molecular layer of the intermediate rostral VCo subdivision is less rich in fibers than the superior and inferior rostral VCo subdivisions between which it is interspersed. As is the case in these two subdivisions, L2 is poorer in fibers. In contrast, the deep cell layer (L3) is characterized by the presence of numerous obliquely coursing fibers that contribute to the buildup of a moderately rich fiber plexus. Many of the small bundles constituting these obliquely oriented fibers appear to be deflected from their ventrally directed course by the IMG (Fig. 22.7b).

Compared with the two dorsally located subdivisions, the **inferior division** of the rostral VCo nucleus (If RVCo in Figs. 22.3, 22.4, and 22.9) is characterized by wider L1 and L2 layers. The former is practically cell free and the latter is made up of slender, pyramidal neurons rather loosely but regularly arranged with

their apical dendrites, oriented perpendicular to the brain surface. The superficial cellular layer blends without transition into the deep cellular layer, from which it can be barely separated, although closer observation reveals that its neuronal population is of smaller size and less slender contours than those in the deep layer. These architectonic characteristics allow easy differentiation of the inferior rostral VCo subdivision from its immediate dorsal and ventral neighbors, the intermediate rostral VCo subdivision and the APir transition area, and from the IMG which at this level occupy a wedge between the BM and the small-celled ventromedial BL nucleus.

In fiber preparations the molecular layer of the inferior rostral VCo subdivision regains the richness of fibers seen in the superior rostral VCo subdivision. These are similarly oriented tangentially and cover the whole width of the layer. Here, however, the fibers show some stratification, with a dense fiber peripheral sublayer, an intermediate wider sublayer with few fibers, and another deeper one again densely fibrous. The superficial cellular sublayer is not well endowed in fibers. Radially oriented fibers are observed here, although they are not as dense as the similarly oriented plexus in the deeper cell layer (L3). This arrangement of the fiber component in the inferior rostral VCo facilitates its differentiation not only from its intermediate counterpart but more particularly from the AP-ir transitional area with which some authors have grouped it.

The **caudal VCo division** (CVCo in Figs. 22.5a, 22.6a, 22.7a, and 22.11) presents a more cortex-like arrangement of its cells and fibers than the rostral VCo division, which is particularly appreciable in its **superior subdivision** (Figs. 22.5a–22.6a, 22.7a–22.11). This latter part of the caudal VCo division lies intercalated between the superior rostral VCo subdivision rostrally and the AHi transition area caudally, and is separated dorsally from the ventral Me nucleus by a rather narrow fiber septum. Beneath an inconspicuous molecular layer the caudal VCo division shows a relatively wide superficial cell layer that appears to be much more organized than its counterpart in the rostral superior subnucleus of the VCo nucleus. As in the latter, the superior caudal VCo subdivision possesses an accessory superficial cellular sublayer, but in preparations examined personally this is less clearly defined. The main superficial layer is wider and denser than the equivalent layer in the superior rostral VCo subdivision and contains many fork-like cells oriented perpendicular to the brain surface. On the other hand, the far more well-developed deep cellular layer appears to be composed of somewhat smaller cells showing no particular orientation.

In fiber preparations the molecular layer is occupied by fibers coursing parallel to the brain surface all of its width, showing few signs of substratification. In neurofibrillar preparations many randomly oriented fibers form a still not well-differentiated network that appears to overlap the accessory superficial cellular layer. This network diminishes sharply in density at the level of the main cellular layer and becomes almost entirely made up of randomly oriented fibers at level L3. However, these are however, still denser than in the superficial layer (L2).

The **intermediate subdivision** of the caudal VCo division (Figs. 22.5–22.6a, 22.7a–22.11) has a molecular layer that becomes gradually wider as one moves away from the superior caudal VCo subdivision. The superficial cell layer appears to be more densely populated by darkly staining pyramid-like neurons although they are still more loosely arranged in a more disorderly way than in the more ventrally located inferior caudal VCo subdivision. Because of this it is difficult to recognize an accessory superficial cellular layer. Between the main (L2) and the deep (L3) cellular layer is a rarefication of the cell population, a zone that is at times occupied by larger, more deeply staining angular neurons. The deep layer, in turn, is made up of medium-sized, moderately staining neurons with no particular orientation, but which appear to be more densely arranged and smaller than their counterparts in the superior caudal VCo subdivision.

In fiber preparations the intermediate caudal VCo subdivision appears to be separated from the superior caudal VCo subdivision by a rather dense fiber septum. The fiber plexus at the level of the secondary superficial layer is better differentiated than its dorsal neighbor but still does not reach the density observed in the inferior caudal VCo subdivision. In the gap between the superficial and deep cellular layers, the fiber plexus is less dense but richer than in the deep layer, both layers being randomly arranged. However. a sharp increase in density takes place at the very border with the medial medullary lamina.

In the **inferior subdivision** of the caudal VCo (Figs. 22.5a, 22.6a, 22.7a–22.11), an increase in the width of its molecular layer causes further sinking of its superficial layer. This rarefication of its deep cell layer contributes to a sharper border with the intermediate caudal VCo subdivision. The inferior subdivision of the caudal VCo division is further characterized by a more homogeneous pattern in the cell layers, with the majority of cells oriented perpendicular to the surface. Accompanying its expansion one may observe in fiber preparations a clearer substratification of the molecular layer. This is readily subdivisible into a richly fibered outer sublayer (L la) and a poorly fibered inner one

(L lb). The fiber plexus at the superficial cellular layer, on the other hand, becomes even richer than in more rostral levels away from the superior caudal VCo subdivision. The superficial cell layer appears to be more densely populated by darkly staining pyramid-like neurons although they are still more loosely arranged in a more disorderly way than in the more ventrally located inferior caudal VCo subdivision. Because of this it is difficult to recognize an accessory superficial cellular layer. Between the main (L2) and the deep (L3) cellular layer is a rarefication of the cell population, a zone that is sometimes occupied by larger, more deeply staining angular neurons. The deep layer, in turn, is made up of medium-sized, moderately staining neurons with no particular orientation, but which appear to be more densely arranged and smaller than their counterparts in the superior caudal VCo subdivision.

As here described, the VCo corresponds to the cortical amygdaloid nucleus of Crosby and Humphrey (1940) and Humphrey (1968, 1972), the latter author having recognized in the human embryo medial (If VCo), intermediate (It VCo), and lateral (Sp VCo) subdivisions. The superior subdivisions of the rostral and caudal VCo correspond approximately to Hilpert's (1928) fields pa4 and 2, respectively; while the intermediate subdivisions of the rostral and caudal VCo correspond to the his fields pa3 and pa1, respectively. Finally, Hilperts's field 2 seems to correspond to both rostral and caudal parts of the inferior subdivisions of the VCo. On the other hand, the superior and intermediate subdivisions of the VCo nucleus correspond approximately to Brockhaus' (1938) periamygdaleum oralis dorsalis and amygdaleum superficialis dorsalis pars oralis and intermedium. The latter designation indicates the deep cell layers of the VCo. He further subdivided the periamygdaleum oralis into oral and caudal parts that are represented by the superficial layers of the rostral and caudal divisions of the VCo, respectively, of the present terminology. In the same line, this author subdivided his amygdaleum superficialis dorsalis into oral, intermediate, and caudal parts, where the oral and intermediate parts correspond to the deep cellular layers of the superior and intermediate subdivisions of the rostral and caudal VCo, respectively. The superficial layers of the inferior subdivisions of the rostral and caudal VCo correspond to Brockhaus' periamygdaleum oralis ventralis, while the deep layers of the VCo correspond to amygdaleum superficialis (pars oralis ventralis and pars intermedium ventralis medialis). All of these different terminologies and subdivisions proposed by the classical authors, reflect the complexity of this superficially located amygdaloid nucleus, complexity that seems to have defeated attempts to simplify it on the basis of cytoarchitectonic criteria alone. However, the situation has not changed much in the present time because modern authors who have depended on sophisticated immunohistochemical procedures have changed the parcellations which they themselves had used previously.

Chemoarchitectonics

Heavy Metals In Timm-Danscher-stained sections of macaque, squirrel, and marmoset brains, the entire VCo nucleus appears moderately to heavily stained. The silver granular deposits vary in decreasing order from maximal activity in the deepest layer to lowest activity in the superficial cell layer. The molecular layer appears to be homogeneously stained except at the level of the inferior subdivision of the caudal VCo nucleus, where a semilunar subpial blank area can be detected (Alheid and J.S. de Olmos, unpublished observations). This latter property allows a clear differentiation from the posteromedial division of the AHi area, which does not show this subpial negatively stained band that most probably corresponds to the place of termination of olfactory pathways coming from the main olfactory bulb or from other olfactory-related cortical and subcortical grisea.

It should be pointed out that iontophoretic injections of sodium selenite in some of the main targets of the rat APir area produce retrograde labeling of neurons in all cell layers of this transitional cortical field. As mentioned before, this experimental procedure allows the identification of zinc-containing neurons which usually use glutamate as a neurotransmitter.

Neurotransmitters and Neuromodulators

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) In AChE preparations are placed at the disposition of the present writer, the enzyme activity appears to be concentrated in the deep cellular layers of all subdivisions of the VCo nucleus. However, at the level of the inferior subdivision of the VCo nucleus the AChE activity seems to diminish ventrally, so that it contrasts markedly with that in the posteromedial division of the APir area and that in the nearby IMG, filling the wedge-like area between the medium-celled ventromedial BM nucleus and the small-celled ventromedial BL nucleus. According to Darvesh *et al.* (1998), the neuropil of the nucleus is lightly AChE positive at rostral levels, gradually increasing in a caudal direction. AChE-positive triangular perikarya of small to medium size are present, their number diminishing in a caudal direction (5% rostrally; just isolated neurons caudally). According to Amaral and Basset (1989), in the macaque monkey, the PAC3 division of their periamygdaloid

cortex (PAC) shows the lowest AChE positivity of the whole PAC.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Emre *et al.* (1993), this nucleus displayed a moderate density of mostly varicose and thin ChAT-positive fibers. The density was higher at the periphery of the nucleus, but in a patchy fashion, and its density was slightly higher in the posterior parts of the nucleus.

Together with the small-celled VL/VM BL nucleus and with the BM nucleus, the VCo nucleus is ranked third concerning the density of ChAT-ir fibers and varicosities.

In the macaque monkey, Amaral and Basset (1989) PAC3 subdivision shows the lowest density of ChAT-ir fibers in what they define as periamygdaloid cortex (PAC). The ChAT-ir fibers are diffusely arranged and of about equal density in all of the layers. The low staining of this subdivision provides a clear boundary with PACs (here the PM APir area), which has the densest fiber and terminal ChAT-ir.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Experimental tract tracing data obtained in rats with tritiated D-aspartate indicates that a considerable number of neurons in layer II and III of the rat of the periamygdaloid cortex, i.e., the posterolateral cortical amygdaloid nucleus (see Paxinos), which would be the homolog of the present VCo nucleus, give rise to GLU/ASPergic projections to all components of the ventral striatum (Acb, Tu, and IPAC) and to the ventral pallidum (Fuller *et al.*, 1987).

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to McDonald and Augustine (1993) and Pitkännen and Amaral (1994), in the macaque monkey, the distribution of GABA-ir neurons and neuropil is similar throughout what they term the periamygdaloid cortex, which includes (besides the present VCo nucleus) the APir area after the present parcellation. The latter-named authors also found that the density of GABA-ir neurons is high and the number of cells expressing GAD mRNA matches that of these ir neurons. Furthermore, the density of these GABA-ir cells is noticeably higher than that of similar type of cells in the deep amygdaloid nuclei. The same can be said about the GABA-ir neuropil.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey, the periamygdaloid cortex shows light to moderate DBH-ir, with denser staining at the subpial area.

HISTAMINE (HA) According to Airaksinen *et al.* (1989), in the tree shrew (*Tupaia belangeri*), HA-ir fibers collected in dense bundles along the stria terminalis continue to the amygdaloid complex to spread as a dense and diffusely distributed network of HA-ir fibers within the amygdala. At the level of the VCo nucleus this network reaches a moderate density (3 on an scale from 0 to 5).

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey the periamygdaloid cortex shows high to moderate 5-HT-ir except for subpial regions where a moderate density of fine 5-HT-ir fibers can be observed.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey, the TH-ir terminal labeling is light to absent.

NEUROPEPTIDES

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human amygdala, this nucleus together with the BM nucleus contains a lower density of BDNF-ir neurons and fibers than the rest of the amygdaloid nuclei.

CORTICOTROPIN-RELEASING FACTOR (CRF) According to Basset *et al.* (1992), in the macaque monkey, the density of CRF-ir fibers in the superficial and the so-called cortical regions of the amygdala seems to be light to moderate in comparison with that observable in the Ce and La amygdaloid nuclei. Within their periamygdaloid cortex and "nucleus of the lateral olfactory tract," darkly coarse CRF-ir fibers with numerous large varicosities are present that are confined to the most superficial portion of La. In addition, a lesser density of medium to coarse CRF-ir fibers and occasional CRF-ir neurons, similar to those present in the MeA, are present in the deeper layers.

CHROMOGRANIN B According to Marksteiner *et al.* (1999), in the human brain, this nucleus displays a high density of PE-11-like ir which consist of varicose fibers and mixed size varicosities, though it does not seem to contain PE-11-like ir neurons.

DYNORPHIN (DYN) According to Sukhov *et al.* (1995), the cortical amygdaloid nucleus (here VCo) contains PDYN-containing neurons.

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992), in the macaque monkey amygdala, this member of the superficial amygdala, like its other components, does not contain GAL-ir cell

bodies but seems to contain at least a small number of GAL-ir fibers.

NEUROPEPTIDE Y (NPY) In their mapping of the distribution of the NPY in the human telencephalon, Walter *et al.* (1990) do not mention this nucleus but they depict it in their mapping as devoid of NPY-ir fibers or cells. However, according to McDonald *et al.* (1995), in the macaque monkey NPY fibers and puncta can be observed in all amygdaloid nuclei, though their density varies from place to place, showing high concentrations in all superficial amygdaloid nuclei with NPY-ir fibers coursing near the surface of the brain tending to run parallel to the pial surface. Bons *et al.* (1990) found likewise that in the lemur *Microcebus murinus* the cortical nucleus exhibits a dense superficial network of NPY-ir fibers and terminals. The plexuses of this type of fiber are less compact in the deeper aspect of the nucleus. The nucleus presents a small number of NPY-ir perikarya exhibiting bipolar, spindle, or pyramidal shapes.

NEUROTENSIN (NT) According to Benzing *et al.* (1992), their cortical nucleus, which is equivalent in most regards to the present VCo nucleus, contains moderate levels of NT-ir sufficient for its clear delineation from the laterally adjacent, lightly staining BM nucleus (AB in their account). The NT-ir is exclusively located in the L2 and L3 of the nucleus, while the superficial L1 contains little if any NT-ir. Their dorsal division (Cod) (superior and intermediate subdivisions in the R and C VCo) shows a denser staining than their ventral one (inferior subdivisions in the R VCo and C VCo). In the whole nucleus the NT-ir consists mostly of fine beaded fibers although fewer coarse-beaded fibers as well as dot-like punta are also present. It should be stressed that both divisions are described as showing a distinct anterior to posterior gradient of NT-ir with the posterior level showing a denser staining.

OXYTOCIN (OXT) According to Caffé *et al.* (1989), in the macaque monkey, OXT-ir fibers accumulate in the cortical nucleus where there is most dense innervation. A similar VP-ir innervation takes place in the cortical nucleus of the common marmoset monkey (Wang *et al.*, 1997).

SECRETONEURIN (SECR) High density of SECR-ir has been detected in the cortical nuclei (Kaufman *et al.*, 1997). Examination of the illustration available in the literature allows differentiation of the three subdivisions suggested in the present account, characterized by the presence of a strong SECR-ir in L1 and L3 of the three subdivision, but absence in L2 of the superior and inferior subdivisions and dense presence in this layer in the intermediate subdivision. On the other hand, the relatively high levels of the SECR-ir in this nucleus, and the even higher concentration of this neuropeptide in the AHi area, allows clear delineation of the deep layer of the VCo from this latter area, separation not evident when using other, more current histological, histochemical, and immunocytochemical procedures. This latter fact is why in some published accounts of this superficial structures the deep layers of VCo has been included as part of the AHi area.

VASOPRESSIN (VP) According to Caffé *et al.* (1989), in the macaque monkey, dense accumulations of VP-ir fibers are found in the their cortical nucleus, which, according to the present amygdaloid parcellation, includes among others the VCo nucleus.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human brain all of the amygdaloid nuclei contain BDNF-ir neurons and fibers. In the case of their cortical nucleus, the number of BDNF-ir neurons and the density of the BDNF-ir neuropil was said to be lower than that of the Ce nucleus. On the other hand, from examining their Fig. 4 A it is possible to infer that the density of the BDNF-ir in the inferior subdivision of the VCo nucleus is higher than its other two subdivisions but even higher than in the ACo according to the present parcellation of the amygdaloid complex in humans.

ENZYMES

ANGIOTENSIN-CONVERTING ENZYME (ACE) According to Chai *et al.* (1990), the VCo nucleus shows low binding levels for ACE.

BUTYROCHOLINESTERASE (BUCHE) The VCo nucleus contains many BuChE-containing neurons of small to medium in size with round, fusiform, or triangular perikarya. Some have multiple branching dendrites, their number dropping in the caudal direction (14%, 2%, and &% of the neuronal population) (Darvesh *et al.*, 1998).

NICOTINE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) According to Sims and Williams (1990), APir shows a moderate NADPH-d, an observation that has been confirmed for both the human and squirrel monkey amygdalae (Brady *et al.*, 1992).

P450 AROMATASE (P450 AROM) According to Roselli *et al.* (2001), in the macaque monkey amygdala, the VCo nucleus contains a very high density of

P450 AROM mRNA-containing cells. However, by examining their illustrations (Fig. 5), it seems that in rostral transverse sections (Fig. 5A) the P450 AROM labeling is restricted to the superior and ventral subdivisions of the rostral VCo, while further back (Fig. 5B) the labeling is restricted to intermediate subdivision, and even further back (Fig. 5C) back to the inferior division, labeling that is directly continuous with that taking place at the level of the PM AHi area, which these authors have included as part of their cortical nucleus.

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), the PAC3 subdivision of their periamygdaloid cortex (i.e., the If subdivision of the both rostral and caudal divisions of the VCo nucleus) has a higher density of CAB-ir neurons than the adjacent PACs (i.e., the PM APir area of the present parcellation). The neurons are type 1 and 3 cells and their dendrites were oriented perpendicular to the pial surface. Compared to the dorsally located nucleus of the lateral olfactory tract (i.e., the superior and intermediate subdivisions of the rostral VCo nucleus), the CAB-positive neurons in PAC3 are smaller. The intensity of CAB-ir fiber and neuropil staining is slightly higher than in the adjacent PACs.

After the same authors, in their "nucleus of the lateral olfactory tract," as in other pseudocortical periamygdaloid areas, L1 contains a 1ow density of CAB-ir neurons. L2 and L3 contain by contrast a moderate density of CAB-ir neurons. In L2, the small, darkly stained type 1 and 2 CAB-ir neurons form clusters that corresponded to the cellular clusters seen in Nissl-stained preparations. In L3, the density of diffusely scattered ir neurons is high. Characteristic of the CAB-ir neurons in this part of the present R ACo nucleus is their variable morphology, which ranged from small, darkly stained type 1 cells to large, lightly stained type 2 and 3 cells. On the other hand, L2 of CAB-ir while in L3, the intensity of ir is lower than in L2; and L1 contains only a few CAB-ir fibers oriented perpendicular to the pial surface. While the immunoreactivity of the neuropil was high in all three layers, it was highest in layer 2. A low density of CAB-ir bundles was observed in L2 and L3.

CALRETININ (CR) According to Sorvari *et al.* (1996a), in the human amygdala, the CR-ir neurons are distributed in a laminar fashion at the level of their PAC3 subdivision (inferior subdivision of both rostral and caudal divisions of the VCo nucleus) of the periamygdaloid cortex. This part of the VCo nucleus, therefore, would have the same density of CR-Ir neurons than the ventrally located PACs (here, PM APir area). Most of the ir neurons are of the type 1 or small type 3 cells. Furthermore, their "nucleus of their nucleus of the lateral olfactory tract" in humans (here included within the superior and intermediate subdivisions of the R VCo nucleus) contains a large number of small type 1 and some type 3 CR-ir neurons. The density of CR-ir cells is higher in the cellular L2, while in L3 these types of cells are scattered distributed.

The CR fiber and neuropil has a higher density than in the PM APir area. Finally, the rostral part their "posterior cortical nucleus" (here the superior and intermediate subdivisions of the caudal division of the VCo nucleus) is described as containing a small density of CR-ir small type 1 and type 3 cells.

The CR-ir fiber, terminals, and neuropil distribution in this superficial structure, has been described as being higher in PACs than in the adjacent PACs, while that in their "nucleus of the lateral olfactory tract" is moderate and its intensity of staining is as high as in the MeA nucleus. Finally, the CR-ir pattern in the rostral part of their posterior cortical nucleus is differentiated from the caudal one (i.e., from PM AHi area) by the fact that more CR-ir fibers can be detected parallel to the pial surface in the former sector than in the latter one.

It is important to stress that since the so-called nucleus of the lateral olfactory tract has been proposed to be homologous with an equally named nucleus present in macrosmatic mammals, its comparison with that of the rat in this type of CR immunohistochemical preparation indicates the existence of an almost completely different staining pattern that contrasts for its scarcity, particularly when compared against the very rich one in the neighboring AAA (personal observation).

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), at rostral levels of their posterior cortical nucleus, [approximately equivalent to the superior and intermediate(Sp and It) subdivisions of the caudal VCo], the few PAV-ir cells present are mostly small, palely stained type 1 or 2 cells. Concordantly, the density of PAV-ir fiber and terminals is low, with some of them running parallel to the pial surface. According to the same authors, their PAC3 subdivision of the periamygdaloid cortex [approximately homologous to the inferior (rostral and caudal subdivisions of the VCo nucleus)] is said to contain some PAV-ir neurons in L2 and L3 which are small type 1 and type 2 cells, their density being higher toward the boundary with the SP VCo or with APir (their PACs).

Finally, their "nucleus of the lateral olfactory tract" (which in more medial and ventral sectors corresponds

approximately to the superior and intermediate subdivisions of the R VCo nucleus) is described as containing a moderate number of PAV-ir neurons of type 2 cells and some type 1 cells located mostly in L2 and L3 of this sector of the VCo.

OTHER PROTEINS

CALPASTATIN (CALPT) According to Mouatt-Prigent *et al.* (2000), large CALPT-ir neurons are present especially in the cortical nucleus, high proportion of these neurons are bipolar and strongly immunostained. They are surrounded by a dense plexus of CALPT-ir fibers and puncta corresponding very probably to nerve terminals.

DOPAMINE- AND ADENOSINE 3',5'-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DAPP-32) AND PHOSPHATASE INHIBITOR 1 (I-L) According to Barbas *et al.* (1998), in the macaque monkey, most of the DARP-32-ir and I-1-ir neurons can be detected in the VCo nucleus. Moderately or densely stained DARPP-32-ir and I-l-ir neurons can be seen in all cortical subdivisions, but their prevalence within each differed. DARPP-32-ir neurons are more numerous in the It VCo subnucleus while I-1-ir are more sparsely distributed in the If VCo subnucleus. The I-l-ir neurons are found in all parts of the VCo nucleus, with gaps noted in the central sector.

Within the VCo nucleus, DARPP-32-ir and I-l-ir neurons are present in layers 2 and 3, and there is some overlap in their laminar distribution. However, the DARPP-32-ir neurons are located superficially in layer 2 and in the deep part of layer 3, whereas I-1-ir neurons are concentrated primarily, though not exclusively, in the inner part of layer 2 and the upper part of layer 3.

LIMBIC SYSTEM-ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996) in the macaque amygdala, their PAC2 subdivision of the periamygdaloid cortex, i.e., approximately the rostral division of the VCo, is devoid of LAMP-ir, while their PAC3 subdivision, i.e., the present caudal division of VCo, displays a light to moderate LAMP-ir.

NEUROFILAMENT PROTEIN SMI32 (SMI32) According to the low magnification atlas published by Petrides *et al.* (2000), the inferior subdivision of the posterior VCo contains some SMI32-ir, while the remaining subdivisions, except for a sector at the rostral pole of the nucleus, show a completely negative staining. Within the inferior subdivision of the P VCo, the distribution of the SMI32-ir is rather homogeneous not showing the stratified distribution apparent in those neocortical fields that show positively stained profiles. In the sector located at the rostral pole of VCo mentioned before, a very strong and stratified SMIR32-ir can be appreciated. The cells in the L2 of this sector stand out on account of the negative staining of layer 1 and 3 and of surrounding structures. This sector of the VCo, which has received different names, lies within what Barbas and de Olmos (1990) designated as the superior subdivision of the VCo nucleus, Price *et al.* (1987) as PAC 2, Turner *et al.* (1978) and Pitkannen and Amaral (1993) as NLOT, and Paxinos *et al.* (2000) as BAOT. As pointed out by Turner *et al.* (1978), this sector of the superficial amygdala of the macaque monkey receives a direct afferent supply into L1a from the main olfactory bulb, is strongly AChE positive, and displays a strong ChAT-ir (see above), meeting some of the hitochemical and immunohistochemical features of the NLOT in some subprimates mammals. However, it remains to be seen whether the full hodological characteristics that have been established for this nucleus in lower mammals are met by this so-called NLOT or BAOT.

RECEPTORS

BENZODIAZEPINE RECEPTOR The cortical amygdaloid nucleus has been reported to contain high densities of benzodiazepine receptors (Zezula *et al.*, 1988).

CCK RECEPTORS (CCK-R) According to Kritzer *et al.* (1988), keeping with the general pattern of CCK binding site concentration in the ventral medial margins of the macaque monkey amygdala, the VCo shows a prominent concentration of CCK-R.

CHOLINERGIC RECEPTORS

MUSCARINIC RECEPTOR (MACH-R) According to Cortés *et al.* (1987), the molecular layer of the human cortical nucleus (here the VCo nucleus) BM nucleus) contains one of the lowest densities of mACH-R. On the other hand, according to Smiley *et al.* (1999), the amygdala as a whole contains a low density of m_2-ir neurons.

NICOTINIC RECEPTORS (NACH-R) This type of receptor as labeled [^{3}H]ACh or [^{3}H]nicotine shows very low concentrations in all nuclei of the rat amygdaloid complex (Rainbow *et al.*, 1984; Clarke *et al.*, 1985). No other source of this type of data is available to the present writer about the distribution of this type of receptors in the primate amygdala.

OPIOID RECEPTORS (OR) According to Daunais *et al.* (2001), low to moderate concentrations of [^{3}H]DAMGO binding sites could be measured in the cortical nucleus.

STEROID RECEPTORS

ANDROGEN RECEPTOR (AR) The distribution of AR mRNA-containing cells in the amygdala was mainly confined to the cortical and basomedial amygdaloid nuclei (Roselli *et al.*, 2001).

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), in both human and monkey brains, their nucleus of the lateral tract, which corresponds according to their illustrations (Fig. 3A) to the superior subdivision of the rostral VCo of the present account, is described as having moderate amounts of ER-α mRNA-labeled nuclei. In their periamygdala cortex (here the VCo nucleus), the ER-α mRNA expression is most abundant in the human and monkey brains.

Amygdalopiriform Transition Area (APir)

Topographical Landmarks This extensive band-like gray formation (Figs. 22.1c, 22.2–22.6a, 22.7a–22.11) [CxA plus PHA in Plates 21–27 (-0.6–6.7 mm) of Mai *et al.* (1997), *Atlas of the Human Brain*; and APir in Plates/Figs. 45–62 (interaural 20.55 mm to 12.99 mm) of Paxinos *et al.* (2000), *The Rhesus Monkey Brain in Stereotaxic Coordinates*] occupies the fundus and lower lip of the semicircular (or semiannular s., sas) sulcus that lies intercalated mainly between the superficial amygdala, and the putative olfactory sector of the entorhinal cortex (Price *et al.*, 1987) (Ent; Plate 24, 2.7 mm), though at its rostral-most pole it becomes interposed between the temporal area of the (pre-) piriform paleocortex (PirT) and the rostral pole of the Ent (Plates 21–22) a relationship that is also maintained in the monkey bran [Figs. 41–45 of Paxinos *et al.* (2000)]. Likewise, the rostral end of APir will also bind with the temporopolar periallocortex (Fig. 42, TPPal in Paxinos *et al. Atlas of the Macaque Brain*), maintaining in this manner it transitional character with respect to the several expressions of the temporal periallocortex.

Furthermore, by comparing sections of the human brain with that of the macaque monkey, it is apparent that, at least in the human brain, this structure not only lies entirely confined to the above described territory but in conjunction with a clear topographical relationship with the semiannular sulcus (sas). It also seems to extend further caudally than in the monkey so as to end up abutting a transitional field of the hippocampal formation, Rosene and Van Hoesen's (1987) hippocampal–amygdaloid transition area (HATA)). On the other hand, it should be pointed out that in the macaque (Old World) and squirrel (New World) monkeys, APir has been generally depicted as covering not only the bottom and the lower lip of sas but also its dorsal lip (Price and colleagues PACs subdivision of their periamygdaloid cortex). However, closer fibroarchitectonical analysis reveals that even in these lower primates the dorsal lip of the sas is made up, at least in part, by the inferior division of the ventral cortical amygdaloid nucleus.

Cytoarchitectonics On account of some cytoarchitectonic variations that are more or less coincidental with successive intercalations among the different modalities of temporal periallocortex, APir can be divided into anterolateral (APir AL) and posteromedial (APir PM) portions. The former is further susceptible to be subdivided into lateral (APir ALl), intermediate (APir ALi), and medial (APir ALm). While APir is easily distinguishable from Pir T by an abrupt disappearance of the pattern of densely packed cells that characterizes the superficial pyramidal cell layer of this allocortex, its borders with the periallocortical fields of ambiens gyrus are that clear. The posteromedial division of APir has an oval or circular shaped area in transverse sections extending itself throughout much of the caudal half of the amygdaloid body. It has been said that the neurons that make up this formation belong to either an inward extension of the caudal VCo nucleus or a medial extension of the ventromedial subdivision of the BL nucleus. Caudally this transitional griseum is replaced posteriorly by the anteroventral division of the AHi area.

Fibroarchitectonics In neurofibrillar preparations, the APir area appears to be separated from neighboring structures by fiber septa of different densities and thicknesses, although this is more particularly the case in its posteromedial division.

As here described, the APir area corresponds to the claustrocortex preamygdaleum of Brockhaus (1940), the field sem 1 of Hilpert (1928), and the subfields PACo, PACs, and PAC1 of Price (1973) and to PACo (lateral AL APir 0) plus PAC1 (medial AL APir), the rostral (intermediate AL APir) and caudal (PM APir) PACs of Sorvari *et al.* (1995, 1996a,b).

Chemoarchitectonics

Heavy Metals In Old (macaque) and New World (squirrel, marmoset) monkeys, APir area as a whole shows as it can bee seen in all allo- and periallocortical formations as very strong Timm-Danscher-silver/selenide deposits in all of their layers except around the superficial cell layers, where the precipitate is only moderate. It deserves to be mentioned here that in rat experiments made in my laboratory of the present writer in which Na selenite was injected iontophoretically in the bed nucleus of the stria terminalis or in the region of the central amygdaloid nucleus/sublenticular substantia innominata, a dense retrograde labeling with silvered selenide of a dense population of neurons in

both superficial and deep layers of both anterolateral and posteromedial divisions of the APir occurs. Such findings may mean that this transitional formation may be one of the main sources of a zinc-reach glutamatergic innervation of the central extended amygdala.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) In AChE preparations the APir area shows, in the material to my disposition, moderate to weak enzyme reactivity which seems to be slightly greater than that for the neighboring entorhinal periarchicortex. The laterodorsal subdivision of the PM division of this transitional gray formation shows however higher reactivity [Figs. 22.10 and 22.11). In the macaque monkey amygdala, APir stains intensely for AChE and ChAT (Amaral and Basset, 1989- their area PACs), but in humans Sims and Williams (1990) and Benzing *et al.* (1992) found virtually no AChE staining.

EXCITATORY AMINO ACIDS

GLUTAMATE (GLU) No human or nonhuman primate information is available to the present writer

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), the distribution of GABA-ir neurons and neuropil as well as the distribution of cells that contain GAD mRNA is quite similar throughout the periamygdaloid cortex (i.e., including PACs, equivalent to the present APir area). The density of the GABA-ir- and/or GAD mRNA-labeled neurons being high as that of the neuropil in where numerous pericellular baskets surrounding unstained cells can be observed.

NEUROPEPTIDES

CORTICOTROPIN-RELEASING FACTOR (CRF) Although it has been stated that all of the amygdaloid nuclei contain dense accumulation of CRF-ir fibers (Powers *et al.*, 1987; Zaphiropoulos *et al.*, 1991), with large varicosities and terminals, their density would not reach that detected at the level of the LBNC (Zaphiropoulos *et al.*, 1991).

NEUROPEPTIDE Y (NPY) Also in humans APir seem to contain NPY-ir cell bodies and fibers (Zech *et al.*, 1986).

NEUROTENSIN (NT) According to Zech *et al.* (1986), APir contains NT-ir positive perikarya and dense plexuses. According to Benzing *et al.* (1992), APir contains a moderate amount of NT-ir and is characterized mainly by coarse-beaded as well as some fine-beaded fibers. These fibers are similar in appearance to those found in the medial aspect of the VM BL nucleus, but the former contains more coarse fibers that the latter.

SOMATOSTATIN (SOM) In agreement with the suggested subdivisions into anterolateral and posteromedial sectors, the former appears to be densely innervated by SOM-containing fibers while the latter only contains a modest amount of these elements. This rather modest concentration of SOM-ir elements in APir helps to distinguish this transition field from the dorsally adjacent VCo.

According to Amaral *et al.* (1989), the SOM-ir at the level of what they define as periamygdaloid cortex (PAC) is widespread and does not distinguish between subdivisions. In general there is a dense SOM-ir fiber network and terminals in layer 1 which extended less densely in the deeper layers but is a lesser degree than in their PAC2 subdivision (approximately AL APir L here). The large-celled region of their PACs was described as containing a dense accumulation of SOM-ir neurons.

VASOPRESSIN (VP) According to Caffé *et al.* (1989), in the macaque monkey, dense accumulations of VP-ir fibers are found in the their cortical nucleus, which, according to the present amygdaloid parcellation, includes among others the PM APir area.

ENZYMES

NICOTINE ADENINE DINUCLEOTIDE PHOSPHATE DIAPHORASE (NADPH-D) According to Sims and Williams (1990), APir shows a moderate NADPH-d. Thus observation has been confirmed for both the human and squirrel monkey amygdalae (Brady *et al.*, 1992). Furthermore, according to Unger and Lange (1992), 90% of the NPY-ir and SOM-ir neurons and *neuropil* are positively ir for NADPH-d.

P450 AROMATASE (P450 AROM) A close examination of the illustrations (Fig. 5A–C) presented by Roselli *et al.* (2001) about the distribution of this enzyme in the macaque monkey amygdala would indicate that while the rostral PM subdivision of APir areas does not seem to contain any P450 AROM mRNA-labeled cells, in more caudal planes (Fig. 5 C), this area does, though to a lesser degree than the other superficial amygdaloid nuclei.

CALCIUM BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), their "sulcal part of the periamygdaloid cortex" in humans (i.e., the PM APir of the present account), the CAB staining pattern, in accordance with

the cytoarchitectonic organization of this transition field, also reveals some differences between the dorsal and ventral parts of PACs. The dorsal part of the PACs contained a moderate density of CAB-ir neurons, which in L2 are mostly small type 1 cells. In L3, there were type 3 cells which have dendrites oriented perpendicular to the pial surface. In the ventral part of PACs (L2 and L3), CAB-ir neurons are not as clearly oriented as in the dorsal part. In addition, the ventra1 part contains a high number of lightly stained CAB-ir neurons, which resemble the pyramidal neurons found in the entorhinal cortex. The fiber bundle separating the ventral part of PACs from the entorhinal cortex contained several CAB-ir neurons. PACs contains a moderate density of CAB-ir fibers and CAB-ir neuropil. L2–L3 of the PACs are the only parts with few CAB-ir bundles.

CALRETININ (CR) According to Sorvari *et al.* (1996a), their "sulcal portion of the periamygdaloid cortex" (i.e., PM APir area) contains a low density of CR-ir neurons. L1 contains only few small type 1 neurons. Most of the CR-ir neurons in this territory are located in L2 and L3. In the ventral portion of PACs neurons of the small type 2 are also found. At the rostral level, the territory they assign to their "nucleus of the lateral olfactory tract" contains considerably more cells in L3 than in PACs. On the other hand, their PAC1 subdivision (i.e., the lateral and intermediate subdivisions of AL APir area) contains few CR-ir cells most of which are of the small type 1 and are located in L2 and L3. Finally, L1 and L2 of their PACo subdivision (i.e., the medial AL APir subarea) contain few CR-ir neurons but the clusters of cells in L2 that characterize this subdivision are free of CR-ir cells. A slightly higher density of CR-ir neurons is found in L3, which contains some small type 1 and 2 cells.

The CR-ir fibers and terminals as well as the neuropil in the PACs division is high and of equal density in both dorsal and ventral subdivisions. In L2 and in L3 fibers run perpendicularly to the pial surface. On the other hand, the CR-ir neuropil in PACo is dense throughout it, and CR-ir fibers in L3 run, like in PACs, perpendicularly to the pial surface. Both PACs and PACo are easily distinguished from the entorhinal cortex because the latter has a large number of CR-ir neurons in L3 and in L5 and the fiber bundle that runs between PACs and this periarchicortical field contains CR-ir fibers. Finally, in PAC1, the CR-ir neuropil I highly stained particularly in L2 and L3 but the number of CR-ir fibers is low.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), the oral part of their periamygdaloid cortex (here AL APir M) almost completely lack PAV-ir neurons, and the density of PAVC-ir fibers and terminals is low. A similar picture is also applicable to their PAC1 subfield (here AL APir I+L). With respect to the subfield they label as PACs (sulcal portion of their periamygdaloid cortex; here PM APir), the picture does not seem to vary significantly since they observed a low density of lightly stained PAV-ir neurons. These neurons have no visible dendrites, and the cells in the ventral sector of this structure appeared less fusiform in shape than those in the more dorsal sectors. A low number of PAV-ir fibers and terminals were seen here, but this scarcity becomes apparently more pronounced in the ventral nonsulcal sector. In layers 2 and 3 of APir, the PAV-ir fibers appeared oriented perpendicularly to the brain surface, but at the level of the fundus of the sas, they formed in layer 1 of this field a triangular plexus.

OTHER PROTEINS

DOPAMINE- AND ADENOSINE-3′,5′-MONOPHOSPHATE (CAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-L) According to Barbas *et al.* (1998), in the macaque monkey, very few DARP-32-ir or I-1-ir neurons can be found in the APir, which when detected were very lightly labeled. This feature contrasts sharply with the relative preponderance of immunoreactive neurons demonstrable in the VCo nucleus, which is interposed between APir area and the MeA nucleus.

DOPAMINE TRANSPORTER (DAT) According to Ciliax *et al.* (1999), in humans APir contains a moderately dense concentration of varicose axons.

RECEPTORS

BENZODIAZEPINE RECEPTOR (BNZ-R) According to Zezula *et al.* (1988), the corticoamygdaloid area (here the APir area) contains high densities of BNZ-R.

CHOLECYSTOKININE RECEPTOR (CCK-R) According to Kritzer *et al.* (1988), keeping with the general pattern of CCK binding site concentration in the ventral medial margins of the amygdala, the APir area shows a prominent concentration of CCK-R.

MONOAMINERGIC RECEPTORS

ADRENORECEPTOR α_2 According to Flügge *et al.* (1994), in the tree shrew, the area semiannularis of the cortical amygdaloid nucleus shows a high density of [^{3}H]rawolscine (its antagonist) binding sites.

ADRENORECEPTOR β_1 According to Flügge *et al.* (1994), in the tree shrew, the area semiannularis of the cortical amygdaloid nucleus contain β_1-adrenoreceptors as revealed by its antagonist [^{3}H]iodocyanopindolol.

SEROTONIN RECEPTORS

5-HT_{1A} RECEPTOR (5-HT_{1A}-R) According to Flügge *et al.* (1994), in the tree shrew, the area semiannularis of the cortical nucleus (here the APir area) is strongly labeled by [^{3}H]8-hydroxy-2(di-*n*-propylamino) tetraline (a specific agonist of the 5-HT_{1A}-R).

STEROID RECEPTORS

ESTROGEN RECEPTOR α (ER-α) According to Österlund *et al.* (2000), in both the human and monkey APir, the ER-α mRNA expression is most abundant together with that seen in the other posterior superficial nucleus, i.e., their AHi and posterior amygdaloid nucleus (the present AP/AL AHi).

Superficial Cortical-like Tertiary Olfactory Amygdala

Amygdalohippocampal Area (AHi)

Topographical Landmarks The AHi area in humans, as in the monkeys [AHi plus PCo in Plates 30 and 31 (10.7–12.0 mm) of Mai *et al.* (1997), *Atlas of the Human Brain*; AhiMC plus AHiPC in Plates/Figs. 57–66 (interaural 15.15–11.10 mm) of Paxinos *et al.* (2000), *The Rhesus Monkey Brain in Stereotaxic Coordinates*], is the most caudal of all the amygdaloid nuclei, extending between the posterior aspect of the amygdaloid complex and the anterior portion of the uncus of the hippocampal formation. Rostrally it extends ventrocaudally to the posterior division of the Me nucleus to constitute an elongated mass of rather complex shape, cell composition, and special arrangement of the neuronal population that forms it. Thus, in the formation of the AHi area participate at least two somewhat differently arranged set of neurons that merge gradually with each other and are represented mainly by a deep, wider, and nonstratified anteroventral (AV AHi) division and a superficial, narrower, but stratified posteromedial division (PM AHi). Implied by this modified naming of the major divisions of the AHi area is the inclusion of both de Olmos'(1990) "amygdalo-hippocampal area" and "posterior cortical amygdaloid nucleus" (see Heimer *et al.*, 1999). As such, the AHi area, or more exactly its posteromedial division, is separated from the large-celled CM subdivision of the BM nucleus by the compact segment of the medial medullary lamina (ml) that occupies the space intercalated between them, while at its rostral tip it is separated from the posterior Me nucleus by a narrow acellular area through which run markedly less compactly arranged strands of fibers. Caudally, PM AHi area comes to occupy a rostral portion of the uncal bridge connecting the hippocampus with the amygdala. At this level a small gap marks the boundary with Rosene and Van Hoesen's (1987) "hippocampalamygdaloid transition area" which can be distinguished by the greater width of its molecular layer, by a less clear layering of the fiber plexus that contains a richer fiber content in its superficial cell layer (L2), and, finally, by a lack of sublayering in its deep cell layer (L3). The deeper, wider, and more heterogeneous AL AHi area, which ventrally replaces the PM AHi area, stands out among the superficial nuclei of the human amygdala on account of its wide cellular area consisting mostly of large, deeply staining, densely packed neurons. This sector of the AHi area in contrast to its posteromedial counterpart is not so clearly separated from the deeper-lying amygdaloid nuclei laterally, and from the deep layers of the VCo nucleus rostrally, with which apparently it merges.

Cytoarchitectonics The molecular layer (L1) of the AHi area, which varies in width in the different sectors of this transitional gray formation, is well delineated and in its deeper aspect displays superficially a well-developed granular pial lining (Fig. 22.30). The neurons in L1 are mostly oriented parallel to the brain surface, whereas most neurons in the deeper cell layers are oriented perpendicularly. The more superficial of these cell layers (L2), although made up in great part of large pyramidal cells, also contain smaller neurons of diverse shapes. Actually, the superficial cell layer can be subdivided into two sublayres. The more superficial one is very narrow and is formed by cells arranged more loosely and more lightly staining than those in the underlying L2 proper. Some of the latter have their main axis oriented parallel to the brain surface. The deep cell layer, in contrast with L2, consists mostly of medium–sized pyramidal neurons that stain more lightly and are more densely packed.

Because of cell composition and fibroarchitectonic characteristics, the AHi area in the human amygdala can be divided into anteroventral (AV AHi) and posteromedial (PM AHi) divisions. The former shows a less clear stratification than its counterpart, the posteromedial AHi division, which can be distinguished on account of a noticeable expansion of its deep layer and a gradually and by a gradual decrease in the size and stainability of its neurons toward its depth. Nevertheless, in general, neurons are smaller and more densely arranged in the posteromedial AHi division than in the anteroventral one.

The molecular layer of the PM AHi division is wider than that seen at the level of the superior subdivision of the caudal VCo nucleus, but, it is narrow when compared with the molecular layer of the anteroventral AHi division. At first sight the cell layer in the PM AHi subarea appears to be nonstratified, but closer examination reveals that the more superficially located

neurons in this layer are more scattered and randomly arranged than those in the deeper aspect of the area whose main axes are oriented perpendicular to the brain surface. Together with large rounded or spindle-shaped neurons, there are also medium-sized neurons of different shapes, including inverted pyramids. These deeper neurons are somewhat darker staining than the superficial ones, but not as intensely staining as those in the principal anteroventral sector of the AHi area. The presence of a third cell layer together with the widening of the molecular layer marks the boundary between the PM AHi subarea and the main AV AHi division. In addition, the granular subpial layer in the surface of this subarea is better developed than in the main AHi body.

Fibroarchitectonics In neurofibrillar preparations the PM AHi subarea appears to be characteristically encapsulated in both its dorsal and lateral deep portions and is therefore clearly separated from the ventral Me and the large-celled dorsomedial BM nucleus. These fibers eventually join the medullary fiber systems linked to the stria terminalis. At its rostral pole this fiber capsule separates this AHi subarea from the caudal division of the VCo nucleus; it is also at this level that the PM AHi division experiences a densification of its cell layer and shows a more cortical-like appearance than more caudally. Immediately superficial to the cell layer and occupying the whole width of the molecular layer are fine fibers running in every direction, forming a relatively rich network. The cell layer, on the other hand, is traversed by a not-so-rich system of radially oriented fibers that converge in the deep aspect of the nucleus to form a richer fiber plexus that constitutes part of the fiber capsule covering the nucleus laterally and dorsally.

As here described, the AHi area corresponds to Broackhaus' (1938) area periamygdalae caudalis ventralis and dorsalis or the greater part of Stephan's (1975) area parahippocampalis, and coincides with that defined by Gloor (1997). With respect to Sorvari *et al.* (1995–1996) mapping in the human brain of this transition field, the present parcellation of the AHi area corresponds to the caudal sector (here the AV AHi division) of the much larger area defined by them as such. As was been stated before, the present definition of AHi area includes their posterior cortical nucleus (here the PM AHi division).

Sasagawa (1960a) reports that in the chimpanzee the AHi area is identified as part of the periamygdaloid cortex (pam), with his subdivision Pam3 alpha corresponding to the AL AHi subfield and his subdivision Pam2 alpha, to the PM AHi subdivision of the present parcellation. This was also done in the woolly howling monkeys (Sasagawa, 1960) and in the macaque monkey (Mikami,1952). The AHi area as delimited by Barbas and de Olmos (1990) and by Paxinos *et al.* (2000) would probably correspond to its homonimous as here described.

Chemoarchitectonics

Heavy Metals The Timm-Danscher selenium pattern in monkeys shows a rather uniformly distributed Timm-positive neuropil throughout the nucleus, including the whole width of its molecular layer. This staining contrasts with the moderate to weak staining of the superficial cell layer in the main AHi, which is even more moderate than in the deeper aspects of this region. Also, though in a reverse manner, the heavier Timm-Danscher staining of the molecular layer in both divisions of the AHi area contrasts sharply with that in the subjacent superficial and deep layers of this transitional formation, so that when taken at its whole the main body of the AHi area appears enclosed by Timm-Danscher heavy silver deposits that are present in surrounding tissue. By generating such a picture, this histochemical procedure provides a very accurate means of separating the AHi area from surrounding superficial grisea such as the APir area and the VCo nucleus, more particularly from its deep cell layers which appear markedly densely stained (Alheid and de Olmos, unpublished observations). Is important to point out that in trying to find homologous brain structures among different mammalian species, in terms of the distribution pattern of the Timm-Dancher–positive staining in monkey material examined by us, a striking similarly in such distribution seems to take place in a presumably homologous division of the rat amygdala (de Olmos *et al.*, 1985). More specifically, as happens in the monkey brain, its molecular layer is totally filled with silver granules. Such disposition clearly contrast with the presence in both posteromedial (the posterior cortical nucleus of Canteras *et al.*, 1992) and posterolateral amygdaloid nuclei de Olmos *et al.*, 1985; Alheid *et al.*, 1995; Swanson, 1992), as also happens in the primary olfactory cortex of very sharply and negatively stained subpial laminae 1a intervening between brain surface and an otherwise densely stained sublamina 1b in the molecular layer of all these structures. Importantly, such a pattern is even more clearly displayed in the amygdala of Timm-Danscher's stained sections of the rabbit and guinea pig amygdala (unpublished observations).

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) In AChE preparations of the human amygdala, Benzing *et al.* (1992)

described the AHi area as being moderately stained but nevertheless delineated from the anterior hippocampal formation and the nuclei of the posterior amygdala.

According to Amaral and Basset (1989) in the macaque monkey, the amygdalohippocampal area (here the AL AHi subdivision) contains the greatest density of cholinergic markers, showing a AChE staining that parallels the ChAT staining except for the occasional presence of AChE-positive cells.

CHOLINE ACETYLTRANSFERASE (CHAT) Although Emre *et al.* (1993) had a moderate density of ChAT-positive fibers, such a statement applies to a transition field that intervenes between the caudal end of the amygdalohippocampal area proper, which they labeled as cortical amygdaloid nucleus, and the hippocampal formation.

According to Amaral and Basset (1989), in the macaque monkey, the amygdalohippocampal area (here the AL AHi subdivision) contains the greatest density of cholinergic markers, showing a relatively dense ChAT-ir that has a particulate appearance similar to that seen in the nuclei of the LBNC.

EXCITATORY AMINO ACIDS

GLUTAMATE (GLU) No primate or nonhuman primate information is available to the present writer concerning this point. See, however, the section on heavy metals.

INHIBITORY AMINO ACIDS

γ-AMINOBUTYRIC ACID (GABA) According to Pitkänen and Amaral (1994), in the macaque monkey, the AHi area (here the anterolateral division of AHi) contains a high number of GABA-ir cells that are very similar to those in the VCo nucleus. Many GAD mRNA-labeled cells are evenly distributed in this transitional gray formation. The GABA-ir neuropil is also highly dense, and basket-like plexuses around non-ir somata are common. On the other hand, the caudal part of their posterior cortical nucleus, which here is considered to be part of the posteromedial division of the AHi area, also contains a very high number of GABA-ir neurons. There is a dense GABA-ir in the neuropil of this sector of the caudal amygdala which in the superficial aspect of L2 presents numerous basket-like profiles.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) (NORADRENALINE/NOREPINEPHRINE) According to Sadikot and Parent (1990), in the squirrel monkey, the AHi area shows only light DBH-ir.

SEROTONIN (5-HT) According to Sadikot and Parent (1990), in the squirrel monkey, the AHi area is notable for a very heavy concentration of 5-HT-ir terminal varicosities.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey the AHi area shows no TH-ir terminal varicosities.

NEUROPEPTIDES

CHROMOGRANIN B Although Marksteiner *et al.* (1999) do not mention this transitional field among the amygdaloid nuclei that express PE-11-like ir, their illustrations (Fig. 3C, D) clearly indicate that the whole extent of the AHi area contains high amounts of this neuropeptide.

COCAINE- AND AMPHETAMINE REGULATED TRANSCRIPT (CART) According to Hurd and Fagergren (2000), both their posterior cortical nucleus and amygdala–hippocampal area (corresponding jointly to the present AHi), together with MeA nucleus, show the highest CART mRNA expression in the human amygdala.

CORTICOTROPIN-RELEASING FACTOR (CRF) According to Basset *et al.* (1992), in the macaque monkey, the density of CRF-ir fibers in the superficial and the so-called cortical regions of the amygdala seems to be light-to moderate to that observable in the Ce and La amygdaloid. Within their posterior cortical nucleus (here the PM AHi subdivision) darkly coarse CRF-ir fibers with numerous large varicosities are present that are confined to the most superficial portion of L1a. In addition, a lesser density of medium to coarse CRF-ir fibers and occasional CRF-ir neurons similar to those present in the MeA are present in the deeper layers.

GALANIN (GAL) According to the mapping of the forebrain distribution of this neuropeptide presented by Kordower *et al.* (1992), in the macaque monkey amygdala, this member of the superficial amygdala, like its other components, does not contain GAL-ir cell bodies, although it seems to contain at least a light amount GAL-ir fibers.

NEUROPEPTIDE Y (NPY) In their mapping of the distribution of NPY in the human telencephalon, Walter *et al.* (1990) do not mention this nucleus. However, they depict it in their mapping (Fig. 1e) as containing a low number of NPY-ir fibers or cells.

NEUROTENSIN (NT) The AHi contains a light to moderate NT-ir that is homogeneously distributed

across its extent, consisting primarily of beaded fibers and dot-like puncta. NYT-ir neurons are not present in this transitional formation (Benzing *et al.*, 1992).

OXYTOCIN (OXT) Caffé *et al.* (1989) state that in the macaque brain the telencephalic are most densely innervated by the OXT-ir fibers is the cortical nucleus. However, from a close examination of their schematic mapping concerning the distribution of these fibers within the amygdala, it can be inferred that at least some of that innervation takes place in the PM AHi area.

SOMATOSTATIN (SOM) In the macaque monkey (Amaral *et al.*, 1989), the AL AHi area has a moderate plexus of SOM-ir fibers and terminals and scattered SOM-ir cell bodies. The dense fiber staining seen in layer 1 of other superficial amygdaloid nuclei also covers the superficial surface of AHi, which stops sharply at the boundary of the hippocampal formation [Rosene and van Hoesen's (1987) HATA]. In this animal, the caudal part of the so-called posterior cortical nucleus (here the PM AHi area) by Sorvari *et al.* (1996a, b) contains a dense plexus of fibers in L1 and relatively few scattered SOM-ir cell bodies.

VASOPRESSIN (VP) According to Caffé *et al.* (1989), in the macaque monkey, dense accumulations of VP-ir fibers are found in the cortical nucleus, which according to the present amygdaloid parcellation seems also to include, among others, the PM AHi subarea, though such presence may be due to fibers of passage with destiny to the hippocampal formation.

NEUROTROPHINS

BRAIN-DERIVED NEUROTROPHIC FACTOR (BDNF) According to Murer *et al.* (1999), in the human brain, all of the amygdaloid nuclei contain BDNF-ir neurons and fibers. However from their Fig. 4A and guided by topographical landmarks, it seems plausible that the density of the BDNF-ir in the AHi area is relatively high at least in its nonsuperficial anterolateral division.

ENZYMES

NICOTINAMIDE ADENINE DINOCLEOTIDE PHOSPHATE DIAPHORASE (NADHP-D) In Figs. 10D and 11D of Simms and Williams (1990) report on the distribution of this enzyme in the human amygdala, the AHi, both its posterior and anterolateral divisions, appears positively stained for NADHP-d included in the medial and lateral divisions of their cortical nucleus. In addition, their description of the NADHP-d–ir neuronal population corresponding to these divisions do not seem to correspond to the neuronal population proper of the posterior VCo but rather to the AHi neuronal pool. However, the existence of this type of neurons has been postulated for the whole amygdala by Unger and Lange (1992).

P450 AROMATASE (P450 AROM) Close examination of the illustrations presented by Roselli *et al.* (2001) indicates that these authors have included both the AL and PM divisions of the AHi in what they call the cortical amygdaloid nucleus. If this criterion is accepted, then the conclusion is that the AHi has the highest density of P450 AROM mRNA-labeled cells in the amygdaloid nucleus.

PROTEINS

CALCIUM-BINDING PROTEINS

CALBINDIN (CAB) According to Sorvari *et al.* (1996b), the caudal half of their amygdalohippocampal area (i.e., the AL AHi division) contains a high density of CAB-ir type 1 neurons. Numerous large type 2 and a few type 3 neurons with long, thick dendrites can be also observed. In the so-called posterior cortical nucleus (i.e., the PM AHi division), L1 contains virtually no CAB-ir cells. In L2, which is seen as a dark band of darkly stained angular cells in Nissl-sections, there are a moderate number of small and round type 1 CAB-ir neurons. In L3, the CAB-ir neurons are morphologically more heterogeneous. They consist of type 1 and 2 cells that are larger and have thicker and longer dendrites than the neurons in L2. A few type 3 neurons are also observed.

The intensity of CAB-ir fibers in the AL division of the AHi area is high and the CAB-ir of the neuropil is moderate, similar to that in the PM division of this transitional area. The AL division of the AHi area contains the highest density of CAB-ir bundles in the human amygdala. In the PM division of the AHi area, the density of the CAB-ir fibers and of the CAB-ir neuropil is high in L2 and L3; however, L1 contains significantly fewer fibers. Finally, L2 and L 3 have a moderate density of CAB-ir bundles, which are oriented perpendicular to the pial surface.

CALRETININ (CR) According to Sorvari *et al.* (1996a), their posterior cortical nucleus, which in their illustrations (Figs .2A, 4A, and 6A) includes the P AHi as well as the superior subdivisions of both rostral and caudal divisions of the VCo nucleus, contains a moderate density of small CR-ir neurons of their class 1 and 3. The density of the CR-ir fibers, terminal, and neuropil is stated to be moderately high, but not as high as in the MeA nucleus or in their AHi. A difference between the fiber distribution in rostral and caudal parts of their posterior cortical nucleus is noted.

Furthermore, their AHi includes Al AHi of the present account and also the intermediate subdivision of both rostral and caudal VCo contains their three types of CR-ir neurons. Their medial subdivision of AHi, most probably corresponding to the intermediate subdivisions of both rostral and caudal VCo in the present account, is said to contain numerous large type 2 and type 3 neurons with their main axis oriented perpendicularly or obliquely to the pial surface. Furthermore, the neuronal density in this medial part is higher than in their lateral part of AHi (AL AHi proper), and coincidentally with it, it is here the only place in the whole amygdala that displays CR-ir neurons showing dendritic spines. Finally, the density of the CR-ir fibers is moderate with the highest number of these fibers in their medial part.

PARVALBUMIN (PAV) According to Sorvari *et al.* (1995), in their posterior cortical nucleus, which corresponds to superior subdivisions of both rostral and caudal major divisions of the VCo nucleus, as well as de Olmos (1990), the number of PA-ir neurons is scarce, and such neurons are mostly small, palely stained type 1 and 2 cells. On the other hand, their AHi is said to contain all three types of PAV-ir neurons. The cell density is described as relatively high in their lateral part of AHi (here AL AHi), while the density in their medial AHi (i.e., the intermediate subdivisions of both rostral and caudal VCo here, is said to be lower. The density of PAV-ir cells increases toward the caudal end of AHi. Furthermore, the density of PAV-ir fibers correlates with the cell density. Consistent with that, the largest proportion of these fibers is found in the area corresponding to the caudal levels AL AHi.

Other Proteins

DOPAMINE- AND ADENOSINE-3′,5′-MONOPHOSPHATE (cAMP)–REGULATED PHOSPHOPROTEIN OF M, 32 KDA (DARPP-32) AND PHOSPHATASE INHIBITOR 1 (I-1) According to Barbas *et al.* (1998), in the macaque monkey, the AHi area contains both DARPP-32-ir and I-1-ir neurons, but the former are more numerous and more densely stained than the latter. I-1-ir fibers can be detected in the AHi area. The posterior cortical nucleus of this autors, i.e., the posteromedial division of AHi, is said to contain many I-1-ir and DARPP-32-ir neurons.

LIMBIC SYSTEM–ASSOCIATED MEMBRANE PROTEIN (LAMP) According to Côté *et al.* (1996), in the macaque amygdala, their amygdalohippocampal area and their posterior cortical nucleus, i.e., the anterolateral and posteromedial divisions of the AHi of the present account, display different LAMP-ir with the former being apparently devoid of this protein and the latter showing a moderate LAMP-ir.

SMI32 NEUROFILAMENT PROTEIN (SMI32-IR) From the low-magnification atlas on the distribution of this protein in the macaque brain published by Petrides *et al.* (2000), it seems that the most medial sectors of the AL AHi area contain some SMI32-ir whereas the PM AHi is completely devoid of SMI32-ir.

RECEPTORS

Cholinergic Receptors

MUSCARINIC RECEPTOR (M-R) From the mapping of the distribution of M-R in the human brain by Cortés *et al.* (1987), it is evident that in their Fig. 20 they include both divisions of the AHi in what they depict as the cortical nucleus. If this interpretation is correct, then AHi would contain moderate concentration of this receptor. On the other hand, according to Smiley *et al.* (1999), the amygdala as a whole contains a low density of m_2-ir neurons.

NICOTINIC RECEPTOR (N-R) No primate information is available to the present writer.

CCK RECEPTOR (CCK-R) According to Kritzer *et al.* (1988), keeping with the general pattern of CCK binding site concentration in the ventral medial margins of the macaque monkey amygdala, the AHi area shows a prominent concentration of CCK-R.

Steroid Receptors

ESTROGENIC RECEPTOR (ER)

Estrogen Receptor α (ER-α) According to Blurton-Jones *et al.* (1999), the AHi in humans can display a large, very dense population of ER-α-labeling nuclei (Fig. 3C). By contrast, at least in their studies, only rarely could this type of receptors be detected in the hippocampus proper. This confirms the studies of Osterlund *et al.* (2000), made in human and monkey brains, in which they also found a most abundant expression in their amygdalohippocampal area and their posterior cortical nucleus.

NEUROKININ-1 RECEPTOR (NK-1R) According to Mileusnic *et al.* (1999), in the human amygdala, the density of NK-1R shows the highest expression at the level of AHi and in the ACo, but no mention is made of other superficial amygdaloid nuclei.

Serotoninergic Receptors (5-HT-R)

5-HT_{1A} RECEPTOR (5-HT_{1A}-R) According to Flügge *et al.* (1994), in the tree shrew, the AHi area is strongly labeled by [^{3}H]DPAT, a specific agonist of 5-HT_{1A}-R.

5-HT_{2C} RECEPTOR (5-HT_{2C}-R) Examination of the illustration presented by Lopez-Gimenez *et al.* (2001) it seems that they have included the AHi as a part of their medial amygdaloid nucleus and as such this area would also contain a high density of this type of receptors.

Non Assignable Amygdaloid Formations

Amygdalostriatal Transition Zone (AStr)

The Amygdalostriatal transition zone (Figs. 22.1a, b, 22.8, 22.11, 22.28) [AStr in Plates 25 to 38 (4.0–21.2 mm) in Mai *et al.* (1997), *Atlas of the Human Brain*; not identified in Paxinos *et al.*'s (2000), The Rhesus Monkey Brain in Stereotaxic Coordinates"], named as IPAC in the *Atlas of the Human Brain*, as its name implies, is a transitional zone which at rostral levels of the amygdala appears intervening between the lateral division of the central amygdaloid nucleus (Ce) and the temporal limb of the anterior commissure and at caudal levels comes to lie between the lateral Ce and the striatum. This comparatively small-celled transitional area displays cytoarchitectonic features which, in Nissl sections, look like those of the main member of the nonassignable amygdaloid formations, making it difficult to distinguish the AStr from the latter. A closer look reveals that the neuronal population of the AStr zone is made up of somewhat smaller, rounder cells quite loosely arranged. In sections impregnated with a modification of the Glees procedure, the AStr neurons do not show the characteristic fishlike appearance of the central nucleus neurons, and this facilitates the distinction between these two grisea. Furthermore, it has been possible to establish that in monkeys of the New World at least, but not in macaque monkeys, AStr does not display, under normal conditions, the typical argyrophilic reaction described for the central division of the extended amygdala. This evidence is complemented by differential staining of these structures by the AChE procedure, being denser in AStr than in the lateral Ce. As described here, the AStr seems to be comparable to Brockhaus' (1940) striatum limitans.

Chemoarchitectonics

Heavy Metals In sections of the squirrel and marmoset brains stained by the Timm-Danscher (1981) procedure, it is apparent the less precipitate

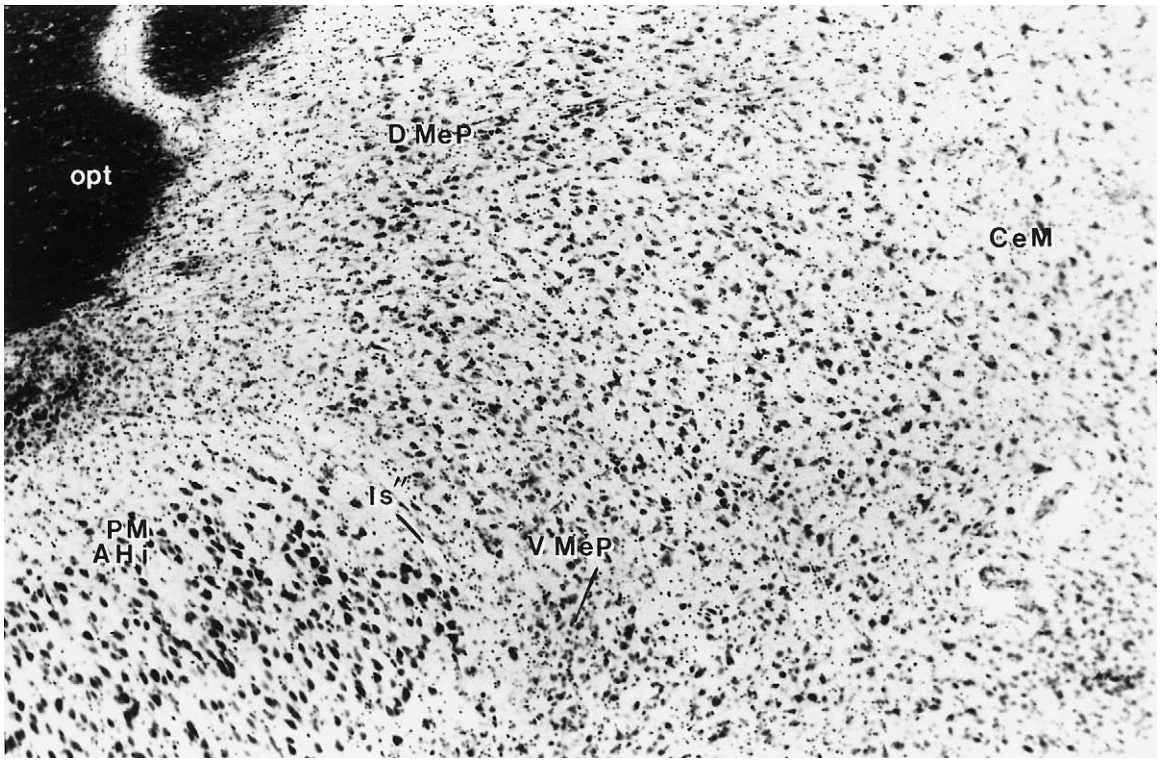

FIGURE 22.28 Medium power photomicrograph of a Cresyl violet-stained coronal section through the caudal portion of the human amygdaloid nuclear complex to show the topographical relationships between the two main members of the MeNG, the medial amygdaloid nucleus (D MeP and V MeP) and the amygdalohippocampal transition area (PM AHi).

distinguishes this structure from the heavily labeled central amygdaloid nucleus. On the other hand, the AStr zone stains darker than its neighbor, the ventral caudal putamen.

Neurotransmitters and Neuromodulators

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (ACHE) While a denser AChE staining allows one to discriminate between the AStr zone and the central amygdaloid nucleus, the situation becomes reversed when comparing its level of AChE positivity with that of the striatum proper (more specifically, the ventral caudal putamen, a structure that shows a much higher AChE activity).

CHOLINE ACETYLTRANSFERASE (CHAT) No human or nonhuman primate data is available to the present writer.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey, the ventral striatum is difficult to distinguish from the CeL division on the basis of DBH immunochemistry due to the similar uniform and moderate DBH-ir present in the two areas. The amygdalostriatal area shows moderately dense DBH-ir terminal labeling.

DOPAMINE TRANSPORTER (DAT) According to Celiax *et al.* (1999), many DAT-expressing fibers were found in the human AStr. Punctate neuropil appears to consist of dense varicose axons and shows similar in appearance to that seen in striatum proper. However, the fibers were not as densely arranged as in the striatum. Consequently, many straight, branching, non-varicose axons were also seen through the neuropil.

SEROTONIN (5-HT) According to Sadikoy and Parent, in the squirrel monkey, the periamygdaloid ventral striatum (IPAC?) Shows a rostrocaudal gradient of increasing 5-HT-ir terminals ranging from dense at the amygdalostriatal area to very dense at the caudal interface with the CeL division of the Ce nucleus.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), the intra-amygdaloid ventral striatum (IPAC?) shows dense terminal TH-ir rostrally at the amygdalostriatal area and at its caudal interface with the CeL division of the Ce nucleus.

NEUROPEPTIDES

CALCITONIN GENE–RELATED PEPTIDE (CGRP) According to De La Calle and Saper (2000), in the human brain, patches of CGRP-ir fibers bridge this area with the Ce nucleus.

CHOLECYTOKININ (CCK) In the baboon monkey, the AStr zone not only contains moderate amounts of CCK–ir varicose fibers and punctate profiles but also a few CCK–ir neurons (Martin *et al.*, 1991).

ENKEPHALIN (ENK) According to Heimer *et al.* (1999), the AStr zone in humans is strong in ENK-ir On the other hand, in three different monkeys (macaque, green monkey, and baboon), apart from containing a moderate density of ENK-ir varicose fibers and punctate profiles, the AStr zone also contains ENK–ir perikarya (Martin *et al.*, 1991).

NEUROTENSIN (NT) While the density of NT-ir varicose fibers and punctate profiles ranges from low to moderate in the AStr zone of the macaque, green, and baboon monkey AStr zone, few NT–ir neurons are present at least in the green and baboon monkeys (Martin *et al.*, 1991).

SECRETONEURIN (SECR) Although the AStr zone in the human brain contains SECR-ir fibers, their concentration is lower than in the central amygdaloid nucleus (Kaufman *et al.*, 1997).

SOMATOTASTIN (SOM) While in humans the CCK–ir at the level of the AStr zone seems to be limited to punctate profiles and even these are not abundant, in the macaque monkey, to the contrary, the density of SOM-ir varicose fibers and punctate profiles is significantly high (Martin *et al.*, 1991).

SUBSTANCE P (SP) According to Heimer *et al.* (1999), the AStr zone in human is poor in SP-ir.

CALCIUM BINDING PROTEINS

CALBINDIN (CAB) Although not mentioned by Sorvari *et al.* (1996) in their report of the distribution of this protein in the human amygdala, examination of their illustrations clearly shows that the area here assigned to the AStr zone in humans would contain both CAB-ir fibers and perikarya in clear contrast with the central amygdaloid nucleus, which almost completely lacks CAB-ir.

CALRETININ (CR) Although not mentioned by Sorvari *et al.* (1996) in their report on the distribution of this protein in the human amygdala, examination of their illustrations clearly shows that the area here assigned to the AStr zone in humans contains both CR-ir fibers and cell bodies, but no particular differences

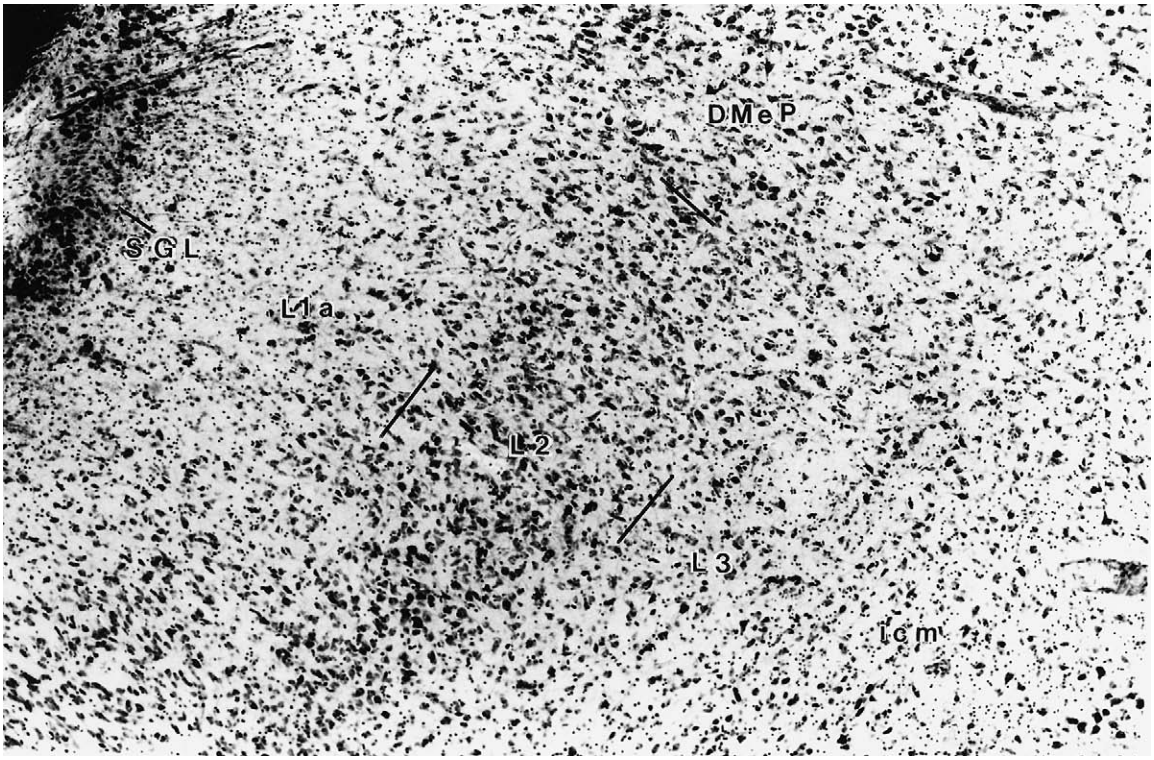

FIGURE 22.29 High-power photomicrograph of a more rostrally cut coronal section from the same brain stained with Cresyl violet showing the cytoarchitectural organization of the ventral part of the posterior division of the medial amygdaloid nucleus (V MeP).

in density of staining can be seen with respect to either the striatum or the central extended amygdala.

PARVALBUMIN (PAV) Although not mentioned by Sorvari *et al*. (1995) in their report on the distribution of this protein in the human amygdala, examination of their illustrations clearly shows that the area here assigned to the AStr zone in humans contains both PAV-ir fibers and cell bodies in clear contrast with their almost complete absence in the immediately adjacent central amygdaloid nucleus. At the same time, it is also visible that the AStr zone contains a lesser amount of PAV-ir than the ventral caudal putamen. The same appears to be true for the macaque AStr zone (Pitkänen and Amaral, 1993).

Interface Islands (IC)

The islands of granular neurons or interface islands (IC), a term shared by Sakamoto and Pearson (see Heimer *et al.*, 1999), are concentrated primarily in the ventral parts of the accumbens and putamen, and are constituted by numerous, more or less compact clusters of basal forebrain cells which are not related to the "islands of Calleja" in the macrosmatic animals, or to Sanides' (1957b) "terminal islands." As noted by Heimer *et al*. (1999), these islands are not restricted to the ventral striatal areas but are also found throughout much of the basal forebrain, especially in relation to the extended amygdala from which they are also components. In the amygdaloid body, where practically all islands are of the parvicellular variety, they are known as intercalated islands since they are located almost without exception between the extended amygdala and the rest of the amygdaloid body, or between components of the extended amygdala. These interface islands can be grouped on the basis of their cell composition in two groups: granular and parvicellular interface islands. The former, as their name indicates, are composed of granular cells, the best example of which are the gamma 1 insulae terminales of Sanides (1957). The second are constituted by somewhat larger and more heterogeneous neurons, the best example of which are the so-called gamma 2 and gamma 3 terminal islands of Sanides (for more details, see Heimer *et al.*, 1999).

From the archipelago-like chain of parvicellular ICs that extends caudally from the dorsomedial accumbens to the lateral bed nucleus of the stria terminalis, a string of this type of cell can be traced along the

supracommissural portion of the bed nucleus of the stria terminalis (BSTS), a route by which they eventually reach the amygdala. Along the course of the stria terminalis lying intercalated between the caudate nucleus and the BSTS grisea that accompanies it are prominent accumulations of interface islands, named paracaudate (interface islands by Heimer *et al.*, 1999) who provide a detailed report.

Chemoarchitectonics

Neurotransmitters and Neuromodulators

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) Histochemical studies by Heimer *et al.* (1999) indicate that many of the parvicellular and granular interface islands show moderate to strong AChE reactivity. Although many interface islands can show AChE reactivity even stronger than surrounding striatal formations, there are, AChE-poor islands irregularly distributed in the human and monkey basal telencephalon. On the other hand, since the islands do not possess intrinsic cholinergic neurons, the AChE reactivity should be in fiber and terminals having presumably their source in some of the cholinergic cell groups in the basal telencephalon.

CHOLINE ACETYLTRANSFERASE (ChAT) Although no specific data deal with ChAT in the neuroanatomical literature consulted by the present writer, and in view of the general coincidence encountered when comparing AChE-stained sections with ChAT-immunostained sections, it is assumed here that the distribution pattern of ChAT-ir fibers and terminals would be consistent with such a pattern.

NEUROPEPTIDES

ENKEPHALIN (ENK) Within many of the parvicellular interface islands, many groups of cells distribution patterns that are complementary or not with that they possess for the SP-ir (Heimer *et al.*, 1999).

NEUROPEPTIDE Y (NPY) According to Walter *et al.* (1990), the parvicellular islands in the above-described chain are characterized by NPY-ir fibers and cell bodies which are in continuity with the NPY-positive region in the BSTL division of the bed nucleus of the stria terminalis. Both features allow its discrimination from the neighboring caudate nucleus.

CHOLECYSTOKININ (CCK) According to Heimer *et al.* (1999), in the human telencephalon the interface islands seems to be special targets for axons containing CCK. On the other hand, in the paracaudate interface island CCK-ir neuronal perikarya are also present.

SOMATOTASTIN (SOM) According to Heimer *et al.* (1999), in the human telencephalon, the interface islands seem to be special targets for axons containing SOM possibly coming from the Ce nucleus (Mufson *et al.*, 1988).

SUBSTANCE P (SP) According to Heimer *et al.* (1999), many of the parvicellular interface islands existing in the human basal telencephalon contain moderate to strong SP-ir processes and perikarya while others may have little or none.

Intercalated Cell Masses (ICMs)

As in nonhuman primates and subprimate mammals, the human amygdala contains groups of closely packed, granule-like neurons generally scattered among the different amygdaloid nuclei lying between, around, or within them. These groups of cells appear most prominently in the caudal half of the amygdaloid complex. In Nissl sections these groups of granule-like neurons show varying staining, so that in some of these masses the cells show somewhat light staining and in others even a prominently dark staining. The most outstanding ICM is located between the Ce and BM, and in appropriately oriented horizontal or sagittal sections it can be seen that, as in nonprimate mammals, one of these islands which is intercalated between the Ce and BM nuclei extends along the boundary line between them and eventually turns laterally around the back of Ce where it comes to lie between this nucleus and descending fascicles of the stria terminalis. Another conspicuous group is located between the ACo and Ce nuclei, or between this latter and the AStr, or between this transitional field and the La; or in the intersection between BM, VMBL, and VCo, etc. ICM are seen less often within the BM nucleus or the AAA area.

Chemoarchitectonics

Heavy Metals In Timm's/selenite-stained sections, the distribution of the silver precipitate shows exactly the inverse pattern as that observed for the AChE reaction. That is, while a majority of the ICM show heavy silver deposits, those around La appear rather weak.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) Although most of the island-like gray formations stain negatively or show a rather weak AChE reaction, some of them, particularly those around La, present a high level of reactivity, the same as that located in the intersection between BM,VMBL, and VCo, and situated dorsally,

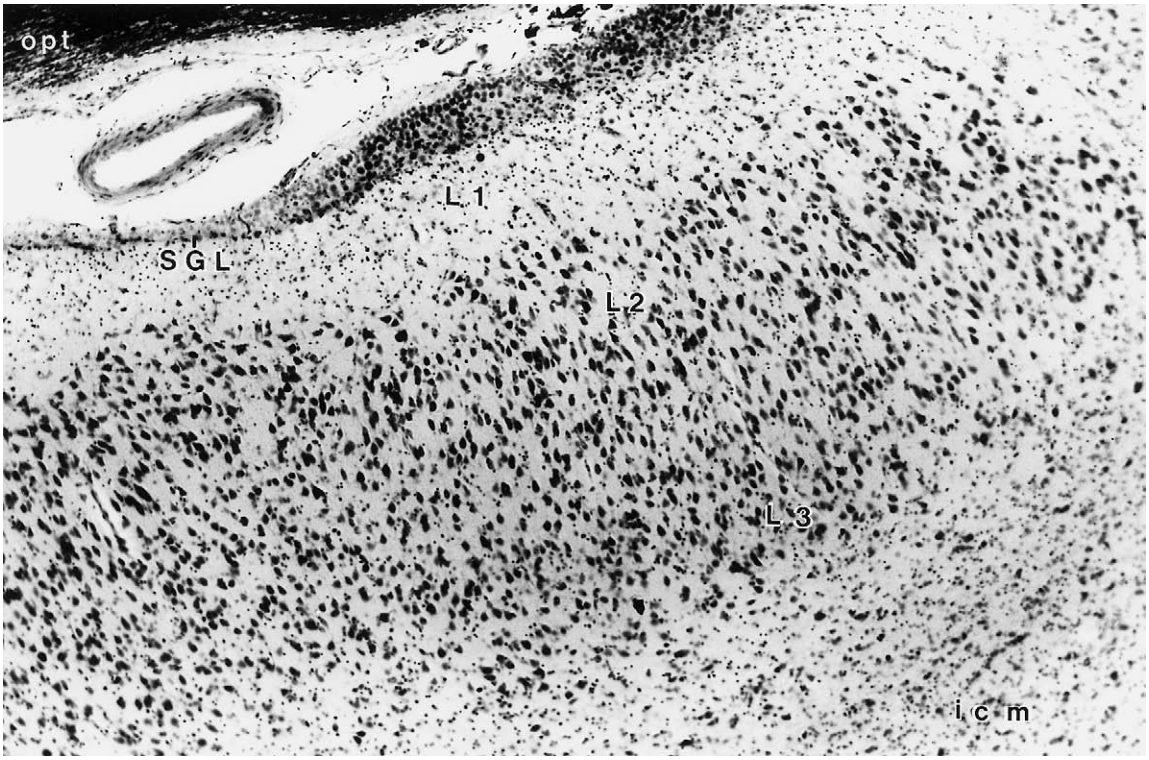

FIGURE 22.30 High-power photomicrograph of a Cresyl violet-stained coronal section through the posteromedial division of the amygdalohippocampal transition area of the human amygdala to show some details of its cytoarchitectonic organization.

caudally, and ventrally surrounding the ACA (see Simm and Williams, 1990; de Olmos, 1990; Heimer *et al.*, 1999).

According to Amaral and Basset (1989), in the macaque monkey most of the ICMs show a moderate AChE staining. However, some of these cell conglomerates contain high levels of this cholinergic marker. The ICMs located medially to the APir area contain a dense AChE activity. In the amygdala of the New World monkeys (i.e., squirrel monkey and marmoset), a similar distribution can be found according to AChE-stained material available to the present writer.

CHOLINE ACETYLTRANSFERASE (CHAT) According to Amaral and Basset (1989), in the macaque monkey most of the ICMs show a moderate ChAT-ir. However, as it happens in AChE-stained material, some of these cell aggregates show high levels of ChAT-ir. The ICMs located medially to the APir area likewise show a dense ChAT-ir.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) According to Sadikot and Parent (1990), in the squirrel monkey, the intercalated masses display very light and moderate DBH-ir terminal labeling.

HISTAMINE (HA) According to Airaksinen *et al.* (1989; Fig. 3), in the tree shrew, the ICM islands would be innervated by HA fibers.

SEROTONIN (5-HT) According to Freedman and Shi (2001), in the macaque monkey, there are relatively heavy concentrations of 5-HT-ir in an intercalated group ventromedial to Ce nucleus. In the squirrel monkey, the intercalated masses show a light density of 5-HT-ir terminal labeling.

TYROSINE HYDROXYLASE (TH) According to Sadikot and Parent (1990), in the squirrel monkey, the intercalated masses show a dense to moderately dense field of TH-ir terminal varicosities.

EXCITATORY AMINO ACIDS

GLUTAMATE/ASPARTATE (GLU/ASP) Retrograde tracing experiments made in rats using tritiated D-aspartate indicate that a considerable number of the ICMs ventral to the BL nucleus would be a source of

GLU/ASPergic strong projections to the ventral pallidum and olfactory tubercle and in a more reduced manner to the ventral striatum (Fuller *et al.*, 1987).

INHIBITORY AMINOACIDS

γ-Aminobutyric Acid (GABA) According to McDonald and Augustine (1993), in the macaque monkey all of the small cells but none of the large neurons present in the ICM nuclei are GABA-ir. These authors, together with Pitkännen and Amaral (1994), agree that most of the intercalate nuclei show a higher number of GABA-ir or GAD mRNA labeled cells than that present in the nuclei of the LBNC. A few intercalated nuclei present substantially fewer GABA-ir or GAD mRNA-labeled cells. The most distinctive feature of the intercalated nuclei is their very high density of GABA-ir fibers and terminals being the densest in the whole monkey amygdala.

NEUROPEPTIDES

Galanin (GAL) From the description and mappings presented by Kordower *et al.* (1992), on the basis of macaque monkey material, it does not seem that these cells contain any type of GAL-ir.

Neuropeptide Y According to McDonald *et al.* (1995), in the macaque monkey, very few NPY neurons are present in the ICMs.

Neurotensin (NT) According to Benzing *et al.* (1992), these island formations were densely NT-ir, consisting of a dense network of ir fibers and puncta. These formations are also characterized by the presence of numerous darkly stained and densely packed small to medium-sized multipolar or round neurons. The number of NT-ir neurons varies across the different IC accumulations both within and between cases.

Somatotastin (SOM) In the Macaque monkey the IC islands show light to moderate SOM-ir fibers and terminals as well as few SOM-ir cell bodies. McDonald *et al.* (1995) report few if any SOM-ir cell bodies in the ICMs. According to Desjardins, in the squirrel monkey, the intercalated masses display a neuropil staining whose intensity ranges from light to moderate.

CALCIUM-BINDING PROTEINS

Calbindin (CAB) According to Sorvari *et al.* (1996b), in the human amygdala, the amount of CAB-ir in the different intercalated nuclei varied. Most of the intercalated nuclei contained a large number of small, round, and densely packed CAB-ir neurons, while some of them contained few or no cells. Furthermore, the fiber and neuropil CAB-ir also varied greatly among the intercalated nuclei.

Parvalbumin (PAV) According to Sorvari *et al.* (1995), the PAV-ir varies slightly between the ICMs, with some nuclei showing only a few small PAV-containing neurons with short dendrites and others being completely negative. Moreover, the density of the PAV-ir-containing fibers and terminals was low.

OTHER PROTEINS

Dopamine- and Adenosine-3′,5′-monophosphate (cAMP)–Regulated Phosphoprotein of M, 32 kDa (DARPP-32) and Phosphatase Inhibitor 1 (I-l) According to Barbas *et al.* (1998), in the macaque monkey amygdala, many neurons moderately or robustly labeled for DARPP-32 or I-l can be found in the intercalated masses located between the medial, central, basolateral, and lateral nuclei. I-l-ir fibers can be found in the IC masses between the La and BL nuclei and between the BL and BM nuclei. These immunoreactive fibers joined laterally and continued through the central part of the basal forebrain.

Limbic System–Associated Membrane Protein (LAMP) According to Côté *et al.* (1996) in the macaque amygdala, the intercalated nuclei are devoid of LAMP-ir.

Neurofilament Protein SMI32 (SMI32) To judge from the low magnification in the Petrides *et al.* (2000) atlas on the distribution of the SMI32 neurofilament protein in the macaque monkey brain, these islands formations do not seem to contain any SMI32-ir.

RECEPTORS

Adrenergic Receptors

adrenoreceptor α_1 According to Flügge *et al.* (1994), in the tree shrew, the IC nuclei show a strong binding of [^{3}H]PRA, an α-adrenoreceptor antagonist indicative of the presence of this type of adrenoreceptor.

adrenoreceptor α_2 According to Flügge *et al.* (1994), in the tree shrew, IC nuclei show a high density of [^{3}H] RAU binding sites, RAU being indicative of the presence of this type of receptor.

benzodiazepine receptor (BNZ-R) According to Zezula *et al.* (1988), in the human amygdala, the IC cell masses contain very high concentrations of BNZ-R.

Cholinergic Receptors

muscarinic receptor (mACh-R) According to Cortés *et al.* (1987), in the human amygdala, the highest

densities in mACh-R can be detected in small cell masses lateral to the dorsal pole of the BL nucleus and along the ventrolateral surfaces of the La nucleus, which are identified as ICMs.

NICOTINIC RECEPTOR (NACH-R) This type of receptor, labeled as [^{3}H]ACh or [^{3}H]nicotine, shows very low concentrations in all nuclei of the rat amygdaloid complex (Rainbow *et al.*, 1984; Clarke *et al.*, 1985). No other source of this type of data is available to the present writer about the distribution of this type of receptor in the primate amygdala.

Intramedullary Griseum (IMG)

The intramedullary grisea (IMG) was first described for the rat amygdala as a narrow gray formation associated with the Ce. Such association was induced by the difficulty that it presented its full identification in the very narrow interface between the components of the LBNC themselves, on one side, and between them and the rest on the amygdaloid nuclei. However, in the guinea pig brain (unpublished personal observations) it is not as difficult to verify its existence, but this becomes far more evident in the amygdala of primates. Thus, whereas in the Nissl sections of the rat brain IMG appears represented by small, narrow clusters of neurons or even single neurons aligned along the fiber septa separating the Ce from the BL but becomes far more difficult to follow in its prolongation to other sectors of the amygdala, in the primate brain the IMG constitutes a much more generalized and easily traceable morphological entity.

IMG is composed of neurons of various sizes and shapes with well-defined perikarya but of varying stainability that are interspersed among the fibers of the medullary laminae, which are intercalated not only between the components of the LBNC but also among those less conspicuous fiber contingents lying interposed between this latter gray mass and the rest of the amygdaloid nuclei. At this point, however, it is convenient to stress that the intramedullary grisea that are intercalated between BL VM and BM, on one side, and the superficially located amygdaloid nuclei Me, ACo, VCo, and APir, on the other, show the same disposition than their more well-defined counterparts in the major medullary laminae. That is to say, they appear enmeshed by fibers running parallel to the deep border of the above-listed superficial nuclei, although at some places they become less obvious showing instead variable arrangements (see Figs. 22.4, 22.5a, b, 22.6a, 22.7a). Therefore, there is a question regarding the so-called morphological continuity between the superficial cortical nuclei and some of the representatives of the LBNC.

As in the previous version of this chapter (de Olmos, 1990), it is important to stress again the existence of several distinguishing cytoarchitectonic features that allow identification of the widely dispersed constituents of the IMG. These are as follows: (1) The cells making up the IMG, though of varying in size and shape, are always larger than those in the intercalated islands, but smaller and of more divergent shape than those shown by the main neuronal components of the LBGC. (2) The main cell body axes of the IMG cells are predominantly oriented parallel to the course of fiber bundles in which they are enmeshed, and many times this orientation contrasts sharply with the cells in the neighboring main nuclear divisions. This is particularly noticeable in horizontal sections showing the boundaries between VCo and BLVM.

On this basis it is possible to recognize the presence of the heterogeneous gray formation as strings of clusters forming real cell corridors intercalated between the various nuclei of the laterobasal complex separating them from each other as well as from the centromedial and cortical amygdaloid nuclei. However, at certain poinrs they form prominent accumulation of cells as is the case where they form a wedge between the BM VM, the BL VM, and the PCoV (lamina 27, plane 6.7 mm of Mai *et al. Atlas of the Human Brain*), i.e., where the lower medial end of the intermediate medullary lamina (li) meets the lower end of the medial medullary lamina (mm). This wedge-like area is filled with neuronal clusters which in the human amygdala may attain such a large volume that they have been considered by some authors to be subnuclei in their own right. As previously noted, the gray mass labeled Abvm in Sorvari *et al.* (1995) may be part of this extensive intramedullary grisea and at least one of the deep located subdivisions of Brockhaus (1940), i.e., their amygdala superficiale intermedia pars ventrolateralis, Asf ivl. Less conspicuous IMG clusters or even scattered neurons are found in the fiber strata separating BL from La, BM, ACA, and EN.

It is notable that this heterogeneous structure has escaped the attention of so many morphologists who, even if capable of identifying them, did not consider the IMG islands important enough to be differentiated from their neighboring nuclei. If this has been so, as will be shown below, these intramedullary grisea possess enough differentiating chemoarchitectonic and probably connectional features to speak strongly in favor of IMG as a separated anatomical entity.

Chemoarchitectonics

Cupric Silver Technique In cupric silver–stained sections of the amygdala of Old World (macaque) and New World (squirrel) monkeys, strips of lightly stained

granular neuropil can be found along the borders between the La and BL and BL and BM, i.e., overlapping the medullary strata separating these nuclei. This positive though light Cu-Ag reaction at the level of the IMG contrast with its total absence in the main components of the LBNC.

Heavy Metals

TIMM-DANSCHER PROCEDURE In Timm-stained New World monkey (squirrel) amygdala, many of the IMG islands show a moderate to strong reactivity, particularly those lying between BL and La.

Neurotransmitters

CHOLINERGIC MARKERS

ACETYLCHOLINESTERASE (AChE) In AChE preparations, the IMG islands show some staining variations, so that those located dorsal to La show strong AChE reactivity, whereas the greater part of the islands in the wedge-like region between BM and BL are negatively stained. The largest IMG island lying at the point of reunion of the medial and intermediate medullary laminae show instead a moderate to high AChE reactivity (Fig. 22.11, IMG). The same it occurs with some smaller IMG islands in the boundary region between BL VM, BM VM, and the inferior subdivision of the caudal VCo.

CHOLINE ACETYLTRANSFERASE (ChAT) In examining the ChAT material presented by Emre *et al.* (1993), it is possible to appreciate in their Fig. 2A and B a staining pattern close to the one just described above using AChE histochemistry. However, the isolation of this IMG island (interpreted by these authors as an intercalated island) from the main collections of amygdaloid neurons is much clearer.

MONOAMINE MARKERS

DOPAMINE-β-HYDROXYLASE (DBH) In the human amygdala, as in the squirrel monkey and even in a lower macrosmatic mammal like the rat, DBH-ir fibers detached from the ansa peduncularis/ventral amygdalofugal pathway can be seen to run in an almost preferential manner along the extent of the IMG elements sprinkled along the medullary laminae lying between the main nuclei of the LBNC or separating them from the cortical superficial nucleus. In their course these DBH-ir fibers show all the typical manifestations on the bouton en passage and even direct terminals.

NEUROPEPTIDES

CHOLECYSTOKININ (CCK) In IMG of the baboon monkey, Martin *et al.* (1991) reported the presence of CCK-ir varicose fibers and punctate profiles in moderate amounts, as well as the presence of CCK-ir neurons.

ENKEPHALIN (ENK) In all of the primates studied by Martin *et al.* (1991), fibers, punctate profiles, and cell bodies immunoreactive for ENK were detected.

NEUROTENSIN (NT) As with other neuropeptides, the IMGs show in primates a moderate amount of NT-ir (Martin *et al.*, 1991).

SOMATOTASTIN (SOM) Close examination of some of the images (Figs. 2A–F asterisks, and 6) published by Amaral *et al.* (1989) on the SOM-ir distribution in the macaque monkey amygdala, suggests the existence, along major medullary laminae that separate the main components of the LBNC or the BM nucleus from the superficial pseudocortical and superficial amygdaloid nuclei, of very thin fence-like SOM-ir deposits or island-like accumulations of varying size. These deposits vary in density, from being somewhat higher than in the nuclei it separates to places where they are almost completely negative. Unfortunately, because of the low magnification of the published material it is not possible to infer weather these formations contain SOM-ir cell bodies.

Acknowledgments

The author thanks Dr. Lennart Heimer and Dr. John Jane and the Department of Neurological Surgery, University of Virginia Health System, Charlottesville, VA, USA, for constant support and encouragement. To Dr. George Alheid for having collaborated in many projects which helped the writing of this chapter and Dr. Carlos Beltramino for advice and valuable comments. To Soledad de Olmos for all her technical support. I would also like to dedicate this chapter to my wife Esther de Olmos, for all her support and patience. This work has been supported by the Consejo Nacional de Investigaciones Cientificas y Tecnicas of Argentina (CONICET) PIP #02908, the Fundación Interior Argentina (FUNINAR), and the Fogarty International Research Award—IRO3TW00963. Dr. Jose S. de Olmos is a senior scientist of CONICET, Argentina.

CHAPTER

23

Hippocampal Formation

RICARDO INSAUSTI
University of Castilla-La Mancha, Spain

DAVID G. AMARAL
University of California, Davis, California, USA

It has been more than a decade since the first edition of this chapter appeared in the *Human Nervous System*. In the intervening period, there has been a burgeoning of interest in the functional organization of the human hippocampal formation. Much of this has been motivated by the use of noninvasive imaging techniques such as PET (positron emission tomography) or fMRI (functional magnetic resonance imaging). For the decade 1992–2002, the U.S. National Library of Medicine has no fewer than 8400 papers indexed under the keywords "human" and "hippocampus" Structural MRI has also become an integral component of diagnosis and assessing the progression of neurodegenerative processes in disorders such as Alzheimer's disease (e.g., Gosche *et al.*, 2002; Killiany *et al.*, 2002).

So, what has changed and what has stayed the same in the current chapter? Basically, the core of the previous version has not changed substantially. However, we have attempted to update areas where there have been new findings and revise other areas where our thinking about the structural organization of the hippocampal formation has changed somewhat. While we had previously addressed aspects of the gross anatomy of the hippocampal formation near the end of the chapter, we have moved that discussion to the front of the first section. This is due, in part, to our belief that gross anatomical features of the hippocampal formation are taking on increasing importance as landmarks in neuroimaging studies. The second section deals with the cytoarchitetonic organization of the hippocampus with a comparison to the rodent and nonhuman primate. The next section deals with the connectivity of the hippocampal formation (based on

experimental data obtained primarily from the nonhuman primate brain). The fourth section presents an overview of normal development of the human hippocampal formation, while the fifth section deals with pathological conditions that have a direct impact on human hippocampal formation. It necessarily provides just a brief overview of this area because there has been an explosion of research, both at the basic and clinical levels, dealing with topics such as Alzheimer's disease and the hippocampus. Finally, the last section briefly surveys the results obtained with modern neuroimaging techniques and how they have influenced thinking about the function of the hippocampal formation.

GROSS ANATOMICAL FEATURES

Rostrocaudal Extent of the Hippocampal Fields

The entire human hippocampal formation has a rostrocaudal extent of approximately 5 cm (Fig. 23.1). Fig. 23.4 provides an estimate of the location along the rostrocaudal axis of the different components of the hippocampal formation. The length of each one can be calculated from the distance to the anterior limit of the temporal pole. The rostrocaudal extent of the major portion of the hippocampal formation that is visible in the lateral ventricle (mostly CA1, CA2, and distal CA3) is approximately 4 cm (Figs. 23.2 and 23.4). The entorhinal cortex is the most rostrally situated of the hippocampal fields, and it can be identified slightly behind the limen insulae (frontotemporal junction). The entorhinal cortex (Fig. 23.1) begins rostrally approximately 2.0 cm from the temporal pole. The rostralmost 5 mm of the entorhinal cortex is located rostral to the amygdaloid complex. The next 5 mm lie in a position ventromedial to the amygdaloid complex. Thus, a full centimeter of the entorhinal cortex is located rostral to any other component of the hippocampal formation. The dentate gyrus, hippocampus, subiculum, presubiculum, and parasubiculum bend medially and then caudally at the rostral limit of the lateral ventricle. The dentate gyrus makes this bend most caudally and is not seen in coronal sections less than 6 mm from the anterior pole of the hippocampus. The last field to make the medial bend is the subiculum, which thus forms the most rostral portion of the hippocampal formation (excluding the entorhinal cortex). The medial or "uncal" region of the hippocampal formation makes up a large portion of what is commonly called the uncus (Figs. 23.1, 23.2, and 23.5–23.10). This uncal portion extends for a rostrocaudal distance of approximately 1 cm and, as we will discuss later, comprises several different hippocampal fields.

The various hippocampal fields also have different caudal termination points. The entorhinal cortex ends first, approximately 1.7 cm caudal to the anterior limit of the lateral ventricle and approximately 1.5 cm caudal to the start of the subiculum. The caudal border of the entorhinal cortex generally occurs approximately at the rostral limit of the lateral geniculate nucleus (if the plane of the section is orthogonal to a horizontal line through the anterior and posterior commissures). The parasubiculum ends at approximately the same level as the entorhinal cortex. However, the caudal border of the presubiculum is more difficult to determine precisely. This is because near the caudal border of the entorhinal cortex there is a subtle change in the cytoarchitectonic characteristics of the presubiculum, which, in the monkey (Insausti *et al.*, 1987a), marks the transition to a ventrotemporal extension of the retrosplenial cortex (Kobayshi and Amaral, 2001). It is likely that this occurs in the human brain as well.

As the remaining fields of the hippocampal formation curve dorsally to meet the retrosplenial region, their cytoarchitecture becomes increasingly difficult to interpret. As a general topographical rule, the hippocampal fields that make up the rostral extreme of the hippocampus (i.e., the subiculum and CA1 of the hippocampus) also make up the caudal extreme. Therefore, the remainder of the hippocampal fields (the dentate gyrus, CA3, and CA2) are enclosed at the rostral and caudal extremes by CA1 and the subiculum. For this reason, the dentate gyrus and CA2 and CA3 fields of the hippocampus appear to end at a more rostral level than the CA1 field and subiculum (Figs. 23.6–23.8 and 23.14). The dentate gyrus ends approximately 7 mm in front of the caudal pole of the hippocampal formation at a level that is just caudal to the emergence of the calcarine sulcus of the occipital lobe (Fig. 23.10).

Ventromedial Surface Anatomy

In the following paragraphs, we will describe the surface appearance of the temporal lobe regions that contain the hippocampal formation and associated structures. We will refer to illustrations showing the ventral and medial surfaces of the human brain (Figs. 23.1 and 23.3) and to illustrations showing dorsolateral views of the hippocampal formation as seen through dissection of the temporal lobe (Fig. 23.2). We will attempt to relate the gross anatomical features visible in these views to the familiar cytoarchitectonic terms

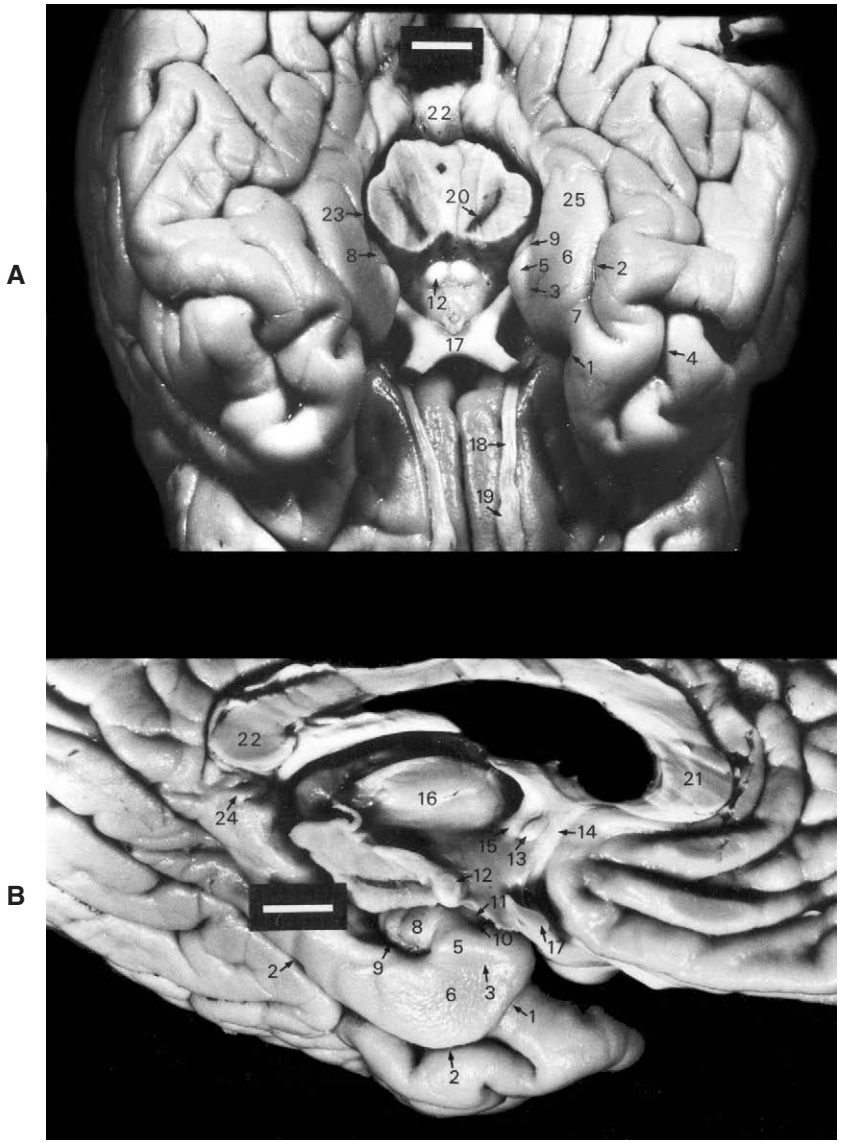

FIGURE 23.1 **(A)** The ventral surface of the human brain after removal of the brainstem and the cerebellum. The gyri and sulci of the ventral surface of the temporal lobe are clearly exposed and the relationships of the medial temporal lobe to other diencephalic and mesencephalic structures can be seen. **(B)** The ventromedial aspect of the left temporal lobe of the same brain after being bisected along the midline. The hippocampal structures situated at the medial and dorsal aspect of the temporal lobe that could not be demonstrated in the ventral view are now visible. The scale bar in both panels equals 1 cm. 1, rhinal sulcus; 2, collateral sulcus; 3, intrarhinal sulcus; 4, occipitotemporal sulcus; 5, gyrus ambiens; 6, entorhinal cortex; 7, perirhinal cortex (anterior portion); 8, uncus; 9, hippocampal fissure; 10, sulcus semiannularis; 11, gyrus semilunaris; 12, mammillary bodies; 13, anterior commissure; 14, precommissural fornix; 15, postcommissural fornix; 16, thalamus; 17, optic chiasm; 18, olfactory tract; 19, olfactory bulb; 20, substantia nigra; 21, corpus callosum (rostrum); 22, corpus callosum (splenium); 23, choroidal fissure; 24, gyri Andreae Retzii; 25, parahippocampal gyrus.

of the hippocampal fields. There is a rich heritage of gross anatomical analysis of the hippocampal formation dating back to Arantius (1587), who first described the appearance of human hippocampal formation and gave it the name hippocampus. Beautiful examples of illustrations of the gross anatomical appearance of the hippocampal formation were produced by Klingler (1948). This work, while rarely referenced, contains elegant drawings of various dissections of the human hippocampal formation.

FIGURE 23.2 Dorsolateral view of the human hippocampus after removal of the overlying structures. The preparation is seen from slightly different angles in A and B. The lateral ventricle (5) has been opened, thus exposing the shape of the hippocampus. It is possible to follow the hippocampal formation caudally as it ascends toward the retrosplenial region. Ultimately the fornix (3) extends rostrally and then ventrally to bifurcate around the anterior commissure (7) and innervate the septal nuclei and diencephalons. The lateral surface of the temporal lobe can be seen at the bottom of the two views. Scale bar equals 2 cm. 1, pes hippocampus; 2, hippocampus (body); 3, fimbria-fornix; 4, hippocampal commissure; 5, temporal horn of the lateral ventricle; 6, amygdala, 7, anterior commissure; 8, optic nerve; 9, corpus callosum.

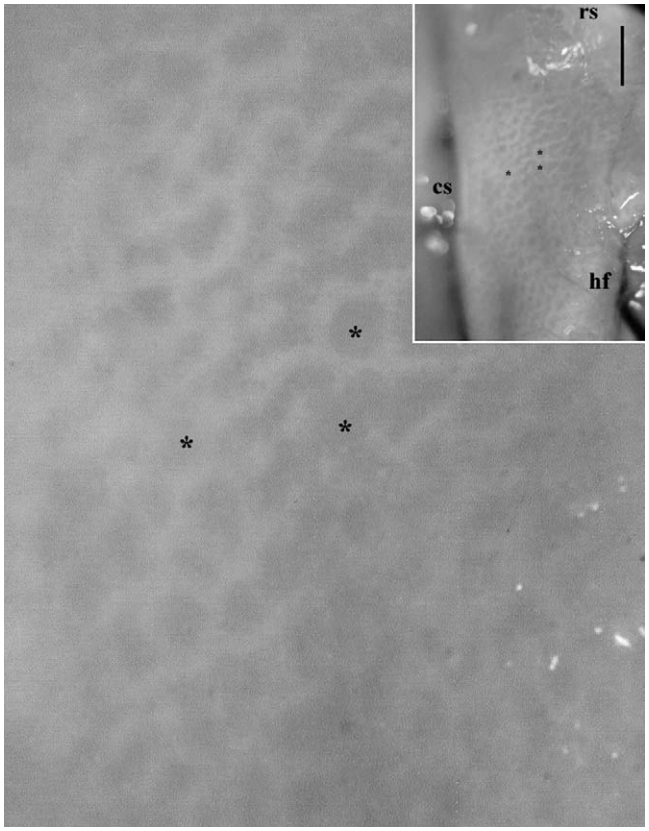

FIGURE 23.3 Unfixed surface of the human entorhinal cotex in a 72-year-old control case. Differences in density allow the clear appreciation of a latticework design that corresponds to cell islands in layer II. Note also the white matter surrounding the darker patches of layer II cell islands, the so-called substantia reticularis alba of Arnold. Scale bar equals 5 mm.

The ventral and medial surfaces of the temporal lobe are organized into strips by two prominent rostrocaudally oriented sulci. The more lateral of the two (Fig. 23.1) is the occipitotemporal sulcus (4) which is often broken forming small, transverse gyri. The more medial of the sulci, and the one that is more highly associated with the hippocampal formation, is the collateral sulcus (3) (Fig. 23.1). Not infrequently, both the collateral and the occipitotemporal sulcus are in continuity with each other. The collateral sulcus is usually continuous rostrally with the rhinal sulcus (41.9% of the cases according to Hanke, 1997), although there is a remarkable amount of individual variability in the configuration of these sulci [Insausti *et al.*, 1995; Heinsen *et al.*, 1994; Ono *et al.*, 1990; Figure 23.1(1)]. These two sulci form the lateral border of what has been classically termed the parahippocampal gyrus (Van Hoesen, 1995). The term "parahippocampal gyrus" or "parahippocampal region" (Scharfman *et al.*, 2000) has been used in different ways by different authors because the parahippocampal gyrus is a complex region that contains a number of distinct cytoarchitectonic fields. In recent years, the parahippocampal gyrus has been broken up into an anterior part that is mainly made up of the entorhinal cortex and associated perirhinal cortex and a posterior part

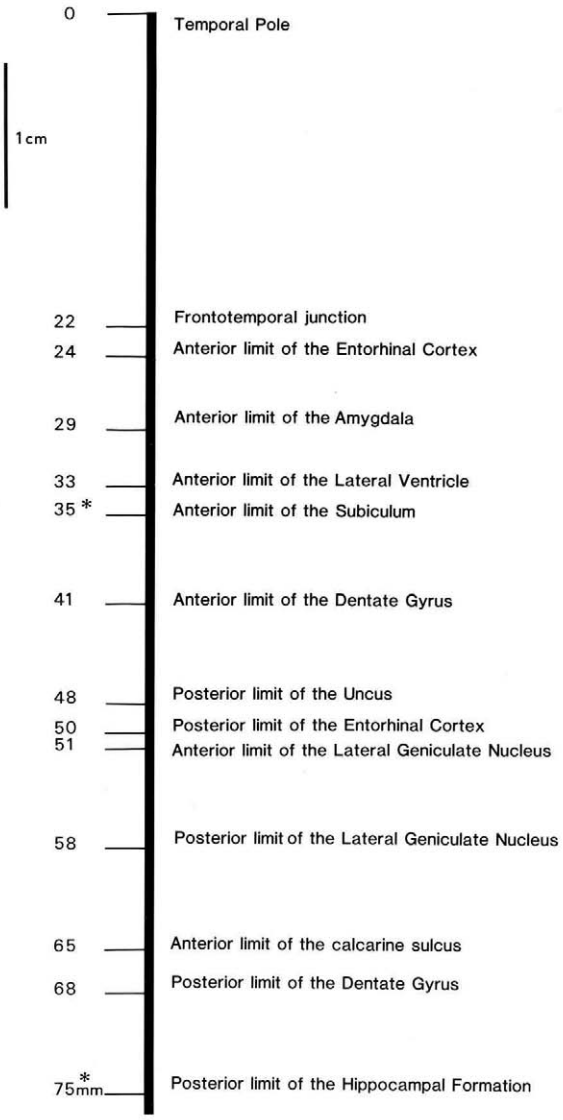

FIGURE 23.4 A representation of the approximate linear extents of each of the subdivisions of the hippocampal formation and related structures as reconstructed from a series of coronal sections through the temporal lobe of one brain. The numbers on the left are the distances in millimeters from the rostral pole of the temporal lobe to each of the anatomical points indicated on the right side of the bold vertical line. The distance between the asterisks indicates the length of all hippocampal fields excluding the entorhinal cortex.

(posterior parahippocampal cortex or PPH) that includes the TF and TH fields of Von Economo (1929; see Van Hoesen, 1982). In nonhuman primates, the parahippocampal gyrus consists of the TF and TH fields (Insausti *et al.*, 1987a). As we will describe in more detail in the cytoarchitectonic description, the collateral sulcus does not provide a discrete lateral boundary for the entorhinal cortex, which ends somewhere along the medial bank of the sulcus. The two fields of the perirhinal cortex (area 35, or more properly the perirhinal cortex, and area 36, or more properly the ectorhinal cortex, of Brodmann, 1909) actually form the remainder of the medial bank, fundus, and a portion of the lateral bank of the collateral sulcus (Fig. 23.14). The perirhinal cortex, in different brains, may or may not extend onto the most medial surface of the fusiform gyrus (the cortex located lateral to the collateral and/or occipitotemporal sulci). This appears to depend on the depth of the collateral sulcus. When the collateral sulcus is shallow, the perirhinal cortex not only covers all of the surface of the lateral bank but also extends a variable distance lateral to the collateral sulcus along the ventral surface of the temporal lobe (Insausti *et al.*, 1995).

The anterior portion of the classically defined parahippocampal gyrus is formed largely by the entorhinal cortex (Figs. 23.1 and 23.3). Much of the entorhinal cortex can actually be visually determined by identifying the conspicuous bumps [verrucae (or warts) gyri hippocampi; Klingler, 1948] that mark its surface, and that are best developed in humans, although they can be observed in apes as well (Van Hoesen, 1995). These bumps are located above the islands of cells that form layer II of the entorhinal cortex (Van Hoesen *et al.*, 1991). However, in unfixed specimens of the entorhinal cortex, discrete grayish patches are evident on the surface of the entorhinal cortex, surrounded by pale rims of white matter that give a lattice-like appearance (Fig. 23.3). The dorsomedial aspect of the entorhinal cortex (or anterior parahippocampal gyrus) is marked by a conspicuous mound or secondary gyrus that is referred to as gyrus ambiens (5) (Fig. 23.1). The lower limit of the gyrus ambiens is separated from the rest of the entorhinal cortex by a shallow sulcus that Retzius (1896) referred to as the inferior rhinal sulcus. Because this sulcus is entirely confined within the limits of the entorhinal cortex and is not related to the more prominent rhinal sulcus, we have referred to it as the intrarhinal sulcus. The position of this sulcus can be clearly seen in Figures 23.1–23.3. The location of the intrarhinal sulcus might be coincident with the imprint of the free edge of dura mater known as the tentorium cerebelli (Duvernoy, 1988; Hanke, 1997). The dorsomedial limit of the entorhinal cortex is marked by the shallow sulcus semiannularis (10) (Fig. 23.1). The gyrus semilunaris that is situated just dorsal to the sulcus semiannularis is made up of the periamygdaloid cortex (11) (Fig. 23.1).

There is a series of prominent bulges located caudal to the dorsomedial portion of the entorhinal cortex that is generally labeled as the uncus (or hook, 8) in gross anatomical descriptions (Figs. 23.1 and 23.7). The

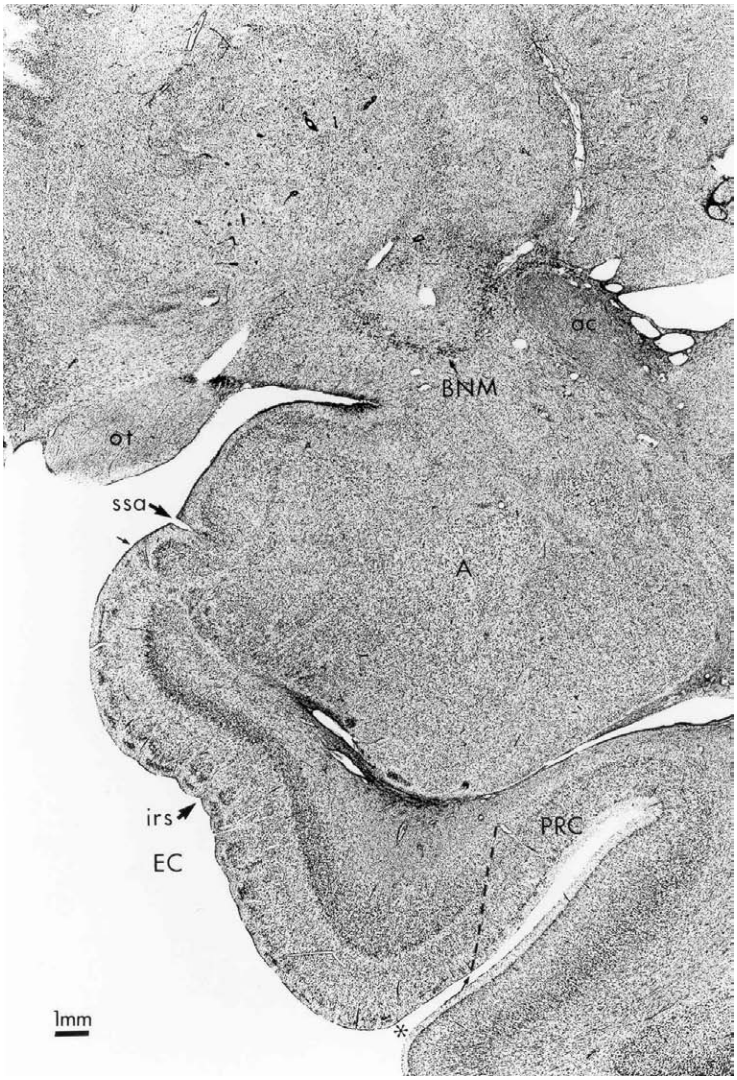

FIGURE 23.5–23.10 A representative series of coronal, thionin-stained sections [arranged rostrally (Fig. 23.5) to caudally (Fig. 23.10)] through the human hippocampal formation. A, Amygdaloid complex; a, alveus; ab, angular bundle; ac, anterior commissure; AHA, amygdalohippocampal area; BNM, nucleus basalis of Meynert; CA1, CA1 field of the hippocampus; CA2, CA2 field of the hippocampus; CA3, CA3 field of the hippocampus; cas, calcarine sulcus; cf, choroidal fissure; cos, collateral sulcus; DG, dentate gyrus; EC, entorhinal cortex; f, fimbria; gl, GL, granule cell layer of the dentate gyrus; hc, hippocampal commissure; hf, hippocampal fissure; irs, intrarhinal sulcus; LGN, lateral geniculate nucleus; 1-m, stratum lacunosum-moleculare of the hippocampus; ml, ML, molecular layer of the dentate gyrus; o, stratum oriens of the hippocampus; ot, optic tract; p, pyramidal cell layer of the dentate gyrus; PaS, Parasubiculum; PHG, parahippocampal gyrus (areas TF and TH); pl, PL, polymorphic layer of the dentate gyrus; PRC, perirhinal cortex (areas 35 and 36); Prs, presubiculum; r, stratum radiatum of the hippocampus; RSP, retrosplenial cortex; S, subiculum; ssa, sulcus semiannularis; V, temporal horn of the lateral ventricle.

FIGURE 23.5 A dashed line indicates the oblique border between the entorhinal cortex and the laterally adjacent perirhinal cortex. Here, and in Figures 23.4–23.7, small arrows mark the dorsomedial and ventrolateral extents of layer II of the entorhinal cortex and an asterisk marks the collateral sulcus.

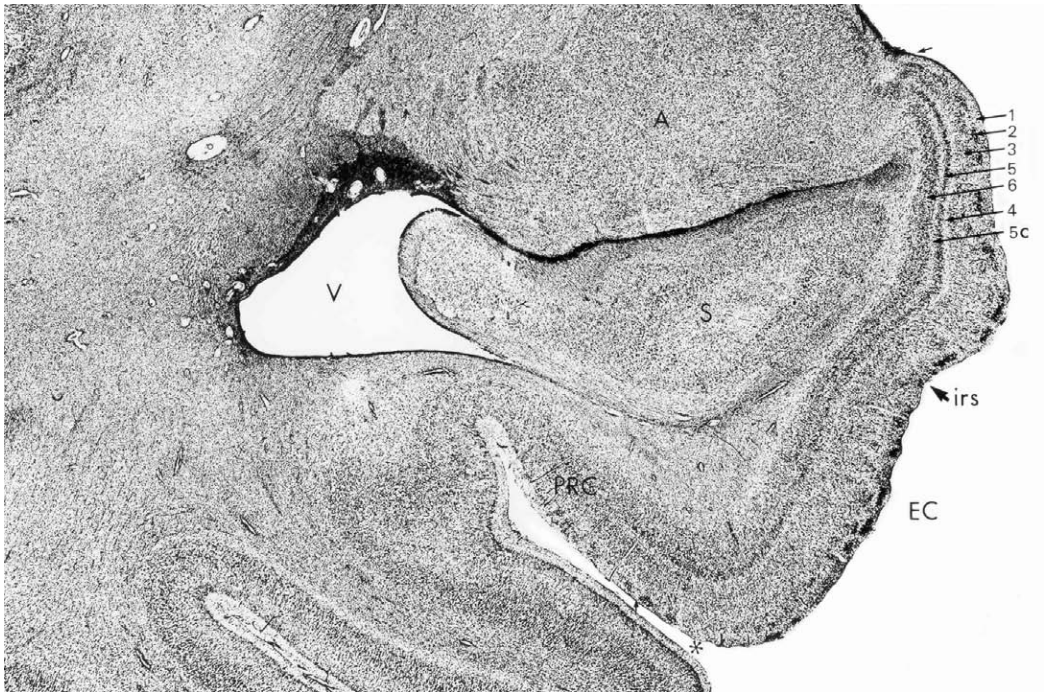

FIGURE 23.6 Numbers at the top right of this illustration indicate the layers of the entorhinal cortex. Note the shallow intrarhinal sulcus (irs) that is located in the entorhinal cortex.

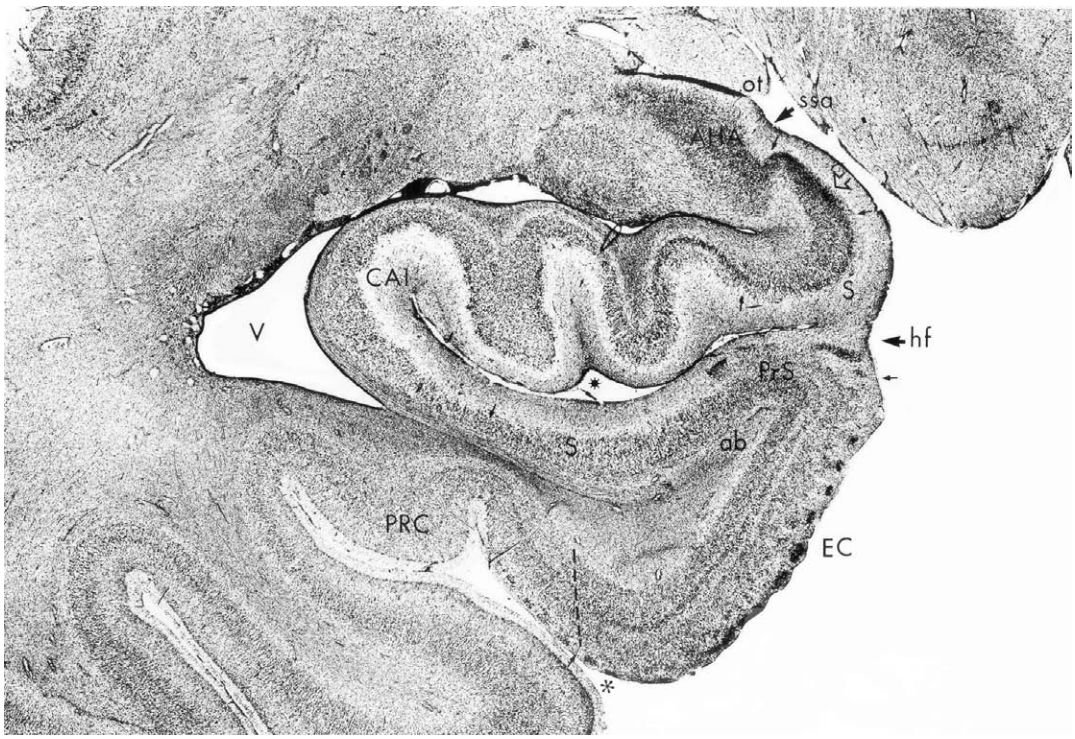

FIGURE 23.7 In Figures 23.5–23.8, small arrows mark the borders of each of the cytoarchitectonic fields of the hippocampal formation. A dashed line indicates the oblique border between the entorhinal cortex and the adjacent perirhinal cortex. The open arrow at top right indicates a transition region between the amygdala and hippocampal formation, which appears to be cytoarchitectonically distinct from other hippocampal fields. The asterisk in the center of the field marks the enclosed region of subarachnoid space called the diverticulum unci

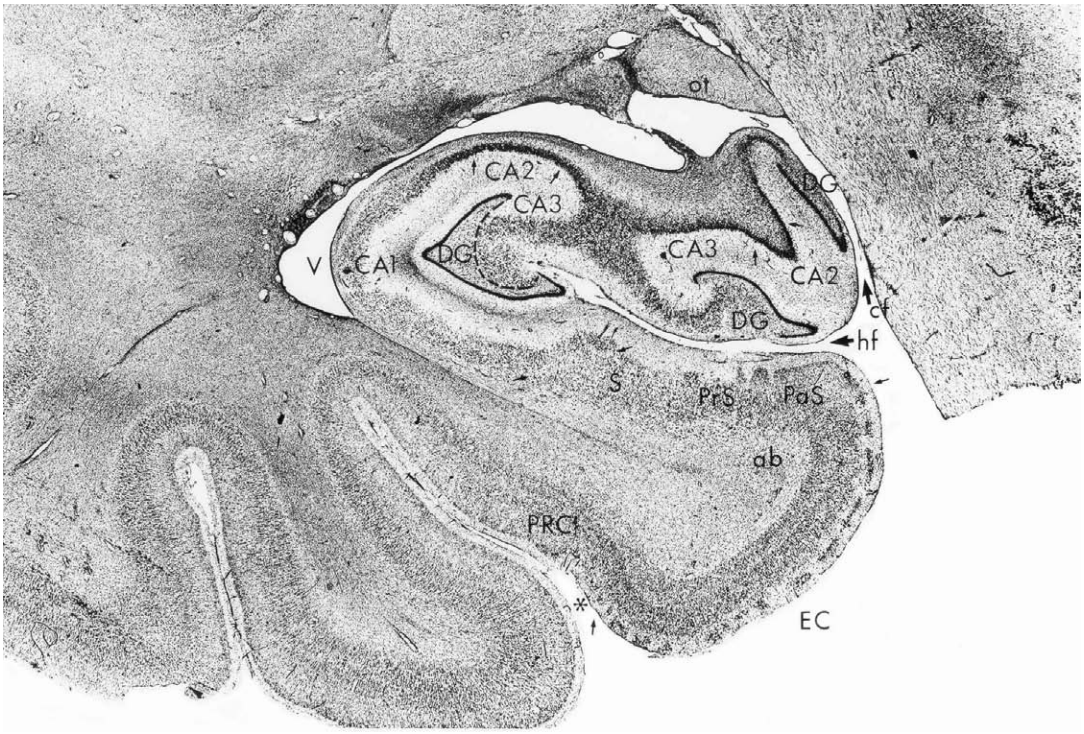

FIGURE 23.8 Dashed line in the dentate gyrus separates the polymorphic layer (hilus) of the dentate gyrus from the CA3 field of the hippocampus. Note that both the hippocampal fissure (hf) and the choroidal fissure (cf) are apparent at this level of the medial or uncal hippocampal formation. Note also that the border between CA1 and the subiculum (marked by arrows) is obliquely oriented relative to the pyramidal cell layer.

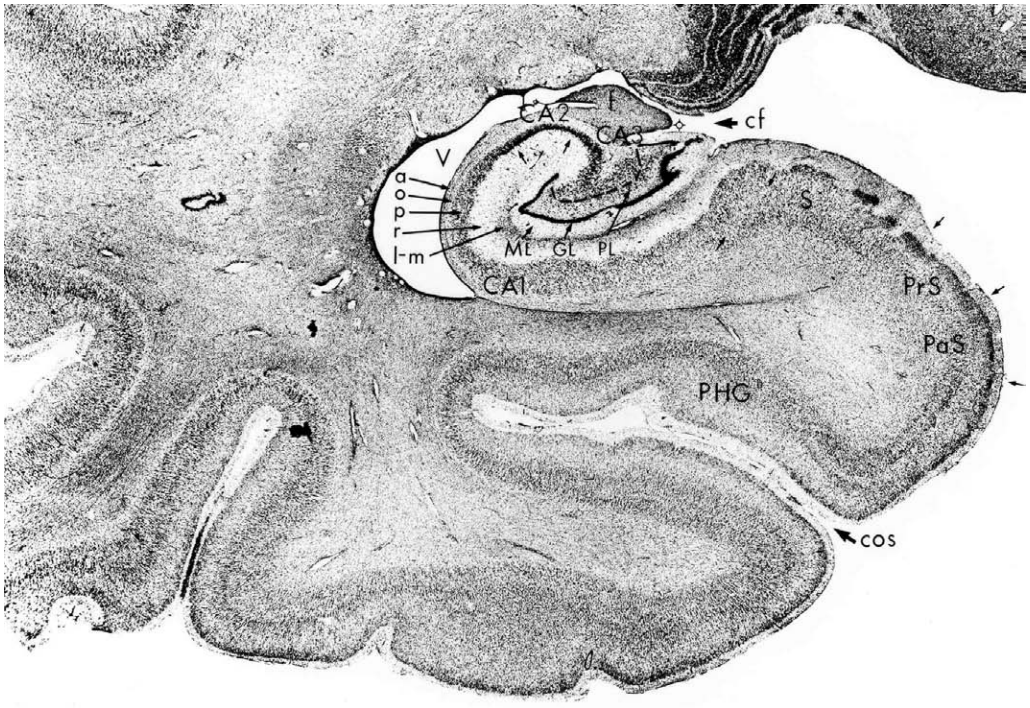

FIGURE 23.9 Dashed line in the dentate gyrus indicates the border between the polymorphic layer of the destate gyrus (PL) and the CA3 field of the hippocampus. Note that at this level the entorhinal cortex is no longer present and the parasubiculum (PaS) of the hippocampal formation abuts the parahippocampal cortex (PHG), which has replaced the perirhinal cortex. Note also that a small groove (target sign) called the fimbriodentate sulcus separates the molecular layer of the dentate gyrus from the fimbria.

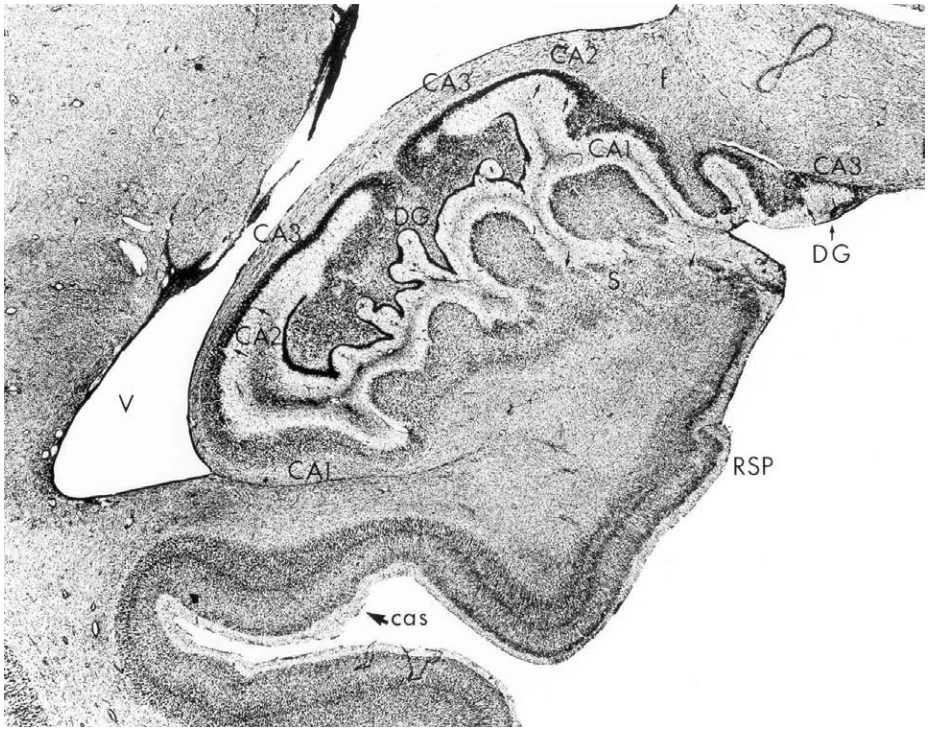

FIGURE 23.10 A coronal section near the caudal pole of the hippocampal formation. The hippocampal formation is bending dorsally and medially toward the corpus callosum. It is at about this level that the dentate gyrus and the CA2 and CA3 fields end though CA1 and the subiculum continue caudally for some distance. The presubiculum and parasubiculum are replaced by the retrosplenial cortex (RSP) and the collateral sulcus is replaced by the calcarine sulcus (cas). Fibers of the hippocampal commissure (hc) are apposed to the ventral surface of the corpus callosum.

most rostral of the uncal bulges is often separately labeled the gyrus uncinatus. In histological sections, the gyrus uncinatus is made up of the amygdalo-hippocampal region and the transition zone between the amygdala and hippocampus. The middle bulge is called the band or limbus of Giacomini and is generally composed of the most medial bend of the dentate gyrus (Fig. 23.8). The most caudal of the uncal bulges is called the gyrus intralimbicus and is composed mainly of field CA3 of the hippocampus. As seen in Figure 23.1, and in the coronal sections in Figures 23.5 and 23.6, the ventral boundary of the uncus is formed by the rostral extension of the hippocampal fissure (9), also known as the uncal sulcus (Fig. 23.1). Caudal to the level of the uncus, the hippocampal fissure (9) becomes attenuated (Fig. 23.1), and the choroidal fissure (23) marks the medial surface of the dentate gyrus and fimbria (Fig. 23.1). In this region, a small indentation can be seen between the fimbria and the molecular layer of the dentate gyrus that Gastaut and Lammers (1961) have called the fimbriodentate sulcus (Fig. 23.9, target sign). At rostral levels of the hippocampal formation, the hippocampal fissure extends laterally to separate the dentate gyrus or hippocampus from the underlying subiculum. Rostral to the medial closure of the hippocampal fissure, there is a narrow region of subarachnoid space between the hippocampus and the subiculum (Fig. 23.5). Klingler (1948) has labeled this ventricular pocket the diverticulum unci.

As the parahippocampal gyrus meets the retrosplenial region caudally, a group of small bumps known as the gyri Andreae Retzii (24) become noticeable (Fig. 23.1) on the medial surface. This irregular region of cortex marks the caudal limit of the hippocampal formation and is thus composed principally of the CA1 field of the hippocampus and the subiculum. Although they are difficult to see in Figure 23.1, two obliquely oriented small gyri are located deep to the gyri Andreae Retzii. The more medial one is known as the fasciola cinerea and corresponds to the caudalmost part of the dentate gyrus. The lateral gyrus is called the gyrus fasciolaris and corresponds to the end of the CA3 field. There is still some dispute about which of the fields of the hippocampal formation surround the splenium to

form the induseum griseum (or supracommissural hippocampal formation); however, our analysis indicates that the subiculum and field CA1 mainly form this small band of supracallosal tissue.

Dorsomedial Surface Anatomy

The classical gross anatomical image of the human hippocampal formation is of a prominent, bulging eminence in the floor of the temporal horn of the lateral ventricle (Fig. 23.2). As we have already described, and as seen in the histological coronal sections (Figs. 23.5–23.8), a number of distinct cytoarchitectonic fields, including the dentate gyrus, hippocampus, and subicular cortices, are included in this region.

The term "hippocampus" (or sea horse) was first applied to this region by the anatomist Arantius (1587), who considered the three-dimensional form of the grossly dissected human hippocampus to be reminiscent of this sea creature. It is actually unclear from the account of Arantius which particular aspect or surface of the hippocampal formation reminded him of the sea horse since he also likened the hippocampus to a silkworm. An historical and often amusing account of the etymology of the term "hippocampus" is provided by Lewis (1923). As he noted, others such as Winslow (1732) likened the hippocampus to a ram's horn, and de Garengeot (1742) named the hippocampus Ammon's horn after the mythological Egyptian god. The term Cornu Ammonis was appropriated by Lorente de Nó (1934) for his terminology of the hippocampus proper (CA1–CA4), and Ammon's horn has been used used synonymously with the hippocampus. Recent use appears to favor the term "hippocampus", however.

The ventricular portion of the hippocampal formation is seen in two slightly different views in Figure 23.2. This portion of the hippocampal formation is widest at its anterior extent where the structure bends toward the medial surface of the brain. The subtle gyri (digitations hippocampi) formed in this region (which can range from 2 to 5 in number; Gertz *et al.*, 1972) give it a footlike appearance and the name pes (foot) hippocampus (1) has classically been applied to this area (Fig. 23.2). The pes hippocampus is formed by several of the hippocampal fields, and the constituents differ at different rostrocaudal levels. Continuing caudally from the pes hippocampus, the unreflected "body" of the hippocampus (2) (Fig. 23.2) becomes progressively thinner as it bends upward toward the splenium of the corpus callosum.

The medial surface of the hippocampus is invested with a fringe of fibers called the fimbria. Fibers originating from the pyramidal cells of the hippocampus and subiculum travel in the white matter which sheaths the hippocampus (the alveus) and coalesce in the medially situated fimbria (3) (Fig. 23.2). At rostral levels, the fimbria is thin and flat, but it becomes progressively thicker caudally as fibers are continually added to it. The fibers in the fimbria, like those in the corticospinal tract, are given different names at different positions along their trajectory. As the fimbria leaves the caudal extent of the hippocampus, it fuses with the ventral surface of the corpus callosum and travels rostrally in the lateral ventricle. The region between the caudal limit or the hippocampal formation and the fusion with the corpus callosum is called the crus of the fornix, whereas the major portion of the rostrally directed fiber bundle is called the body of the fornix. At the end of its rostral trajectory, the body of the fornix descends and is called the column of the fornix. The fornix then divides around the anterior commissure to form the precommissural fornix, which innervates the septal region, and the postcommissural fornix, which terminates in the diencephalon (Fig. 23.2A). At about the point where the fimbria fuses with the posterior portion of the corpus callosum, fibers extend across the midline to form the hippocampal commissure. A variety of gross anatomical terms have been applied to this commissural projection but the term "psalterium" (alluding to an ancient instrument "psaltery" made of strings stretched over a board) is most common. As we will discuss in a future section, the primate hippocampal commissural connections are much more limited than in the rodent (Amaral *et al.*, 1984; Demeter *et al.*, 1985). Stereotaxic depth encephalography indicates that, as in the monkey, there is little commissural interaction of the human hippocampal formation (Wilson *et al.*, 1987). Gloor and colleagues have confirmed that the ventral hippocampal commissure is virtually absent in the human brain whereas the dorsal hippocampal commissure is similar to that observed in the nonhuman primate brain (Gloor *et al.*, 1993).

CYTOARCHITECTONIC ORGANIZATION OF THE HIPPOCAMPAL FORMATION

Introduction and Terminology

It would be relatively easy for someone familiar with rat or monkey neuroanatomy to identify the human hippocampal formation. The dentate gyrus is characteristically C-shaped and the fields that comprise the remainder of the hippocampal formation—

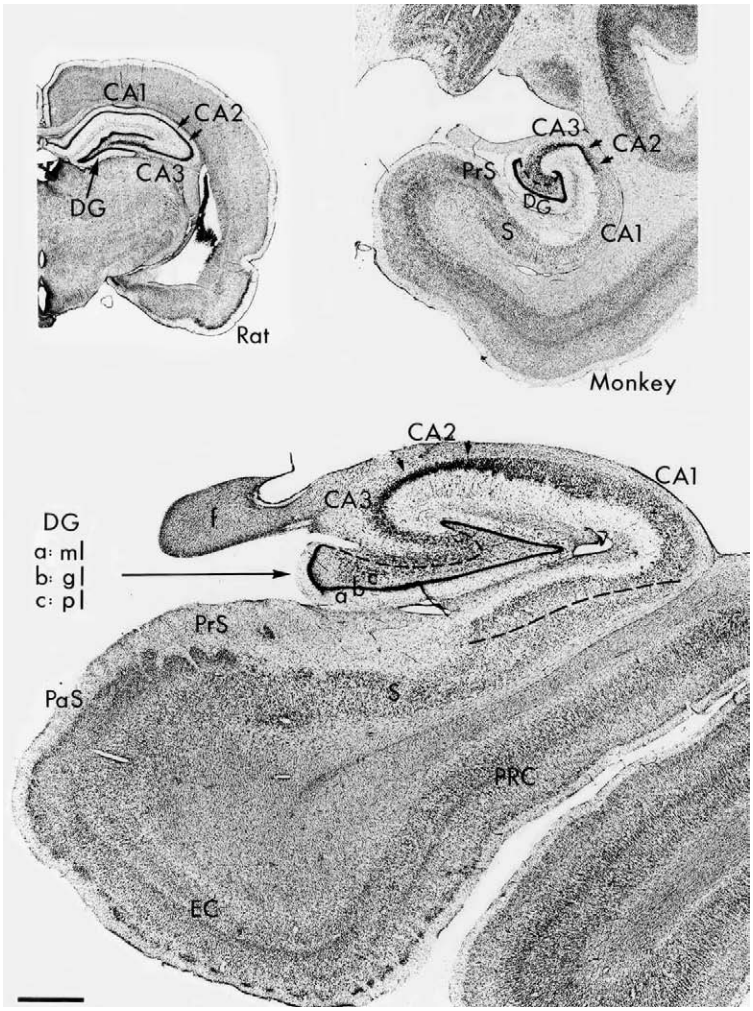

FIGURE 23.11 Coronal sections through the hippocampal formation of the rat, monkey, and human brains presented at the same magnification. Preparations are stained with thionin for the demonstration of neuronal cell bodies. The dashed line in the monkey and human dentate gyri separates the polymorphic layer of the dentate gyrus from the CA3 field of the hippocampus. In the human section, a dashed line also indicates the oblique border between field CA1 and the subiculum.

the hippocampus, subiculum, presubiculum and parasubiculum, and entorhinal cortex—are all reasonably recognizable (Fig. 23.11). Yet, even a cursory survey of the cellular infrastructure of the human hippocampal formation gives the impression that there are qualitative and quantitative differences in its organization relative to that in other species. Certain fields in the human hippocampal formation, such as CA1 of the hippocampus, appear to be disproportionately large. And, unlike in the rat where CA1 has a relatively homogeneous appearance, in humans it is characterized by a heterogeneity of cellular constituents that at some levels take on a multilaminate look (Fig. 23.11). Borders between the various fields of the human hippocampal formation are also more difficult to establish than in other species. This is due, in part, to the incessant overlapping of neuronal layers at the interfaces of fields. Rather than sharp, linear boundaries running perpendicular to the pial surface, demarcations between fields are often obliquely oriented (Figs. 23.5, 23.7, and 23.11).

Our perspective in revising this chapter ten years later has not substantially changed from the first edition. Although a number of studies have been reported in the literature, serious anatomical investigation of the human hippocampal formation is still meager, and it will be some time before the subtleties of its organization are completely understood. We describe the human hippocampal formation from a comparative point of view using the substantial data

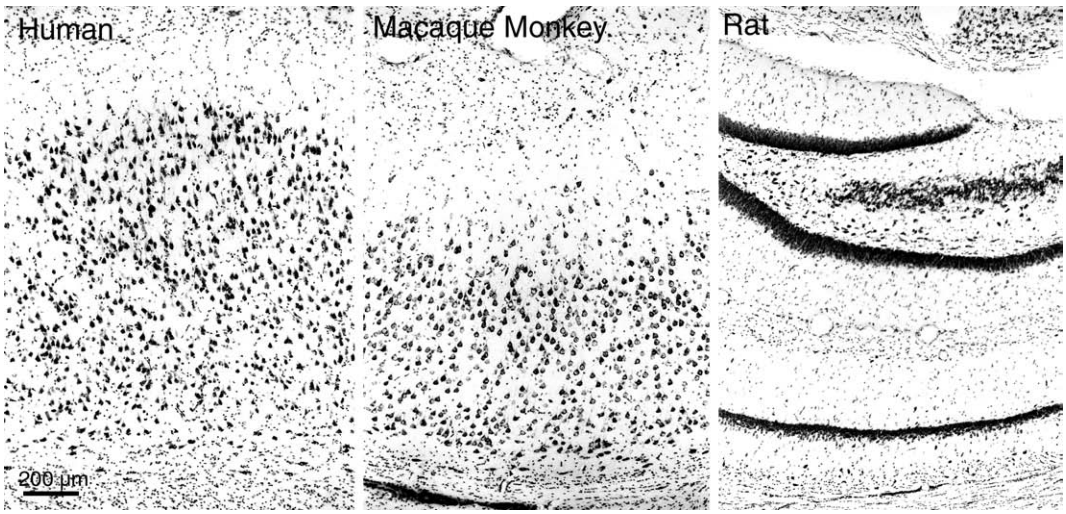

FIGURE 23.12 Higher magnification photomicrographs of approximately the same region of the CA1 field of the hippocampus in the rat, monkey, and human. This is a standard Nissl-stained preparation, and all of the images are at the same magnification. The calibration bar at the lower left applies to all three panels. Note that CA1 in the rat, which is the dark line at the bottom of the image, consists of three to five layers of tightly packed pyramidal cells (individual cells are difficult to resolve at this magnification). The monkey pyramidal cell layer, in contrast, is approximately 30 cell layers thick and there is a hint of sublamination with the top half of the layer having a slightly higher density of neurons. The pyramidal cell layer in the human CA1 field is even thicker and has a much more heterogeneous or laminated appearance.

from the rodent and monkey as the basis for our description of the general organizational features of the human hippocampal formation. Several detailed analyses of various morphological aspects of the human hippocampal formation are available in the literature. Most notable among these are the extensive pigmentoarchitectonic studies of Braak (1980, and references therein), the comparative morphometric studies of Stephan (1975, and references therein), "The Human Hippocampus" by Duvernoy (1988) and more recently, the comprehensive monograph of Gloor (1997) "The Temporal Lobe and Limbic System."

We will describe various aspects of the histological appearance of the human hippocampal formation. Where possible, we will relate conspicuous gross anatomical features of the human hippocampal formation to the underlying cytoarchitectonic structures. We will first survey the cytoarchitectonic characteristics and spatial organization of each of the fields of the hippocampal formation. This description will be referenced to a series of Nissl-stained coronal sections spaced throughout the rostrocaudal extent of the hippocampal formation (Figs. 23.5–23.10). The borders of the individual cytoarchitectonic fields are based on observations of adjacent Nissl- and fiber-stained coronal sections through several neurologically normal temporal lobes. This material was supplemented with histochemical preparations stained for the localization of acetylcholinesterase, by the Timm's sulfide silver method for the localization of heavy metals and by inmunohistochemical preparations using antisera directed against somatostatin, nonphosphorylated neurofilaments, or calcium-binding proteins.

We will also provide a brief summary of the connectivity of the hippocampal formation; more complete reviews can be found in Amaral (1987), Swanson *et al.* (1987), and Witter *et al.* (1989). Throughout this section, we will relate some of the more arcane terminology used in gross anatomical descriptions of the hippocampal formation to currently employed neuroanatomical terms.

The term "hippocampal formation" is usually applied to a group of cytoarchitectonically distinct fields associated with the hippocampus. The constituents of the group, however, vary with different authors. In this chapter, the term hippocampal formation includes the dentate gyrus, hippocampus, subiculum, presubiculum and parasubiculum, and entorhinal cortex. The major justification for grouping these fields together is that they are linked by prominent and largely unidirectional connections that appear to unite them as a functional entity (Figs. 23.16 and 23.17).

A variety of nomenclatures have been used to label the portions of the hippocampal formation. The use of one terminology rather than another has been dictated, in part, by what species is being described or

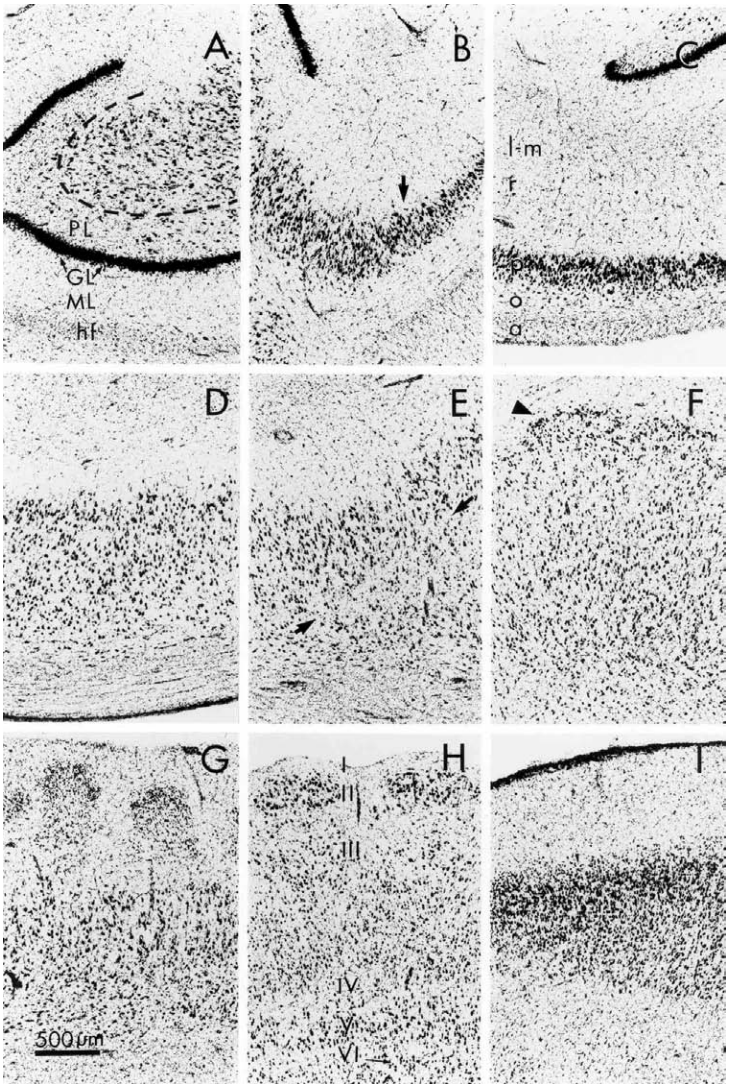

FIGURE 23.13 Higher-magnification photomicrographs to demonstrate the major cytoarchitectonic features of each of the fields of the human hippocampal formation. **(A)** the molecular (ML), granular (GL), and polymorphic (PL) layers of the dentate gyrus are indicated. The dashed line marks the border between CA3 of the hippocampus and the polymorphic layer. hf, huppocampal fissure. **(B)** Region of transition between the CA3 (on the left of the arrow) and CA2 (on the right) fields of the hippocampus. Note that the pyramidal cell layer in CA3 is both wider and more diffusely organized than in CA2. **(C)** Field CA2 of the hippocampus has the narrowest and most densely packed pyramidal cell layer of the hippocampal fields. The principal laminae of the hippocampus are also indicated: a, alveus; o, stratum oriens; p, pyramidal cell layer; r, stratum radiatum; l-m, stratum lacunosum-moleculare. **(D)** Field CA1 of the hippocampus has a wider pyramidal cell layer than fields CA3 or CA2 and the cells tend to be smaller and more widely separated. The most superficial pyramidal cells are more tightly packed, are somewhat larger, and stain somewhat darker than the deeper cells. **(E)** Transition region between CA1 (on left) and the subiculum (on right). A narrow cell-free zone (marked by arrows) often corresponds to the oblique border between the two fields. The region of overlap of the two pyramidal cell layers varies from brain to brain but in some cases can extend for several millimeters. **(F)** The pyramidal cell layer of the subiculum is often wider than of CA1. There are roughly two major layers of pyramidal cells, with the superficial ones being somewhat smaller than the deeper ones. The subicular pyramidal cell layer is also characterized by islands of small darkly stained cells (arrowhead) that lie at its superficial edge. **(G)** The presubiculum is characterized by a densely packed layer II that, at rostral levels (as illustrated in this photomicrograph), breaks up into spherical islands. The outer cap of layer II cells is more densely packed and somewhat darker staining than the cells in the remainder of the layer. (H) The entorhinal cortex is a multilaminate region that is generally considered to make up at least six distinct layers. The most distinctive feature of the entorhinal cortex is the islands of darkly stained modified pyramidal and stellate cells that make up layer II. In some regions, the surface of the entorhinal cortex forms bumps (verrucae or warts in the gross anatomical terminology) above the islands of layer II cells; these bumps are present in this section. Another distinguishing characteristic of the entorhinal cortex is the lack of an internal granular layer—layer IV. In its place through much of the entorhinal cortex is a cell-free space, the so-called lamina dissecans. (I) Transition region between the amygdala and hippocampus. This field is located in the rostral aspect of the uncal hippocampal formation (open arrow in Figure 23.5). Its small, darkly stained, and tightly packed neurons do not resemble those in any other hippocampal field.

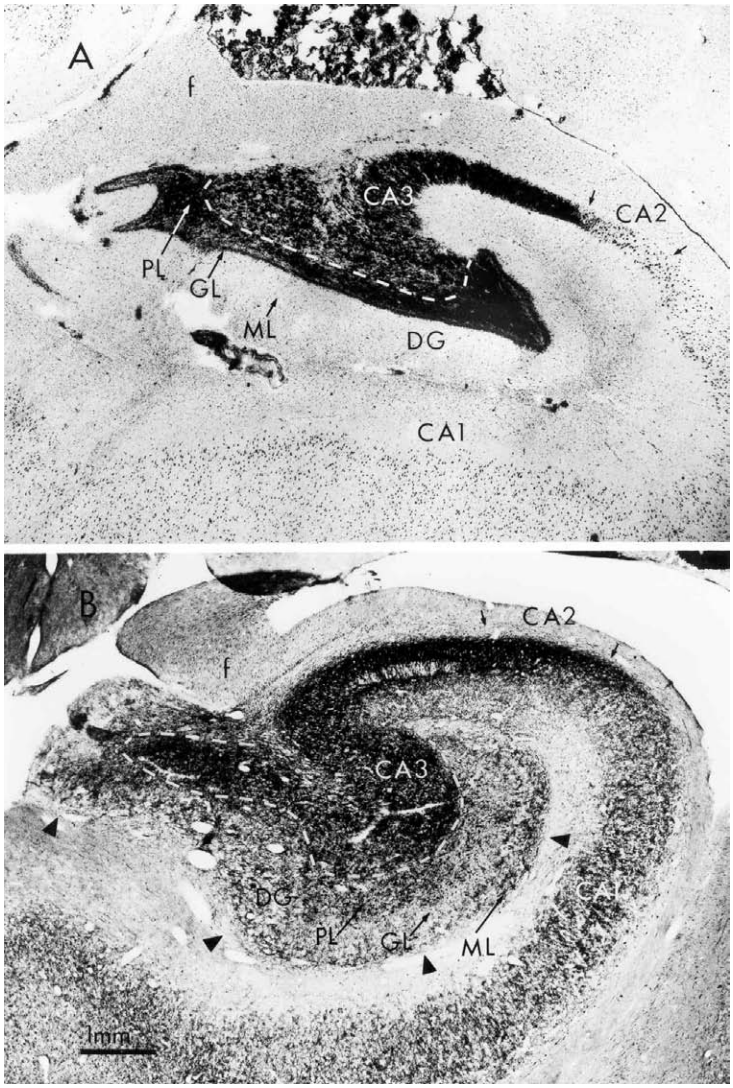

FIGURE 23.14 **(A)** A coronal section through the human hippocampal formation stained by the Timm's sulfide silver method for the demonstration of heavy metals. The section has also been counterstained with cresyl violet for the demonstration of neuronal cell bodies. Dark precipitate is confined to the polymorphic layer of the dentate gyrus and to the region within and immediately surrounding the CA3 pyramidal cell layer. The region of dark precipitate corresponds to the distribution of the mossy fiber axons arising from the granule cells of the dentate gyrus. Staining is attributable to the high level of zinc contained in the en passant presynaptic mossy fiber boutons. The termination of staining in the hippocampus marks the border between the CA3 and CA2 fields. This section was prepared and kindly made available to us by Carolyn Houser, University of California, Los Angeles. **(B)** A coronal hipppocampal section stained for the demonstration of AchE. In the dentate gyrus, staining is dense in the outer portion of the molecular layer (the superficial limit of which is marked with arrowheads) and in the polymorphic layer. There are numerous AchE-positive neurons in the polymorphic layer that distinguish it from the adjacent CA3 field. AchE staining is heavy in the CA3 field, especially in stratum oriens, and it gets somewhat darker in area CA2. There is a marked decrease in staining in CA1 and a further decrease in the subiculum.

to what discipline the description is directed. For the human hippocampus, the terminology first suggested by M. Rose (1926) is often used. Based on cytoarchitectonic criteria, he divided the human hippocampal formation into five fields and used labels H1–H5. While this nomenclature is still used in certain neuropathological communications, it has never been widely adopted for experimental animals and is difficult to apply to currently accepted subdivisions of the hippocampus. Perhaps the most commonly

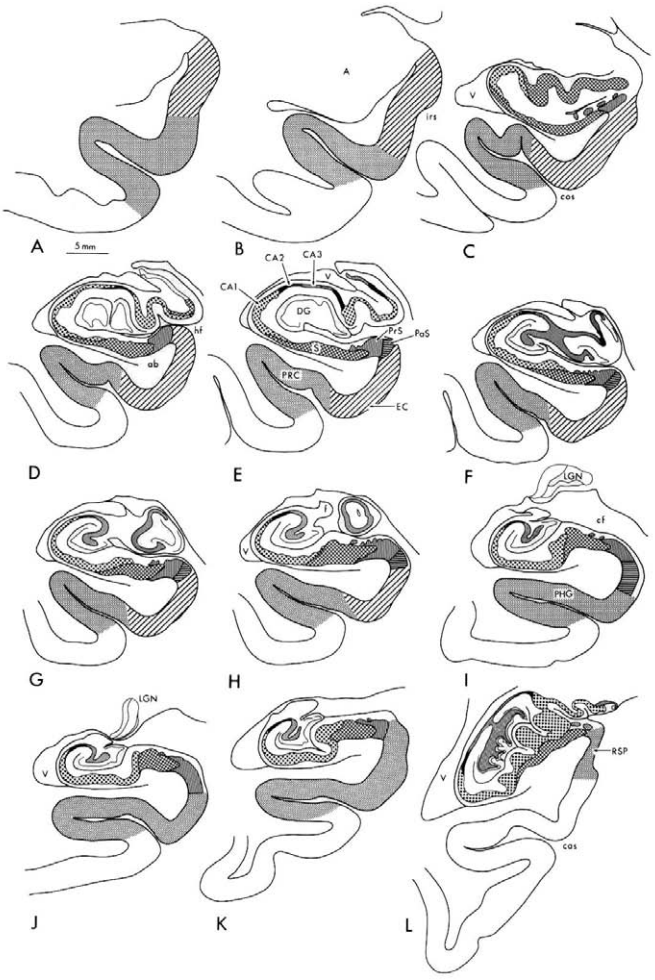

FIGURE 23.15 A series of coronal sections of the human temporal lobe arranged from rostral (A) to caudal (I). The various cytoarchitectonic fields of the hippocampal formation have been shaded with different hatching patterns (panel E is marked as a template) to show the varying extents of each of the fields at different rostrocaudal levels.

employed nomenclature for nonhuman primates and other experimental animals is that provided by Lorente de Nó (1934) based on his observations of Nissl, fiber, and Golgi preparations. He divided the hippocampus into four fields and labeled them CA1–CA4. While some lack of clarity in his description has led to confusion about the borders of some of the defined fields, the terms have the merit of common usage and can, with adequate presentation of criteria for boundaries, be easily employed in the human brain. There are several minor controversies concerning the naming of the other fields of the hippocampal formation, but they will be addressed during the description of the cytoarchitectonic characteristics of those fields.

Topographical Considerations

We presented a description of the topographical organization of the human hippocampal formation in the preceding section that should facilitate the interpretation of the cross-sectional photomicrographs shown in Figures 23.5–23.10. Much of the hippocampal formation lies in the floor of the temporal horn of the lateral ventricle (Fig. 23.2A, B). The individual fields of the hippocampal formation can be envisioned as adjacent bands of simple cortical tissue running rostrocaudally in the temporal lobe. The distinctive C-shape of the hippocampal formation is obtained when the fields fold over each other mediolaterally in an interlocking fashion. In its midportion or "body," the hippocampal formation has its simplest shape (Figs. 23.9 and 23.11). Each field is seen only once in coronal sections through this region. As the hippocampal formation approaches the rostral limit of the ventricle, however, it bends sharply in a medial direction and then in a caudal direction. The number of rostrocaudal flexures in this bend of the hippocampal formation varies substantially from individual to individual and can number as many as five (Gertz *et al.*, 1972). The photomicrographs (Figs. 23.6–23.8) of coronal sections through "uncal" (so called because of the bulge to which it contributes on the medial surface of the temporal lobe) levels show complex images of the hippocampal formation. It is difficult to determine solely on the basis of Nissl-stained coronal sections which fields of the hippocampal formation are seen at these levels. Only with the aid of other histochemical and inmunohistochemical series were we able to differentiate the fields that are designated in Figures 23.5–23.10, and schematically shown in Figure 23.15.

At caudal levels, the human hippocampal formation again loses its simple C-shaped organization. It bends dorsally as it ascends toward, and ultimately around, the splenium of the corpus callosum. Coronal sections through these caudal levels (Fig. 23.10) again provide complex images with discontinuous representations of several of its fields.

Dentate Gyrus

As in other species, the human dentate gyrus is a trilaminate cortical region. Its organization is most easily appreciated at mid rostrocaudal levels of the hippocampal formation (Figs. 23.9 and 23.11). Here it forms a C-shaped structure that is separated ventrally from the CA1 field of the hippocampus and the subiculum by the fused hippocampal fissure (Figs. 23.7 and 23.8). The principal cell layer of the dentate gyrus (the granule cell layer) is populated primarily by

one class of neuron, the granule cell, that sends a unipolar dendritic tree into the overlying molecular layer. Golgi-like staining of human granule cells show that dendrites extending into the molecular layer are invested with spines except for the most proximal 20–30 mm (Lim *et al.*, 1997a). Seress (1988) has estimated that the human dentate gyrus contains approximately 9×10^6 granule cells. More recent reports (West and Gundersen, 1990; West *et al.*, 1994; Simic *et al.*, 1997; Sá *et al.*, 1999) using unbiased stereological techniques have come up with figures that are substantially higher (i.e., 15×10^6 neurons in the granule cell layer of the human dentate gyrus). Interestingly, Sá *et al.* (1999) report a right–left asymmetry in the number of dentate granule cells, which are 20% more numerous on the right side. Human dentate granule cells often give rise to basal dendritic trees that extend into the subjacent polymorphic layer (Seress and Mrzljak, 1987). Lim *et al.* (1997a) note the presence of basal dendrites in 30% of the neurons they investigated. Such basal dendrites are rarely observed in nonprimates. The granule cell and molecular layers are sometimes referred to as the fascia dentata.

The third layer is generally called either the polymorphic layer or the hilus of the dentate gyrus. This is a complex region (Amaral, 1978), and there has been substantial confusion as to whether it should be included as a part of the dentate gyrus or is another, independent field of the hippocampus proper (the so-called field CA4). The situation is further complicated by the fact that the appearance of the region enclosed by the granule cell layer varies from species to species. With the use of powerful anatomical techniques in this region, there is increasingly convincing evidence in the rat and nonhuman primate that the polymorphic layer is a part of the dentate gyrus. Perhaps the most salient data come from connectional studies of the hilus, which indicate that its cells give rise to projections only to the dentate gyrus and not to any other field of the hippocampal formation (Laurberg and Sorensen, 1981). Connectional studies in the *in vitro* human hippocampal slice preparation also support the distinction of the polymorphic layer from the hippocampus; Lim *et al.* (1997a) demonstrated a dense plexus of fibers arising from the polymorphic layer that separates it from the remainder of CA3.

In the human dentate gyrus, it is not easy to differentiate the cells of the polymorphic layer from those of the hippocampus in standard Nissl preparations. Yet both Timm's stained preparations (Fig. 23.13A), which yield a patchy distribution of dark precipitate in the polymorphic layer, and acetylcholinesterase preparations (Fig. 23.13B), which demonstrate numerous precipitate-laden cells in the polymorphic layer, make the establishment of the border much easier. In Figures 23.8, 23.11, 23.12A, and 23.13A, B, a dashed line indicates the border of the polymorphic layer with the hippocampus.

The other question that commonly arises concerning this region is what to label the portion of the hippocampal pyramidal cell layer that is enclosed by the granule cell layer. As illustrated in Figures 23.8 and 23.9, these cells are rather numerous in the human hippocampal formation and are organized in a complex pattern. In fact, the pyramidal cell layer typically makes a sharp bend as it extends toward the hilus of the dentate gyrus and folds back on itself (the so-called end-blade). Lorente de Nó (1934) included some portion of the enclosed pyramidal cell layer as his field CA4. However, in some illustrations, he also appears to have applied the term "CA4" to the cells of the polymorphic layer of the dentate gyrus. Since that time, the term "CA4" has been applied either to the polymorphic layer or to the inserted portion of the pyramidal cell layer with about equal frequency in the literature. Because there is no cytoarchitectonic or connectional reason to distinguish the CA3 pyramidal cells enclosed within the granule cell layer from those that are outside it, we have dropped the use of the confusing term "CA4" and simply referred to all of the hippocampal pyramidal layer in this region as CA3.

Hippocampus

The human hippocampus can be divided into three distinct fields, which we have labeled CA3, CA2, and CA1 according to the nomenclature of Lorente de Nó (1934). In most respects, the overall organization of these fields is similar to that observed in the macaque monkey (Bakst and Amaral, 1984).

Field CA3 borders the hilus of the dentate gyrus, where it terminates in a complex fashion (as described earlier). At its other end, it borders field CA2. Cassell (1980) and Seress (1988) have estimated that there are about 2.1×10^6 neurons in the CA3 region and Cassell (1980) has estimated that there are about 0.22×10^6 pyramidal cells in CA2. More recent accounts of the number of neurons for CA3–CA2 combined derived using stereological techniques offer a figure of approximately 2.8×10^6 neurons (West and Gundersen, 1990; West *et al.*, 1994; Simic *et al.*, 1997; Sá *et al.*, 1999). Sá *et al.* (1999) reported hemispheric asymmetry so that CA3–CA2 contains 14% more neurons on the right side compared to on the left hippocampus. The CA3 pyramidal cells are the largest of the hippocampus and stain darkly in Nissl stains. While the layer is approximately 10 cells thick, it nonetheless has a relatively homogeneous appearance. There is no indication of

sublamination or marked variation of neuronal size or shape in different regions. The hallmark of CA3 is that its neurons receive input on their proximal dendrites from the axons of the dentate granule cells (the mossy fibers). The mossy fiber projection is located either within or immediately above the pyramidal cell layer in what is generally called stratum lucidum. The pattern of mossy fiber termination is best illustrated in Timm's silver sulfide preparations (Fig. 23.13A), in which the terminal varicosities of the mossy fibers are densely labeled with precipitate, presumably owing to their high content of zinc (Frederickson *et al.*, 1983). Lim *et al.* (1997a) analyzed the mossy fiber projection in slices of hippocampal tissue from human temporal lobe. Immunohistochemical stains have also been used to map the projections of the mossy fibers (see also Sloviter *et al.*, 1991; Seress *et al.*, 1993). Most of the dentate gyrus granule cells are immunoreactive for calbindin, as are interneurons in the external part of the molecular layer of the dentate gyrus (Seress *et al.*, 1993). The mossy fibers occupy the pyramidal cell layer and the stratum oriens. Fascicles of mossy fibers cross the pyramidal cell layer of CA3 to accumulate in the stratum lucidum, where they form the so-called end-bulb, and form presynaptic terminals to dendrites (mossy fiber giant boutons). Also, at this point intrahippocampal fibers travel for some distance along the longitudinal axis of the hippocampus.

Before proceeding, it might be appropriate to review the laminar nomenclature of the hippocampus. While it has essentially one cellular layer, the pyramidal cell layer, the plexiform layers above and below the pyramidal cell layer have all been given distinctive names. The limiting surface with the ventricular lumen deep to the pyramidal cell layer is formed by axons of the pyramidal cells and is called the alveus. Between it and the pyramidal cell layer is stratum oriens, which is occupied mainly by the basal dendrites of the pyramidal cells, though it also harbors a variety of neurons, many of which are interneurons. The region superficial to the pyramidal cell layer (toward the hippocampal fissure) contains the apical dendrites of the pyramidal cells and a number of interneurons. This plexiform region has historically been divided into a number of laminae. Stratum lucidum, in which the mossy fibers travel and form en passant synapses on the proximal dendrites of the pyramidal cells, is located immediately above the pyramidal cell layer in CA3. In the rat and monkey, stratum lucidum is apparent even in Nissl-stained sections owing to a noticeable decrease in glial staining. It is not as prominent in Nissl-stained sections of the human hippocampus because many of the mossy fibers also travel within the pyramidal cell layer and the difference in background glial staining is not as distinctive. Stratum lucidum is missing in fields CA2 and CA1 because pyramidal cells in these fields do not receive mossy fiber input. The remainder of the plexiform region is mainly occupied by stratum radiatum, and the most superficial portion (adjacent to the hippocampal fissure) is occupied by stratum lacunosum-moleculare. In stratum radiatum (as well as in stratum oriens), the CA3 and CA2 cells receive associational projections from other rostrocaudal levels as well as subcortical inputs from regions such as the septal nuclei and the supramammillary region. In CA1, the projections from CA3 and CA2 (the so-called Schaffer collaterals) terminate in stratum radiatum and stratum oriens.

The perforant pathway projection from the entorhinal cortex to the dentate gyrus travels, in part, in stratum lacunosum-moleculare of the hippocampus and makes en passant synapses on the distal apical dendrites of the hippocampal pyramidal cells.

The border between CA3 and CA2 is not readily apparent in Nissl-stained sections. This is because CA3 cells appear to extend under the border of CA2 for a short distance. The CA2 region has the most compact and narrow pyramidal cell layer of the hippocampus (Fig. 23.12C). Its cells are about as large and darkly stained as those in CA3, but there is far less space between the cell bodies. These characteristics, coupled with the lack of mossy fiber input, are the distinguishing features of the CA2 field. Even though the borders of CA2 are among the most difficult to establish with confidence, since CA2 has distinct connectional characteristics (in monkey, for example, it receives a particularly heavy input from the supramammillary region of the hypothalamus, Veazey *et al.*, 1982; and it is also recipient of a distinctive substance P projection from the hypothalamus, Nitsch and Leranth, 1994) and appears to be particularly insensitive to pathology (it is the so-called resistant sector of classical neuropathology, Brierly and Graham, 1984; Sloviter, 1994), it clearly deserves to be thought of as a distinct cytoarchitectonic field.

Field CA1 is unquestionably the most complex subdivision of the human hippocampus. According to Stephan (1983) and Stephan and Manolescu (1980), it is also one of the most phylogenetically progressive of the hippocampal fields. Not only does it appear to be populated by a far more heterogeneous group of neuronal elements than the other hippocampal fields, but its appearance also varies substantially along both its transverse (subiculodentate) and its rostrocaudal axes.

The border of CA1 with CA2 is not sharp because some CA2 pyramidal cells appear to extend over the emerging CA1 pyramidal cell layer. The boundary of

CA1 can be placed, however, shortly after the pyramidal cell layer starts to broaden. The border with the subiculum is equally difficult to place unless one is prepared to indicate a rather oblique border zone. As shown most clearly in Figures 23.8, 23.11, and 23.12E, the pyramidal cell layer of CA1 overlaps that of the subiculum for a considerable distance. There is often a cell-free zone between the two layers that helps to define the border (Fig. 23.12E). After the overlapping nature of this border is recognized, the boundary can then be fairly readily placed by using cytoarchitectonic criteria in Nissl-stained material.

Before describing the features of field CA1, we should discuss the origin and usefulness of the term "prosubiculum". Lorente de Nó (1934) used it to describe a field situated between CA1 and the subiculum. Analysis of his Figures 22 and 33 indicates that the area he illustrated as the prosubiculum is actually much of what contemporary authors consider to be the subiculum proper. Rosene and Van Hoesen (1987) continue to use the term "prosubiculum" to label the region of overlap of CA1 and the subiculum. However, we would agree with Braak (1972, see Fig. 23.1; Braak, 1974, see Fig. 23.2) and Cassell (1980) that overlap of elements from two adjacent fields does not constitute sufficient grounds for declaring the existence of a new field. If the cells in this region are ultimately shown to have input and output characteristics distinctly different from other parts of CA1 or the subiculum, then use of the term "prosubiculum" might be warranted. Until then, we have separated this border region into CA1 and subicular components.

According to Casell (1980) and Seress (1988), the CA1 field of the human hippocampus contains 4.6×10^6 to 4.7×10^6 neurons. Of these, Olbrich and Braak (1985) have estimated that 9.4% or approximately 430,000 are interneurons, and the remainder are pyramidal cells. More recent studies using nonbiased counting methods, yield counts that are three to four times larger, as reported by Sá *et al.* (1999, 11×10^6), West and Gundersen, (1990) and West *et al.* (1994, 14.4×10^6), and Simic *et al.* (1997, 20×10^6) without detectable differences between left and right sides of the hippocampus. As Braak (1974) pointed out, the human CA1 pyramidal cell layer can generally be subdivided into two main laminae that are each many cells thick. At many levels of the hippocampus, however, each of the sublayers also appears multilaminate. The pyramidal cell layer varies in thickness from about 10 cells to more than 30 cells. In general, the outer layer of pyramidal cells is more compact, and the cells tend to stain somewhat more darkly than the more deeply placed cells.

The CA1 pyramidal cell layer has a variable appearance at different rostrocaudal levels. And at any particular level, there is a gradient of changing organizational features along the transverse or subiculodentate axis. Close to the CA2 border, the CA1 pyramidal cell layer is at its thinnest, and the cells of both sublayers appear most tightly packed. Toward the subicular border, the pyramidal cell layer gets appreciably thicker and more loosely organized. It is often difficult to identify two discrete sublayers of CA1 in this region because the cells are often organized in a more patchy fashion. The stratum radiatum is much broader in the region of CA1 closest to CA2 and becomes much thinner toward the subiculum (Figs. 23.8, 23.9, and 23.11).

Subiculum

An early estimate of the number of pyramidal cells in the subiculum was approximately 2.55×10^6 (Cassell, 1980). However, more recent studies yield counts that are nearly twice as large (West *et al.*, 1994; Simic *et al.*, 1997), that is, around 5×10^6 neurons. The subiculum is the origin of major subcortical projections to the septal complex, nucleus accumbens, anterior thalamus, and mammillary nuclei, as well as projections to the entorhinal cortex. However, the precise organization of most of these projections is not well understood even in experimental animals. Moreover, the cellular and laminar organization of this region has nor yet been clearly delineated.

As noted earlier, the subiculum and field CA1 of the hippocampus overlap at their border (Figs. 23.8, 23.11, and 23.12E) The laminar organization of both regions is complex in this zone. More medially (i.e., closer to the presubiculum), the subiculum can easily be divided into three layers. Superficially there is a wide molecular layer into which the apical dendrites of the subicular pyramidal cells extend. The molecular layer of the human subiculum tends to be relatively wider than in the monkey and rat and, as in these species, is distinct from the stratum radiatum of CA1. At some levels, islands of what appear to be layer II presubicular cells invade the distal portions of the subicular molecular layer (Braak, 1972). The pyramidal cell layer of the subiculum is 30 or more cells thick and can be divided into at least two sublaminae. Relative to CA1, the subicular pyramidal cells tend to be somewhat larger and more widely spaced. Braak (1972) has labeled the two sublaminae of the pyramidal cell layer the external (nearest the molecular layer) and internal layers. The cells of the external pyramidal cell layer are larger than those in the internal layer, and many of the pyramidal cells contain a distinctive dense

accumulation of lipofuscin in the proximal portion of their apical dendrites. Neither of the subicular pyramidal cell layers is homogeneous. In particular, the superficial limit of the external pyramidal cell layer contains islands of small, darkly stained cells (Fig. 23.12F). This characteristic also distinguishes the subiculum from CA1, which contains large, darkly stained cells at its superficial limit (compare Fig. 23.12D and F). The deepest portion of the subicular pyramidal cell layer contains a variety of smaller neurons which appear to be analogous to the polymorphic layer identified in the monkey (Bakst and Amaral, 1984). As indicated in Figure 23.14, the subiculum makes up much of the uncal flexure of the hippocampal formation. We should note also that a unique field lies between the rostromedial subiculum and the amygdalohippocampal area of the amygdaloid complex (Fig. 23.7, open arrow). This transition region contains a high density of small, darkly stained cells (Fig. 23.12I) that are unlike neurons in any of the other hippocampal fields. This region has been termed hippocampoamygdaloid transitional area (HATA) by Rosene and Van Hoesen (1987).

Presubiculum and Parasubiculum

The laminar organization of the presubiculum and parasubiculum is complex and only poorly understood. It is perhaps most useful to consider that the presubiculum consists of a single, superficially located cellular layer (layer II), which is formed by densely packed, small, modified pyramidal cells.

Layer II of the presubiculum tends to be narrow and continuous at posterior levels of the hippocampal formation but breaks up into larger-diameter islands at more rostral levels. As in the monkey (Bakst and Amaral, 1984), layer II in the human can be further divided into a narrow, superficial rim that contains more densely packed and darkly stained neurons and a broader band of more widely separated cells. The parasubiculum also contains a single cellular layer that is difficult to clearly differentiate from the presubiculum. The layer II cells of the parasubiculum tend to be somewhat larger than those in the presubiculum and more widely spaced.

Entorhinal Cortex

The term "entorhinal cortex" was coined by Brodmann (1909) as a synonym for his area 28. More than any other hippocampal field, the entorhinal cortex has undergone substantial regional and laminar differentiation in the primate brain relative to the rodent (Stephan, 1983). In the rat, the entorhinal cortex is usually considered to comprise two regions (medial and lateral) that were originally proposed by Brodmann (1909, his areas 28a and 28b). In the macaque monkey, the entorhinal cortex demonstrates a marked gradient of cytoarchitectonic changes from its rostral to caudal extents and can be partitioned into at least seven different cytoarchitectonic fields (Amaral *et al.*, 1987; Fig. 23.15 upper part). The human entorhinal cortex has been studied by several authors (Braak, 1972; Macchi, 1951; Rose, 1927; Sgonina, 1938), who have partitioned it into as many as 23 fields (Rose, 1927; Sgonina, 1938). Our own studies suggest that the laminar organization of the human entorhinal cortex is not nearly as distinct as in the macaque monkey. Nonetheless, we have observed the same rostrocaudal gradient of cytoarchitectonic differentiation in the human entorhinal cortex and, using similar criteria, up to eight fields, largely comparable with those defined for the monkey, can be distinguished in the human (Insausti *et al.*, 1995; Fig. 23.15 lower part). Other cytoarchitectonic parcellations for the human entorhinal cortex have also been proposed, based either on the peculiarities of the pigment staining of layer II neurons (Hanke and Yilmazer-Hanke, 1997, 12 subfields) or more classical cyto- and myeloarchitectonic approaches (Krimer *et al.*, 1997, 9 subfields).

In the monkey, the entorhinal cortex is spatially associated with the amygdaloid complex rostrally and the other fields of the hippocampal formation caudally. It extends rostrally to about the mid rostrocaudal level of the amygdala and caudally to the level of the anterior limit of the lateral geniculate nucleus or about midway back through the hippocampus (Fig. 23.4). In the human, the entorhinal cortex appears to extend relatively more rostrally than in the monkey.

Structures that form the medial and lateral borders of the entorhinal cortex are different at various rostrocaudal levels. At rostral levels, the entorhinal cortex borders the periamygdaloid cortex medially, and the boundary is approximately marked by the location of the sulcus semiannularis (Fig. 23.5). As the other fields of the hippocampal formation emerge at more caudal levels of the entorhinal cortex, the medial boundary is formed either by the presubiculum or the parasubiculum. Unlike in the rat and monkey, where the lateral border of most of the entorhinal cortex is marked by the rhinal sulcus, there is no easily identifiable lateral limit of the human entorhinal cortex. In fact, the rhinal sulcus in the human is for the most part situated rostral to the entorhinal cortex. The collateral sulcus lies lateral to the entorhinal cortex for its full rostrocaudal extent but at no level does it form the lateral border of the entorhinal cortex. As in the

monkey, the human entorhinal cortex is laterally adjacent to the perirhinal cortex (areas 35 and 36 of Brodmann) for much of its rostrocaudal extent. In the monkey, we have found that area 35 forms the lateral border of rostral levels of the entorhinal cortex, whereas area 36 (which is differentiated from area 35 principally by the presence of a distinct layer IV) borders caudal levels. In the human brain, the lateral border of the entorhinal cortex is formed throughout its rostrocaudal extent by a cortical field that lacks a distinct layer IV and has many of the other cytoarchitectonic characteristics of area 35. However, the border between area 35 and the entorhinal cortex is not easily placed. As indicated in Figures 23.5 and 23.7, these two fields appear to have an obliquely oriented boundary. The deep layers of the entorhinal cortex appear to extend somewhat more laterally than the superficial layers. This distinctly angled border between area 35 and the entorhinal cortex has been emphasized by Braak (1980), who has labeled the region of overlap the "transentorhinal zone." The caudal limit of the human entorhinal cortex also presents a complex cytoarchitectonic appearance. In the monkey (Amaral *et al.*, 1987), the entorhinal cortex is continuous caudally with a lateral extension of what appears to be the parasubiculum and then with fields TH and TF of the parahippocampal gyrus. For some distance, however, neural elements from all these fields appear to be intermixed. A similar situation appears to hold for the human entorhinal cortex as well.

While the entorhinal cortex is a multilaminate structure, its cellular constituents and laminar organization are quite distinct from those of other neocortical regions. Several numbering schemes have been adopted for its various layers. According to Ramón y Cajal (1901–1902), Hammarberg (1895) provided the first account of entorhinal lamination and recognized five distinct layers. Ramón y Cajal (1901–1902) described seven cellular and plexiform layers in the entorhinal cortex while Lorente de Nó (1933) assigned six. Other authors (Braak, 1972; Sgonina, 1938; Heinsen *et al.*, 1994; Hanke and Yilmazer-Hanke, 1997) have not numbered the layers of the entorhinal cortex but simply divided it into two laminae, the laminae principalis externa and principalis interna, with a cell-free space, the lamina dissecans, interposed. By doing this, they stressed the perceived impropriety of associating layers of the entorhinal cortex with those of the neocortex. We (Amaral *et al.*, 1987) have adopted with minor modifications (Fig. 23.6) the scheme of layering proposed by Ramón y Cajal (1901–1902). Because there has been substantial confusion concerning the laminar organization of the human entorhinal cortex, it is worthwhile to review briefly the major characteristics of each of its laminae.

The entorhinal cortex can be conveniently divided into six layers (Fig. 23.12H). Layer I is an acellular or plexiform layer that tends to be somewhat thicker at more posterior levels. Layer II is a cellular layer made up of islands of relatively large and darkly stained modified pyramidal and stellate cells (Fig. 23.12H). Layer II is one of the most outstanding and distinguishing characteristics of the entorhinal cortex (see Fig. 23.3 for unfixed appearance). The islands are distributed all over the entorhinal cortex, although they tend to be thinner, more elongated, and less noticeable rostrally, at dorsal and medial portions (Braak, 1980, tangential sections; Insausti *et al.*, 1995; Hanke and Yilmazer-Hanke, 1997, tangential sections). In the fixed brain, the cell islands of layer II form small mounds (Fig. 23.12H) on the surface of the brain that can be observed with the naked eye (Figs. 23.1, 23.3, 23.5, and 23.8). These raised bumps on the surface of the entorhinal cortex (the verrucae hippocampi illustrated by Klingler, 1948) provide a useful macroscopic indication of the entorhinal location. The white strands surrounding layer II cell islands have been referred to as substantia reticularis alba of Arnold. The presence of modularity in the human entorhinal cortex has been suggested based on the demonstration of cytochrome oxidase activity in the upper layers of the human entorhinal cortex (Hevner and Wong-Riley, 1992). Interestingly, the cytochrome oxidase pattern loses the patchy appearance at the caudal limit of the entorhinal cortex. Further support for the presence of modules in the human entorhinal cortex is given by the immunoreactivity for nonphosphorylated neurofilaments and the calcium-binding proteins calbindin and parvalbumin (Beall and Lewis, 1992) and by a more detailed study using several techniques by Solodkin and Van Hoesen (1996). Although there are no reported studies of the ultrastructure of layer II neurons in the human entorhinal cortex, the study by Goldenberg *et al.* (1995) in the rhesus monkey shows differences along the rostrocaudal extent of the entorhinal cortex: rostrally (ER) neurons are grouped in clusters with frequent appositions of contiguous somata. These appositions were absent at intemediate and caudal levels. In contrast, axosomatic synapses and the presence of myelinated fibers increases caudally in the entorhinal cortex.

There is usually an acellular gap between layer II and the broad layer of medium-sized pyramidal cells that populate layer III. This gap increases at more posterior levels of the entorhinal cortex so that, in myelin-stained preparations, the layer II cell islands are conspicuous as negative images outlined by the dense fiber labeling in layer I and in the space between layers II and III. Layer III contains a relatively homogeneous population of pyramidal cells. Layer III

cells have a columnar appearance at caudal levels of the entorhinal cortex but tend to be arranged in large patches rostrally and medially. In myelin preparations, layer III contains delicate bundles of radially oriented fibers that run to the pial surface. These bundles of fibers are more noticeable at rostral levels of the entorhinal cortex, and they become particularly dense close to the boundary with the perirhinal cortex. Golgi studies of the monkey entorhinal cortex (Amaral *et al.*, 1987; Carboni *et al.*, 1990) show that dendrites of layer III pyramidal neurons bend and pass through the interstices of layer II cell islands, a morphological feature that has also been observed in the human entorhinal cortex after intracellular filling of neurons in fixed slices (Mikkonen *et al.*, 2000)

One of the most characteristic features of the entorhinal cortex in all species is the absence of an internal granule cell layer. In its place is an acellular region of dense fiber labeling, the lamina dissecans (Rose, 1927), which is most noticeable at mid rostrocaudal levels of the entorhinal cortex. In the entorhinal regions where the lamina dissecans is not prominent, layers III and V are apposed. Fiber preparations through these regions, however, still demonstrate a heavy plexus of fibers at the interface of the two layers. To emphasize the lack of a typical internal granule cell layer in the entorhinal cortex, the lamina dissecans has been labeled as layer IV. In some reports of the human entorhinal cortex (Hyman *et al.*, 1984), the term "layer IV" is applied to the layer of large pyramidal cells that lies deep to the lamina dissecans. To avoid the confusion that might arise from labeling a layer of large pyramidal cells with the same number typically applied to a layer of small cells in the neocortex, we have followed Ramón y Cajal's lead and labeled the large cells deep to lamina dissecans as layer V.

Layer V is about five or six cells deep and comprises primarily large and darkly stained pyramidal cells. At rostral levels of the entorhinal cortex, layer V merges with layer III while at mid levels the lamina dissecans clearly separates the two layers. Layer V becomes most highly developed at mid to caudal levels of the entorhinal cortex, and here three sublaminae can be differentiated. The most superficial layer (sublayer Va) contains the largest pyramidal cells in the entorhinal cortex, while the middle sublayer (Vb) contains somewhat smaller and more loosely arranged cells. The deep sublamina (layer Vc) contains fewer neurons and a fairly dense plexus of fibers (Figs. 23.6 and 23.7; Insausti *et al.*, 1995). At the same time that the lamina dissecans becomes less noticeable in the caudal half of the entorhinal cortex, layer Vc becomes much more pronounced, and it is easy to mistake Vc for a caudal extension of the lamina dissecans. At rostral levels of the entorhinal cortex, layer VI is not easily distinguished from layer V. Close to the border with the perirhinal cortex, layer VI is rather broad and diffuse. The border of layer VI with the white matter is not sharp rostrally, and there is a gradient of decreasing cell density from this layer into the white matter. Caudally, however, layer VI presents a sharp border at the transition with the white matter (Figs. 23.7 and 23.8). The subcortical white matter situated deep to the subicular complex is given the name angular bundle (Figs. 23.7 and 23.8) because of its trajectory in nonprimates. It is within this region that the perforan path fibers travel to caudal levels of the hippocampal formation. At the border of the entorhinal cortex with the perirhinal cortex, layer VI tends to fade out in a gradual fashion and finally ends somewhat more laterally than the termination of layer V. This contributes to the oblique orientation of the border between the entorhinal and perirhinal cortices that we discussed earlier.

Since the first writing of this chapter, several, studies have been conducted in order to estimate the number of neurons in the human entorhinal cortex (Heinsen *et al.*, 1994; Gómez-Isla *et al.*, 1996; West and Slomianka, 1998a; *corrigendum*, West and Slomianka, 1998b; Price *et al.*, 2001; Kordower *et al.*, 2001). The counts generally are carried out relative to layers but do not take the various subfields into consideration. The number of neurons of the human entorhinal cortex is on the order of 7×10^6 to 8×10^6 neurons. Of these, about 10% are in layer II, approximately 45% are located in layer III, about 15% of the total belong to layer V, and 31% are in layer VI.

A simple comparison of these figures has important implications for the understanding of the anatomical connections of the human hippocampal formation. For instance, these numbers, compared to those of the human hippocampus, emphasize how divergent the axonal projection of layer II neurons must be, both to the dentate gyrus and CA3 (West and Slomianska, 1998a, b). In addition, 6.1×10^6 neurons in layer III of the entorhinal cortex and 16×10^6 neurons in the human CA1 field of the hippocampus, yields a ratio of approximately 1:2.5. In other words, almost one half of the total number of neurons of the human entorhinal cortex might be projecting to CA1 (Witter and Amaral, 1991).

HIPPOCAMPAL CONNECTIVITY

Having reviewed the cytoarchitectonic organization of the human hippocampal formation, we now present a summary of its major connections. Virtually all the information we survey here was derived from experimental studies conducted in the rat, cat, or

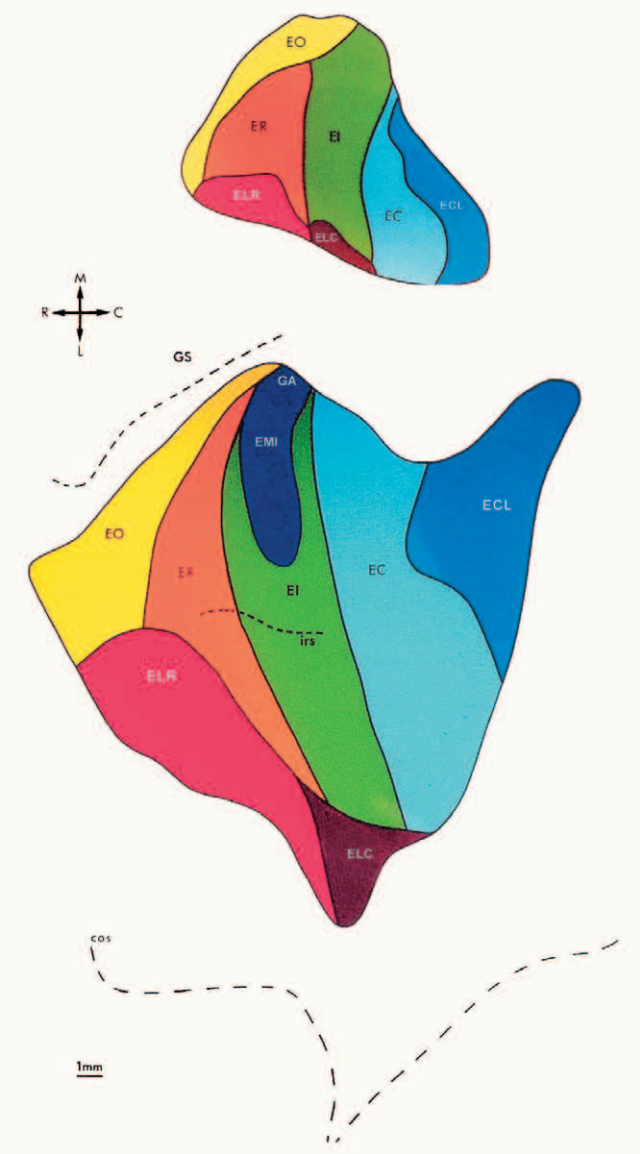

FIGURE 23.16 Two-dimensional unfolded maps of the entorhinal cortex in the nonhuman primate (*Macaca fascicularis* monkey, upper panel) and in the human brain (lower panel). In both cases, the same scale and orientation (arrows) applies to both species. While in the nonhuman primate, no special mention to adjacent sulci, the rhinal sulcus in particular, is made; in the case of the human entorhinal cortex, the location of the the gyrus semilunaris (GS) above the upper dashed line (sulcus semiannularis), the location of the intrarhinal sulcus (irs) in the middle of the mediolateral extent of the entorhinal cortex, and the fundus of the collateral sulcus (cs) separated some distance from the lateral border of the entorhinal cortex by the laterally adjacent perirhinal cortex are indicated. Subfields of the entorhinal cortex, which presumably share homology between both species, are color-coded in a similar way. Despite the fact that only one more subfield could be reliably identified, note the expanse of the caudal entorhinal portions of the human brain compared to nonhuman primates.

monkey. The fundamental intrinsic circuitry of the hippocampal formation and a listing of its major inputs and outputs is illustrated in Figure 23.16.

Intrinsic Connections

The dentate gyrus can, for convenience, be considered the first step in the intrinsic hippocampal formation circuit. It receives its major input from cells located primarily in layer II of the entorhinal cortex that give rise to the so-called perforant path (Andersen *et al.*, 1966; Hjorth-Simonsen, 1971, 1972; Hjorth-Simonsen and Jeune, 1972; Ruth *et al.*, 1982; Steward, 1976; Steward and Scoville, 1976; Witter and Groenewegen, 1984; Witter *et al.*, 1988a, 1989, Witter and Amaral, 1991). According to Witter and Amaral (1991), layer II neurons originate the projection to the molecular layer of the dentate gyrus and stratum lacunosum-moleculare of CA3, while layer III neurons project almost exclusively to CA1 and the subiculum. These fibers travel caudally from the entorhinal cortex in the angular bundle and ultimately perforate through the subiculum and hippocampus to terminate in the outer two-thirds of the molecular layer of the dentate gyrus. The course of the perforant path fibers is complex. Some of the fibers cross the obliterated hippocampal fissure to enter the dentate molecular layer directly from the subiculum, while others travel first through the stratum lacunosum-moleculare of CA1 and CA3 to enter the molecular layer at the tip of the dentate gyrus. As illustrated in Figure 23.16, the entorhinal fibers also terminate in the subiculum, CA1, and CA3 (Nafstad, 1967; Steward, 1976; Steward and Scoville, 1976; Van Hoesen and Pandya, 1975b). This direct projection to the hippocampus and subiculum has largely been neglected, though it is by no means trivial and is likely to be of substantial importance to the normal functioning of the hippocampal formation (Witter *et al.*, 1988a; Soltesz and Jones, 1995; Sybirska *et al.*, 2000). One of the few tracing studies conducted in the post-mortem human hippocampal formation reveals that specific entorhino-hipocampal (CA1, CA3 and subiculum) projections are present at 19 post-gestational weeks and originate in the appropriate layers, while entorhino-dentate projections lag a few weeks behind (Hevner and Kinney, 1996). The same study also reports that CA1 and subiculum contain retrogradely labeled neurons, similar to the connections of CA1 and subiculum of the monkey hippocampal formation (Kosel *et al.*, 1982; Insausti and Amaral, unpublished observations). Anterogradely DiI-labeled fibers were likewise demonstrated, although, in contrast to the monkey, the alvear path seemed more robust than in the monkey, while the

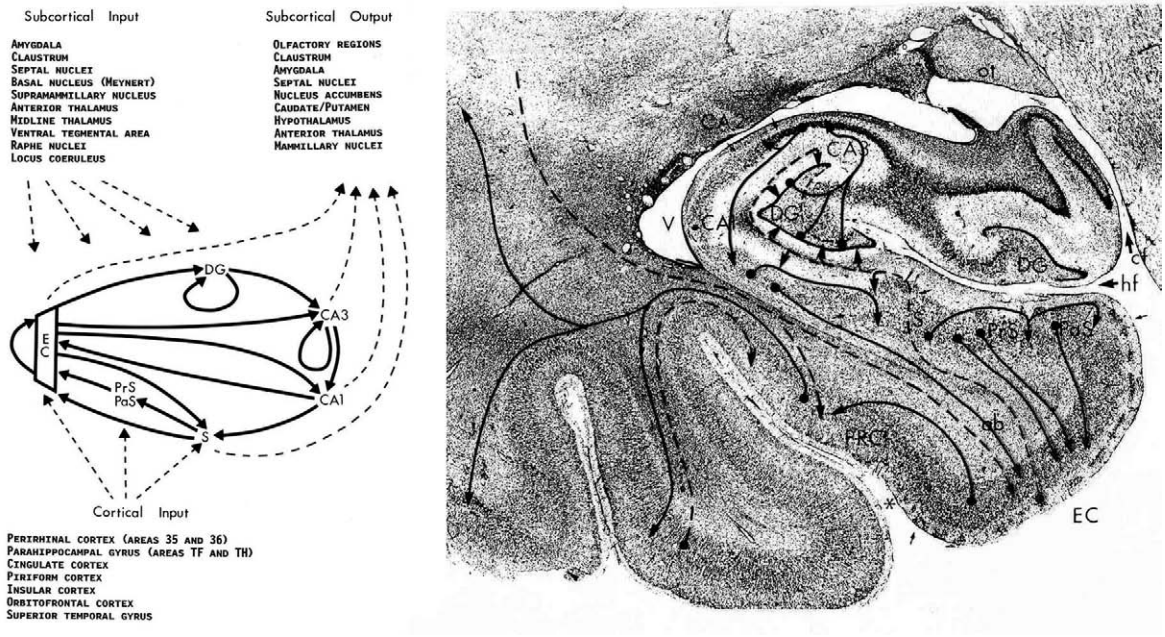

FIGURE 23.17 Illustration of the major connections of the hippocampal formation and a listing of prominent afferent and efferent connections (see text for details). Curved arrows in the dentate gyrus (DG) and in the CA3 field of the hippocampus indicate the presence of associational projections that link different levels of the fields. The curved arrow in the entorhinal cortex (EC) indicates the presence of associational projections between different levels of the field and projections from deep layers to superficial layers. Dashed lines at the right represent efferent projections carried by the fornix. Several of the subcortical afferents listed at the left enter the hippocampal formation through the fornix. A separate list of cortical outputs has not been included in this illustration. It is likely, however, that most, if not all, of the areas listed as afferents to the hippocampal formation receive return projections from the subiculum or entorhinal cortex.

labeling of the perforant path was similar to that reported in the monkey by Witter and Amaral (1991).

Cells of the dentate gyrus do not project outside of the hippocampal formation. Rather, the dentate granule cells project via their distinctive axons, the mossy fibers, upon cells of the dentate gyrus's own polymorphic layer (Clairbone *et al.*, 1986) and onto the proximal dendrites of the pyramidal cells of the CA3 region of the hippocampus (Blackstad *et al.*, 1970; Gaarskjaer, 1978, 1981; Rosene and Van Hoesen, 1977). The other main constituent of the granule cell layer is the dentate basket pyramidal cell that gives rise to a dense plexus of GABAergic fibers and terminals that surround the granule cell bodies (Ribak and Seress, 1983). The deep, or polymorphic layer of the dentate gyrus has a mixture of neuronal types that give rise to local and associational projections (Fig. 23.16). In nonprimates, cells in the polymorphic layer also contribute a commissural projection to the contralateral dentate gyrus, but this connection is largely vestigial in the monkey (Amaral *et al.*, 1984; Demeter *et al.*, 1985), as well as in humans (Wilson *et al.*, 1987; Gloor *et al.*, 1993). One class of cell, the mossy cell, originates a prominent associational system of fibers that terminates in the inner one-third of the molecular layer (Laurberg and Sorensen, 1981; Swanson *et al.*, 1978). Interestingly, this projection does not terminate locally (at the level of origin) but projects to distant portions of the dentate gyrus (Buckmaster and Amaral, 2001) and thus tends to associate different septotemporal (or rostrocaudal in the human) levels of the dentate gyrus. There is a second population of cells in the polymorphic layer, immunoreactive for the peptide somatostatin and for γ-aminobutyric acid (GABA), that gives rise to a fiber system that is complementary to the associational fibers. These fibers terminate in the outer two-thirds of the molecular layer and terminate most densely at a level close to the cells of origin (Bakst *et al.*, 1986). There are a number of other neuronal cell types in the dentate gyrus, many of which are immunoreactive for one or more peptides (Amaral and Campbell, 1986) or other transmitter candidates. The precise connectivity of most of these cells is not currently established.

Collaterals of single CA3 pyramidal cells project to other levels of CA3, to CA1, and to subcortical regions, especially the septal nuclei. CA3 pyramidal cells in the rat originate an extensive associational system that

projects widely along the septotemporal axis of the field (Ishizuka *et al.*, 1990; Swanson *et al.*, 1978). CA3 cells also contribute the mayor input system to CA1 (the Schaffer collaterals), which terminates throughout stratum radiatum and stratum oriens (Ishizuka *et al.*, 1990; Rosene and Van Hoesen, 1977; Swanson *et al.*, 1978; Lim *et al.*, 1997b). The CA3 field of the hippocampus also contains a number of nonpyramidal cells, many of which are interneurons, but the connectivity of these has not been well studied. CA1 pyramidal cells have a pattern of connections that is distinct from that of CA3. What is perhaps most striking is that CA1 pyramidal cells do not project significantly to other levels of CA1. Rather, CA1 pyramidal cells project predominantly to the subiculum (Finch and Babb, 1981; Finch *et al.*, 1983; Rosene and Van Hoesen, 1977; Swanson and Cowan, 1977). The subiculum, in turn, projects to the pre- and parasubiculum, and all three components of the subicular cortices project to the entorhinal cortex (Amaral *et al.*, 1984; Beckstead, 1978: Finch *et al.*, 1983; Köhler, 1984, 1985; Köhler *et al.*, 1978; Rosene and Van Hoesen, 1977; Shipley, 1974, 1975; Sorensen and Shipley, 1979).

As indicated in Figure 23.16, one of the more striking features of the intrinsic circuitry of the hippocampal formation is that it is largely unidirectional. The CA3 field does not project back to the granule cells of the dentate gyrus. Nor do CA1 pyramidal cells project back to CA3. Thus, aside from the initial entorhinal input that reaches all the hippocampal fields in parallel, information flow from the dentate gyrus through the other fields follows an obligatory serial and largely unidirectional pathway.

Extrinsic Connections

Until the mid 1970s, the prevailing view of the extrinsic connectivity of the hippocampal formation was largely that enunciated by Papez (1937). Papez suggested that the hippocampus was the recipient of sensory information from a variety of cortical regions (though the sources and pathways of these projections were only vaguely set forth). The hippocampus was thought to funnel this sensory information through the fimbria and fornix to the mammillary nuclei where it could marshal appropriate emotional responses. (The hippocampal projections to the septal nuclei and anterior thalamus were not experimentally demonstrated until the 1950s and early 1960s.) Because the fornix was such an obvious efferent pathway, alternative hippocampal efferents were largely overlooked. And because little was known about the specific connectivity of the individual hippocampal subdivisions, the fimbria was assumed to arise exclusively from the pyramidal cells of the hippocampus. It is now clear, however, that the subiculum, rather than the hippocampus proper, gives rise to the postcommissural projection to the mammillary complex. Moreover, recent studies conducted mainly in the primate brain have shown that the fornix is not the sole output pathway of the hippocampal system. Both CA1 and the subicular cortices form the non-entorhinal neocortical output of the hippocampal formation (Insausti and Muñoz, 2001), directed to polymodal association cortices (Barbas and Blatt, 1995; Blatt and Rosene, 1998; Ding *et al.*, 2000; Yukie, 2000; Insausti and Muñoz, 2001). Likewise, the entorhinal cortex projects to neighboring cortices such as the perirhinal and parahippocampal cortices and to more distant regions such as the orbitofrontal cortex. The concept has emerged that the interaction of the hippocampal formation with the neocortex is at least as important to its normal function as its subcortical interactions. The hippocampal formation can also influence a variety of brain regions through nonfimbrial projections to the amygdaloid complex and striatum. The literature on the extrinsic connectivity of the hippocampal formation is rapidly expanding, and it is beyond the scope of this chapter to review exhaustively this body of work. The following is intended to be an overview of the major extrinsic hippocampal connections.

Subcortical Connections

The fimbria and fornix form the classical efferent system of the hippocampal formation and the human fornix contains about 1.2 million fibers (Powell *et al.*, 1957). The precommissural fornix, which innervates primarily the lateral septal nucleus, arises mainly from cells of the hippocampus proper and to a lesser extent from the subiculum and entorhinal cortex (Alonso and Köhler, 1984; Siegel *et al.*, 1974, 1975; Swanson and Cowan, 1977). The cells of CA3, which project bilaterally to the septal complex, are the same cells that give rise to the Schaffer collaterals to CA1 (i.e., axon branches distribute terminals to both structures). The nucleus accumbens also receives a projection through the fornix that arises in the subiculum and entorhinal cortex (Groenewegen *et al.*, 1982; Kelley and Domesick, 1982; Lopes da Silva *et al.*, 1984; Sorensen, 1985; Swanson and Cowan, 1977). The subiculum and entorhinal cortex give rise to additional projections to the caudate nucleus and putamen (Groenewegen *et al.*, 1982; Sorensen, 1985; Sorensen and Witter, 1983). As noted previously, it is the subicular complex, rather than the hippocampus, is the origin of the postcommissural fiber system (Swanson and Cowan, 1975). Presubicular fibers innervate the anteromedial,

anteroventral, and lateral dorsal nuclei of the thalamus, and fibers originating in the subiculum and presubiculum provide the major extrinsic input to the mammillary nuclei (Chronister *et al.,* 1975; Edinger *et al.,* 1979; Irle and Markowitsch, 1982; Kaitz and Robertson, 1981; Meibach and Siegel, 1975, 1977: Poletti and Creswell, 1977; Raisman *et al.,* 1966; Rosene and Van Hoesen, 1977; Sherlock and Raisman, 1975; Simpson, 1952; Swanson and Cowan, 1975, 1977). The lateral mammillary nucleus is innervated by the subiculum and presubiculum, and the medial mammillary nucleus is innervated by the subiculum. In the rat and cat, the ventromedial nucleus of the hypothalamus is reciprocally connected with the ventral portion of the subiculum (Irle and Markowitsch, 1982; Krettek and Price, 1978; Swanson and Cowan, 1977), though this connection has not yet been confirmed in the primate.

Starting with the work of Krettek and Price (1977) in the rat and cat, it has become increasingly clear that the hippocampal formation is interconnected with several regions of the amygdala. They showed that the lateral nucleus of the amygdala gave rise to a prominent projection to layer III of the lateral entorhinal cortex. There were additional projections from the basal nucleus to the subiculum and parasubiculum. In the monkey, the lateral and basal nuclei also projects to the entorhinal cortex (Pitkänen *et al.,* 2002) and there are additional projections from the accessory basal nucleus to the subiculum (Aggleton, 1986; Amaral, 1986). The subiculum originates a return projection to the basal nucleus, while the entorhinal cortex projects to both the basal and lateral nuclei (Aggleton, 1986; Amaral, 1986). In the rat, the ventral portion of CA1 is reported to project to the lateral, basal, and cortical nuclei (Ottersen, 1982). (See Chapter 22 for further details on the connections of the amygdala with the hippocampal formation.) The entorhinal cortex is also reciprocally connected to the ventral part of the anterior claustrum (Insausti *et al.,* 1987b; Markowitsch *et al.,* 1984; Witter *et al.,* 1988b).

In addition to the amygdala and claustrum, a number of other subcortical structures project to the hippocampal formation. Most prominent among these are the septal complex and the supramammillary area. The septal projection to the hippocampal formation was first experimentally demonstrated in the early 1950s (Daitz and Powell, 1954; Morin, 1950), and numerous studies have subsequently been conducted to further define the projection (Fibiger, 1982; Meibach and Siegel, 1975; Milner *et al.,* 1983; Mosko *et al.,* 1973; Swanson, 1978; Swanson and Cowan, 1976; Amaral and Kurz, 1985). The septal projection arises from cells of the medial septal nucleus and the nucleus of the diagonal band of Broca and, in the rat brain, travels to the hippocampal formation via four routes: the fimbria, dorsal fornix, supracallosal stria, and a ventral route through the amygdala complex (Milner and Amaral, 1984). Septal fibers terminate in essentially all fields of the hippocampal formation but are most prominent in the dentate gyrus and the CA3 field of the hippocampal formation.

Lewis and Shute (1967; Lewis *et al.,* 1967) first proposed that the septohippocampal projection was cholinergic after showing that fimbrial sections led to a substantial loss of histochemical staining of the degradative enzyme acetylcholinesterase. Mesulam and colleagues, using inmunohistochemical procedures to demonstrate the specific cholinergic marker, choline acetylcholinesterase, in conjunction with retrograde tracer techniques (Mesulam *et al.,* 1983; Wainer *et al.,* 1985) found that 30–50% of the cells in the medial septal nucleus and 50–75% of the cells in the nucleus of the diagonal band that project to the hippocampal formation are cholinergic. Their retrograde tracer studies confirmed the long-held belief that the medial septal nucleus and the nucleus of the diagonal band give rise to the cholinergic innervation of the hippocampal formation but indicated that many cells, especially within the medial septal nucleus, that project to the hippocampal formation are not cholinergic. Many cells in the septal complex contain glutamic acid decarboxylase and are presumably GABAergic; at least some or these project to the hippocampal formation (Köhler *et al.,* 1984a). The entorhinal cortex is also innervated by cells of the medial septal nucleus and nucleus of the diagonal band (Alonso and Köhler, 1984; Insausti *et al.,* 1987b; Segal, 1977). These projections are similarly only partially cholinergic (Alonso and Köhler, 1984; Amaral and Kurz, 1985; see also Chapter 17).

The major hypothalamic projection to the hippocampal formation arises from a population of large cells that cap and partially surround the mammillary nuclei in a zone that has been named the supramammillary area (Amaral and Cowan, 1980; Pasquier and Reinoso-Suarez, 1977; Riley and Moore, 1981; Segal, 1979; Segal and Landis, 1974; Veazey *et al.,* 1982; Wyss *et al.,* 1979a, b; Insausti *et al.,* 1987b). The supramammillary projection terminates in many of the fields of the hippocampal formation but most heavily in the dentate gyrus, in fields CA2 and CA3 of the hippocampus, and in the rostral entorhinal cortex (Haglund *et al.,* 1984; Segal, 1979; Veazey *et al.,* 1982; Wyss *et al.,* 1979b; Nitsch and Leranth, 1993). A pathway containing calretinin and substance P has been reported to originate in the suprammamilary nucleus and terminates as a dense band in the inner

one-fourth of the molecular layer and uppermost granule cell layer of the dentate gyrus. Interestingly, in the adult human brain, this band of calretinin-positive fibers is restricted to the innermost portion of the dentate gyrus. This pathway has been proposed to play a role in the regulation of theta activity (Berger *et al.*, 2001). As already noted, the medial and lateral mammillary nuclei receive prominent projections from the subicular cortices, and the supramammillary projection provides one possible route for reciprocation. It is not presently known, however, whether cells of the supramammillary region receive linking projections from other components of the mammillary complex. In addition to the supramammillary cells, there are other cells scattered in several hypothalamic nuclei, many of which are in a perifornical position or within the lateral hypothalamic area, that project to the hippocampal formation. Taken together, these cells constitute a sizable input to the hippocampal formation. However, their diffuseness and lack of any distinguishing biochemical marker have made it difficult to study their projections. A subset of these cells demonstrate α-melanocyte-stimulating hormone-like inmunoreactivity and give rise to a diffusely distributed pathway to several fields of the hippocampal formation (Köhler *et al.*, 1984b; see Chapter 17).

Until recently, it was thought that the hippocampal formation received little or no thalamic input. More sensitive axonal tracing methods, however, have shown that it receives a substantial innervation from several thalamic nuclei. Projections to the hippocampal formation arise from all divisions of the anterior thalamic complex and associated lateral dorsal nucleus (Amaral and Cowan, 1980; Irle and Markowitsch, 1982; Niimi *et al.*, 1978; Wyss *et al.*, 1979a; Insausti *et al.*, 1987b). These nuclei project primarily to the subicular complex and more specifically to the presubiculum (Domesick, 1972; Niimi, 1978; Shipley and Sorensen, 1975). The "midline thalamic nuclei" (which include the parataenial nucleus, the anterior paraventricular nucleus, the nucleus centralis medialis, and the nucleus reuniens) also project to the hippocampal formation. The entorhinal cortex receives a particularly heavy projection from the paraventricular nucleus and a minor input from the dorsomedial portion of the medial pulvinar nucleus (Insausti *et al.*, 1987b). The nucleus reuniens projection terminates primarily in the stratum lacunosum-moleculare of CA1, in portions of the subicular cortices, and in the entorhinal cortex (Herkenham, 1978).

The hippocampal formation receives minor projections from several brainstem regions, including the ventral tegmental area, periaqueductal gray matter, and dorsal tegmental nucleus. Most hippocampally directed brainstem fibers, however, arise in the locus coeruleus, and in the raphe nuclei, mainly from the central superior and dorsal divisions. The locus coeruleus gives rise to the major noradrenergic input to the hippocampal formation (Kobayashi *et al.*, 1974; Koda *et al.*, 1978; Lindvall and Bjorklund, 1974; Loy *et al.*, 1980; Pasquier and Reinoso-Suarez, 1977; Segal and Landis, 1974; Swanson and Hartman, 1975), while the raphe nuclei give rise to its major serotonergic innervation (Azmitia and Segal, 1978; Conrad and Pfaff, 1976; Köhler and Steinbusch, 1982; Moore and Halaris, 1975). Both of these nuclei project to most of the hippocampal fields, with a particularly prominent innervation of the dentate gyrus. Histochemical (Hokfelt *et al.*, 1974) and inmunohistochemical data suggest that the hippocampus and subiculum may also be innervated by dopaminergic fibers (Pohle *et al.*, 1984: Verney *et al.*, 1985), many of which originate in the ventral tegmental area (Swanson, 1982). The entorhinal cortex of the monkey also likely receives dopaminergic projections from the ventral tegmental area (Insausti *et al.*, 1987b).

Commissural Connections

The classical neuroanatomists Kölliker (1896), Ramón y Cajal (1893), and Lorente de Nó (1934) all described prominent hippocampal commissures. The organization of the commissural connections was not experimentally analyzed, however, until the mid-1950s when Blackstad (1956) demonstrated a massive commissural system in the rat that interconnected most of the fields of the two sides of the hippocampal formation. Since Blackstad's publication, the commissural connections, particularly in rodents, have received intensive anatomical study (Fricke and Cowan, 1978; Gottlieb and Cowan, 1973; Hjorth-Simonsen, 1977; Hjorth-Simonsen and Laurberg, 1977; Laatsch and Cowan, 1966; Laurgerg, 1979; Laurberg and Sorensen, 1981; Raisman *et al.*, 1965; Shipley, 1975; Swanson *et al.*, 1980; West *et al.*, 1979). The commissural connections in the macaque monkey brain have also been studied (Amaral *et al.*, 1984; Demeter *et al.*, 1985). In the monkey, only the most rostral (or uncal) part of the hippocampus and associated dentate gyrus are connected by commissural fibers. This contrasts markedly with the rodent brain, where both CA3 and CA1 of the entire hippocampus receive a strong, topographically organized projection from the opposite CA3, and the dentate gyrus receives a major input from cells of the contralateral polymorphic layer. As in the rat, the monkey presubiculum gives rise to a substantial commissural projection that terminates in layer III of the contralateral entorhinal cortex. It would appear

that in primates, and presumably in humans, this projection constitutes the major link between the hippocampal formation of the two sides. This latter projection system appears to be conserved in the human brain. Gloor *et al.* (1993) studied post-mortem brains and identified a dorsal hippocampal commissue that had an appearance similar to that of the monkey. Also similar to the monkey, the ventral hippocampal commissure (through which dentate and hippocampal commissural connections travel in the rodent) is essentially eliminated.

Cortical Connections

Anatomical studies of the rat hippocampal formation have not uncovered many direct connections between the neocortex and the hippocampal formation. Only recently has it been shown, for example, that the rat subicular complex receives a projection from the perirhinal cortex (Kosel *et al.*, 1983), and even though it has been reported that only a restricted region of the rat entorhinal cortex projects to neocortical regions (Swanson and Köhler, 1986), more recent neuroanatomical studies in the rodent reveal that most of the entorhinal cortex gives rise to neocortical projections (Insausti *et al.*, 1997). In the cat and monkey, increasing evidence points to substantial and direct neocortical interconnections with both the subicular complex and the entorhinal cortex.

Van Hoesen and Pandya (1975a, b) and Van Hoesen *et al.* (1975) used degeneration techniques to study the connections of the macaque monkey entorhinal cortex. They found that several fields within the temporal lobe, especially areas TF and TH of the parahippocampal gyrus, the perirhinal cortex (area 35), and the temporal polar cortex (area TG) project to the lateral portion of the entorhinal cortex. More recently, Insausti *et al.* (1987a) reexamined the cortical input to the monkey entorhinal cortex using retrograde tracing techniques. This study largely confirmed Van Hoesen's findings but identified several additional cortical fields that project directly to the entorhinal cortex (Fig. 23.16). These included several fields along the dorsal bank of the superior temporal gyrus, the ventral or agranular insular cortex, the posterior orbitofrontal cortex (Walker's areas 14, 13, and 12), and, to a lesser extent, the dorsolateral frontal cortex (areas 9, 10, and 46). Sizeable projections were also found from the infralimbic and prelimbic portions of the medial frontal cortex (areas 25 and 32), the cingulate cortex (areas 24 and 23), and the caudally adjacent retrosplenial cortex (areas 29 and 30).

The efferent connections of the primate entorhinal cortex have not yet been intensively studied. There are indications that most, if not all, of the cortical areas that project to the entorhinal cortex receive return projections. In particular, entorhinal projections have been demonstrated to the perirhinal cortex, the temporal polar cortex, the caudal parahippocampal gyrus, and the caudal cingulate gyrus (Baleydier and Mauguiere, 1980; Kosel *et al.*, 1982; Van Hoesen, 1995; Suzuki and Amaral, 1994 for perirhinal–entorhinal connections; Good and Morrison, (1995) for connections with the polymodal area in the upper bank of the superior temporal gyrus; a comprenhensive account of efferent projections can be found in Muñoz and Insausti, submitted). At variance with the study on afferents to the primate entorhinal cortex of Insausti *et al.* (1987b), some projections from the anteroventral portion of unimodal visual association cortex, area TE, located medial to the anterior medial temporal sulcus seems to have reciprocal connections with the lateral portion of the entorhinal cortex, although it is not clear if perirhinal cortex (area 36) was included in some of the tracer deposits. Through these connections, the hippocampal formation is able to influence widespread regions of the temporal, parietal, and frontal lobes. As Van Hoesen (1982) has emphasized, the parahippocampal gyrus, in particular, gives rise to projections to virtually all the associational cortices of the primate brain.

Although available evidence indicates that the entorhinal cortex receives the most prominent cortical innervation, the subicular cortices also receive direct cortical input. Van Hoesen *et al.* (1979) first demonstrated that the temporal polar cortex, the perirhinal cortex, and the parahippocampal gyrus project to one or more divisions of the monkey subicular complex. A projection from the inferior parietal lobe to the medial portion of the caudal presubiculum has also been demonstrated (Seltzer and Pandya, 1984; Seltzer and Van Hoesen, 1979). The presubiculum receives additional inputs from the caudal cingulate cortex (Pandya *et al.*, 1973), the superior temporal gyrus (Amaral *et al.*, 1983), and the dorsolateral prefrontal cortex (Goldman-Rakic *et al.*, 1984). Interestingly, each of the cortical projections to the presubiculum terminates in a columnar fashion in a restricted rostrocaudal and mediolateral region. In addition to its subcortical projections to the anterior thalamus and mammillary nuclei, Rosene and Van Hoesen (1977) and Kosel *et al.* (1982) demonstrated that the monkey subicular cortices project to several cortical fields, including the perirhinal cortex, the parahippocampal gyrus, the caudal cingulate gyrus, and the medial frontal and medial orbitofrontal cortices. Widespread cortical connections have also been demonstrated from the subicular cortices of the cat and bush baby (Cavada

and Reinoso-Suarez, 1983; Irle and Markowitsch, 1982; Pritzel and Markowitsch, 1983). Recently, several studies in the nonhuman primate brain have shown that the subicular cortices, along with CA1 reciprocate the projections to most of these areas (Barbas and Blatt, 1995; Blatt and Rosene, 1998; Ding *et al.*, 2000; Yukie, 2000; Insausti and Muñoz, 2001) with those to the lateral frontal neocortex being least substantial. The precise relationship of this set of projections with the reported head-direction cell responses in the presubiculum (Robertson *et al.*, 1999) remains to be determined.

Chemical Neuroanatomy of the Hippocampal Formation

The ultimate goal of many neuroanatomists is an understanding of the neural circuitry of the human brain. Yet the lack of experimental approaches applicable to human neuroanatomy has forced most workers to conduct studies on experimental animals and extrapolate their findings to the human brain. Until recently, anatomical studies of the human brain had not advanced much beyond the cytoarchitectonic descriptions of the early part of the 20th century. Several new technologies have come together, however, to change this situation, and detailed neuroanatomical analysis of the human brain has once again become a fundamental aspect of modern neuroscience.

The development of noninvasive imaging techniques, including positron emission tomography (PET) and magnetic resonance imaging (MRI), has renewed interest in human neuroanatomy. These technologies allow hitherto unprecedented views of the functioning human brain. The final section of this chapter elaborates on neuroimaging. Perhaps even more important, however, is the development of new histological procedures such as immunohistochemistry, receptor autoradiography, and *in situ* hybridization that allow the direct comparison of the distribution of transmitter-specific or neuron-specific probes in the human brain and in the brains of experimental animals (i.e., Figure 23.18 that shows differences in the staining pattern to a specific marker—nonphosphorylated neurofilaments SMI-32—of the hippocampus in nonhuman primates and humans.

A comprehensive account of the chemical neuroanatomy in the nonhuman primate is provided in Kobayashi and Amaral (2001); therefore, the present account will deal with data elaborated on the human hippocampal formation. This is an area in which substantial progress has been made since the first version of this chapter.

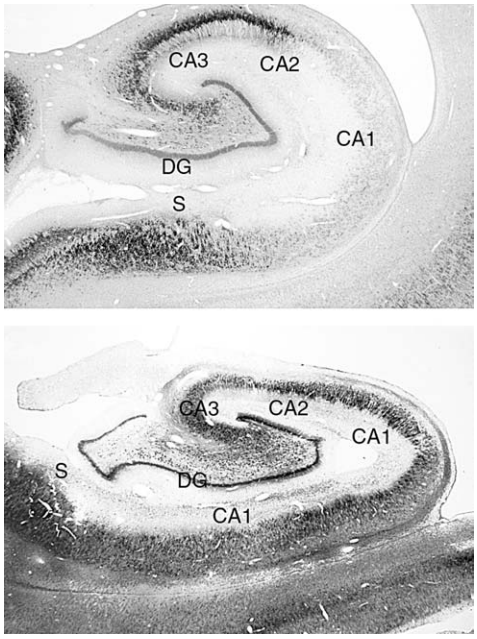

FIGURE 23.18 Brightfield photomicrographs of immunohistochemical preparations from the monkey *(top)* and the human *(bottom)* hippocampal formation stained for nonphosphorylated neurofilament (NF) with antibody SMI-32. Sections have been counterstained by the Giemsa method, which provides a Nissl-like stain. In the hippocampal formation, neurons in the CA3 and CA2 fields are heavily labeled whereas neurons in CA1 are completely unstained. Neurons in the subiculum are again very heavily stained, and the staining extends into the proximal apical and basal dendrites. Thus NF staining provides a very useful marker for the borders of the CA1 field. In the human, in contrast, NF staining appears to be much more generalized; in particular, cells in CA1 are heavily stained. In CA3 of the human, only some of the pyramidal cells are labeled, but the mossy fibers are stained. In the monkey, the mossy fibers are not stained. This human brain material had a postmortem interval to fixation of 6 hours. It is not clear whether the different staining patterns in the monkey and human are true species differences or are related to the differing fixation protocols used in the monkey (perfusion fixation) versus the human (immersion fixation 6 hours after death).

Green and Mesulam (1988) examined the distribution of cholinergic inputs to the human hippocampal formation by studying preparations stained histochemically for acetyl cholinesterase (AChE). The dentate gyrus shows little staining in the granular layer, a band in the innermost portion of the molecular layer of the dentate gyrus, and some neurons in the polymorphic cell layer. Fields CA3–CA1 have strong AChE activity in stratum oriens and the pyramidal cell layer, while stratum radiatum and lacunosum-moleculare display much lighter staining. Staining in the proximal (closer to CA1) part of the subiculum is far less dense than the adjacent CA1; thus, the oblique border between CA1 and the subiculum is quite noticeable. The presubiculum and parasubiculum

present moderate density in the external layer and weak reaction in the deep portion. The entorhinal cortex presents two bands of high AChE density, one corresponds to the layer II cell islands, and the other corresponds to layer V. More recently, De la Calle *et al.* (1994) carried out similar studies using the more specific cholinergic marker, choline acetyl transferase (ChAT). In general, the pattern of staining with ChAT was similar to that of AChE (as determined with an antibody against AChE), although some minor differences were observed such as higher density of ChAT positive fibers in the molecular layer of the parasubiculum. ChAT immunoreactivity in layer V of the entorhinal cortex is not as prominent as AChE activity. No ChAT positive somata were found in any subdivision of the hippocampal formation.

Akil and Lewis (1994) studied the distribution of TH immunoreactivity in the human entorhinal cortex. Marked gradients in the mediolateral and rostrocaudal axes were noted. The entorhinal cortex contained intense TH immunoreactivity in the deep portion of layer I and the superficial portion of layer II. TH fibers surrounded the cell clusters on the upper part of layer III at rostral levels. Layer V displayed the lowest density of TH positive fibers, and layer VI had again moderate density as well as some positive neurons.

Neither the noradrenergic nor the serotonergic innervation of the human hippocampal formation has been studied thus far.

A number of studies have been published in the last few years on the distribution of calcium-binding proteins, parvalbumin (Pv), calbindin (Cb), and calretinin (Cr) in the human hippocampal formation (Sloviter *et al.*, 1991; Braak *et al.*, 1991; Tuñón *et al.*, 1992; Seress *et al.*, 1993; Nitsch and Ohm, 1995; Mikkonen *et al.*, 1997). Parvalbumin mostly stains interneurons in the hippocampus. Braak *et al.*, (1991) describe up to 28 morphologically distinct interneurons in the dentate gyrus of the hippocampus. Electron microscopic examination of Pv-positive neurons show many similarities, despite the various morphological types (Seress *et al.*, 1993). Calbindin immunoreactivity is present in many granule cell neurons, as well as in nongranule neurons in the molecular layer of the dentate gyrus, but it does not appear as frequently in the polymorphic cell layer. In CA3, calbindin immunoreactivity is absent from the pyramidal cell layer but is coincident with that of the mossy fibers. Calbindin is not selective for the mossy fiber system, however, because other calbindin-positive interneurons can also be found (Lim *et al.*, 1997a). Many Cb-positive neurons are present in the pyramidal cell layer of CA2 and CA1, as well as in nonprincipal cells of the subicular cortices (Seress *et al.*, 1993). Calretinin immunoreativity in the human hippocampus has been studied by Nitsch and Ohm (1995). They found small Cr-positive neurons in the molecular layer of the dentate gyrus, as well as Cr-positive terminals both in the innermost part of the molecular layer of the dentate gyrus and around somata of CA2. The latter is similar in distribution to the hypothalamic-hippocampal afferents arising from the supramammillary region containing substance P (Nitsch and Leranth, 1993; Berger *et al.*, 2001). The distribution of calcium-binding proteins in the human entorhinal cortex has been described in several studies (Tuñón *et al.*, 1992; Solodkin and Van Hoesen, 1996; Mikkonen *et al.*, 1997). Only Mikkonen *et al.* (1997) present a comprehensive account of the pattern of distribution for Pv, Cb, and Cr in the various subfields of the entorhinal cortex. Rostral and medial portions of the entorhinal cortex display dense Cb and Cr immunoreactivity, while caudal and lateral portions are denser for Pv. Cr pyramidal cells were present in layers V and VI, while Cb neurons were present in layers II and III (Mikkonen *et al.*, 1997).

A number of peptide or candidate transmitter specific antibodies have also been used to examine the human hippocampal formation, and, in general, the distribution of identified elements is similar to that in experimental animals. Schlander *et al.* (1987), for example, demonstrated a distribution of glutamic acid decarboxylase (GAD, the GABA-synthesizing enzyme) activity in the human dentate gyrus that at the light and electron microscopic level appears similar to that in experimental animals. Cholecystokinin (CCK) immunoreactivity has also been reported in interneurons and fibers of several fields of the human hippocampal formation (Lotstra and Vanderhaeghen, 1987). CCK-immunoreactive fibers and terminals were most dense around the pyramidal cells of the CA2 and CA3 fields of the hippocampus and were also numerous in the molecular layer of the dentate gyrus. Antisera to neuropeptide tyrosine (neuropeptide Y) also identify a population of apparent interneurons in the polymorphic layer of the dentate gyrus, in CA1, subiculum, and entorhinal cortex of the human hippocampal formation (Chan-Palay *et al.*, 1986). Neuropeptide Y-immunoreactive fibers and terminals were most dense in the CA1 field, but other prominent plexuses occurred in the molecular layer of the dentate gyrus, presubiculum, and entorhinal cortex. Finally, Sakamoto *et al.* (1987) have found a fairly large population of neurons in the polymorphic layer of the human dentate gyrus that are immunoreactive for substance P. Substance P-immunoreactive terminals were found to innervate the granule cell layer heavily. In addition, they found fairly dense terminal labeling

among the cell bodies of CA2 and CA3 pyramidal cells with neuronal labeling in the subjacent stratum oriens. However, when they used antisera directed against 'Leu-enkephalin they found little staining in the human hippocampal formation. Characteristically, the distribution of opioid peptides in the hippocampal formation has varied markedly from species to species.

Receptor autoradiography has been conducted in the human hippocampal formation using probes compatible with the immunohistochemical studies cited previously. Often there are marked regional differences in receptor binding. Dietl *et al.* (1987) showed, for example, that the CA2 and CA3 fields, the subiculum, and the entorhinal cortex contain appreciable levels of CCK receptor binding, whereas CA1 has no detectable ligand binding. Similarly, Köhler *et al.* (1987) demonstrated high levels of neurotensin receptor binding in the presubiculum, entorhinal cortex, and polymorphic layer of the dentate gyrus whereas [3H]neurotensin binding was very low in the CA1 field and in the subiculum.

While it is beyond the scope of this chapter to survey the merits and pitfalls of the increasingly rich immunohistochemical and receptor autoradiography literatures, it is clear that these methodologies will play an increasingly important role in the functional neuroanatomical analysis of the human hippocampal formation. Because this analysis will depend on the comparison of human material with the more highly controlled experimental animal data, it becomes increasingly important to adopt a similar terminology for the cytoarchitectonic description of the hippocampal formation for all species.

A Note on the Development of the Human Hippocampal Formation

Taking into consideration the importance of the clinical problems for which a mechanism of failure in neuronal development or migration has been invoked as explanation, it seems timely to review data gathered so far and to present a synopsis of the development of the human hippocampal formation.
